## CLINICAL INTEREST BOX 21.3 Discharge planning—home assessment parameters

**Personal and health data**

Age, gender, height and weight, cultural data (religion), medical history, current health status, surgery

**Abilities to perform activities of daily living (ADLs)**

Abilities for dressing, eating, toileting, bathing (bath, shower, sponge), ambulating (with or without aids such as a cane, crutches, walker, wheelchair), transferring (from bed to chair, in and out of bath, in and out of car), meal preparation, transportation, shopping and the impact medications may have on completing these safely

**Disabilities/Limitations**

Sensory losses (auditory, visual, tactile), motor losses (paralysis, amputation), communication disorder (aphasia), mental confusion or depression, incontinence

**Carers' responses/abilities**

Principal carer's relationship to individual, thoughts and feelings about person's discharge, expectations for recovery, health and coping abilities, comfort with performing required care

**Financial resources**

Financial resources and needs (note equipment, supplies, medications, special foods required), impact of unemployment on financial situation

**Community supports**

Family members, friends, neighbours, volunteers, religious affiliations, resources such as nutrition services, health centres, community health nurses, day programs, specific interest groups (e.g. MS support groups or local diabetes support groups), legal assistance, home care (cooking, cleaning), respite care

**Home hazard appraisal**

Safety precautions (stairs with or without handrails; lighting in rooms, hallways and stairways; nightlights in hallways or bathroom; grab bars near toilet and bath; firmly attached carpets and rugs), self-care barriers (lack of running water, lack of wheelchair access to bathroom or home, lack of space for required equipment, lack of lift)

**Need for healthcare assistance**

Home-delivered meals; special dietary needs; volunteers for telephone reassurance, friendly visiting, transportation, shopping; assistance with bathing; assistance with housekeeping; assistance with wound care, ostomies, tubes, oxygen therapy, intravenous medication

*(Crisp et al 2013; Brown et al 2015)*

## CLINICAL INTEREST BOX 21.4 An individual's risk factors for discharge planning

- Lack of understanding/knowledge of treatment plan
- Altered cognition
- Newly diagnosed chronic disease
- Major or radical surgery
- More than three active medical problems
- Social isolation
- Emotional or mental instability
- Visual or hearing deficits
- Takes more than five medications
- Lack of financial resources
- Lack of available or proximal referral sources
- Terminal illness
- Lack of in-home carer
- Culturally or linguistically diverse background
- Being bedridden for long periods
- A lengthy hospital stay
- Readmission to hospital within 2 weeks of discharge
- Older than 70 years
- Poor family supports (lives alone)
- Aboriginal and Torres Strait Islander people over 60
- Premature admission to residential care

*(Crisp et al 2013; Barkemeyer 2015; Juckett & Unger 2014)*

- All personal possessions have been collected and packed, including any items of value being held in the facility's safe
- The person is assisted to dress, if necessary
- Any dressings or bandages have been applied as necessary
- Intravenous cannula has been removed
- The individual is provided with any prescribed medications together with instructions for their administration. The healthcare facility generally provides an instruction/information sheet that includes this
- The individual is aware of, and understands, any dietary or activity restrictions, including driving
- Reference material on their condition, or direction on how to access this, has been provided
- The visiting nurse service has been notified, if necessary
- The individual is aware of any follow-up appointments including referrals, if necessary
- The individual is confident about performing any self-care activities that have been taught, such as administering insulin, dressing a wound or caring for a colostomy
- The individual and significant others are provided with contact details should there be any problems after

discharge (Brown et al 2015; Berman et al 2012; Crisp et al 2013; Kralik & van Loon 2011).

When the person is ready to leave the unit they are accompanied to the discharge department and any documentation (usually health-insurance related) is completed. The person is then accompanied to the exit. In the unit, the nurse reports to the nurse in charge and documents that the discharge has been completed.

Current research (Chapin et al 2014) suggests that older persons are particularly vulnerable in the first few weeks post discharge; therefore, it is of paramount importance that the discharge planning process is managed effectively to prevent re-admissions and poor clinical outcomes for this age group.

### Transition lounges

Due to the increasing demands on the healthcare bed, discharge planning has taken a step forward with the development and implementation of transition lounges. The implementation of the transition lounge was due to a reduction in bed numbers which tended to result in 'bed blocking'. Utilising the transition lounge allows a safe and timely transfer/discharge. The individual is situated in an armchair in a specific room/unit until their driver arrives at the hospital to collect them (Blay et al 2012). Effective communication and coordination are essential tools needed to successfully implement early discharge strategies. One strategy is the implementation of a specific handover sheet which simplifies the process by streamlining the vast amount of discharge documentation onto one page, including topics such as discharge diagnosis, pharmacy requirements, mode of transport and the individual's specific requirements (Lees 2012). The transition lounges are staffed by Registered and Enrolled Nurses who specialise in efficient and effective patient discharges, ensuring that safe and optimal person-centred care delivery standards are adhered to at all times (Lees 2013).

## Discharging the mental health person

The day of discharge for the individual from the mental health unit is often one that fills the person with happiness, yet is often met with trepidation and apprehension from the family or carer. There are many considerations made when discharging a person from the mental health unit; importantly, bed shortages have seen an increase in discharge acuity levels (Elder et al 2013; Damon et al 2012). As in other areas of healthcare, discharge planning should commence from the time of admission (Elder et al 2013). While every effort should be made to adopt a collaborative approach to organising discharge, with the person heavily involved—with consent—it is highly beneficial for families and carers to also be involved in this process (see Clinical Interest Box 21.5). The burden of care for families with a mentally unwell loved one is very significant. Sensitivity and empathy should be adopted when liaising with families and support services, and resources should be provided for them. In particular, carers (with the person's consent) should be provided with emergency crisis contact details, case manager details and treatment regimen information. All belongings should be returned to the individual, paperwork signed by the treating psychiatrist and, if necessary, transportation arranged. Should the individual be discharged on a community treatment order, copies of this containing any provisions and further contact details (of case manager, general practitioner and treating psychiatrist) and review dates should be included. Where possible, a meeting between the community treating team, family and individual is useful prior to discharge (Noseworthy et al 2014; Elder et al 2013).

### CLINICAL INTEREST BOX 21.5 Discharge considerations in mental health

- Adherence to medication and treatment regimen
- Substance misuse history
- Potential for relapse or exacerbation of psychiatric symptomatology
- Family supports
- Dependants
- Financial considerations
- Commencement of disability support pension as necessary
- Housing (homelessness, housing affordability)
- Severity of illness
- Potential for harm to self/others
- Degree of insight into their illness and need for ongoing treatment
- Ability to identify future stressors and how this may exacerbate their illness
- Information regarding community follow-up care, including crisis intervention contacts
- Judgment

*(Noseworthy et al 2014; Nurjannah et al 2014)*

## Discharge against medical advice

A person may at any time decide to leave a healthcare facility against the advice of the medical officer and nursing staff. The only time healthcare professionals can stop a person from self-discharging is when they are sectioned under the Mental Health Act (Noseworthy et al 2014; Nurjannah et al 2014). In the event of a person requesting to self-discharge, the nurse must immediately report the incident to the nurse in charge and notify the individual's medical practitioner promptly. If the individual cannot be dissuaded from leaving, they are asked to sign a statement to the effect that they are leaving at their own risk and that they are responsible for the consequences. If the individual refuses to sign, this must be documented in their clinical file. The document is signed by at least one witness; this may be the medical officer or the nurse in charge. Given that self-discharge accounts for about 2% of hospital discharges overall, it is important to consider the reasons why people leave against medical advice, in an effort to identify those people potentially at risk

## CLINICAL INTEREST BOX 21.6 An individual's reasons for self-discharge

- Carer issues (dependants, family issues)
- Social issues
- Employment issues
- Unaffordability to pay hospital expenses
- Dissatisfaction with treatment
- Reporting they are feeling better
- Illicit drug and/or alcohol misusers
- Disempowerment
- Fear
- Boredom

*(Crisp et al 2013; Brown et al 2015)*

## CASE STUDY 21.2

You are caring for John, a 45-year-old man, who is 1 day post cardiac angiogram with three stents placed. While you are taking his morning observations he states that he wants to go out for a cigarette. You discuss his plan of care with him as per the cardiologist and say that it would be unsafe for him to go outside, especially to smoke. He becomes angry and starts yelling at you stating that it is none of your business if he goes out for a cigarette. You as the nurse reiterate in an objective manner that while he is on cardiac monitoring you are legally not permitted to disconnect him. You state you need a medical officer's order to disconnect the telemetry. John yells at you to contact the medical officer and tell him he will be going out for a cigarette no matter what he says. You contact the medical officer and advise him of the situation. The medical officer refuses to give the order to disconnect the monitoring equipment. The medical officer orders nicotine patches for John and asks you to tell John that he will be in later to discuss his treatment plan. You advise John of the medical officer's orders. He refuses the nicotine patches and starts to take the monitor leads off. You contact the charge nurse who attempts to change John's mind about leaving. John remains adamant that he is leaving and asks for the paper to sign as he was leaving against medical advice.

1. Discuss the ramifications of self-discharge from hospital.
2. What are the legal requirements a nurse must complete in this situation?

(Lin et al 2014; Rahimi & Khabbazzadah 2014). Statistically, young males without health insurance who misuse substances, have no regular general practitioner and are from lower socioeconomic backgrounds are more likely to discharge themselves from hospital against advice (Lin et al 2014; Rahimi & Khabbazzadah 2014) (Clinical Interest Box 21.6 and Case Study 21.2).

## Transfer

Sometimes it is necessary to transfer a person from one unit at a healthcare facility to another unit, or to an entirely different facility. **Transfer** of an individual may be necessary for a variety of reasons, such as change in condition, utilisation of private health insurance, demand for available beds or the requirement to be isolated from others. Regardless of the reasons, a transfer may be a distressing experience for the person, who is likely to feel apprehensive about the need to adapt to new surroundings and personnel. The individual may also be worried about the impacts on their family, particularly if the new service is a greater distance from home. Conversely, the transfer may be welcomed as an indication of an improvement in the person's condition, or an improvement in facilities available; for example, being transferred to a general ward from intensive care, or from a public hospital with shared accommodation to a private hospital with their own room. It is important to acknowledge that being transferred to rehabilitation, palliation or a long-term facility can be confusing and frightening for individuals. Whenever possible, have family or a close friend travel with the person or meet them when they arrive at the new facility (Wagner et al 2013; Sethi & Subramanian 2014).

As with discharge, when a person is to be transferred it is essential that they and their significant others are informed as soon as possible. A full explanation of the reasons for the transfer provides the person with time to adjust and provides their significant others time to make any changes necessary. In addition to preparing the person for the transfer, it is necessary to inform the staff in the receiving unit or facility of the individual's condition and care plan. Arrangements for transportation are made if necessary. Key aspects involved in transfer are:

- Informing the person and significant others of the date and time the transfer is to occur
- Assessing whether the individual is able to walk or if a wheelchair or trolley is necessary
- Arranging transportation (e.g. an ambulance) if being transferred to another facility
- Notifying the receiving unit or facility of the date and expected time of the transfer
- Notifying admissions department of the transfer
- Assisting the person to pack all personal possessions, including valuables stowed in the safe. The nurse should check the entire room to ensure nothing is left behind
- Assembling the documents that are to accompany the person
- Sending medications with the individual or returning them to the facilities pharmacy department
- Accompanying the person to the receiving unit, the ambulance or private care
- Introducing the person to the nursing staff in the receiving unit and remaining with them until the staff have received the person into their care
- Reporting to the nurse in charge and documenting that the transfer has been accomplished (Figure 21.6).

## Summary

Admission to a healthcare facility, whether by means of an elective or emergency presentation, is a major event for an individual and their significant others. Both the person and their significant others are often anxious about the admission and the implications surrounding this (e.g. emotional, financial). An individual may react to admission in one or more ways, including apprehension, relief, irritability, anger or depression. It is therefore important that the nurse perform the admission in an empathetic, caring and sensitive manner.

Prior to receiving the person onto the unit, the nurse must prepare the room. Reception of the individual is directed towards verifying the person's identity, assessing the physical and psychological status, promoting the individual's comfort in an unfamiliar environment and providing items needed for care. It is also important that the nurse provide both written and verbal information to the person in meaningful language (plain English).

The challenges associated with admitting and discharging the individual from the mental health unit are unique and must be addressed in a sensitive and empathetic manner. It is important, where possible and with consent, to involve family and significant others to ensure the best possible outcomes are achieved for the mental health person with potentially complex issues. Safety is of paramount importance.

The individual may be transferred to another unit or healthcare facility and a full explanation as to the reasons for this is necessary for the person and their significant others. Discharge planning, which begins immediately upon admission (or, in the event of elective procedures, prior to it), is directed towards assisting the individual to make a smooth transition from one setting to another. Discharge planning involves assessment, analysis of data planning, implementation and evaluation.

### DECISION-MAKING FRAMEWORK EXERCISE 21.1

You are working on a busy surgical unit in an inner-city hospital. You have been allocated your section for the day; two beds are reserved for postoperative cases later in the morning. The individuals that are under your care are progressing appropriately in the rehabilitation phase of their surgery and you have managed to complete all your scheduled duties before the first person arrives from PACU. The first person underwent an abdominal laparotomy; he is awake and responding appropriately on arrival to the unit. You manage to settle him into the unit ensuring he has adequate pain management. Five minutes later you are called up to the nurses' station by the unit clerk, Mary, who tells you that the parents of your next postoperative case want to meet the nurse who will be looking after their daughter. You introduce yourself to the parents who appear extremely anxious and upset. The father promptly advises you that under no circumstances are you, or any hospital personnel, permitted to discuss the diagnosis or current treatment plan (palliative nursing care) with their daughter Sally. The parents then advise you that they will be in the waiting room and would appreciate being notified when their daughter arrives on the unit.

You contact the post-anaesthesia care unit (PACU) and ask the nurse caring for Sally what the surgery and diagnosis were. The recovery room nurse informs you that Sally had a stereotactic biopsy for a glioblastoma multiforme (a malignant brain tumour). You prepare the bed for the arrival of Sally, as well as informing the charge nurse about the discussion with her parents regarding her diagnosis and treatment plan. The nurse manager confirms that her parents are in charge of making decisions for Sally as she is only 15 years of age. Sally arrives on your unit 30 minutes later. While you are settling her into the unit she begins to ask what they found in surgery. You respond by telling her that you are not sure as the results are not back yet. Sally replies, 'What are you hiding? The doctor told me he would have the results before I wake up.' Sally begins to get upset thinking you are keeping information from her. You try to calm down Sally, explaining that you will get her parents now that she is settled. Sally tells you that she does not want to see her parents until she is told what is wrong with her.

Using the decision-making framework:

1. What strategies could you use to support the parents while they work through this phase of Sally's diagnosis?
2. What strategies could you use to support Sally until her parents communicate with her about her diagnosis and treatment plans?
3. Which allied health services could you suggest for both Sally and her parents?

## Review Questions

1. How would you plan and implement the care for the individual who requires admission, transfer or discharge?
2. How can you ensure a successful paediatric admission?
3. What are the responsibilities of the nurse in relation to assessment and observation of children?
4. What are the key elements of discharge planning?
5. How can the nurse avert some of the problems regarding risk factors for discharge?
6. What safety considerations must be addressed when admitting the individual to a mental health unit?
7. Discuss the effects of hospitalisation in relation to individuals and stress.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define and explain the key terms
- Discuss the nature of infection
- Explain the links in the chain of infection
- Describe the body's normal defences against infection
- Identify factors that increase susceptibility to infection
- Differentiate between and discuss standard and transmission-based precautions
- Explain nursing responsibilities in relation to preventing transmission of infection
- Identify interventions to reduce risks for infection
- Name the sequence for donning and doffing PPE
- Identify measures that break the chain of infection
- Explain the National Hand Hygiene Initiative 'The 5 Moments for Hand Hygiene'
- Explain and/or demonstrate the principles of aseptic technique
- Define the concepts of standard and surgical aseptic non-touch technique
- Demonstrate recommended and approved infection control techniques when carrying out nursing activities
- Describe the steps to take in the event of a blood-borne pathogen exposure
- Describe the role of the infection control nurse

## CHAPTER FOCUS

Effective infection prevention and control is essential to providing high-quality healthcare for individuals and a safe working environment for those who work in and visit the healthcare setting. Infection prevention and control is everybody's business. Knowledge and understanding of the modes of transmission of infectious organisms and when to apply the basic principles of infection prevention and control is critical to the success of any evidence-based infection control program.

Infectious diseases have not disappeared with advances in drug and medical therapy, and in some cases microorganisms have developed drug-resistant strains. It is essential that healthcare workers (HCW) receive education and develop their knowledge about microorganisms, the infectious process and the application of infection control principles into their daily activities to prevent the spread of microorganisms and transmission of infection. This chapter is intended to further your knowledge which will help to minimise the incidence of healthcare-associated infections (HAIs); the spread of infection between individuals and protect the individual HCW and other healthcare workers from contact with infectious material or exposure to communicable diseases. Nurses are also in a prime position to educate individuals about activities that increase personal resistance to infection, modes of transmission and prevention methods to assist in controlling the spread of infection in the home as well as in the healthcare facility.

Individuals in healthcare settings are at risk of acquiring infections because of lowered resistance and increased exposure to disease-causing microorganisms, and invasive procedures. Sources of infecting microorganisms can be people or environmental objects, such as medical or nursing equipment that has become contaminated.

## LIVED EXPERIENCE

Recently during a hand hygiene education session I was shocked to see how badly I had washed my hands. I was asked to rub a special cream into my hands; once it was all soaked in, I was then asked to wash my hands with soap and water using the same technique that I would use for a social hand wash. On completion of this task my hands were looked at under a black light. I was shocked to see that all around my nails, the outside of my thumb and the backs of my fingers were glowing white. I bite my nails and I was able to actually see potentially how dirty my fingers and nails are when I put them in my mouth after having washed them. The black light also showed up how dry my hands were. I am going to try to never bite my nails again, and I am now aware of the improved technique I should use to wash my hands, especially the tips of my fingers, my thumb and back of fingers which I seemed to omit in my old washing technique. I've also learnt how important it is to use the moisturiser provided by my employer at least 2–3 times a shift. Now I see why hand hygiene technique is so important and why it is necessary to have an audit or assessment process in place.

**Stephanie, Registered Nurse**

## HEALTHCARE-ASSOCIATED INFECTION IS PREVENTABLE

There are approximately 200 000 healthcare-associated infections (HAIs) affecting individuals in Australian acute healthcare facilities each year (Cruickshank & Ferguson 2008). Healthcare-associated ('**nosocomial**') infections are classified as infections that are associated with the delivery of healthcare services in a healthcare facility or healthcare interventions ('iatrogenic'). The infection can occur during admission or may manifest after discharge. As well as causing unnecessary pain and suffering to individuals and their families, these adverse events increase the risk of death, prolong hospital stays and are costly to the health system. The most common settings where HAIs develop are hospital surgical or medical intensive care units. However, HAIs can occur in any healthcare facility and all healthcare workers have a duty of care to take all reasonable steps to safeguard individuals, staff and the general public from infection. The microorganisms that cause hospital-acquired infections can originate from the person themselves (an endogenous infection) or from the hospital environment, personnel or from other individuals via the hands of healthcare workers (exogenous infection).

## IMPROVING HEALTHCARE IN AUSTRALIA

The **Australian Commission on Safety and Quality in Health Care (ACSQHC)** developed the National Safety and Quality Health Service Standards (NSQHS) to encourage and drive the implementation of safety and quality systems and improve the quality of healthcare in Australia. The NSQHS Standards provide a consistent statement about the level of care Australian consumers can expect from any healthcare organisation nationwide. These Standards were developed following consultation and collaboration with a wide range of stakeholders including consumers.

The NSQHS Standards and a national accreditation scheme were endorsed by the Health Ministers in September 2011 and revised in 2015. This has created a national safety

and quality accreditation scheme for healthcare facilities. Infection prevention and control was Standard 3 of the 2012 NSQHS Standards and renamed Standard IP in the Consultation Draft Version 2 (2015).

The intent is to prevent individuals from acquiring preventable HAIs and effectively manage infections when they occur by using evidence-based strategies and antimicrobial stewardship (ACSQHC 2012; 2015a).

## NATURE OF INFECTION

An **infection** is a state that exists when microorganisms have gained entry and have multiplied in the tissues of a host, causing damage to cells or tissues, resulting in either localised or systemic injury. The microorganisms that are capable of causing disease are referred to as **pathogens**. The presence of a pathogen does not always result in an infection (NHMRC 2010).

If the infectious agent fails to cause injury and the person has no signs and symptoms of infection the infection is said to be **asymptomatic**. If the pathogens multiply and cause clinical signs and symptoms, such as pain, high temperature or lethargy, the infection is said to be **symptomatic**. If the infectious pathogen can be transmitted to an individual by direct or indirect contact or as an airborne infection, the resulting condition is known as a **communicable disease**. **Virulence** is a term used to describe the **pathogenicity** of an organism or, in other words, the extent to which it is capable of causing disease. The potential for microorganisms to cause disease depends on **virulence**, a sufficient number of organisms being present and their ability to enter and survive in the host. An opportunistic pathogen causes disease only in a susceptible individual. Infectious diseases are a major cause of death worldwide. The **World Health Organization (WHO)** is the major regulatory body at an international level. In Australia, the **Communicable Disease Network Australia (CDNA)** provides national public health leadership and coordination on communicable disease surveillance, prevention and control. It also provides strategic advice to government and other key bodies on public health actions. The **Australasian College for Infection Prevention and Control (ACIPC)** is the peak body for infection prevention and control professionals in the Australasian region.

## MICROOGANISMS

**Microorganisms** are forms of animal or plant life too small to be seen without the aid of a microscope. One of three events occurs when microorganisms invade the body. They are destroyed by the body's immune defence mechanisms, they stay within the body without causing disease or they cause infection or infectious disease.

### Distribution of microorganisms

Microorganisms are found in every situation where it is possible for life to exist. Microorganisms are present in air, water, soil, dust, in and on food, on every surface and in and on the bodies of living organisms, including human beings. Microorganisms may be pathogenic or **non-pathogenic**. Non-pathogenic microorganisms do not cause disease under normal circumstances or when in their normal environment. Those that normally reside on or in the human body and cause no harm are termed the body's **normal flora**. Normal flora defends the body by curbing invasion by pathogenic microorganisms. If a microorganism is transferred to another area of the body, for example from the normal flora of the gastrointestinal system to the renal system, it could cause an *Escherichia coli* urinary tract or kidney infection.

Normal flora is found on the skin, on the mucous membranes of the upper respiratory tract, in the intestines and in the vagina. For example, *Clostridium difficile* is a bacterium found in people's intestines ('digestive tract' or 'gut'). The bacteria do not cause infection or disease by their presence alone and can be found in healthy people. When the normal balance of bacteria in the gut is disturbed *Clostridium difficile* can multiply to levels where the toxins they produce cause illness such as diarrhoea and severe inflammation of the bowel. This is when an individual is said to have a *Clostridium difficile* infection. During this time the individual is classified as contagious to others and requires additional precautions. In cases where people are more vulnerable (i.e. those whose normal gut bacteria have been disrupted by antibiotic treatment or by other medications), *Clostridium difficile* may be able to multiply in the gut and go on to cause disease. Infective pathogens are the organisms that are able to overcome the normal defences of the body, invade the tissues, multiply and produce poisonous substances such as toxins that damage the tissues and cause disease (see Table 22.1).

#### CRITICAL THINKING EXERCISE 22.1

Mrs Blake is currently being treated with chemotherapy. She has had two previous short admissions with diarrhoea and vomiting. During her last admission 3 weeks ago she was treated with antibiotics for an *Escherichia coli* urinary tract infection.

*Escherichia coli* are considered normal flora in which system of the human body? Are *Escherichia coli* considered normal flora in the urinary tract? How could *Escherichia coli* be introduced into the urinary tract?

On this admission to your healthcare facility Mrs Blake has abdominal cramping, a temperature and watery diarrhoea.

What infection control measures should be considered on her admission? What, if any, investigations or precautions should be implemented? What has happened to her natural defence systems for this to happen?

### Types of infection

Infections can be localised or systemic. A local infection is limited to a specific part of the body where the microorganisms remain. If and when the microorganisms spread and damage other parts of the body it is known as a systemic infection. A **bacteraemia** occurs when a blood culture reveals the presence of a microorganism in the blood. When a

**TABLE 22.1 | Distribution of common residual microorganisms (flora)**

| Body areas | Microorganisms | |
|---|---|---|
| Skin | *Staphylococcus aureus*<br>*Staphylococcus epidermidis* | *Propionibacterium acnes*<br>*Corynebacteria* |
| Nasal passages | *Staphylococcus aureus*<br>*Staphylococcus epidermidis* | *Corynebacteria* |
| Pharynx | *Streptococcus epidermidis*<br>*Streptococcus salivarius* | |
| Mouth | *Streptococcus mutans*<br>*Lactobacillus* | *Staphylococcus epidermidis*<br>*Streptococcus salivarius* |
| Lower gastrointestinal tract<br>Intestine | *Escherichia coli*<br>*Enterococcus faecalis*<br>*Clostridium* sp.<br>*Staphylococcus aureus* | *Bacteroides* sp.<br>*Lactobacillus* sp.<br>*Enterobacteriaceae* |

*(Adapted from Lee & Bishop 2013)*

bacteraemia results in systemic infection, it is referred to as **sepsis** (Berman et al 2015).

There are also acute and chronic infections. Acute infections generally appear suddenly or last a short time, whereas a chronic infection may occur slowly, over a long period of time, and may last months or years.

**Colonisation** is the process whereby the microorganisms become resident flora. In this state, the microorganisms may grow and multiply but do not cause any harm or disease to the person. For example, an individual can be colonised with methicillin-resistant *Staphylococcus aureus* (MRSA) and show no signs of infection or ill health. Infection or disease occurs when the micro-organisms invade parts of the host's body where the defence mechanisms are ineffective and cause tissue damage.

## Risk of contracting infection

Infectious agents (also known as pathogens) are agents that cause disease or illness to their hosts. There are many infectious agents present in all healthcare facilities and there is a very real risk to the individual of both infection and colonisation within a healthcare facility. While the specific risks may differ between healthcare facilities, the basic principles of infection prevention and control apply regardless of the facility (NHMRC 2010).

Transmission of infectious agents within a healthcare setting requires the presence of the following elements:

- A source or reservoir of pathogenic organisms in sufficient numbers (causative/infectious agent)
- A mode of transmission (vehicle to transport an infectious agent to a new destination)
- A susceptible new host.

Transmission occurs when the agent leaves its reservoir or host through a portal of exit, is conveyed by some mode of transmission and enters through an appropriate portal of entry to infect a susceptible host. This sequence of events is sometimes called the **chain of infection**. (See Figure 22.1 and Table 22.2.)

## Types of microorganisms/causative pathogenic agent

The major groups of microorganisms are classified according to size, structure and method of reproduction. Microorganisms include bacteria, viruses, fungi and parasites. **Bacteria** are by far the most common infection-causing microorganism (Berman et al 2015). They are single-celled microscopic organisms without a nucleus that have the capacity to reproduce rapidly. Bacteria make up the largest group of pathogens and are often treated with **antibiotics**. The advent of antibiotics in the 1940s provided a powerful weapon to treat bacterial infections; however, because bacteria continually mutate as they divide, some had natural resistance to the effects of antibiotics and have developed into resistant strains. These pathogens may include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE) and multi-resistant gram-negative (MRGN) microorganisms, such as *Acinetobacter* species. Enterococci are bacteria (or germs) that live in most people's gut and urinary system and usually do not cause illness. However, like many organisms, enterococci can sometimes invade other parts of the body and cause infection. Vancomycin is a very strong antibiotic often used to treat complicated infections when other antibiotics do not work. When enterococci are exposed to vancomycin, they sometimes develop ways to stop the antibiotic working by developing a resistance to the antibiotic, and this has led to the development of 'vancomycin-resistant enterococci' (VRE).

These multi-drug-resistant organisms are dangerous threats, and emphasise the need for nurses and all healthcare workers to practise effective infection prevention and control measures, and for every healthcare facility to optimise antimicrobial use among individuals in order to reduce antibiotic resistance (NHMRC 2010). (Refer to Decision-making Framework Exercise 22.1 and Figure 22.2.)

**Viruses** are specialised microorganisms with a number of distinctive characteristics:

- Most are ultramicroscopic, meaning that they are too small to be seen with a light microscope and can be viewed only with an electron microscope
- They have no cell structure and they lack a rigid cell wall
- They are intracellular parasites, meaning that they can grow and reproduce only when living within a host cell, and cannot be cultured on dead or artificial media.

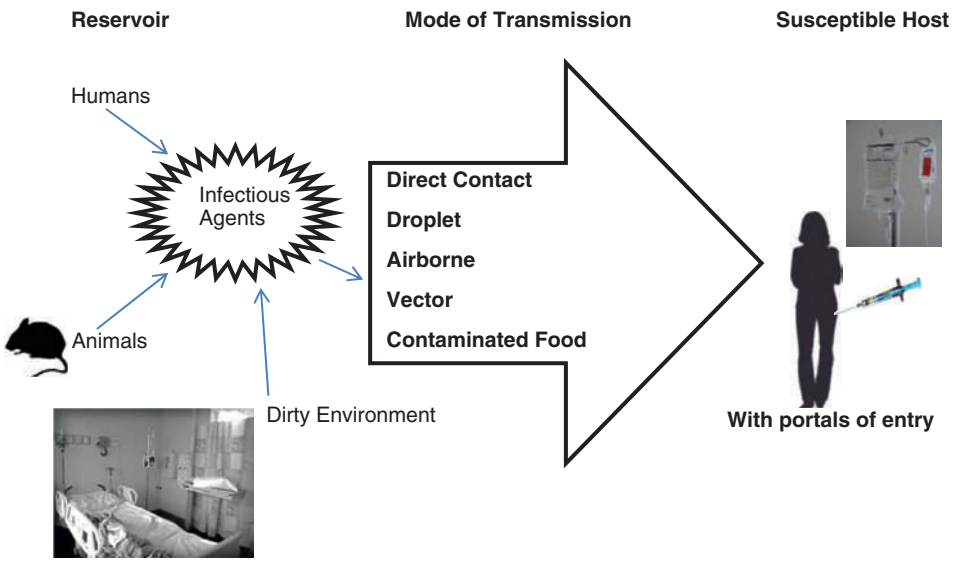

**Figure 22.1** The chain of infection

All infection prevention and control principles and activities are directed towards breaking or controlling the transmission of infectious agents in the chain of infection

*(Courtesy of Teresa Lewis)*

## DECISION-MAKING FRAMEWORK EXERCISE 22.1

You have been employed at a healthcare service as an Enrolled Nurse. The rehabilitation ward you have been assigned to uses a total patient care model of nursing care. On this particular shift there are three (3) Registered Nurses (RNs), two (2) Enrolled Nurses (ENs) and one (1) Assistant in Nursing (AIN). You have been allocated six people to care for. All individuals are in twin share rooms. At handover and upon reading the progress notes you note that one individual has a leg ulcer which has been worsening. Documentation notes that the area is reddened, swollen and tender, and a purulent discharge has been noted over the last three (3) days. One of your colleagues undertook a wound swab for culture and sensitivity two (2) days ago. The other individual sharing the room is five (5) days post total knee replacement.

Three hours into the shift you are notified by the RN in charge that the pathology results have returned and that the patient with the leg ulcer has methicillin-resistant *Staphylococcus aureus* (MRSA) bacteria growing in the wound. You are informed that you need to move the individual to the available single room and implement transmission-based precautions. You need to set up the PPE station outside the room and organise the signage.

Using the decision-making framework:

1. Do you continue to accept all the individuals given to you as part of your allocation?
2. With your knowledge and level of expertise do you undertake this care autonomously as well as the care of the other individual sharing the room?
3. Would you consider undertaking this care upon asking for assistance from someone at your facility who can help with the health education and/or supervision of your care? Perhaps there are processes in place whereby the individuals can receive an educational pamphlet on the subject?
4. Are there processes/policies in place that may help you with undertaking this care?
5. With your knowledge and level of expertise are you able to identify the potential risks and implement the correct strategies to avoid or minimise these risks?
6. Should you consider notifying other relevant departments in your facility to help with some of the infection prevention strategies that may be required?
7. Do you with your level of knowledge understand your accountability and reporting responsibilities in performing this care?
8. Have all these above factors been considered when making the allocation or is it expected that you continue with the care as per your instructions? Considering the staff on this shift, is the model of nursing care appropriate?
9. If the model of care is not appropriate, what model would you suggest would work?

**TABLE 22.2 | Interrupting the chain of infection**

| Link in the chain | Objective | Infection control nursing interventions |
|---|---|---|
| Causative agent (microorganism) | Minimise the number of microorganisms | Ensure all reusable medical devices/equipment is cleaned and disinfected or sterilised in the correct manner before reuse.<br>Education and support of all individuals involved in cleaning, disinfecting and sterilising reusable devices and equipment to reduce the numbers of microorganisms present |
| Reservoir/source<br>• Infected person<br>• Vector<br>• Contaminated object<br>Dirty environment | Eliminate conditions that favour growth of microorganisms<br>Prevent transmission of microorganisms | Correct hand hygiene technique<br>Use of disposable gloves<br>Standard precautions: handling, cleaning/disinfecting/sterilising/disposing of contaminated articles<br>Correct environmental cleaning procedures<br>Correct standard or surgical aseptic technique<br>Additional barriers/isolation precautions as indicated |
| Portal of exit—body fluids, excreta or other secretions | Prevent contamination | Correct hand hygiene technique especially after going to the toilet<br>Use of disposable gloves<br>Use of standard precautions<br>Never recap needles; correct handling of all body fluids/sharps/other equipment<br>Correct standard or surgical aseptic technique<br>Educate individuals/others regarding measures to prevent transmission |
| Route/methods of transmission:<br>• Hands<br>• Mouth/nose<br>• Infected lesions/body fluids<br>• Contaminated food/water<br>• Contaminated objects | Prevent cross-contamination; eliminate vectors | Correct hand hygiene technique<br>Correct cough etiquette<br>Use of disposable gloves<br>Correct use of all PPE<br>Correct handling of all waste<br>Use of standard/transmission-based precautions<br>Correct storage/preparation of consumables<br>Correct standard or surgical aseptic technique<br>Isolation precautions<br>Effective pest control |
| Portal of entry into the susceptible host:<br>• Mouth/nose<br>• Body orifices<br>• Openings in skin/mucous membranes | Prevent entry of microorganisms into a host | Use of standard/additional precautions<br>Use of mask, face shield, goggles, gloves, gown<br>Avoid putting contaminated hands/objects near mouth<br>Correct use of aseptic technique for any invasive procedures<br>Correct standard or surgical aseptic technique<br>Waterproof occlusive covering to protect skin breaks<br>Effective skin and oral hygiene |
| Susceptible host | Improve individual resistance to infection; prevent infection | Assess potential for infection<br>All above precautions<br>Protective isolation if indicated<br>Provide healthy nutrition/sound rest and sleep. Encourage exercise as able<br>Protective skin care, aids as needed (e.g. sheepskin elbow/knee pads, air mattress)<br>Positioning to promote lung expansion<br>Correct aseptic non-touch technique |

*(Modified from deWit & O'Neill 2014)*

Some of the common viral diseases of concern within the healthcare setting are herpes simplex, hepatitis (A, B and C viruses), influenza and human immunodeficiency virus (HIV).

**Fungi** are tiny organisms such as moulds and yeasts that belong to the world of plants but contain no chlorophyll. Fungi are present in the soil, air and water and they multiply by producing various kinds of spores. *Candida albicans* is considered normal flora in the human vagina.

**Parasites** live on other living organisms. They include **Protozoa**, which are single-cell organisms of the animal kingdom. The route of entry is usually by ingestion of

**Figure 22.2** Nursing care plan for infection prevention and control precautions

To be completed by HCW caring for the individual in consultation with infection prevention and control (IPC) practitioner on diagnosis or suspicion of infection. Tick the box that applies to the individual transmission-based precautions required. Review daily or when any changes to current diagnosis, laboratory testing or results become available.

*(ACSQHC 2015b)*

contaminated water or food, which commonly results in severe diarrhoea. Some protozoans are transmitted by insects (**vectors**) to humans; for example, the plasmodium species, which is carried by mosquitoes and causes malaria. **Helminths** are parasitic worms or flukes—multicellular animals that are pathogenic to humans. They are not common in Australia.

## Reservoirs (sources) of infection

A **reservoir** is a place where a pathogen can survive and may or may not multiply. Common reservoirs of pathogenic microorganisms are other humans, the individual's own microorganisms, animal or inanimate sources. The presence of microorganisms does not always cause a person to be ill. In humans, microorganisms can thrive in reservoirs such as open wounds, blood, nasal passages and skin crevices.

Most organisms that infect humans are acquired from human sources. The entrance of a foreign object or organism into a sterile site leads to a high risk of infection. **Endogenous** infection occurs when normal flora cause infection by being transferred from their normal place of residence to a different site in the same host. **Cross-infection** may occur when organisms from one person are transferred to another person; for example, when organisms on a nurse's hands are transferred to a person's wound.

## Portals of exit from reservoir

If microorganisms from the human body are to enter another host and cause disease, they must first find a portal of exit, and then a new site in which to reside. When the human body provides the reservoir, microorganisms can exit through a variety of sites (see Table 22.3).

## Modes of transmission

Microorganisms move from a reservoir to a new host in a variety of ways. Each disease has transmission characteristics based on the nature of the microorganism that causes it. Knowing the method of transmission is important in implementing infection prevention and control measures. In a healthcare setting, the main modes of transmission of infectious agents are *contact* (including blood-borne), *droplet* and *airborne*. In some cases the same organisms can be transmitted by more than one route or a combination of modes (NHMRC 2010).

*Clinical note*: The varicella zoster virus, which causes chickenpox, can be acquired through inhalation of infected airborne particles (airborne transmission) as well as through contact (contact transmission) with infected fluid leaking from skin lesions.

### Contact transmission

Contact is the most common mode of transmission; it may be direct or indirect. This form of transmission requires the implementation of the transmission-based precaution tier 2 contact precautions in addition to standard precautions when caring for such a person (see later in chapter for further explanation).

**Direct transmission** occurs when there is transfer of the infectious agent from one person to another; for example, a person's blood entering the healthcare worker's body through a needlestick injury.

*Clinical note:* The worst epidemic in the history of the Ebola virus occurred in 2014, from Guinea's forests to Liberia and Sierra Leone in West Africa. The Ebola virus is transmitted through direct contact with blood or body fluids

**TABLE 22.3 | Common infectious microorganisms and their portals of exit**

| Body area/reservoir | Examples of common infectious organisms/ infection/diseases | Portals of exit |
|---|---|---|
| Skin or tissue | *Staphylococcus aureus*<br>*Staphylococcus epidermidis*<br>Wound infection | Drainage from wound or cut/break in skin |
| Blood | Hepatitis B virus<br>Hepatitis C virus<br>Human immunodeficiency virus (HIV) | Needle puncture sites, open wounds, non-intact skin or mucous membrane surfaces |
| Respiratory tract | *Mycobacterium tuberculosis*<br>Parainfluenza virus | Nose or mouth through breathing, coughing, laughing, sneezing or talking |
| Gastrointestinal tract | *Escherichia coli*<br>*Clostridium difficile*<br>Hepatitis A<br>*Salmonella* species | Anus: colostomies, or faeces<br>Mouth: saliva and vomitus |

*(Modified from Lee & Bishop 2013; Berman et al 2015)*

of a person who is sick with Ebola; the virus is not transmitted through the air (like the measles virus). However, droplets (e.g. splashes or sprays) of respiratory or other secretions from a person who is sick with Ebola could be infectious, and therefore certain precautions (standard, contact and droplet precautions) are recommended for use in healthcare settings to prevent the transmission of Ebola virus from sick individuals to healthcare staff and other individuals or family members.

**Indirect transmission** involves the transfer of the infectious agent through a contaminated object or person; for example, a healthcare worker's hands touching an infected body site on one individual and the worker not performing hand hygiene before touching the bedrail of another person's bed. This may then be touched by another staff member who touches another individual's intravenous site. Indirect transmission may also occur when a healthcare worker comes in contact with **fomites** (e.g. bedding of an individual with scabies).

*Clinical note*: Some examples of infectious agents transmitted by the contact mode include multi-resistant organisms (MROs), norovirus, *Clostridium difficile* and highly contagious skin infections such as impetigo and scabies. (Refer to Case Study 22.1, Figure 22.2 and the Decision-making Framework Exercise 22.1.)

## Droplet transmission

Droplet transmission occurs when the infected person coughs, talks, sneezes or laughs, or during certain procedures. Droplet particles are larger than 5 microns in size. Distribution is limited by the force of expulsion from the infected person and is usually 1 metre (NHMRC 2010). The droplet particles transmit infection when they travel directly from the infected person to a susceptible mucosal surface (nasal, conjunctivae or oral) of another person. However, droplets can be transmitted indirectly to mucosal surfaces (e.g. contaminated hands rubbing eyes or inserted into a mouth). This form of transmission requires the implementation of the transmission-based precaution tier 2 droplet precautions in addition to standard precautions when caring for such a person (see later in chapter for further explanation).

*Clinical note*: Some examples of infectious agents that are transmitted via the droplet mode include influenza virus, severe acute respiratory syndrome (SARS), pertussis and *Neisseria meningitides,* often referred to as *meningococcus.*

## Airborne transmission

Airborne dissemination may occur via tiny particle aerosols created during breathing, coughing, talking or sneezing containing infectious agents that remain infective over time and distance. Certain procedures, such as airway suctioning, endotracheal intubation, diagnostic sputum induction, positive pressure ventilation via face mask and bronchoscopy, can promote airborne transmission. The infective aerosols can be dispersed over long distances by air currents (e.g. ventilation or air-conditioning systems) and inhaled by susceptible individuals who have had no contact at all with the infectious person. This form of transmission requires the implementation of the transmission-based precaution tier 2 airborne precautions in addition to standard precautions when caring for such a person (see later in chapter for further explanation).

*Clinical note*: Some infectious agents that are transmitted via the airborne mode include varicella virus (chickenpox), *Mycobacterium tuberculosis* and measles (rubeola).

### CASE STUDY 22.1

Recently a person was transferred from another facility into the rehabilitation ward. The person had a severe case of dermatitis. His skin was very itchy, and his body was covered in a raised, reddened rash, with areas of broken skin where he had scratched so much the skin was no longer intact. The person was nursed for 3 weeks in the rehabilitation ward before he was diagnosed with a Norwegian scabies infestation. As soon as the diagnosis was made transmission-based precautions (contact precautions) were implemented and the person was cared for with the appropriate medication treatment.

During the first 3 weeks of his admission standard precautions should have been used at all times, particularly when applying the various lotions and creams that he was being treated with, and also when dealing with his linen. However, in the ensuing 2 to 3 weeks several staff members acquired the scabies infestation along with a couple of other inpatients.

*Upon reflection:* Transmission occurred because it was noted that on several occasions staff did not wear PPE (gloves or aprons) when in contact with his non-intact skin, staff did sit on the person's bed and on many occasions staff carried his used linen up against their bodies and uniforms before depositing the linen in the linen receptacle. This showed there was a breakdown of the minimum standard of infection prevention and control.

*Outcome:* What ensued was the closure of that rehabilitation ward, the treatment of every staff member, every person and every family member that had been in contact with the individuals in that particular ward, the steam cleaning of the carpet in that department, the removal and laundering of every individual privacy curtain as well as the laundering of every piece of clothing that the individuals had in their rooms. This was at a very large cost to the facility: a cost that was preventable if the correct infection control and prevention strategies had been used when applicable.

1. What infection prevention and control strategy should have been implemented on this person's admission?
2. What is considered best practice when handling used linen?
3. How would you describe the mode of transmission of scabies to other individuals including staff within the facility?

### Other modes of transmission

Transmission of infection can also occur via ingestion of contaminated food, water, medications or other common sources such as contaminated devices or equipment.

*Clinical note*: It is of great importance that nursing staff be aware of food being brought into healthcare settings for individuals by friends and family. If foods are not maintained at the correct temperature, the risk of food poisoning is very high. Foods of high risk include seafood, shellfish, soft cheeses and meat dishes. The Australian Food Safety Information Council (nd) has fact sheets available to the public on aspects of food safety. Facilities should have policies in place to help manage this (see Clinical Interest Box 22.1).

Variant Creutzfeldt-Jakob Disease (vCJD) is a disease that emerged in the UK in the 1990s. vCJD is linked to the consumption of meat products from cattle infected with bovine spongiform encephalopathy (BSE or 'mad cow disease'). vCJD is a separate disease to classical Creutzfeldt-Jacob disease (CJD) although some of the symptoms are similar. vCJD typically affects people at about age 30. The link between vCJD and ingestion of infected meat was discovered when 23 people living in Britain contracted CJD in the mid-1990s, about 10 years after the epidemic of bovine spongiform encephalopathy that occurred in the country from 1984–86. No cases of variant CJD have been identified in Australia to date and Australian cattle remain free of BSE (CJD Support Group Network 2010).

**Vector**-borne transmission (via mosquitoes, flies, rats and other animals) as a health concern is not as significant in Australia as it is in other parts of the world. However, in recent times there has been some increase in concern about transmission of Murray Valley encephalitis (MVE) in 2013 and dengue fever, Ross River virus and Barmah Forest virus in Victoria, New South Wales and Far North Queensland in 2014–15. Examples of microorganisms spread by this mode in other parts of the world are *Plasmodium falciparum* (malaria) and *Yersinia pestis* (plague).

## Portals of entry

Before a person can become infected, microorganisms must enter the body. Microorganisms can enter the body through the same routes they use for exiting:

- Inhalation into the respiratory tract
- Ingestion through the mouth into the alimentary canal
- Inoculation through the skin or mucous membrane, which can occur when the skin becomes cracked or when tissue integrity is disturbed during injury, surgical procedures, injections, bites or stings
- Transplacental entry occurs when organisms from a pregnant woman cross the placenta to enter the fetal circulation (e.g. toxoplasmosis).

*Clinical note*: Measures that control the exit of microorganisms also control the entrance of pathogens, for example:

- Maintaining skin and mucous membrane integrity
- Correct handling of urinary catheters and drainage sets
- Cleansing the genital area in a direction away from the urinary meatus to the rectum
- Implementing aseptic techniques, using sterile equipment during invasive procedures
- Cleansing wounds outwards from the wound site to prevent the entrance of microorganisms.

## Host susceptibility

**Susceptibility** is the degree of resistance an individual has to invading pathogens. Whether a person acquires an infection depends on their susceptibility to the infectious agent. A susceptible host is the last link in the chain of infection.

*Clinical note*: Factors that increase susceptibility of a person to infection are age (the very young or old), individuals receiving immunosuppressive treatment for cancer, chronic illness or following an organ transplant and those with immune deficiency conditions (Berman et al 2015). Susceptibility to infection can be reduced by lifestyle practices that boost resistance, such as healthy nutrition, adequate exercise, rest and sleep, stress-management activities and effective hygiene practices (see Clinical Interest Box 22.2).

### Resistance to infection

The body has certain natural resources that give a degree of resistance against infection. It has two main lines of resistance to infection: non-specific defences and a specific immune response. Non-specific defences are those that defend naturally against any invading organism or foreign matter. Such defence is also known as innate immunity, present at birth. It does not recognise specific microbes; it fights off all invading organisms in the same way. It provides us with rapid responses to protect against disease. These defences can be divided into two categories: external and internal. External physical barriers include intact skin, mucous membranes, normal body flora and some body secretions; for example, sweat, sebum, saliva and tears. Internal defences are the automatic protective actions of the inflammatory process, phagocytic cells, 'natural killer' cells and protective proteins. **Inflammation** is a localised and non-specific response of the tissues to an injury or infectious agent. It helps prevent further spread of injury, dilutes or destroys the injuring agent and promotes healing and repair of the injured tissues. It is characterised by five signs: pain, swelling, redness, heat and impaired function of the body part if injury is severe (Berman et al 2015).

Specific defences defend against specific foreign agents or antigens, such as a specific bacterium, virus, pollen or toxin, once it has broken through the innate immunity defences. This defence is also known as adaptive (acquired) immunity (see Table 22.4). Having **immunity** means being resistant to or being unaffected by a particular infectious disease. It means that a specific antibody has been produced to defend the body against a specific pathogen or the toxin it produces (the **antigen**). The body's immune responses are under the control of the lymphatic system. It is a highly efficient system that responds very specifically to the threat of infection. It is made up of lymph, lymphatic vessels, lymph nodes, red bone marrow, the thymus gland, spleen and tonsils.

## CLINICAL INTEREST BOX 22.1 Bringing food in for individuals

Families and friends sometimes bring in food for individuals. There can be a risk of food poisoning when food is not properly prepared, transported or stored. This can have serious consequences for the person.

### Foods that are safe to bring in to individuals

Dry biscuits (Salada, savoy, rice crackers, water crackers)
Sweet biscuits (Scotch finger, butternut, fruit biscuits)
Pretzels, potato chips
Muesli bars
Fresh and dried fruit
Baked products (bread, muffins, bagels, scones, plain cakes)
Boiled lollies, liquorice and mints

### Foods that are extremely unsafe and therefore are NOT recommended to bring in for individuals. Any foods that can spoil if not refrigerated

Meat and poultry
Cooked or raw fish, shellfish, oysters
Rice and pasta dishes
Soft cheeses, deli meats and pâtés
Salads and other items containing dairy products or creamy dressings (e.g. coleslaw, potato salad)
Sweet dishes and cakes which contain custard cream or are made from uncooked eggs
Casseroles, soups and sauces
Sandwiches with potentially hazardous food fillings (meat, fish, poultry, cheese)
Pizza and take-away foods

*If you are unsure about what food is safe or wish to bring in any of the listed items, please speak to the nursing staff or contact the food services department.*

### Safe food guidelines

#### Transport

All potentially unsafe food must be properly transported during the journey to protect from contamination. If the food is served chilled or is to be reheated it should be kept cold during transport in an esky or other cooler-type container.

If the food is being transported hot, you must ensure that it is kept hot. Hot food is difficult to keep hot and is best avoided if you are travelling long distances. It is best to chill the food overnight and reheat before eating.

Nursing staff must be informed of any food brought in for individual consumption.

#### Storage

Any food that is not going to be consumed immediately must be covered, labelled with the individual's name, room number, date and time the food was brought into the hospital and refrigerated within 15 minutes of arriving onto the ward.

Hospital staff will discard all potentially unsafe food that is stored in the fridge and not consumed within 24 hours of being brought into the hospital.

#### Special dietary requirements

It is essential that persons who are on special diets are not provided with food that has not been approved by the dietitian, nursing or food service management.

#### Preparation and reheating

Always wash hands thoroughly before preparation and prior to handling food.

Reheat food until it is steaming hot throughout.

Food reheated to above 75°C for 2 minutes will kill most foodborne bacteria or viruses that can cause illness.

Never reheat food that has been reheated previously.

Please do not offer to share food with other persons.

I have read, understood and accept the risk associated with consuming food brought into this hospital from an external source.

Name:_____

*(NSW Food Authority http://www.foodauthority.nsw.gov.au)*

Lymphocytes are the most significant cells in the body's immune responses. There are two categories of lymphocytes involved in the specific immune response: T-lymphocytes (T-cells) and B-lymphocytes (B-cells).

To function effectively in defending the body from invading organisms, these defence responses must be able to distinguish between the body's own cells and foreign agents. Malfunction of a person's immune system can cause a failure to recognise cells that belong to the self. This results in damage or destruction of 'self' cells. An attack on the body's own cells is the basis of autoimmune disorders such as rheumatoid arthritis, juvenile-onset (type 1) diabetes mellitus, pernicious anaemia, multiple sclerosis and systemic lupus erythematosus.

## CLINICAL INTEREST BOX 22.2 General factors increasing susceptibility to infection

- Compromised skin integrity or mucous membranes
- Decreased mobility
- Very young or advanced age
- Malnutrition
- Alcoholism or other drug addiction
- Decreased cough reflex
- Decreased blood circulation
- Immunosuppressive therapy (e.g. chemotherapy, corticosteroid medication)
- Pregnancy
- Prematurity in infants
- Suppressed inflammatory response
- Chronic underlying illness or chronic stress
- Suppression or insufficient number of white blood cells
- Indwelling tubes (urinary catheter, IV line)
- Virulence of the infectious agent and individual resistance to the infectious agent

*(Modified from Crisp et al 2013)*

## Factors influencing susceptibility to infection

In a healthcare setting there are several factors that influence the individual's outcome after exposure to a pathogenic organism:

- Their immune status at time of exposure
- Age (neonates and the elderly are more susceptible) (see Table 22.5 and Clinical Interest Box 22.3) (*Clinical note*: First-line defence consists of intact skin, mucous membranes and their secretions. Skin becomes very fragile with age; care must be taken to protect the aged person. Naturally acquired passive immunity involves the natural transfer of antibodies from a mother to her baby. These antibodies are transferred via the placenta or the mother's milk, especially the first milk, called colostrum. This immunity lasts only a few weeks or months, covering the baby until its immune system matures. An example of this is if the mother is immune to polio or rubella the baby is also. Care must be taken to protect the neonate from exposure to infection.)
- Health status, history or comorbidities (*Clinical note*: Diabetes can slow the body's ability to fight infection.)
- The virulence of the agent
- Nutritional status (poor nutrition can slow the body's ability to fight infection)
- Wounds, indwelling devices and length of stay in healthcare facility
- Level of stress and coping strategies.

An important component of nursing practice is assessing every individual for existing infection or the potential for contracting an infection. There are some medical and drug therapies, such as corticosteroid medications or chemotherapy, which compromise immunity to infection. Nursing assessment of the individual's history to determine if there is an increased susceptibility to infection related to any

**TABLE 22.4 | Types of acquired (specific) immunity**

| | Type | Antigen or antibody source | Duration of immunity |
|---|---|---|---|
| 1 | Active: self-produced immunity | Antibodies are produced by the body in response to an antigen | Long |
| | a. Natural | Antibodies are formed in the presence of active infection in body; exposure to antigen | Lifelong |
| | b. Artificial | Antigens (vaccines or toxoids) are administered to stimulate antibody production; through vaccination. | Many years but may need to be boosted |
| 2 | Passive: transferred immunity | Antibodies are produced by another source, animal or human | Short |
| | a. Natural | Antibodies transferred naturally from an immune mother to baby (via placenta, breast milk) | 6–12 months |
| | b. Artificial | Injection of immune serum/globulin/antibody from another animal or human. | 2–3 weeks |

*(Modified from Berman et al 2015; Lee & Bishop 2013)*

## TABLE 22.5 | Factors that increase susceptibility to infection in older adults

The normal changes of ageing mean that older adults are at higher risk of infection than younger adults. Any illness experienced by an older adult increases the risk because it places increased demands on the body and a strain on its natural defence mechanisms. Nursing interventions aim to decrease this risk.

| Body area | Effect of ageing process | Nursing interventions |
|---|---|---|
| Skin | Loses resilience because of reduced tissue elasticity and increased dryness, making the skin more susceptible to damage and slower to repair<br>Any opening in the skin provides a portal of entry for microorganisms | Gentle handling during bathing, moving, lifting and other procedures<br>Careful observation of skin for signs of pressure or tears at least once each shift<br>Use of protective aids such as sheepskins<br>Use of skin moisturiser |
| Respiratory system | Decreased number of cilia lining the trachea reduces ability to move mucus, debris and dust into the pharynx<br>Lung elasticity declines and thoracic muscle strength diminishes, making it more difficult to cough effectively so as to expel accumulated material from the airway | Increase fluid intake to thin mucous secretions<br>Deep breathing and coughing exercises to expand the lungs and aid movement of material towards the pharynx to be expelled<br>Effective oral hygiene to reduce potential for microorganisms to invade the trachea/lungs<br>Mobilise as soon as possible<br>Maintain postsurgical individuals (unless contraindicated) in a semi-Fowler's (semi-upright) position to promote lung expansion<br>Motivate/support a person who smokes to reduce/break the habit |
| Immune system | Strength of immune responses decreases<br>Decreased T-cell function due to decreases in cell-mediated and humoral immunity | Recommend annual immunisation against influenza<br>Implement all standard precautions to minimise risk of exposure to pathogens<br>Promote exercise and healthy diet and facilitate regular rest and sleep to strengthen natural defences |
| Gastrointestinal system | Loss of smooth muscle in stomach and decreased peristalsis in intestine leads to slower emptying of contents and any ingested microorganisms, increasing potential for colonisation<br>Alteration to secretions of stomach acid and pepsin lead to a change in pH that interferes with ability to protect against ingested pathogens | Educate about hygienic preparation, storage and cooking of food for consumption<br>Educate regarding handwashing and other hygiene measures to reduce potential for transference of microorganisms into the gastrointestinal tract<br>Promote effective oral hygiene to minimise potential for microorganisms to enter the gastrointestinal tract |
| Urinary/renal system | Structural changes in kidney and renal vessels reduce renal blood flow. Together with general loss of functioning of body cells this results in the body, under the stress of infection, being less able to maintain adequate fluid homeostasis<br>Hypertrophy of prostate gland in males, cystocele or rectocele and degeneration of nerves to bladder causes inadequate emptying of bladder and urine stasis. Stasis predisposes to urinary tract infection | Monitor fluid intake/output<br>Observe and report signs of dehydration/fluid overload<br>Implement all standard precautions to minimise exposure to pathogens<br>Promote intake of sufficient fluid to flush urinary system with dilute urine<br>Encourage person to take sufficient time to empty bladder fully |

*(Modified from Victorian Government Health information: Best Care for older people everywhere—The Toolkit 2014; Berman et al 2015)*

## CLINICAL INTEREST BOX 22.3 Older adults and infection

- Older adults should be immunised annually against influenza
- Circulatory changes related to congestive heart failure and calcified mitral and aortic valves mean that older adults with these conditions are prone to pneumonia and bacterial endocarditis
- Older adults or other persons who are cognitively impaired often need special help with infection control measures (e.g. prompting to wash their hands at appropriate times)
- Symptoms of infections in older adults are often manifested as increased confusion or other changes in behaviour such as tearfulness or irritability. They may no longer have the ability to communicate their discomfort or to tell you about their symptoms verbally

*(Modified from Crisp et al 2013)*

## CLINICAL INTEREST BOX 22.4 Nursing assessment of the individual on admission

- What infections have you had in the past and how were they treated?
- Have any of these infections reoccurred?
- Are you currently taking or have you recently taken any antibiotics, anti-inflammatory, anti-coagulant medications?
- What past surgeries have you had?
- Did you have any complications following your last surgery?
- How would you describe your eating habits?
- Do you have any wounds or broken skin?
- Have you had any recent diagnostic procedures or therapy through your skin or a body cavity?
- Have you had any recent admissions in a healthcare facility and how long were you in hospital?
- Have you recently experienced any loss of energy, loss of appetite, nausea or vomiting?
- Do you take any vitamin supplements?

*(Modified from Victorian Government Health information: Best Care for older people everywhere—The Toolkit 2014 & Royal Children's Hospital Melbourne 2014)*

medications or treatments is important. Clinical Interest Box 22.4 illustrates several questions that could be considered.

Another component of nursing practice is to ensure individuals under your care are given as much information as they require, assisting them in keeping themselves infection free while within a healthcare facility. There are many fact sheets available to the public. The ACIPC Member Services Committee has developed some excellent resources for consumers that can be found on this online link: http://interactivejam.com.au/ACIPC-Consumer-minisite-v2/.

### Infection prevention and control through work health and safety

Not only do we concern ourselves with minimising the risk of acquiring infection for individuals under our care we must also protect the staff. In the course of their duties, healthcare workers can be exposed to infectious agents (through direct contact with infectious individuals, visitors or colleagues, or indirectly with contaminated surfaces and equipment, as well as through the result of a sharps injury). Healthcare workers can also place individuals at risk of transmission of infection if they have an infectious condition that is capable of being transmitted to the person as they perform their duties.

All employers and employees have a responsibility in relation to infection prevention and control and work health and safety. While the organisation has a duty of care to healthcare workers, staff members also have a responsibility to protect themselves and to not put others at risk.

As part of the infection control and prevention program each facility should develop, implement and document effective policies and procedures related to staff health and safety, including strategies to prevent occupational exposures to infectious hazards, chemical safety and staff immunisation programs. Employers should take all reasonable steps to ensure that staff are protected against vaccine-preventable diseases (NHMRC 2010). The most recent edition of *The Australian Immunisation Handbook* (Australian Government, Department of Health 2015) provides detailed information on immunisation schedules and vaccines. Table 22.6 gives the recommended vaccinations for healthcare workers.

## INFECTION PREVENTION AND CONTROL IN PRACTICE

The risk of transmitting healthcare-associated infections (HAIs) or infectious disease among individuals is high. When a person has a suspected or known infection, healthcare workers follow infection control practices (Crisp et al 2013). However, there are many situations where the healthcare worker is not aware that individuals have infections, as the majority of HAIs are found in the colonised blood and body fluids of individuals.

In 1996, the Infection Control Working Party of the National Health and Medical Research Council (NHMRC) in Australia recommended adoption of the term 'standard precautions' as the minimum requirement in work practices to promote infection control and prevention. 'Additional precautions', now known as 'transmission-based precautions', are advised where standard precautions are not sufficient on their own to prevent transmission of infection. This two-tiered approach reflects disease transmission and is how infection prevention and control principles should be viewed (see Table 22.7).

## TABLE 22.6 | Recommended vaccination for all healthcare workers

| | |
|---|---|
| All healthcare workers directly involved in individual care or the handling of human tissues | Hepatitis B<br>Influenza<br>Pertussis (dTpa), tetanus and diphtheria<br>MMR (measles, mumps, rubella—if not immune)<br>Varicella (chickenpox—if not immune) |
| All healthcare workers who work with remote Indigenous communities in NT, QLD, SA and WA; medical, dental and nursing undergraduates (in some jurisdictions) | All of the above +<br>Hepatitis A |
| Healthcare workers who may be at high risk of exposure to drug-resistant cases of tuberculosis | All of the above +<br>BCG |

*(Australian Government, Department of Health 2015. © Commonwealth of Australia 2015)*

## TABLE 22.7 | Standard and transmission-based precautions for infection control: main points

**Standard precautions**

Routine personal hygiene practices to be observed
Hand hygiene must be performed before and after all significant individual contacts, before and after a procedure and after touching the person's environment
Gloves to be worn when touching blood, all body fluids, secretions and excretions, non-intact skin and mucous membranes. Hand hygiene must be performed before putting gloves on and after removal of gloves
Personal protective equipment such as masks or face shields and eye protection to be worn when care activities may generate splashes or sprays of blood, body fluids, secretions or excretions
Impermeable gowns to be worn if clothes are likely to be soiled with blood or body fluid. Hand hygiene must be performed immediately upon gown removal
Use of standard aseptic technique for a simple wound dressing, peripheral intravenous cannulation, blood collection and intravenous drug administration
Use of surgical aseptic technique for large wound dressings, insertion of indwelling catheter and insertion of central intravenous line or portacath
Protocols for handling and disposal of sharps and other clinical wastes to be followed at all times
Environmental control policies to be adhered to (e.g. cleaning, disposal of linen and rubbish, disinfection, sterilisation and spills management)
Care equipment to be cleaned and reprocessed according to protocols or policies
Private room not necessary unless person unable to maintain hygiene practices in accordance with prevention and control strategies

**Transmission-based precautions**

| Type of transmission | Protection | Example |
|---|---|---|
| Airborne | Negative pressure room or private room with door closed; use of P2 or N95 mask, surgical mask for the individual if transported/transfer is required. Gloves and gowns as per standard precautions. Restrict visitor numbers and precautions are as for staff. | Varicella (chickenpox), measles, TB, SARS |
| Droplet | Private room or cohort (same infectious agent and antibiogram); use of surgical mask and goggles/face shield; mask for individual if transported. Gloves and gowns as per standard precautions. | Influenza, rubella, pertussis, mumps, norovirus, meningococcus, respiratory syncytial virus |
| Contact | Private room or cohort (same infectious agent and antibiogram); gloves for direct patient or environmental contact; gowns for direct contact or splashing. Surgical mask required if infectious agent is isolated in sputum. Eye protection as required per standard precautions | MROs, *Clostridium difficile*, *Shigella*, acute diarrhoea, scabies, highly contagious skin infections |

*(National Health and Medical Research Council 2010)*

## Standard precautions and transmission-based precautions

The *Australian Guidelines for the Prevention and Control of Infection in Healthcare* (NHMRC 2010) are the national guidelines for infection control and prevention for healthcare settings. Standard precautions are the basic recommended work practices to be implemented in the treatment and care of all individuals regardless of diagnosis or perceived infectious risk. Standard precautions are the first tier in a two-tiered approach to infection prevention and control. It is a first-line approach, a primary strategy that minimises the risk of transmission of infectious agents from person to person, even in high-risk situations.

## Tier 1: standard precautions

Standard precautions relate to:

- Personal hygiene practices, particularly effective hand hygiene, before and after every episode of individual contact
- Use of personal protective equipment (PPE) such as gloves, gowns, plastic aprons, masks/face-shields or eye protection when appropriate
- Appropriate handling and disposal of sharps
- Implementation of environmental controls including cleaning and spills management
- Appropriate reprocessing of reusable equipment and instruments
- Aseptic non-touch technique
- Appropriate handling of waste and linen
- Practising respiratory hygiene and cough etiquette (NHMRC 2010).

Standard precautions should be used in the safe handling of blood (including dried blood) and all other body substances, secretions and excretions (excluding sweat) regardless of whether or not they contain visible blood, and the safe handling of non-intact skin and mucous membranes.

Standard precautions are all that is required for persons with blood-borne viruses such as HIV, hepatitis B or hepatitis C unless other factors indicate it necessary, such as the presence of an additional highly transmissible disorder; for example, pulmonary tuberculosis (TB).

### CRITICAL THINKING EXERCISE 22.2

Mr Andrews is in hospital following a motor vehicle accident. He is an insulin-dependent diabetic. He has a fractured pelvis, fractured right arm and severe grazes to his left arm and leg. He is confined to bed and has a urinary catheter in situ. He needs assistance with all activities of daily living. His medical notes state he is hepatitis B positive. What infection control measures are appropriate when caring for Mr Andrews to prevent transmission of hepatitis B?

## Implementing standard precautions

In applying standard and transmission-based precautions as part of day-to-day practice, healthcare workers should ensure that their individuals understand why certain practices are being undertaken, and that these practices are in place to protect everyone from the risk of infection. Individuals under their care and visitors should also be aware of their role in minimising risks by following basic hand hygiene, cough etiquette and respiratory hygiene, and informing staff about aspects of their medical history if necessary (e.g. known MRSA colonisation).

Standard precautions involve evidence-based activities aimed at interrupting the chain of infection. These include hand hygiene measures and use of a range of protective devices.

## Standard precautions: hand hygiene

Handwashing with soap and water has been used to improve personal hygiene for centuries; however, the link between handwashing and the spread of disease was only established in the mid-nineteenth century. An Austrian medical officer, Ignaz Semmelweis, is considered to be the first person who recognised that hospital-acquired infection was directly transmitted via the hands of healthcare workers. Since then many further investigations have confirmed the important role that contaminated hands play in the transmission of healthcare-associated pathogens. Hand hygiene remains the cornerstone of infection prevention and control. Yet, even though we know that proper use of hand hygiene is critical to the prevention of infection, compliance among healthcare workers has historically been at 40% (Erasmus et al 2010).

Therefore, poor hand hygiene practice among healthcare workers is strongly linked with healthcare-associated infection transmission and is a major factor in the spread of antibiotic-resistant pathogens within healthcare facilities. Despite this, efforts to improve the rate of hand hygiene compliance have historically been ineffective or poorly sustained. Numerous barriers to appropriate hand hygiene compliance have been reported (Grayson et al 2013) including:

- Hand hygiene products cause skin irritation and dryness
- Individual needs perceived to take priority over hand hygiene
- Handwashing sinks/basins inconveniently located and/or not available
- The perception that glove use dispenses with the need for hand hygiene
- Insufficient time for hand hygiene, due to high workload and understaffing
- Poor knowledge of guidelines or protocols for hand hygiene
- Lack of positive role models
- Lack of recognition or understanding of the risk of cross-transmission of microbial pathogens
- Until recently, the lack of scientific information showing the definitive impact of improved hand hygiene on lowering healthcare-associated infection rates.

The introduction of the **alcohol-based hand rub** has assisted in the improvement of hand hygiene compliance among HCWs as well as a reduction in healthcare-associated

infection (HAI), as shown in recent hospital-based studies. A study by Song and colleagues showed that when hand hygiene compliance increased from poor (<60%) to excellent (90%), each level of improvement was associated with a 24% reduction in the risk of MRSA acquisition. This risk decreased significantly (by 48%) with hand hygiene compliance levels above 80% (WHO 2014).

Hand Hygiene Australia publishes the results of hand hygiene auditing within Australian healthcare facilities on its website. Overall national hand hygiene compliance in October 2014 was 81.9% (HHA 2015). There is convincing evidence that improved hand hygiene can reduce infection rates. More than 20 hospital-based studies (including systematic reviews) of the impact of hand hygiene on the risk of HAI have been published between 1977 and 2014. Despite study limitations almost all reports showed an association between improved hand hygiene practices and reduced infection and cross-transmission rates (CHRISP 2013). The World Health Organisation (WHO) has published an information sheet based on a literature review from January 1980 to December 2013 on the available evidence on the impact of hand hygiene in reducing transmission and infections by multidrug-resistant organisms in healthcare settings (WHO 2014).

Since 2002, the Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines have defined alcohol-based hand rub, where available, as the standard of care for hand hygiene practices in healthcare settings, whereas handwashing is reserved for particular situations only (e.g. caring for an individual with *Clostridium difficile* or norovirus infection, and/or if the hands are visibly dirty). WHO (2009) developed a culture-change program to improve hand hygiene compliance by all healthcare workers. It is known as 'The 5 Moments for Hand Hygiene'.

## National hand hygiene initiative

The ACSQHC has instigated the National Hand Hygiene Initiative (NHHI) and assigned the responsibility of its delivery and rollout to Hand Hygiene Australia (HHA). The key aim of the national initiative is to improve hand hygiene compliance among healthcare workers, and to reduce the transmission of infection in healthcare services throughout Australia. This involves a multifaceted culture-change program to improve hand hygiene compliance through the increased use of alcohol-based hand rubs.

'The 5 Moments for Hand Hygiene' (see Figure 22.3) developed by WHO (2009) and adopted by Hand Hygiene Australia (Grayson et al 2013):

- Protects individuals against acquiring infections from the hands of the healthcare workers

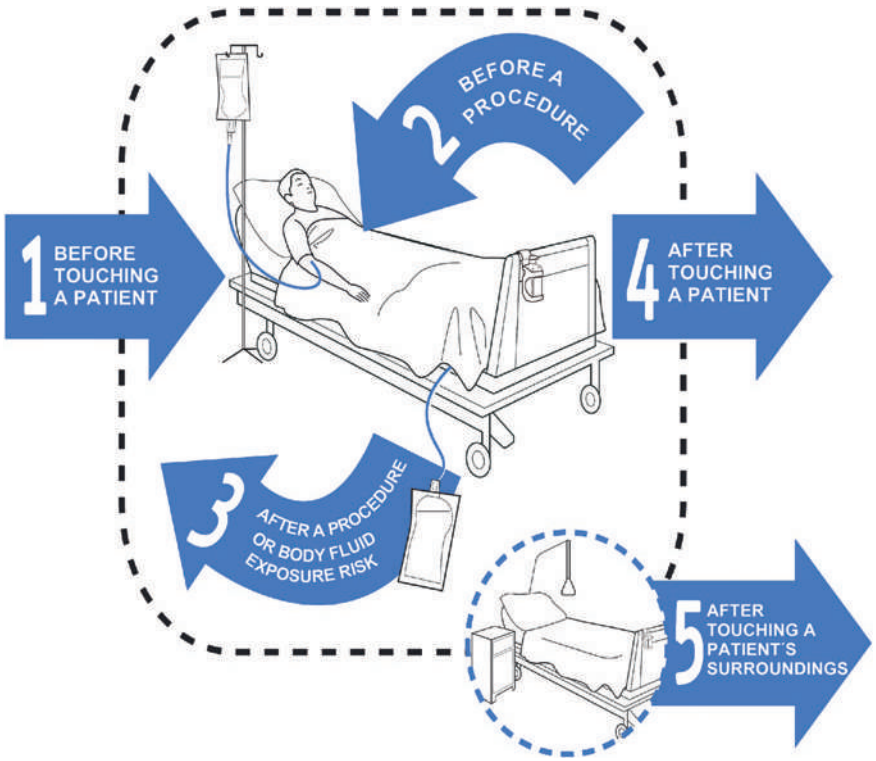

**Figure 22.3** The '5 Moments for Hand Hygiene' tool is based on evidence

It identifies when hand hygiene should be performed. That is, hand hygiene should be practised before every episode of individual contact, including between different individuals and between different care activities for the same person, and after any individual activity or contact. The message for every healthcare worker is, perform hand hygiene before and after contact with each individual or contact with the individual's environment

*(Reproduced with permission of the World Health Organization)*

- Helps to protect individuals from infectious agents (including their own) entering their bodies during procedures
- Protects healthcare workers and the healthcare environment from acquiring individuals' infectious agents

## The 5 moments for hand hygiene

**Moment 1**: Hand hygiene must be performed before touching an individual.
**Moment 2**: Hand hygiene must be performed immediately before a procedure.
**Moment 3**: Hand hygiene must be performed following a procedure or potential body fluid exposure.
**Moment 4**: Hand hygiene must be performed after touching an individual.
**Moment 5**: Hand hygiene must be performed after touching the individual's environment, without touching the individual.

For 'The 5 Moments for Hand Hygiene' initiative to be effective, alcohol-based hand rub needs to be situated at point of use; for example, the end of the bed. Sustained, successful implementation of the initiative within the healthcare facility requires commitment and understanding from management, committed role models and champions throughout the facility, a team approach which should include not only the nursing sector but the medical practitioners as well and, most importantly, it requires understanding of the reason for the initiative and ownership of prevention of transmission of HAIs by each stakeholder (see Figure 22.4).

### CRITICAL THINKING EXERCISE 22.3

Nurse Nguyen enters a person's room, assists the person out of bed, helps the person put on their slippers and dressing gown, and helps the person to the lounge chair, then makes the bed, then leaves the room. How many times should Nurse Nguyen have performed hand hygiene?

## Technique: is it important?

There are two recognised techniques for performing hand hygiene: hand hygiene with an alcohol-based hand rub and handwashing with soap and water (see Figures 22.5 and 22.6 and Clinical Skill 22.1).

*Clinical note*: Effective hand hygiene relies on appropriate technique as much as on the selection of the correct product. If the technique is not appropriate this leads to failure of hand hygiene removing or killing microorganisms on the hands, despite the appearance of having complied with hand hygiene requirements.

## Which product should be used?

Existing guidelines agree that hand hygiene using alcohol-based hand rubs is more effective against the majority of common infectious agents on hands than hand hygiene using plain or antiseptic soap and water. Alcohol-based hand rubs are the products of choice unless the hands are visibly soiled or the HCW is caring for an individual with a *Clostridium difficile* or norovirus infection; in this case handwashing with antiseptic soap and water is required before and after care of the individual and use of personal protection equipment (PPE). Such rubs can also be placed at point of use, are faster to use and the evidence shows they have better skin tolerability. The alcohol-based hand rub product must have Therapeutic Goods Administration (TGA) approval for skin antisepsis and meet the requirements of EN 1500 testing standard for bactericidal effect.

Placement of the hand hygiene product may also play a very important part in the success of the program. In Australia a draft Australian standard titled AS 1071—Placement and presentation of hand hygiene materials in healthcare settings (2015) was released with the intention to standardise the placement of hand care products nationally and to eliminate the possibility of using the wrong product to perform hand hygiene; for example, moisturiser instead of soap. This draft Standard is based on the fact that in 2009 Queensland Emergency Medicine Research Foundation funded a research study that demonstrated that compliance with hand hygiene is directly proportional to the accessibility and availability of products to decontaminate hands. The study also showed that there was no consistency in the positioning of hand hygiene solutions relative to the sink in any healthcare setting. As a result, staff reported the widespread and frequent use of moisturiser instead of handwash to decontaminate their hands, and have self-reported the need to standardise the placement of solutions. This Standard is currently open to review and comment by infection prevention and control professionals throughout Australia.

## Does improved hand hygiene make any difference?

Recent evidence of improved hand hygiene has been associated with:

- Sustained decreases in the incidence of infection caused by MRSA and VRE (Pittet & Boyce 2001)
- Reduction in healthcare-associated infections of up to 45% in a range of healthcare settings (Fendler et al 2002)
- Greater than 50% reduction in the rates of nosocomial disease associated with MRSA and other multi-resistant organisms after 1–2 years (Grayson et al 2013)
- 8.9% reduction in HAIs and decline in the bloodstream infections caused by MRSA and extensively drug-resistant *Acinetobacter baumannii* (Chen et al 2011)
- Significant reduction of MRSA infections/colonisation/10 000 patient days (Mestre et al 2012)
- Reduction in infection rates in four of the six Australian states studied. Two states showed an immediate reduction in rates of 17% and 28%, two states showed a linear decrease in rates of 8% and 11% per year, and two showed no change in infection rates (Barnett et al 2014).

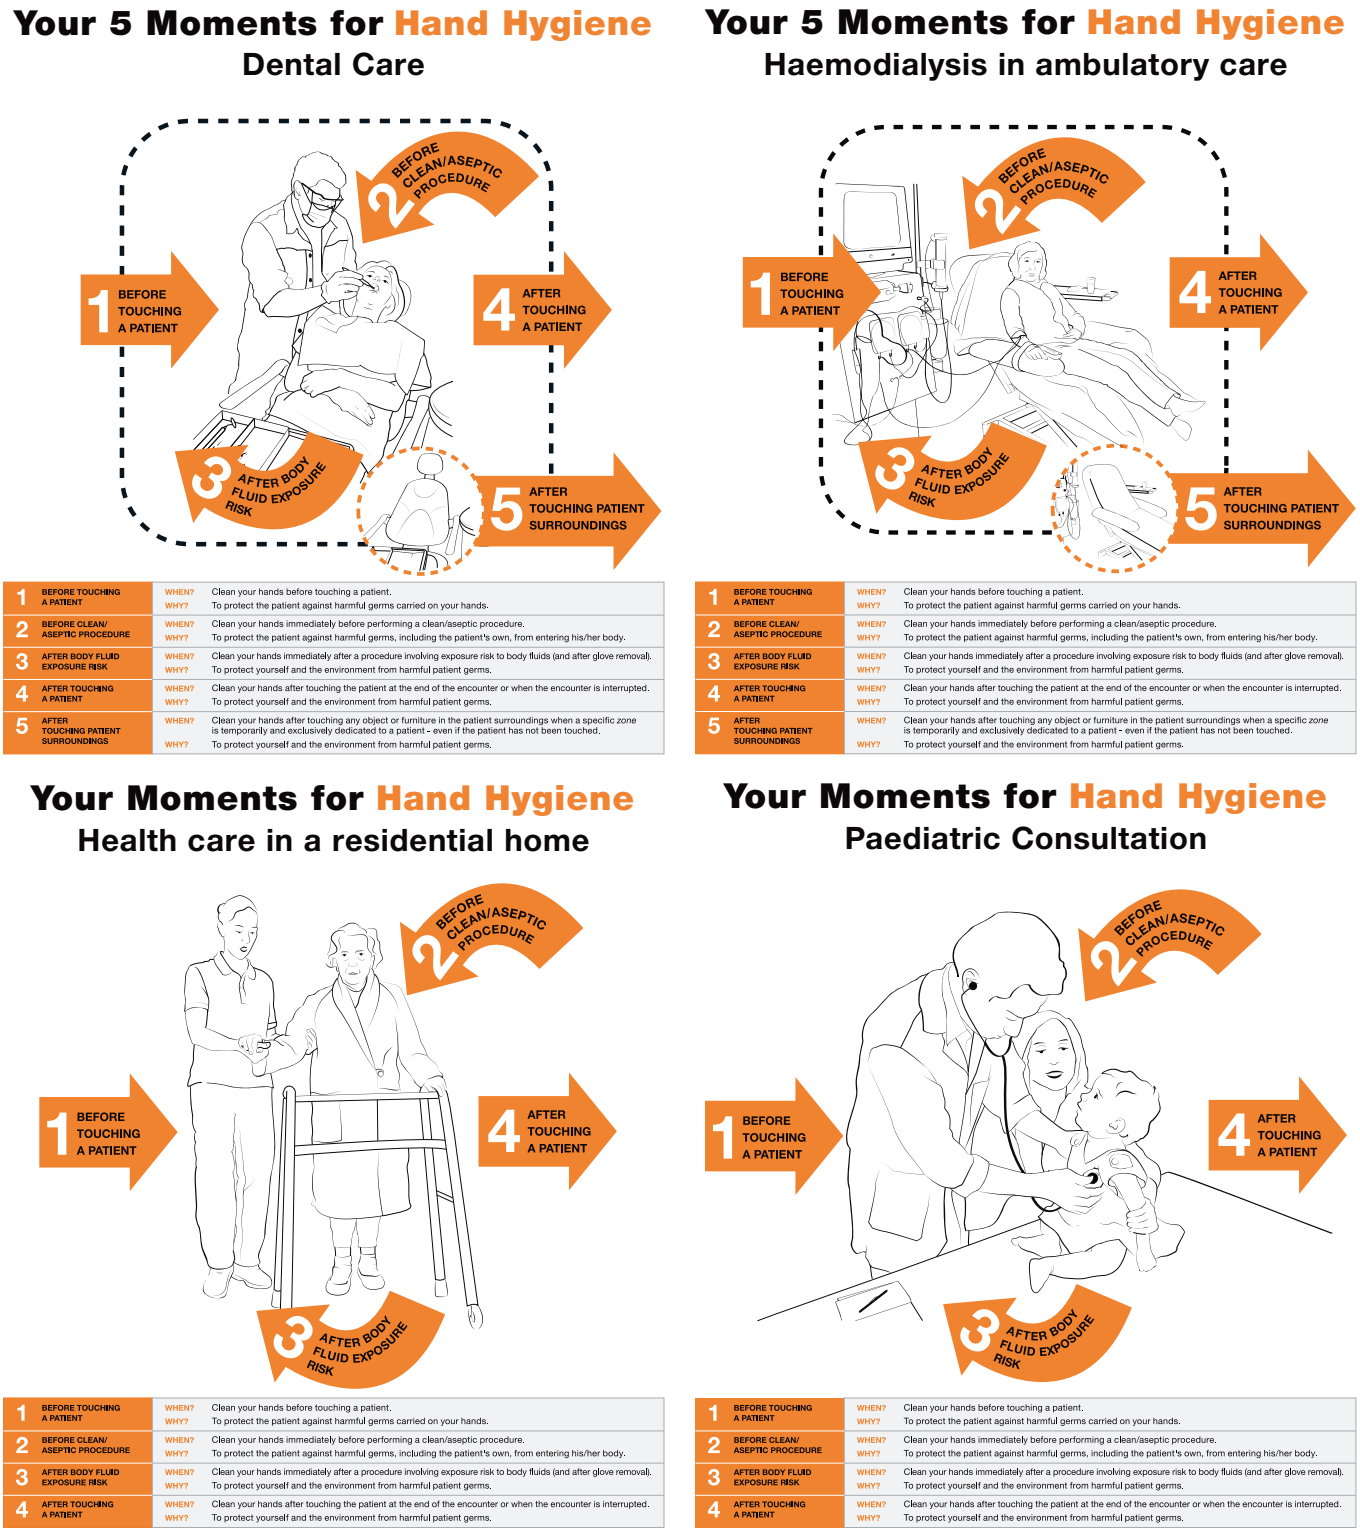

**Figure 22.4** The 5 Moments for Hand Hygiene

These can be applied in any healthcare setting, including the acute, day only, dental surgery, dialysis unit, nursery and clinic setting. The key emphasis is to perform hand hygiene before and after every episode of contact, before and after any procedure and also after contact with the environment. Hand hygiene must also be performed after the removal of gloves

*(Reproduced with permission of the World Health Organization)*

**Figure 22.5** How to use alcohol-based hand rub

1 Apply the amount recommended by the manufacturer onto dry hands 2 Rub hands together so that the solution comes in contact with all surfaces of the hand, paying attention to the tips of the fingers, the thumbs and the webbing between the fingers 3 Continue rubbing until the solution has evaporated and the hands are dry. *Clinical note*: This is of great importance when then donning gloves, because if hands are not dry, manipulation of gloves is very difficult and it may cause reactive dermatitis

*(Reproduced with permission of the World Health Organization)*

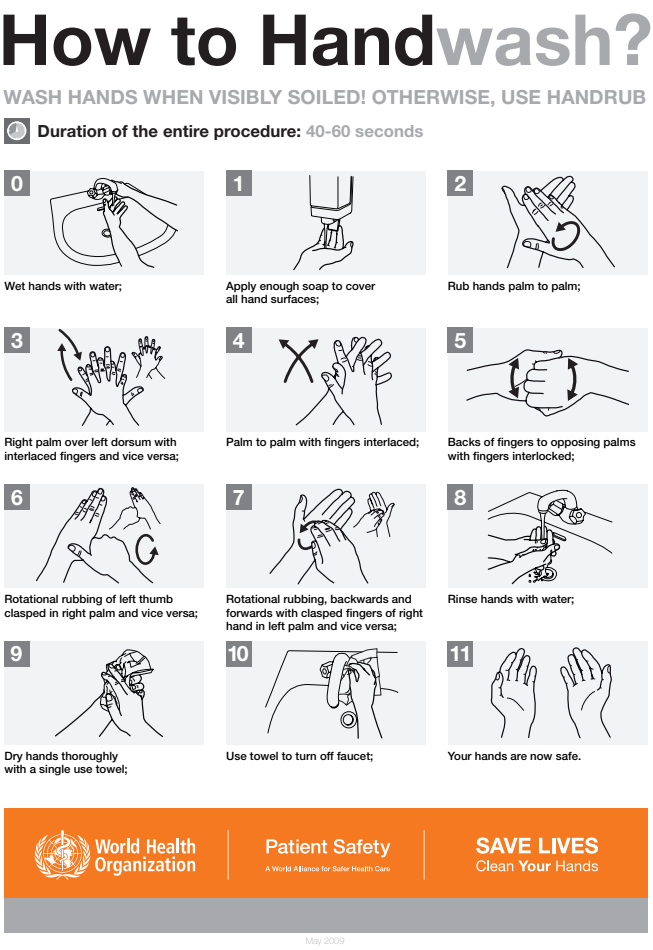

**Figure 22.6** How to handwash using soap (including antimicrobial soap) and water

1 Wet hands under running water and apply the recommended amount of liquid soap 2 Rub hands together for a minimum of 15 seconds so that the solution comes in contact with all surfaces of the hand, paying attention to the tips of the fingers, the thumbs and the webbing between the fingers (these areas are often missed during hand hygiene) 3 Rinse hands thoroughly under running water, and then pat dry with single-use towels. Moist skin becomes chapped readily

*(Reproduced with permission of the World Health Organization)*

Hand hygiene practice alone is not sufficient to prevent and control infection and needs to be part of a multifaceted model of infection prevention and control. Figure 22.7 identifies the areas of the hands most often neglected during washing.

To complement the 5 Moments for Hand Hygiene some healthcare facilities have introduced a Bare Below the Elbow Initiative which adds the need to have long sleeved clothing rolled up above the elbow so as not to interfere with effective hand hygiene practice. Long ties and lanyards are also not recommended (Crisp et al 2013). Retractable (or similar) ID card holders are recommended in place of lanyards and should be cleaned regularly. If ties are worn they should be tucked in or secured.

## Other aspects of hand hygiene

As intact skin is the first line of defence against infection, cuts and abrasions are a possible source of entry for infectious agents and reduce the effectiveness of hand hygiene practices. To reduce the risk of cross-transmission of infectious agents, cuts and abrasions should be covered with waterproof dressings.

An emollient hand cream provided for use at the healthcare facility should be used regularly, such as after performing hand hygiene before a break or going off duty. This assists in maintaining skin integrity. The products supplied by your healthcare facility have been chosen for their compatibility with the alcohol-based hand rubs and antiseptic hand

## CLINICAL SKILL 22.1 Handwashing/hand hygiene

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Accessible sink with warm running water<br>Antimicrobial/regular soap solution or alcohol-based hand rub (ABHR)<br>Paper towel<br>Waste bin/receptacle |
| **Skill activity** | **Rationale** |
| Inspect surface of hands for breaks or cuts in skin or cuticles. Cover lesions with a waterproof dressing before providing care<br>Inspect hands for heavy soiling<br>Ensure nails are short and free of nail polish and/or artificial nails<br>Remove all jewellery including wristwatch, rings and bracelets | Open cuts or wounds can harbour high concentrations of microorganisms<br>Soiled hands may require a more lengthy hand wash<br>Most microbes on hands come from beneath the fingernails<br>Artificial nails can harbour four times the microorganisms than non-artificial<br>Jewellery can harbour microbes and rub against skin causing shedding of skin cells |
| **Handwash**<br>Wash hands when visibly soiled. Otherwise use hand rub<br>Duration of entire procedure: 40–60 seconds<br>Stand in front of sink, keeping hands and uniform away from sink surface (if hands touch sink during handwashing, repeat) | The inside of the sink is considered a contaminated area. Reaching over the sink increases the risk of touching the edge, which is contaminated |
| Turn on water, regulate flow and temperature so that the temperature is warm<br>Avoid splashing water against uniform | Warm water is more comfortable and it removes less of the skin's protective oils than hot water.<br>Microorganisms multiply in moisture and travel |
| Wet hands and wrists thoroughly under running water. Keep hands and forearms higher than elbows during washing<br>Apply the recommended amount of liquid soap or antimicrobial solution | Keeping hands elevated allows water to flow from least to most contaminated areas<br>The amount applied should be as per the manufacturer's instructions |
| Wash hands using plenty of lather and friction for at least 15 seconds<br>Interlace fingers and rub palms, sides and back of hands paying attention to the tips of the fingers, thumbs and the webbing between the fingers | Soap cleans by emulsifying fat and oils. Friction and rubbing mechanically will loosen and remove debris and transient bacteria. Interlacing the fingers and thumbs helps to ensure all surfaces are cleaned |
| Rinse hands and wrists thoroughly | Rinsing mechanically washes away debris and microorganisms<br>Rinse well to prevent residual soap from irritating skin |
| Gently pat hands dry with paper towel<br>Dry from fingers to wrists and forearms | Drying from cleanest (fingertips) to the least clean (forearms) areas avoids contamination<br>Gently patting hands dry helps prevent chapping and roughened skin |
| Discard paper towel into the correct receptacle | Prevents transfer of microorganisms |
| Turn off water<br>(Use clean, dry paper towel if using a hand-operated tap; avoid touching handles with hands) | Minimises contamination of hands |
| If hands are dry or chapped, a small amount of lotion or barrier cream can be applied | Chapped skin becomes a reservoir for microorganisms |
| Inspect hands for obvious signs of debris and contamination | If found, indicates poor techniques. Hand washing should be repeated |

| CLINICAL SKILL 22.1 Handwashing/hand hygiene—cont'd | |
|---|---|
| Inspect hands for dermatitis or cracked skin as this may indicate complications from excessive handwashing or an allergic reaction to the antimicrobial or soap solution | Seek advice from infection-control professional. Note: Use small, single-use containers of barrier cream as large, refillable containers have been associated with nosocomial infections |
| **Alcohol-based hand rub**<br>Alcohol-based hand rub can be used if hands are visibly clean and dry<br>Duration of the entire procedure: 20–30 seconds | Alcohol-based hand rub has been demonstrated to reduce microbial load on hand when solution is vigorously rubbed over all hands and finger surfaces |
| Apply the amount recommended by the manufacturer onto dry hands (usually 15–30 mL) | Minimises wastage<br>Cost efficient |
| Rub your hands together ensuring that the solution comes into contact with all the surfaces of the hand. Interlace fingers and rub palms, sides and back of hands paying attention to the tips of the fingers, thumbs and the webbing between the fingers | Reduces microorganisms |
| Continue rubbing until the solution has evaporated and the hands are dry (usually 10–15 seconds) | This is of great importance when donning gloves, because if hands are not dry, manipulation of gloves is very difficult and it may cause reactive dermatitis |
| *(NHMRC 2010; Berman et al 2015; Rebeiro et al 2013; Tollefson 2016; World Health Organization 2009)* | |

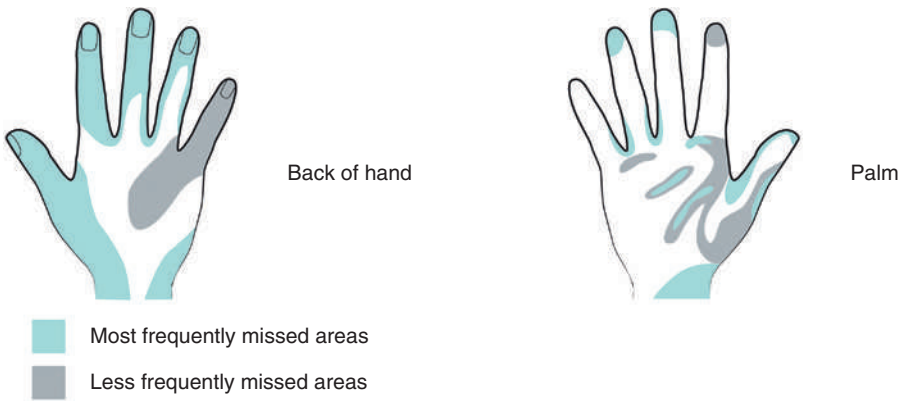

**Figure 22.7** Areas most neglected when handwashing

cleansers provided. A pump pack should be used for dispensing moisturising creams or lotions. If a cream or lotion cannot be dispensed by a measured dose pump dispenser, then a single use applicator or single use spatula should be used.

The effectiveness of hand hygiene can be impacted by the type and length of fingernails (Boyce & Pittet 2002; Lin et al 2003). Artificial nails have been associated with higher levels of microorganisms, especially Gram-negative bacilli and yeasts, than natural nails (Boszczowski et al 2005; Gupta et al 2004; Moolenaar et al 2000). It is recommended, therefore, that fingernails should be kept short (i.e. the length of the finger pad) and dirt free, and artificial nails should not be worn. In a 2008 study by Rupp et al (2008) investigators found that fingernail length greater than 2 mm was associated with increased microbial carriage on hands, suggesting that transmission is less likely with shorter nails. Studies have shown that chipped nail polish may support the growth of organisms on the fingernails (Grayson et al 2013); it is therefore good practice not to wear nail polish.

Although there is less evidence involving the impact of jewellery on the effectiveness of hand hygiene, rings can interfere with the technique used to perform hand hygiene, resulting in higher total bacterial counts (Boyce & Pittet

2002). Hand contamination with infectious agents is increased with ring wearing (Trick et al 2003). The consensus is to discourage the wearing of watches, rings or other jewellery during clinical care.

The *Australian Guidelines for the Prevention and Control of Infection in Health Care* (NHMRC 2010) suggest that each healthcare facility should develop policies about the wearing of jewellery (including body piercings), artificial nails or nail polish by employees. It is recommended that policies take into account the risks of transmission of infection to individuals and healthcare workers, rather than cultural preferences.

Healthcare workers must also involve all individuals and visitors to the healthcare facility in hand hygiene. It is important that the individual's hands as well as the nurses' hands be cleansed before eating, after using the bedpan or toilet and after the hands have come into contact with body substances, such as sputum or drainage from a wound. Strategically placed alcohol-based hand rub will assist with this.

**CRITICAL THINKING EXERCISE 22.4**

You notice one of your colleagues wears multiple rings on each hand, bracelets and a large wrist watch which is not removed for hand hygiene. You also note that recently your colleague has long artificial nails and is using hand moisturiser brought in from home. Is this considered best practice? What can you do to help your colleague understand what is best practice?

## Standard precautions: use of personal protective equipment

Any infectious agent transmitted by the contact or droplet route can potentially be transmitted by contamination of healthcare workers' hands, skin or clothing. Personal protective equipment (PPE) is used to protect mucous membranes, airways, skin and clothing. PPE used as part of standard precautions includes gloves, gowns, aprons, surgical masks, protective eyewear or face shields and, in some circumstances, foot and hair coverings.

In determining the type of PPE to use, the nurse should consider the probability of exposure to blood and body substances, the type of individual interaction and the likely route of transmission. Generally, the selection of PPE for any infection follows a risk-based approach, including factors such as the type of planned interventions, the individual's degree of infectivity and the workplace environment. All PPE must meet the relevant TGA criteria for listing on the Australian Therapeutic Goods Administration (ATGA) and should be used in accordance with manufacturer's guidelines (NHMRC 2010).

### Aprons and gowns

International guidelines recommend that protective clothing (apron/gown) be worn by healthcare workers when:

- Close contact with the individual, materials or equipment may lead to contamination of skin, uniforms or other clothing with infectious agents
- There is a risk of contamination with blood, body substances, secretions or excretion (except sweat) (Pratt et al 2007).

Clean, single-use, impervious, non-sterile, sterile, disposable, long or short sleeved? The type of gown or apron needed depends on the degree of risk and must be changed between individuals.

*Clinical note*: Aprons and gowns must be removed before leaving the care area to prevent contamination of the environment outside the individual's room. Uniforms should be washed daily, even if aprons and gowns have been used.

### Face and eye protection

As discussed earlier, the mucous membranes of the mouth, nose and eyes are portals of entry for infectious agents. Face and eye protection reduces the risk of exposure of healthcare workers to splashes or sprays of blood and body substances and is an important part of standard precautions.

Surgical masks are loose fitting, single-use items that cover the mouth and nose. They protect the person wearing them from splashes or sprays reaching the nose and mouth. Goggles provide reliable eye protection from splashes, sprays and respiratory droplets from multiple angles. Face shields provide protection to other parts of the face as well as the eyes.

P2 masks (N95)/respirators prevent the inhalation by healthcare workers (HCW) of small particles that may contain infectious agents transmitted via the airborne route. In order for the P2 respirator to offer the maximum protection to the HCW the wearer must be properly fit tested and be proficient at donning and performing a fit check prior to entering an infectious room. A fit check is a quick check to ensure that a respirator mask is fitting correctly each time it is applied. The manufacturer's instructions for fit checking of individual brands and types of P2/N95 respirators should be referred to at all times. Correct removal of mask is just as important as correct donning as there is risk of contamination to self if not proficient with this task (Qld Health 2012).

*Clinical note*: Personal prescription glasses and contact lenses are not considered adequate eye protection. Newer styles of goggles are now available, that fit adequately over prescription glasses with minimal gaps.

### Gloves

Gloves can protect both individuals and healthcare workers from exposure to infectious agents that may be carried on hands. Hand hygiene should be performed before putting on gloves and after removal of gloves. Gloves are single-use items and should not be washed, but discarded. Gloves must be changed between individuals and after every episode in individual care. They should be put on immediately before a procedure and removed as soon as the procedure is completed. When removing gloves, care should be taken not to contaminate the hands. Gloves should be worn for each invasive procedure, for contact with sterile sites and non-intact skin or mucous membrane and for any activity that has been assessed as carrying a risk of exposure to blood, body

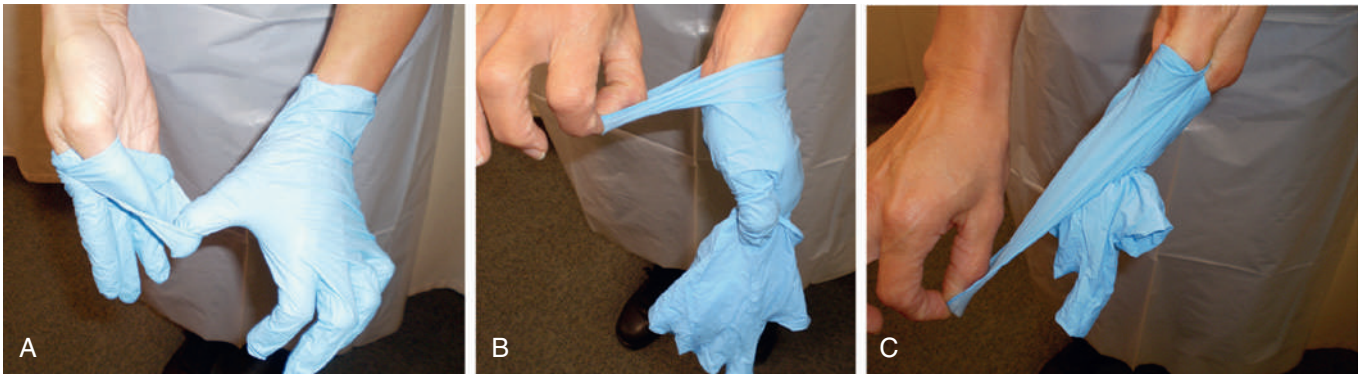

**Figure 22.8** Removing contaminated gloves

A: Removing the right glove. Take hold of the cuff on the glove on the right hand and slide it from the hand, folding the inside of the glove over the outside. This encloses the contaminated outside area. Avoid touching the skin of the right wrist or hand with the fingers of the contaminated glove on the left hand, as to do so would enable microorganisms to be transferred. B: Removing the left glove. Grasp the glove that has been removed from the right hand in the palm of the left gloved hand. Slip two fingers from the ungloved right hand under the band of the second glove at the wrist. Roll the glove off, turning it inside out, over the first glove. This action ensures that exposure of the contaminated surfaces on both gloves is minimal, reducing the risk of transferring microorganisms. C: Safe method of holding contaminated gloves. Ensuring that you hold and touch only the inside surface of the left-hand glove, drop the rolled up gloves into the appropriate receptacle for rubbish. The gloves should be disposed of in this way immediately after removal. This reduces the risk of spreading infection. Wash your hands promptly because there is no guarantee that gloves provide 100% protection. This also reduces the risk of developing an allergy to the latex in the gloves. Nurses who are left-handed may prefer to reverse this process.

*(Courtesy of Teresa Lewis)*

substances, secretions and excretions. Glove use does not replace hand hygiene. Hand hygiene must always be performed after removal of gloves because gloves may have tiny defects and because hand contamination may take place during removal. Hands should be dry before donning gloves as skin reactions have been known to occur if hands are not dry under gloves.

*Clinical note*: Consideration of the task at hand and whether glove use is required is important, as latex sensitisation of healthcare workers is a risk. General research studies show a prevalence of 8–30% latex allergy among healthcare personnel worldwide (Manori et al 2010). Use of unpowdered latex gloves or latex-free gloves may reduce the risk of increasing latex sensitisation. Figure 22.8 illustrates the correct method of removing contaminated gloves.

### Hair covers

An elasticised paper cap is the most common hair covering. It is used whenever there is a risk of the hair becoming contaminated or if microorganisms from the hair might endanger the person. Hair covers are often used as part of a bundle care plan when inserting central lines (NSW Health 2011; ACSQHC/ANZICS 2012). Nurses wear caps in the operating room environment and kitchen staff wear hair nets to prevent contamination of food.

### Shoe covers

Disposable paper covers are worn over shoes whenever there is a risk of body substances splashing onto shoes during procedures. The covers are removed before leaving the room to prevent pathogens being carried away from the area. Overshoe cloth or paper covers are used in the operating room environment to contain any microorganisms that might be on the shoes of operating room staff.

To reduce the risk of transmission of infectious agents or contamination of self, PPE must be used appropriately. The sequence for putting on and taking off PPE (see Clinical Skill 22.2) is:

- Donning PPE (putting on)
  - Gown
  - Mask
  - Protective eyewear or face shield
  - Gloves
- Doffing PPE (taking off) (see Figure 22.9)
  - Gloves
  - Eyewear or face shield
  - Gown
  - Mask.

  (NHMRC 2010)

## Standard precautions: safe handling and disposal of sharps

Sharp instruments represent the major cause of accidents involving potential exposure to blood-borne disease. Sharps must not be passed by hand between workers and handling should be kept to a minimum. Needles or any other sharp implement should not be recapped, bent or disconnected from syringes but instead disposed of intact. All sharp instruments and needles must be disposed of immediately after use by placing them into a special puncture-proof sharps container which conforms to Australian Standards AS 4031 or AS/NZ 4261. The container should be available as close as practicable to the place the sharp is used. The person using

## CLINICAL SKILL 22.2 Donning and doffing PPE (gloves, gown, mask, eyewear)

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Gown<br>Mask<br>Eyewear<br>Disposable gloves<br>Face shield |
| **Skill activity** | **Rationale** |
| **Donning PPE** | |
| Determine which equipment/supplies you may need to take into room based on type of precautions in place, activity to be performed | Ensures efficiency<br>Reduces contamination<br>Some PPE needs to be put on before entering room |
| Perform hand hygiene | Removes bacteria from skin surfaces and reduces transmission of infection |
| **Gown**<br>Fully cover torso from neck to knees, arms to end of wrists, and wrap around the back<br>Fasten at the back of neck and waist | Fastening the gown will keep it from falling away from the body and prevent contamination of clothing |
| **Mask**<br>Secure ties or elastic bands at middle of head and neck | The mask must cover the nose and mouth to be effective as air moves in and out of both |
| **Protective eyewear or face shield**<br>Place over face and eyes and adjust to fit | Prevents infection<br>Ensures comfort |
| **Gloves**<br>Extend to cover wrist of isolation gown | Maintains sterility |
| **Doffing/removing PPE** | |
| **Gloves**<br>Outside of gloves is contaminated<br>Grasp outside of glove with opposite gloved hand; peel off<br>Hold removed glove in gloved hand<br>Slide fingers of ungloved hand under remaining glove at wrist<br>Peel glove off over first glove<br>Discard gloves in waste container | Remove gloves first as they are the most contaminated<br>Reduces the risk of spreading infection<br>Encloses the contaminated outside area<br>Used gloves are contaminated with the microbes of the wearer and handled contaminants |
| Perform hand hygiene | Microorganisms multiply in dark, moist, warm conditions (e.g. on hands when gloves are worn)<br>Gloves may contain microscopic perforations permitting the entry of microbes, which can proliferate on the wearer's hands |
| **Protective eyewear or face shield**<br>Outside of eye protection or face shield is contaminated<br>To remove, handle by head band or ear pieces<br>Place in designated receptacle for reprocessing or in waste container | Reduces the risk of spreading infection |
| **Gown**<br>Gown front and sleeves are contaminated<br>Unfasten ties<br>Pull away from neck and shoulders, touching inside of gown only<br>Turn gown inside out<br>Fold or roll into a bundle and discard | Reduces the risk of spreading infection |

the sharp should be the person to dispose of it into the container. If a sharp is dropped onto the floor or bed it should be picked up and placed into the container using forceps. Sharp containers must not be filled above the mark that indicates the bin is three-quarters full.

Healthcare workers face the risk of injury and potential exposure to blood-borne infectious agents, including hepatitis B and C virus, and human immunodeficiency virus (HIV) from needles and other sharp instruments during many routine procedures. Hollow-bore needles are of particular concern, especially those used for blood collection or intravascular catheter insertion. This is because they are likely to contain residual blood and are associated with increased risk for blood-borne virus transmission. Training and education in the risks associated with procedures and the use of equipment used in the facility, safe working practices and correct handling and disposal procedures, including not overfilling containers, should be mandatory.

### Sharps injury

If a sharps injury is sustained, how do you reduce the risk?

- Seek care or first aid if an injury is sustained
- If the skin has been penetrated, wash the affected area immediately with soap and water
- Alcohol-based hand rub can be utilised if soap and water is not available
- Do not squeeze the affected area
- Report the incident to your supervisor immediately
- Complete an incident or accident report; include date and time of exposure, how the incident happened and the name of the source (if known)
- Obtain informed consent from source if possible (if known) for serology to check for hepatitis B and C virus and human immunodeficiency virus
- Seek counselling. Ask about follow-up care, including post-exposure prophylaxis (which is most effective if given soon after the exposure). Knowing your immune status to at least hepatitis B will help alleviate some anxiety.

If a sharps injury happens to you, you can be reassured that only a small proportion of accidental exposures result in infection. Taking immediate action will lower the risks even further (Crisp et al 2013).

*Clinical note*: Individual insulin pens brought into the healthcare facility pose a great risk to staff. Where possible, the individual should self-administer their own insulin and remove and discard the used needle. If this is not possible, the facility should have policies in place which state the staff should administer the insulin from an insulin vial using a single-use disposable insulin syringe instead of the insulin pen. (There are tools on the market which are designed to assist the individual to remove the needle from the pen; however, they are not designed as a risk-reducing tool for staff use.) There have also been many reported incidents of injury to staff when retrieving the insulin pen from the bedside drawer, due to the insulin pen being placed back in the drawer with used exposed needle still in situ.

## Standard precautions: implementing environmental controls

Infectious agents can be widely found in healthcare settings and there is clinical evidence suggesting a connection between poor environmental hygiene and the transmission of infectious agents in healthcare settings (Dancer 1999; NHMRC 2010).

General surfaces can be divided into two groups: those with minimal hand contact (e.g. floors and ceilings) and those with frequent skin contact (e.g. frequently touched surfaces such as doorknobs, light switches and bedrails etc). The recommendation for cleaning should be based on the risk of transmission of infection within a particular healthcare facility. All organisations should have a documented cleaning schedule that outlines clear responsibilities of staff, a roster of duties, the frequency of cleaning and the products required to clean specific areas (NHMRC 2010).

A detergent solution designed for general purpose cleaning is adequate for cleaning general surfaces as well as surfaces in close proximity to the individual, unless there is uncertainty about the nature of the soiling on the surface, or there is presence of a multi-resistant organism or other infectious agent requiring transmission-based precautions. Many facilities have introduced detergent-impregnated wipes which may be used to clean equipment in between individual use and small surface areas.

Floors are generally damp mopped in preference to dry mopping. Carpets in public areas and in general clinical-care areas should be vacuumed daily with well-maintained equipment fitted with high efficiency particulate air (HEPA) filters to prevent dust being released into the air. In the case of a spill, clean up the excess as much as possible then the carpet should be cleaned using the hot water extraction method which is recognised by AS/NZ 3733:1995, to minimise chemical and soil residue.

Spillages of blood or any other body fluid in general areas should be contained and confined. Remove visible organic matter with absorbent material such as disposable paper towels, remove any broken glass or sharp material with forceps and soak up excess fluid using an absorbent clumping agent. The area should then be cleaned with a detergent solution, followed by a hypochlorite solution or a hospital-grade chemical disinfectant in accordance with the routine infection control policies and practices of the healthcare facility. A spill kit should be available in all clinical areas. It should contain a scoop and scraper, single-use gloves, protective apron, surgical mask and eye protection, absorbent agent, clinical waste bags and ties and detergent. All components should be disposable to prevent cross-contamination. Cleaning is generally a non-nursing duty, but nurses have a responsibility to ensure that cleaning is carried out effectively and in line with infection control policies. Healthcare facilities use a variety of systems to ensure that cleaning standards are met. These include checklists, colour coding of cleaning equipment to reduce the risk of cross-infection, cleaning manuals, infection control guidance and monitoring strategies such as audits.

Auditing is mostly done through visual checking; however, just because it looks clean does not necessarily mean it is free of infectious agents.

*Clinical note*: At the time of writing, more objective methods of assessing cleanliness and benchmarking (such as black spot auditing, fluorescent markers and detection of bacterial load using adenosine triphosphate (ATP) bioluminescence tests) are being investigated and trialled (TIPCU 2012).

Nurses also have a responsibility to ensure that linen is handled carefully; for example, bedclothes should not be carried up against the healthcare worker's uniform, flicked or shaken, as these actions liberate dust and microorganisms which contaminate the uniform and the environment. Soiled linen should be rolled up or folded and placed immediately into the appropriate receptacle. All healthcare workers should wear clean washable clothing that is changed daily. If linen is heavily soiled with blood or other body substances, the linen should be placed into a leakproof bag before placing it into the appropriate receptacle.

Actions should be taken to keep all areas free from the possibility of vector transmission (flies, other insects and animals) by placing rubbish and soiled linen immediately into the appropriate containers, by disposing of food scraps correctly, by keeping any food or fluid covered and by emptying toilet utensils (bedpans and urinals) immediately.

Rubbish containers should be equipped with close-fitting lids and must be emptied frequently and never left with material overflowing from them.

## Standard precautions: reprocessing of reusable instruments and equipment

Disposable single-use equipment must be disposed of immediately after use and should not be reprocessed. How do you know if a device is for single use only? It will have a symbol on the packaging. Non-disposable instruments and equipment must be reprocessed according to their intended use and manufacturers' guidelines and instructions for use. Reprocessing protocols are implemented in order to reduce or eliminate microorganisms. Reprocessing of instruments and equipment includes general cleaning, disinfection (by heat and water, or chemical disinfectants) and/or sterilisation. The level of reprocessing that is necessary depends on the body site where specific items are used and, therefore, the level of contamination risk involved. The Spaulding system was devised over 30 years ago; it has been retained and refined and is still widely used by infection control professionals and others when planning methods for disinfection or sterilisation (Rutala et al 2008). The levels of risk are:

- *Critical*: the instruments are used to enter or penetrate into sterile tissue or body cavities or into the blood stream. These items must be cleaned thoroughly as soon as possible after using and then sterilised
- *Semi-critical*: these items come into contact with mucous membranes or non-intact skin. These items must be cleaned thoroughly as soon as possible after using and then undergo steam sterilisation. If the item will not tolerate steam, high-level chemical or thermal disinfection is required
- *Non-critical*: these items come into contact with intact skin. Thorough cleaning with a detergent solution is required. In the case where the item has been used on a person requiring transmission-based precautions decontamination may be necessary using a low or intermediate level TGA-registered disinfectant after cleaning. Recent revision of AS/NZS 4187:2014 Reprocessing of Reusable Medical Devices in Health Service Organisations was made available December 2014. This document replaces and overrides AS/NZS 4187:2003. The new document states that it is mandatory for all healthcare facilities that reprocess reusable medical devices (this is all reusable medical devices including endoscopes) to formulate policies and procedures and an auditing process to satisfy this new standard. This is in progress at time of publication.

## Routine cleaning of instruments

Cleaning is an essential factor in preventing cross-infection. Cleaning is the removal from items of all foreign material, such as soil and organic material. Detergent and water is generally sufficient for routine cleaning. All reusable instruments and equipment should be cleaned as soon as possible after use, regardless of risk level and any other infection control measures required. If items are not thoroughly cleaned they cannot later be effectively disinfected or sterilised. If an item cannot be cleaned it cannot be disinfected or sterilised (NHMRC 2010). A plastic apron, general purpose utility gloves and protective face and eyewear should be worn when cleaning equipment that may be contaminated with material such as blood, mucus, pus, sputum or faeces. For checking effectiveness of cleaning, Australian Standard (AS 2945:2002) outlines specific test methods to verify manual and automated processes.

### Disinfection

The first links in the chain of infection, the infectious agent and the reservoir, are interrupted by the use of antiseptics and disinfectants. **Disinfection** is not a sterilising process. It is a process intended to destroy pathogenic microorganisms (with the exception of spores) or render them inert, using either thermal (using heat and water, at temperatures that destroy infectious agents) or chemical means. Examples of disinfectants are alcohols, chlorine and chlorine compounds, formaldehyde, hydrogen peroxide, phenolics and quaternary ammonium compounds; they are used on inanimate objects. Disinfectants can be caustic and toxic to tissues. An antiseptic is a chemical preparation used on skin or tissue. Both disinfectants and antiseptics are said to have bactericidal or bacteriostatic properties. A **bactericidal** preparation destroys bacteria, whereas a **bacteriostatic** preparation prevents the growth and reproduction of bacteria. Different grades of disinfectants are used for different purposes. Spore-forming bacteria such as *Clostridium difficile* may be inhibited by only a

few of the agents normally effective against other forms of bacteria. Each healthcare institution should have its own policy in relation to disinfection techniques.

### Sterilisation

**Sterilisation** is a process that is intended to destroy all types of microorganisms, including bacterial spores and viruses. Four commonly used methods of sterilisation are moist heat, gas, boiling water and radiation. A sterile article is one that is totally free from all microorganisms. Sterility is an all-or-none state, because a single living cell renders an article unsterile.

Records of sterilisation must be kept to verify that an appropriate reprocessing system is in place according to state and federal legislation. Details of documentation required can be found in Australia Standards AS/NZ 4187:2014 and AS/NZ 4815.

### Storage and maintenance of sterile items

All sterile or high-level disinfected items must be stored in a way that maintains their level of reprocessing. Dry, sterile, packaged instruments and equipment should be stored in a clean, dry environment and protected from sharp objects that may damage the packaging. It is the nurse's responsibility to check that the packaging of the sterile item about to be used has not been compromised (NHMRC 2010).

## Standard precautions: asepsis and aseptic technique

The basic principles employed in preventing the spread of infection are the same in all situations, regardless of whether persons are cared for in the community, in aged-care facilities, in day clinics or in hospitals. Aseptic techniques and all infection prevention and control activities are directed towards breaking the chain of infection.

### Principles of Aseptic Non-Touch Technique (ANTT®)

Aseptic non-touch technique (ANTT) is a framework for safe aseptic technique originated by Rowley (2001). ANTT® is used in conjunction with standard precautions and the 5 Moments for Hand Hygiene. It is based upon a concept termed Key-Part and Key-Site Protection used to maintain the asepsis of Key-Parts and Key-Sites when performing invasive clinical procedures. Based upon the technical difficulty of achieving asepsis, the ANTT risk assessment selects either Surgical-ANTT or Standard-ANTT. ANTT® is included in the NSQHS Standards, and therefore is core business for every healthcare facility in Australia. The ANTT® framework is being researched, taught, trained, learnt and assessed within every healthcare facility. The introduction of ANTT is based on the resources provided by the Association for Safe Aseptic Practice (ASAP) UK which oversees the ANTT project (http://www.antt.org) (see also Chapter 29).

Australian facilities using these resources are asked to make no changes so as to maintain the integrity of the ANTT Practice Framework and thus a standard and meaningful practice language for safe aseptic technique. The information below explaining ANTT is from the ANTT Practice Framework and used with permission from www.antt.org.

Terminology for aseptic technique historically has generated an inaccurate and confusing paradigm loosely based on the terms sterile, aseptic and clean techniques.

**Clean**: 'Free from dirt, marks or stains' (McLeod 1991). The ANTT Practice Framework does not use the term 'clean' because a visible standard is of no use for controlling invisible microorganisms.

**Sterile**: 'Free from micro-organisms' (Weller 1997).

Due to the large number of organisms in the atmosphere it is not possible to achieve a sterile technique in a typical healthcare setting. Near-sterile techniques can only be achieved in controlled environments such as laminar air-flow cabinets or theatres. The commonly used term 'sterile technique' (the instruction to maintain sterility of equipment exposed to air) is not possible and is often applied incorrectly.

**Asepsis**: 'Freedom from infection or infectious (pathogenic) material' (Weller 1997). It is defined as the absence of infectious agents that may produce disease (NHMRC 2010).

**Aseptic technique** refers to practices used by healthcare workers to reduce the number of infectious agents; prevent or reduce the likelihood of transmission of infectious agents from one person or place to another; and render and maintain objects and areas as free as possible from infectious agents. It protects persons during invasive clinical procedures (ANTT Project 2012).

An ANTT **risk assessment** is performed prior to undertaking a clinical procedure. This is done to decide which level of practice/technique must be used; that is, either Standard-ANTT or Surgical-ANTT (Rowley et al 2010; ANTT Project 2012). This risk assessment is based on a number of variables that determine the technical difficulty of maintaining asepsis (e.g. the complexity of the procedure, the competency and confidence level of the healthcare worker and the number and size of Key-Parts and Key-Sites.

Asepsis in ANTT is maintained and/or ensured by the use of six core infection prevention and control components:

1. Key-Part and Key-Site identification and protection
2. Hand hygiene
3. Glove use and a non-touch technique
4. Aseptic fields to promote and ensure asepsis
5. Environmental controls
6. Sequencing of procedures.

These are discussed in detail below:

1. A **Key-Part** is the part of the equipment that must remain aseptic, such as the syringe hub, and must only make contact with other Key-Parts or Key-Sites (ANTT Project 2012). A **Key-Site** is the area on the person such as a wound or intravenous insertion site that must be protected from microorganisms. After standard precautions Key-Sites are protected by non-touch techniques and effective usage of aseptic fields (ANTT Project 2012).
2. Hand hygiene involves using alcohol-based hand rub or soap and water using correct technique and performed at the correct time in the sequence for the procedure.

3. Glove use and non-touch technique reduces the risk of contamination for the individual and carer during contact with the procedural equipment.
4. **Aseptic fields** help to provide a controlled aseptic working space to help promote or ensure the integrity of asepsis during clinical procedures. There are two main types of aseptic fields used in ANTT, depending on whether a Standard-ANTT or Surgical-ANTT approach is being utilised:
   i. A **Critical Aseptic Field** (typically sterile drapes) is used for Surgical-ANTT. This is used when open or invasive procedures demand large aseptic working areas for long durations, such as in the operating room. Only equipment that has been sterilised can come into contact with the field. Such a Critical Aseptic Field requires the use of sterile gloves.
   ii. A **General Aseptic Field** (typically a plastic tray) is used for Standard-ANTT. Key-Parts are optimally protected by **Micro-Critical Aseptic Field** and a non-touch technique. The main General Aseptic Field does not have to be managed critically as it is essentially promoting rather than ensuring asepsis. Although the aim is still asepsis, Standard-ANTT is subsequently simplified and involves the use of non-sterile gloves (ANTT Project 2012). Micro-Critical Aseptic Fields protect Key-Parts individually, such as covers or caps that help to protect the Key-Parts (e.g. syringe caps, sheathed needles, covers or packaging). The inside of these caps and covers have been sterilised and therefore provide an optimum aseptic field for Key-Parts (ANTT Project 2012). (See Figure 22.10.)
5. Prior to an aseptic procedure, healthcare workers must ensure that there are no avoidable nearby **environmental risks**, such as bed making, individuals using a commode, or visitors within close proximity. In the home environment uncontrolled pets can pose a risk.
6. ANTT Procedure Guidelines sequence practice to ensure an efficient, safe and logical order for the procedure, such as performing hand hygiene before gathering equipment required for the ANTT procedure about to be performed, decontamination of the IV bung before connecting an IV giving set and disposing of used equipment appropriately when procedure is complete. See Figure 22.11.

The ANTT practices are classified as follows. It is important to note that the aim of Standard-ANTT and Surgical-ANTT is asepsis. However, their approaches are different.

Standard-ANTT is based on an approach that identifies and protects all the procedure Key-Parts and Key-Sites individually. This is achieved by standard precautions such as hand hygiene and PPE use followed by the use of a General Aseptic Field and Micro-Critical Aseptic Fields integrated with non-touch technique and wearing non-sterile gloves. Procedures requiring Standard-ANTT will characteristically be technically simple and short in duration (usually less than 20 minutes). Procedure examples include simple wound dressings, insertion of a peripheral intravenous cannula, administering an intravenous drug and removing an endotracheal tube, sutures or drains. Figure 22.12 illustrates how to establish an aseptic field.

The components of Standard Aseptic Technique (ANTT Project 2012) are:

- General Aseptic Field
- Micro-Critical Aseptic Fields are essential
- Non-sterile gloves or sterile gloves where Key-Parts or Key-Sites require touching
- Hand hygiene
- Standard precautions
- Non-touch technique is essential (ANTT Project 2012). See Figure 22.13.

Surgical-ANTT is based on an approach that identifies and protects all the procedure Key-Parts and Key-Sites in one main Critical Aseptic Field. It is designed to establish and maintain the asepsis of surgical incisions, tissues or wounds or patient orifices. Procedures requiring Surgical-ANTT are typically technically complex to achieve asepsis and involve extended periods of time. They are most often (but not always) practised in the operating room, obstetric areas and major diagnostic or special treatment areas such as a burns unit or an intensive care unit. In the operating room, nurses follow a process to ensure that asepsis is maintained. Surgical-ANTT may also be used by the nurse in a general medical or surgical unit or in a person's home; for example, when performing a urinary catheterisation or redressing large wounds.

**Figure 22.10** Micro-Critical Aseptic Field on a General Aseptic Field
*(ASAP 2012)*

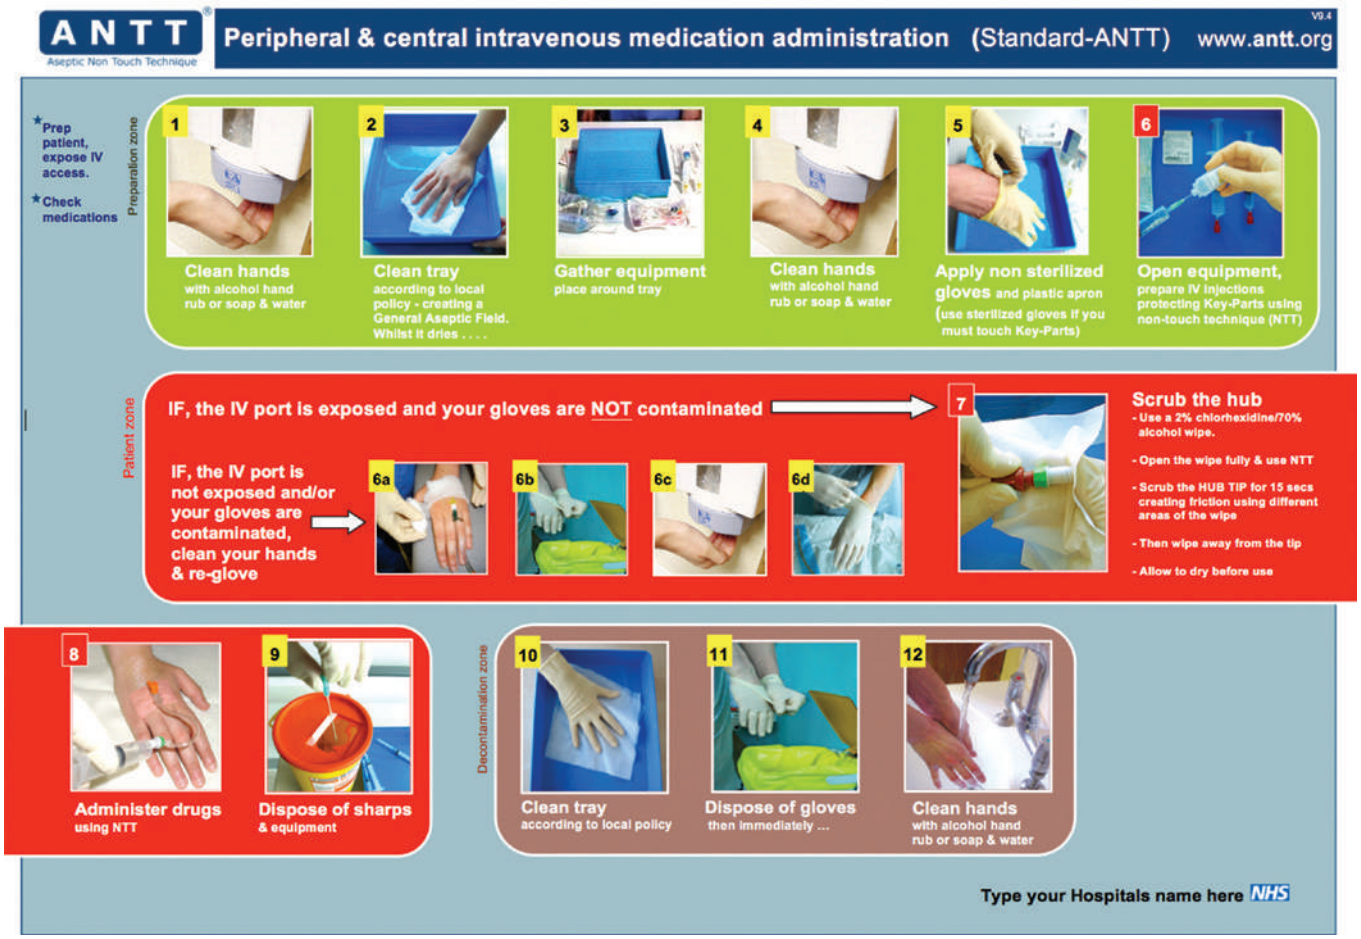

**Figure 22.11** Peripheral and central intravenous medication administration—Standard-ANTT
*(ASAP 2012. www.antt.org.uk, enquiries@antt.org)*

In such procedures the amount of sterilised equipment such as sterile drapes and personal full-barrier precautions will be fewer but the principle approach of Surgical-ANTT will be the same.

The components of Surgical-ANTT are:

- Standard precautions to full precautions (sterile gown, sterile gloves, hair cover and mask)
- Critical Aseptic Fields
- Micro-Critical Aseptic Fields are desirable where practical but not essential
- Sterile gloves are essential
- Hand hygiene
- Non-touch technique is desirable where practical (ANTT Project 2012).

See Figure 22.14.

## Principles of Surgical-ANTT

Principles of Surgical-ANTT are applied when nurses create a Critical Aseptic Field, add supplies or liquids to this field and don sterile gloves. The principles of Surgical-ANTT are that:

- Asepsis is preserved by touching an aseptic Key-Part with only another Key-Part that is aseptic (e.g. picking up a sterilised dressing with sterilised forceps or sterilised gloves)
- Only aseptic objects may be placed on a Critical Aseptic Field
- Once an aseptic item touches something that is not aseptic it is contaminated (e.g. if the nurse touches a sterilised dressing with an ungloved hand)
- If a Critical Aseptic Field becomes wet it is considered contaminated
- Whenever there is the slightest doubt about an article being aseptic it is considered contaminated and discarded.

## Establishing and managing an Aseptic Field for either Standard-ANTT or Surgical-ANTT

Prior to commencing a procedure the nurse must determine what aseptic field is required and how that field will need to be managed. This is important because Standard-ANTT and Surgical-ANTT utilise different types of aseptic fields. Surgical-ANTT involves managing all of the procedure Key-Parts on one main Critical Aseptic Field—a sterile drape. This involves protecting all of the procedure Key-Parts individually

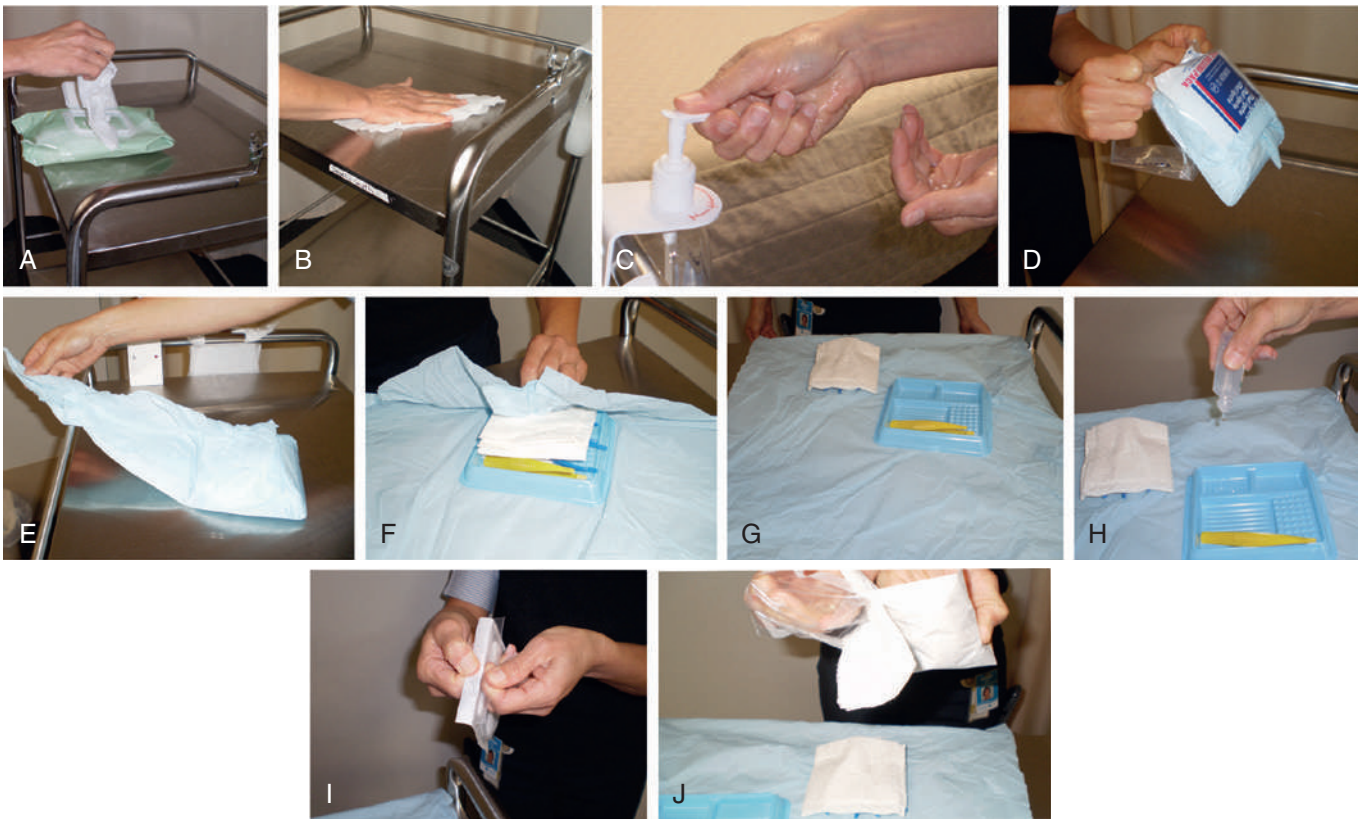

**Figure 22.12** Establishing a Critical Aseptic Field for Surgical-ANTT

To be used for a simple dressing. Review and carry out the standard steps for all nursing procedures/interventions that require standard aseptic technique. 1: Using neutral detergent: wipe down the dressing trolley/flat surface used to set up the aseptic dressing field (A & B) 2: Perform hand hygiene (C) 3: Open up commercially packaged sterile dressing pack (D) 4: Open the outer flap of the sterile package away from you (E) 5: Open the side flaps, one at a time, followed by the flap closest to you. Using this last flap gently manipulate the sterile tray and empty contents onto the field (F, G) 6: Add sterile solutions to the aseptic field. Lean across the field over the shortest distance. Hold the container at a height to prevent splashing. Pour/squeeze from a single patient use container; discard any unused solution to prevent cross infection (H) 7: Open a commercially prepared sterile package (e.g. gauze). Hold the outer wrapping tightly, empty contents onto the sterile field. Take care not to contaminate the contents or aseptic field (I, J)

*(Courtesy of Teresa Lewis)*

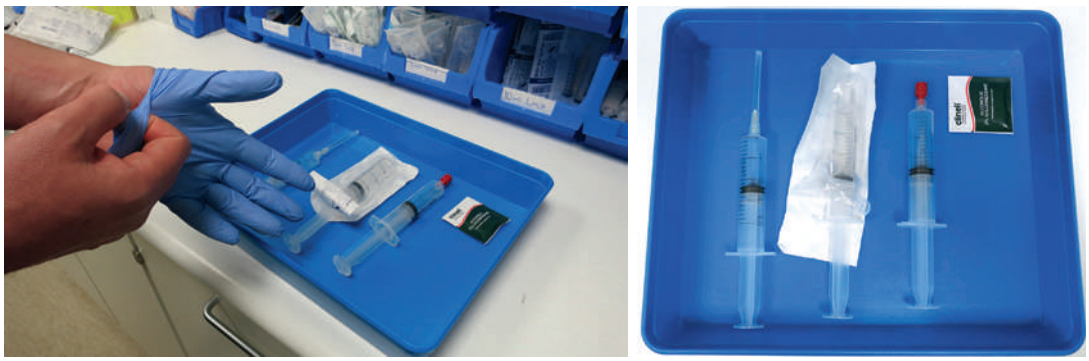

**Figure 22.13** Standard-ANTT—All Key-Parts are protected individually with Micro Critical Aseptic Fields (Caps and covers)

*(ASAP 2012)*

with Micro-Critical Aseptic Fields (caps, covers and inside of sterilised packaging). This individually protected equipment is then typically placed on a plastic or disposable tray which is not considered aseptic. The tray is subsequently termed a General Aseptic Field.

## Preparing a main Critical Aseptic Field (Surgical-ANTT)

Preparing and managing a main Critical Aseptic Field requires thoughtful handling. It should be prepared as close as possible to the time of actual use.

**Figure 22.14** Surgical-ANTT
*(ASAP 2012)*

- Remove unnecessary objects from the area to be used
- Assemble all equipment needed
- Perform hand hygiene
- Check the date or sterilisation indicator tape on all sterile packages to be used.

Sterilised items that have been packaged commercially are generally designed so that the outer paper or plastic wrapper can be torn away simply without contaminating the inner contents. The outer wrapper should be removed by tearing away from the body. Items sterilised within the facility may have an outer wrapper of thick strong paper or cloth. To open these items the nurse follows this procedure:

- Place the package in the centre of a flat surface at or above waist level
- Remove tape that seals the item
- Position the package so that the outermost (distal) triangular flap can be moved away from the front of the body
- Care is taken to only touch the outside corners so that the inside remains an aseptic field (any area touched needs to be considered contaminated)
- Smoothly open the first triangular side flaps, keeping the arms flat and away from the inner sterilised area. Ensure the opened flap lies flat on the working surface
- Standing away from the package, take hold of the outside surface of the last flap, pull the flap back towards the body, allowing it to fall flat on the working surface
- The aseptic field may also need to be extended by draping the individual using a sterilised drape. This sterilised drape provides additional workspace where sterilised equipment may be placed as well as protecting the Key-Site from contamination.

### Adding sterilised items to a Critical Aseptic Field (Surgical-ANTT)

Sterilised items can be added directly from their packaging onto the aseptic field or by transferring them with sterilised gloves or forceps. A packet containing a sterile item must be opened in such a way that the sterilised item does not come into contact with the non-sterile outer wrapper. The item may be gently allowed to fall onto a main Critical Aseptic Field with care taken not to contaminate the aseptic field with the wrapper, or it may be retrieved directly from its packaging by a person holding sterilised gloves or forceps. Figure 22.15 and Clinical Skill 22.3 illustrate the procedure for open gloving. (Closed gloving is the method used when sterile gloves are worn in conjunction with sterile gowns.)

- The procedure should be performed ensuring all Key-Parts/components are protected at all times
- Only sterilised items may come into contact with Key-Sites and sterilised items must not come into contact with non-sterilised items.

### Adding sterilised solutions to a Critical Aseptic Field (Surgical-ANTT) or a General Aseptic Field (Standard-ANTT)

Use of 'once-only' solutions is best practice. Pour the required amount onto the Critical Aseptic Field in a manner that prevents splashing. Discard unused solution to prevent cross-infection. If using Standard-ANTT the solution would be added to a sterilised pot acting as a Micro-Critical Aseptic Field within a General Aseptic Field.

**CRITICAL THINKING EXERCISE 22.5**

Mrs Adams has a venous ulcer on her left leg. The dressing on the ulcer is wet, contaminated with blood-stained bodily fluids and requires replacement. How do you decide what level of ANTT is required?

## Standard precautions: appropriate handling of waste and linen

There is potential for contamination from blood or body secretions when handling soiled linen, pathology specimens, equipment or waste. Waste includes sharps, clinical and cytotoxic waste, human tissues and general, recycling and radioactive waste. When handling waste apply standard precautions to protect against exposure to blood and body substances; perform hand hygiene following procedure. Gowns and gloves, for example, should be worn by anyone handling clinical waste, and linen soiled with blood or body substances should be placed and transported in an impermeable (leakproof ) bag. Waste should be segregated at point of generation and disposed of according to type of waste (as discussed above) and the facility waste management program. It should be contained in the appropriate receptacle, identified by colour and label. All healthcare workers should be trained in the correct procedures for waste handling. Healthcare facilities should refer to the current Australian Standard AS/NZS 3816 and the *Waste Management Association of Australia Industry Code of Practice for the Management of Clinical and Related Wastes* (2010).

Healthcare facilities must have documented policies on the collection, transport and storage of linen. Those organisations that process or launder linen must have documented policies consistent with AS/NZ 4146. All used linen should be handled with care to avoid dispersion of microorganisms into the environment and to avoid contact with staff clothing.

**Figure 22.15** Donning sterile gloves

Review and carry out the standard steps for all nursing procedures/interventions that require surgical aseptic technique. 1: Perform hand hygiene (A) 2: Remove outer glove bag by peeling sides away. Slide correct-size gloves, covered by inner paper wrapper, onto a clean dry flat surface above waist level 3: Perform procedural hand hygiene 4: Carefully move inner wrapper away to expose sterile gloves. Keep gloves on inside surface of the inner wrapper. Position gloves with wrist opening nearest to the body (B) 5: Identify the right and left gloves. Prepare to glove dominant hand first 6: Use thumb and first two fingers of non-dominant hand to pick up first glove. Lift at least 12 cm off wrapper (C) 7: Grasp the folded-over part of the cuff (each glove has a cuff about 5 cm wide that is folded back to reveal inside of glove). Take care to touch only the inside surface of the glove 8: Insert fingers of other hand into the held glove and pull the glove up over the dominant hand without touching the outer surface of the glove (D) 9: With gloved hand slide fingers underneath the cuff of the second glove (E) 10: Ease second glove up over non-dominant hand. Be careful not to touch outside of glove or other gloved hand with bare skin. Keep thumb of dominant hand abducted back. Once hand is settled in glove, slide cuff carefully up over the wrist, being careful to touch only the sterile sides (F) 11: Adjust fingers in gloves by pulling glove fingers out with the opposite hand to straighten and adjust until fitted neatly. Hands can be interlocked to help ease gloves into correct position (G)

*(Courtesy of Teresa Lewis)*

The following infection control principles apply whether or not the person requires transmission-based precautions. (See Case Study 22.1.)

Appropriate PPE must be worn during handling of soiled linen to prevent skin, uniform or mucous membrane exposure to blood or bodily substances. Used linen is 'bagged' into an appropriate laundry container at the location of use (i.e. linen should not be carried under the arm of the staff member down the corridor of the healthcare facility looking for the receptacle).

Used linen must not be sorted, rinsed or washed in domestic washing machines in clinical-care areas. Linen

## CLINICAL SKILL 22.3 Open gloving (donning and removing sterile gloves)

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile gloves of appropriate size<br>A clean work surface on which to open the gloves |
| **Skill activity** | **Rationale** |
| Perform hand hygiene | Removes bacteria from skin and reduces transmission of microorganisms |
| Remove gloves from outer packaging and place gloves in the inner wrapper on a clean, dry surface above waist level | Maintains integrity of the gloves, any moisture on the surface contaminates the gloves |
| Carefully remove inner wrapper to expose sterile gloves<br>Keep gloves on inner surface of the inside wrapper<br>Position gloves with wrist opening nearest to the body | The inner packaging must remain sterile |
| Identify the right and left gloves. Prepare to glove dominant hand first | Correct identification helps with correct gloving<br>Gloving the dominant hand first helps with dexterity |
| Use thumb and first two fingers of non-dominant hand to pick up first glove. Lift at least 12 cm off wrapper | Prevents accidental contamination |
| Grasp the folded-over part of the cuff (each glove has a cuff about 5 cm wide that is folded back to reveal inside of glove). Take care to touch only the inside surface of the glove | The hands are not sterile, so by only touching the inside of the glove contamination is avoided |
| Insert fingers of other hand into the held glove and pull the glove up over the dominant hand without touching the outer surface of the glove | |
| With gloved hand slide fingers underneath the cuff of the second glove<br>Ease second glove up over non-dominant hand. Be careful not to touch outside of glove or other gloved hand with bare skin. Keep thumb of dominant hand abducted back. Once hand is settled in glove, slide cuff carefully up over the wrist, being careful to touch only the sterile sides | This helps to prevent accidental contamination |
| Adjust fingers in gloves by pulling glove fingers out with the opposite hand to straighten and adjust until fitted neatly. Hands can be interlocked to help ease gloves into correct position | Ensures a smooth fit |
| **Removing gloves**<br>Grasp the outside of one cuff with the other gloved hand. Pull glove off, turning inside out. Hold removed glove in your gloved hand, then use the fingers of your bare hand to pull the remaining glove from the cuff over the hand<br>Discard in appropriate waste receptacle<br>Perform hand hygiene | Minimises contamination of underlying skin<br>Contains contaminated gloves |

*(NHMRC 2010; Berman et al 2015; Rebeiro et al 2013; Tollefson 2016)*

soiled with blood or body substances should be placed into a leakproof bag before being placed into the laundry receptacle (this is to ensure safe handling and transport).

Hand hygiene must be performed after handling used linen and before touching other surfaces. Individual personal items may be washed in a domestic washing machine, but only if hot water and an appropriate detergent are used. If these are not available, only individual person loads can be washed at one time.

Double-bagging is not performed routinely but this is necessary when the outside of a bag is visibly contaminated. Linen bags and rubbish bags should never be overfilled and should be tied securely before being transported.

*Clinical note*: Care must be taken not to overfill linen and rubbish bags as many manual handling staff injuries occur each year in Australia.

### Specimen collection and transport

Standard precautions should be followed when handling laboratory specimens. If additional precautions are needed (e.g. if the specimen is from a person diagnosed with a particularly virulent, unusual or epidemiologically important pathogen, such as Creutzfeldt-Jakob disease (CJD)) advice should be sought from an expert in the pathology laboratory. The nurse should wear gloves when collecting specimens. Enrolled Nurses (ENs) may be required to obtain specimens such as a midstream specimen of urine (MSU), wound swab or a stool (faecal) specimen. Other specimens that may be requested include swabs from wounds or body orifices such as the nose, throat or vagina. Personnel from a pathology department often obtain these or blood specimens from individuals. ENs are advised to check their code of practice and the policies of the employing agency or healthcare facility with regard to collecting pathology specimens from individuals. All specimen containers should be sealed tightly to prevent spillage and contamination of the outside of the container. The individual's details should be written on the container label. The container should be placed in a sealed plastic bag, also clearly labelled, and taken as soon as possible to the pathology department. Hand hygiene must be performed upon removing PPE (see Figure 22.16 and Clinical Skill 22.1).

## Standard precautions: respiratory hygiene and cough etiquette

Standard precautions incorporate respiratory hygiene and cough etiquette at all times. Covering sneezes and coughs helps prevent infected persons from dispersing potentially infectious respiratory secretions into the air. When coughing or sneezing, use a tissue to cover the nose and the mouth, this tissue should be disposed of immediately afterwards and if a tissue is not at hand, cough or sneeze into the elbow. Hands must be washed with soap and water after coughing, sneezing, using tissues or after any contact with respiratory secretions or objects contaminated with these secretions (such as picking up and disposing of a used tissue) (NHMRC 2010).

Healthcare workers must assist elderly or very young persons who need assistance with containment of respiratory secretions. Those who are immobile will need a receptacle readily at hand for the disposal of contaminated tissues (e.g. plastic bag or rigid container lined with plastic bag) and hand hygiene facilities should be offered (e.g. moistened single-use face and hand wipes or alcohol hand rub if the person is deemed capable of using the product safely). All individuals should be screened on admission for signs and symptoms of acute respiratory infection. Anyone displaying signs and symptoms of respiratory infection, regardless of cause, should be instructed on how to follow respiratory hygiene and cough etiquette and possibly be asked to wear a surgical mask (see Clinical Interest Box 22.5).

*Clinical note*: This is extremely important for individuals on droplet transmission-based precautions.

### CLINICAL INTEREST BOX 22.5 Cough etiquette

- Cover the nose/mouth with a disposable single-use tissue when coughing, sneezing, wiping and blowing the nose
- Use tissues to contain secretions
- Dispose of tissues in the nearest waste bin after use
- If no tissues are available, coughing or sneezing into the inner elbow rather than the hand is acceptable
- Hand hygiene must be practised after contact with any respiratory secretions, objects or material contaminated with respiratory secretions
- Keep contaminated hands away from the mucous membranes of the eyes and nose

*(NHMRC 2010; NSW Government Health 2014)*

## Tier 2: Transmission-based precautions applied in addition to standard precautions

### When are transmission-based precautions applied?

Transmission-based precautions are applied to persons in the presence of known or suspected infectious agents that are spread by direct or indirect contact, droplet or airborne routes. Whether used singly or in combination, transmission-based precautions are always applied in addition to standard precautions (NHMRC 2010). For an example of an entry into progress notes see Progress Notes Example 22.1.

*Indirect or direct contact transmission* occurs when healthcare worker hands or clothing become contaminated, care devices are shared between persons, infectious persons have contact with other individuals or environmental surfaces are not regularly decontaminated.

*Droplet transmission* occurs when healthcare workers' hands become contaminated with respiratory droplets and are transferred to susceptible mucosal surfaces such as the eyes, when infectious respiratory droplets are expelled by

**Figure 22.16** Collecting wound swab

Review and carry out the standard steps for all nursing procedures/interventions. 1: Perform hand hygiene (A) 2: Don PPE (B, C) 3: Open commercially packaged bacterial swabs (D) 4: Remove cap of transport medium container (E) 5: Carefully insert bacterial swab into the transport medium to pre-moisten swab (taking care not to contaminate swab) (F, G) 6: Remove swab from transport medium and gently roll over wound to be swabbed (H, I) 7: Gently insert the swab stick back into the transport medium (J, K) 8: Remove PPE (L, M, N) 9: Perform hand hygiene (O) 10: Write on outside of transport medium container (P) 11: Place inside pathology specimen bag (Q, R) 12: Perform hand hygiene (S)

*(Courtesy of Teresa Lewis)*

coughing, sneezing or talking, and come into contact with another's mucosa (eyes, nose or mouth), either directly into or via contaminated hands.

*Airborne transmission* occurs when healthcare workers or others inhale small particles that contain infectious agents.

Extra precautions are implemented to interrupt transmission of highly contagious or epidemiologically important pathogens that are transmitted via the respiratory droplet or airborne mode, direct or indirect contact mode or via any combination of these routes. For example, a person with influenza, active pulmonary TB, measles, Ebola,

## PROGRESS NOTES EXAMPLE 22.1

| | |
|---|---|
| 17/03/2015 1200 hrs | Nursing: Mary has experienced several episodes of loose, watery diarrhoea this morning. She describes a loss of appetite and some nausea with slight abdominal tenderness. Observations: T 38, P 88, R 26, BP 160/85. Mary has not received any aperients in the last two days. A stool sample has been collected for culture and sensitivity at 1100 hrs today. On consultation with the infection prevention and control practitioner transmission-based precautions have been implemented today at 1130 hrs due to high risk of possible norovirus or *Clostridium difficile* infection. Infection prevention and control care plan has been completed, to be reviewed daily. Information sheet has been given to Mary and her questions answered. She voiced concerns re her grandchildren visiting and she was advised that it would be best for them not to visit while she is feeling so unwell. Her family have been notified.<br>***J. Lewis* (Lewis) EN** |

Creutzfeldt-Jakob disease, vancomycin-resistant *Enterococci* or methicillin-resistant *Staphylococcus aureus* would be in this category.

Transmission-based precautions are also used in the event of an outbreak (e.g. gastroenteritis, whooping cough) or pandemic to assist in containing the outbreak, contact tracing in the event of a pandemic and preventing further infection. Transmission-based precautions are tailored to the specific infectious agent concerned and its mode of transmission and may include any combination of the following practices:

- Nursing the individual in a single room with closing door (isolation)
- Screening of individuals on admission, especially for acute respiratory infection (see Clinical Interest Box 22.6)
- Placing individuals colonised or infected with the same infectious agent and **antibiogram** (result of laboratory testing for the sensitivity of an isolated bacterial strain to different antibiotics) in a room together (cohorting)
- Wearing specific personal protective equipment (PPE)
- Providing dedicated equipment
- Special room ventilation systems to maintain the room air at negative pressure. Negative pressure rooms are used for individuals requiring airborne droplet nuclei isolation. Individuals are placed in negative pressure rooms to reduce transmission of disease via the airborne route. Class N or negative pressure rooms are also known as 'airborne infection isolation' and 'infectious isolation units'

## CLINICAL INTEREST BOX 22.6 Admission screening questionnaire: acute respiratory infection (season/pandemic)

URN:
Family name:
Given names:
Address:
Date of Birth: Sex: ☐ M ☐ F

Vigilance regarding the management of acute respiratory infections (seasonal or pandemic) is a recommendation of the Australian Government Department of Health and Ageing and state Health Departments. Therefore, this screening procedure has been developed to assist with contact tracing should a person subsequently be diagnosed with acute respiratory infections and/or a pandemic influenza occurs.

The following admission screening questionnaire should be routinely completed prior to or on admission to determine any at-risk persons (i.e. those who show signs and symptoms of an acute respiratory illness, have a history of recent travel to areas of high prevalence (either overseas or in Australia), had contact with confirmed/probable cases within 7 days prior to onset, have an existing illness or are pregnant), in order to ensure the safety of all HCWs, individuals and consumers, and assist with follow-up if required.

1. Do you have a fever and respiratory symptoms e.g. cough, sore throat, runny nose? ☐ Y ☐ N
   AND EITHER
2. Have you had recent contact with people diagnosed with acute respiratory infections or acute respiratory illness (seasonal or pandemic) in the last 7 days (refer to any circulating pandemic/seasonal definitions) ☐ Y ☐ N
   OR
   Have you travelled to areas of high prevalence for acute respiratory infections (seasonal or pandemic), either overseas or in Australia, within 7 days of onset of symptoms? ☐ Y ☐ N
   (NB: For further information on affected countries refer to:
   > The Australian Government Department of Health and Ageing (DoHA) www.health.gov.au
   > World Health Organisation (WHO) www.who.int/en
3. Do you have any other medical or chronic illnesses, or are you pregnant? ☐ Y ☐ N

If individual answers YES to at least questions 1 and 2 please contact the relevant person immediately as per your infection prevention and control policy, as transmission-based precautions may be necessary.

*(Modified from The Department of Health Influenza Infection CDNA National Guidelines for Public Health Units & Guidelines for Minimising Transmission of Influenza in Healthcare Facilities 2010 Influenza Season)*

- Using TGA-registered disinfectant with label claims specifying its effectiveness against specific infectious organisms (NHMRC 2010)
- Restricting movement of both individuals and HCWs.

**CRITICAL THINKING EXERCISE 22.6**

Mrs Farah has been admitted with the diagnosis of tuberculosis for investigation. You have been asked to check her blood pressure. You can only find a surgical mask outside her room. What transmission-based precautions should be implemented? Would you enter her room wearing the surgical mask?

## Contact precautions

Contact precautions consist of:

- Single room or cohort with same infectious agent and antibiogram
- Gloves
- Gowns
- Surgical mask if the infectious agent is isolated in the sputum or as per standard precautions
- Eye protection as required, depending on task performed or as per standard precautions
- Single-use equipment or reprocess equipment before reuse on next person.
- Signage of room. Refer to the standardised infection prevention and control signs available on the ACSQHC website (http://www.safetyandquality.gov.au/our-work/healthcare-associated-infection/national-infection-control-guidelines/).

## Droplet precautions

Droplet precautions consist of:

- Single room or cohort with same infectious agent and antibiogram. Refer to the infection prevention and control precautions in Figure 22.2
- Gloves to be worn whenever there is potential of direct or indirect contact with blood or body fluids
- Gowns to be worn whenever there is potential of direct or indirect contact with blood or body fluids
- Surgical mask
- Eye protection to be worn whenever there is potential of exposure to splashes or sprays to mucosa
- Single-use equipment or reprocess equipment before reuse on next person
- Restrict visitor numbers and implement precautions as for staff.
- Signage of room (see above for website link to access standardised signage).

## Airborne precautions

Airborne precautions consist of:

- Single negative pressure room (if not available, a single room with door closed)

**CLINICAL INTEREST BOX 22.7**
**Transmission-based precautions**

In our ward we have patients who are colonised with methicillin-resistant *Staphylococcus aureus* (MRSA) and they appear in good health with no signs of infection or inflammation. It is present in their nose and on their skin. If these colonised individuals are identified prior to admission, they undergo a de-colonisation program prior to their surgery. Two months ago we also had a patient who developed an MRSA infection in their wound postoperatively. It was deduced that poor hand hygiene caused transmission of this microorganism from the colonised patient in the ward at the time to the susceptible postoperative patient. This resulted in a longer hospital stay for that patient, but thankfully he did recover and we managed to clear his wound infection sufficiently for discharge.

**Kathryn, NUM surgical ward**

- Gloves to be worn whenever there is potential of direct or indirect contact with blood or body fluids as per standard precautions
- Gowns to be worn whenever there is potential of direct or indirect contact with blood or body fluids as per standard precautions
- P2 (N95) respirator/mask
- Single-use equipment or reprocess equipment before reuse on next person
- Restrict visitor numbers and implement transmission-based precautions as for the staff.
- Signage of room (see above for website link to access standardised signage).

The aim of implementing transmission-based precautions early is to reduce further transmission opportunities that may arise due to the specific route of transmission of the particular pathogen. While it is not possible to identify all persons needing transmission-based precautions on admission, at times when an increased risk is recognised (such as in the acute respiratory infection questionnaire in Clinical Interest Box 22.6) their use is warranted while confirmation is pending. When transmission-based precautions are implemented the infection prevention and control practitioner should be consulted and a care plan completed (see Figure 22.2 and Clinical Interest Box 22.7) by the HCW and then reviewed on a daily basis or when any changes to the individual's current diagnosis, laboratory testing or results become available. When implementing transmission-based precautions the nurse must recognise there is potential for adverse effects such as anxiety, mood disturbances and perceptions of stigma and reduced contact with clinical staff. Clearly explaining to individuals why these precautions are necessary may help to alleviate these effects. Individuals and their carers should be offered clear, consistent information and advice through all stages of their care (NHMRC 2010).

**CRITICAL THINKING EXERCISE 22.7**

Mrs Smith is 68 years old and has been admitted to hospital with a temperature, history of rigors, a moist cough which has been troubling her for the past 4 days, headache and myalgia. She has a recent history of overseas travel. What infection control and prevention activity should take place upon Mrs Smith entering the facility? What are the nursing interventions necessary to control transmission of the infection? What other education should take place to assist in prevention of cross-transmission?

## Isolation precautions

A person requiring transmission-based precautions is usually nursed using isolation precautions. Although healthcare facilities develop and implement their own isolation policies, isolation precautions are based on the following general principles:

- Each step in the care plan is carefully devised to minimise the risk of cross-infection, as one act of carelessness can result in a spread of infection. Before any nursing activity is performed, the technique to be used should be planned carefully so that the risk of cross-infection is minimised. Once the nurse's hands have become contaminated, possessions such as watches, pens, scissors or any part of the uniform must not be handled. To reduce the risk of acts of carelessness, items such as pens and scissors should be kept in the person's room. To avoid the need to use personal watches for measuring the individual's vital signs, the room should be equipped with a wall clock that has a second hand
- People should avoid touching their hair, nose, mouth or eyes while caring for a person in isolation
- Protective clothing such as gowns, masks and gloves are put on before entering or immediately on entering the room. Disposable single-use impervious gowns are preferred
- Hand hygiene should take place on entering the room, before donning gloves, after contact with the person or contaminated articles, upon removing gloves and other PPE and before leaving the room and as per the 5 Moments for Hand Hygiene while caring for the person in isolation
- Items used during care of the person should be disposable when possible. Reusable items should be kept in the room and, when they are removed for decontamination and reprocessing, should be bagged. When articles need to be removed from the room two people are required. The nurse inside the person's room places the contaminated articles into a bag held by the staff member outside the room and the bag is sealed securely. If the items inside the bag cannot be processed immediately by the person handling the bag, a label is placed on the outside of the bag to signify that the contents are contaminated. Both persons wash and dry their hands after handling the bag(s) (NHMRC 2010).

***Protective isolation*** In some isolated cases, extremely **immunocompromised** individuals may need to be protected from contracting infections and, therefore, must be protected from microorganisms carried into the room by those who enter. No one with an active infection such as a common cold is allowed in the room. Anyone who does enter is required to wear gown, mask, gloves and disposable coverings on the head and feet. When possible the person is nursed in a room with its own ventilation system. This would be implemented with the advice and attention of the infection control practitioner, as well as the medical officer caring for the person. Each healthcare facility will differ, but should have a policy and procedure in regards to which individual protective isolation would apply to upon admission.

***Preparation of individual and family for isolation*** Before isolation precautions are implemented, the individual and significant others require thorough explanations about the precautions and the reasons for them. Healthcare workers should ensure that individuals under their care understand why certain practices are being undertaken, and that these practices are in place to protect everyone from infection. Individuals under their care and visitors should also be aware of their role in minimising risks by following basic hand hygiene (see Figure 22.4) and respiratory hygiene and cough etiquette (Clinical Interest Box 22.5) and informing staff about aspects of their care or services if necessary. The information provided must be clear and comprehensive to prevent spread of infection through ignorance or carelessness. The information should be provided sensitively to reduce any feelings of embarrassment, resentment or apprehension that the person may experience. Individuals should be given the opportunity to ask questions and have them answered in a clear and sensitive manner. Persons nursed in isolation may feel that they are a nuisance, are unclean or are afflicted with some disease that makes them unacceptable to others. Such individuals may also be anxious that no one will come into their room to care for or visit them.

Because isolation may lead to withdrawal or sensory deprivation, the individual is reassured that measures will be implemented to provide adequate stimulation. The person should be provided with any means of diversion or intellectual stimulation that they need, such as a television set, telephone, books and magazines, craft projects or other forms of activity that may be of interest. Ideally the room should have an outside view as a means of reducing the individual's feeling of being isolated.

The person's room should be set up with equipment that will remain in that room; for example, there should be a thermometer, stethoscope and sphygmomanometer that will be used only for that person. These items must remain in the room, and used only with the individual being nursed in that room. Lined rubbish containers with lids and a soiled linen receiver are also placed in the room. Signage of transmission-based precautions must also be displayed. The ACSQHC has tools and resources available to all healthcare facilities in Australia and standardised infection control and

prevention signs are available from the website; see above for details.

## Transporting individuals requiring transmission-based precautions

It may be necessary to transport individuals with infections to surgery or centres for diagnostic tests. Individuals infected with microorganisms transmitted by the airborne route should only leave their rooms if it is essential to do so. Respiratory secretions should be contained by asking the person to wear a mask. The individual should also be provided with tissues and a bag in which to seal them if necessary. The person transporting any individual who is infectious should wear appropriate barrier protection. The nurse needs to take precautions to prevent and contain, or be ready to clean or cover, any leakage of body excreta (e.g. faeces, vomitus, sputum and urine), blood and other body fluids and exudates from infected wounds or skin lesions. The nurse provides the person with a clean (non-colonised) gown to wear as a robe en route and explains as sensitively as possible how the individual can assist with preventing transmission of infection during the transfer and throughout any procedure. The individual may be transported in a wheelchair or on a stretcher or hospital trolley. These may be protected with extra layers of linen or disposable protectors. Any person in another area who is to be in contact with the infectious individual, such as ambulance officers and surgical staff, should be informed of the precautions necessary before the transfer. Information concerning the isolation precautions should also be clearly documented on the person's chart. Equipment used should be cleaned according to infection control guidelines after use. While it is necessary to inform other care givers of the transmission-based precautions that are required, it is to be done with individual confidentiality in mind.

## Transmission-based precautions and multi-resistant organisms in outbreak situations

The application of transmission-based precautions is particularly important in containing MROs such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococci* (VRE) and multi-resistant gram-negative bacteria (MRGN) and is also an integral part of outbreak management. (Refer to Decision-making Framework Exercise 22.1 and the infection prevention and control precautions care plan in Figure 22.2.)

An outbreak may be identified by a healthcare worker, laboratory personnel or health authorities conducting routine surveillance. An **outbreak** may be defined as an occurrence of more cases of disease than expected in a given area, among a specific group of people, over a particular period of time, or two or more linked cases of the same illness. Commonly detected outbreaks are diarrhoeal pathogens (norovirus, *Salmonella, Clostridium difficile*), respiratory pathogens (influenza), MRSA, Legionnaires' disease, chickenpox (varicella) and measles (rubeola).

Upon suspicion of an outbreak a quick infection control response is directly related to minimising cross-infection. Infection control strategies may differ according to the nature of the disease, the virulence of the organism and the vulnerability of the individuals concerned (NHMRC 2010).

*Clinical note*: Communication with the persons and their family or carers will alleviate anxiety and uncertainty. Clear and concise information highlighting the specific transmission-based precautions required to minimise cross-infection will allay fears. All facilities must have policies or guidelines in place for management of an outbreak.

Case Study 22.1 illustrates an example of the spread of infection/infestation due to inadequate adoption of standard precautions on admission of a person to a healthcare facility.

**CRITICAL THINKING EXERCISE 22.8**

Explain what you understand by the terms 'standard precautions' and 'transmission-based precautions'.

## Preparation for discharge to the home environment

When individuals are discharged from a healthcare setting the nurse has a responsibility to ensure that the person and family members have the knowledge and ability to control and prevent the onset or the spread of infection at home. Several social, demographic and cultural factors influence this knowledge and ability.

***Factors affecting knowledge and ability to prevent and control infection*** Factors that influence the ability of individuals to absorb and retain information imparted to them include their age, educational level, language and cognitive abilities. Factors that influence a person's ability to perform the infection prevention and control measures include their physical abilities, financial status and living conditions. Additionally a person's cultural beliefs may impact on perceptions concerning the cause of infection and the need to comply with the recommended control measures. Assessing all these factors is essential when the nurse prepares an individual for discharge home.

***Living conditions and financial situation*** Individuals live in a range of different environments: some live in poverty—being homeless, or living in extremely poor conditions. Some of the most disadvantaged persons the nurse will encounter are Indigenous people, many of whom live in rural and remote areas where housing is inadequate and there is a lack of clean water because there is no mains water supply. Some live in overcrowded and unsanitary conditions where leakages of sewage are common (Human Rights and Equal Opportunities Commission 2006).

The lack of water and the lack of money impact on the ability of these people to:

- Maintain bodily hygiene
- Keep the home clean, wash clothes and bed linen
- Purchase medications, equipment, linen or other essential items
- Purchase and safely prepare nutritious food.

See Chapter 11 for more information on issues that impact on health risks for Indigenous people.

***Cultural beliefs*** One of the most significant issues in infection control is an understanding of bacteria and viruses, how they spread and how they cause illness. This understanding of the cause of illness is widely accepted and understood in western cultures, but other cultures may have quite different perceptions. According to a person's cultural beliefs, illness may be perceived as being a natural punishment for wrongdoing, caused by God's will or by magical, mystical or spiritual intervention. Without the belief and understanding that illness is the result of bacterial or viral invasion there is little incentive for compliance with infection control measures dictated by western understandings. The nurse who tries to explain western perceptions to persons from other cultures may find language and cultural barriers difficult to overcome, and the help of an interpreter familiar with the culture and language of the individual is strongly recommended.

***Going home with an infection*** The advantage of the home environment is usually that there is less exposure to the organisms that cause HAIs and therefore, when poverty and clean water are not primary issues, the home usually presents less risk of infection than a hospital and it provides a healing environment. Before being discharged home, the individual should be provided with the necessary education verbally and in written form. Some general points for healthcare education in relation to preventing infection are identified in Clinical Interest Box 22.8.

If a person goes home with an infection, health education appropriate to the specific type of microorganism and mode of transmission of the infection is essential. Education might need to include advising the person to:

- Launder the clothes, towels and bed linen of the person with the infection separately to those of the rest of the household.
- Use a solution of chlorine bleach and hot water for laundering, as this will destroy most organisms. If possible, hang laundered items in the fresh air and sunshine to dry, or dry in a dryer at the highest possible temperature, as most organisms do not survive in hot dry conditions.
- Use a 1:10 solution of chlorine bleach and water for cleaning the bathroom and toilet facilities, kitchen surfaces or equipment used by the person with the infection (e.g. wheelchair, commode, bedpan or urinal).
- If the person is on antibiotics, they must be instructed to complete the course.
- The person should be instructed to perform hand hygiene before touching any wound or indwelling devices.
- Wash dishes on the strongest cleaning cycle of the dishwasher. If there is no dishwasher, soak dishes in scalding water after washing them with gloves on, then allow them to air-dry.
- Tie up soiled dressings or other contaminated materials in plastic bags and mark with a biohazard sign. Contact the local hospital, council or community health nurse for advice on safe disposal.
- Use a heavy plastic container with a secure lid for the disposal of needles, syringes or other sharp objects used in caring for the person with the infection.
- Use clean disposable gloves for wound care. (The nurse must educate the person about correct hand hygiene techniques, use of gloves and aseptic technique before discharge.) Education must include the importance of hand hygiene prior to donning gloves and after the removal of gloves. The person and their family should be encouraged to purchase some alcohol-based hand rub and be instructed on how to use it. The discharge

## CLINICAL INTEREST BOX 22.8 Preventing infections in the home: general discharge education

**Nursing assessment**

- Knowledge deficit relating to transmission of microorganisms and causes of infection

**Objectives**

- Individual will be aware of and implement ways to prevent occurrence or transmission of infection at home
- Individual will demonstrate correct hand hygiene technique

**Nursing interventions: health education**

- Reinforce need for daily personal hygiene, including mouth care
- Advise the individual to keep the home environment as clean and uncluttered as possible, using household bleach (1:10 solution) as a disinfectant
- Advise that fresh air should be allowed to circulate in the home regularly
- Advise that frequent damp dusting and vacuuming reduces the number of microorganisms in the environment
- Advise person to perform frequent handwashing, especially before preparing food, eating and after visits to the toilet or contact with body fluids
- Advise person to avoid sharing personal care items such as towels, razors, cups and toothbrushes
- Ensure that individual understands the need to keep food refrigerated until use, to discard food that is beyond the use-by date and to cook food thoroughly
- Educate person on preventive healthcare (e.g. immunisations, nutrition, exercise, relaxation and stress management techniques)

**Evaluation**

- Individual will be asked to describe techniques that will reduce risk of infection
- Individual's handwashing technique will be observed

*(Modified from Crisp et al 2013)*

plan may need to include arranging for the district or community health nurse to conduct a follow-up visit.
- Dedicate a separate area in the home for all 'clean' items. Ensure no contaminated item enters this 'clean zone'.

Nurses frequently visit persons in their own home and often need to perform aseptic procedures such as wound dressing and catheterisation. Nurses may find it challenging in some homes to conduct such procedures without the advantages that the hospital provides, but the principles of asepsis must always be followed.

## Infection prevention and control for healthcare workers

Australia has legislation relating to the transmission of infection. All the legislation relates to common goals and principles and contains the following elements in some form:
- Work health and safety plan. These are designed to minimise or eliminate employee exposure. The plan describes how to avoid exposure to infectious agents, such as when to use protective equipment, and what should be done in the event of an exposure occurring; for example, exposure to hepatitis virus or HIV via a needle-stick injury. In Australia, influenza vaccination should be offered to healthcare workers in accordance with *Australian Immunisation Handbook* (Australian Government, Department of Health 2015).
- Compliance with standard precautions. Personal protective clothing and equipment must be provided at no cost to employees and should be readily available.
- High-risk exposure. Needlestick or mucous membrane exposure to blood or infectious body fluids must be reported immediately. Appropriate prophylactic treatment for HIV and hepatitis viruses must be put in place as soon as practicable after the exposure or suspected exposure. Most Australian healthcare facilities utilise safety needles and needleless systems to help in the prevention of blood and body fluid exposure risk.
- Housekeeping. Routine schedules for cleaning and decontamination procedures must be established in all facilities. Regular audits will determine if cleaning is being carried out as it should be.
- Education. Education programs, written policies and guidelines must be provided for all personnel in relation to infection prevention and control activities relevant to their facility for their own and individual safety (NHMRC 2010). This could be in the format of self-directed learning packages, online education packages or lectures.

## Role of the infection control and prevention nurse

### Responsibilities

Many healthcare facilities employ one or more members of staff to be responsible for the area of infection prevention and control. In a hospital a committee is often responsible. Individual nurses may be members of the committee, as may be representatives from the laboratory, housekeeping, maintenance, food services and laundry (if applicable). An important member of this committee is the infection control and prevention nurse. This nurse is specially trained to be knowledgeable about the latest research and practices in preventing, detecting and treating infections.

In Australia the nurse should be a member of the Australasian College for Infection Prevention and Control (ACIPC); it is the peak national body representing the interests of the specialist practice of infection prevention and control within Australia. The College commenced in January 2012 bringing together the various state and territory infection control associations that were formerly in AICA (the **Australian Infection Control Association**) to support and encourage collaboration across Australasia using a corporate model. There is also a move to have all Australian infection control and prevention practitioners credentialled (with ACIPC or the Certification Board of Infection Control and Epidemiology (CBIC)). The role of the infection prevention and control committee is to maintain surveillance of HAIs throughout the hospital. All infections are reported to the infection control and prevention nurse in a manner that allows for recording and analysing statistics that can assist in improving infection control practices at the healthcare facility. The facility may have an infection control surveillance form in use, which will allow all nurses to highlight any possible infections to the infection control nurse (see Clinical Interest Box 22.9).

The infection prevention and control nurse's role is to facilitate the implementation of policies established by the committee. The combined roles of the nurse and the committee include:
- Monitoring for outbreaks of infection within the facility
- Monitoring antibiotic-resistant organisms
- Ensuring that staff are advised on all aspects of safe aseptic practice
- Implementation of a method that assesses staff for competency in aseptic technique
- Ensuring that the Infection Prevention Standard of the NSQHS Standards is fulfilled for accreditation purposes
- Educating staff and individuals on infection prevention and control policies and procedures
- Reviewing infection control policies and procedures
- Recommending appropriate isolation procedures and transmission-based precautions
- Researching laboratory reports and records for incidence of infections and establishing a close working relationship with the hospital microbiologist and all departments to investigate unusual events
- Identifying and rectifying infection control problems (equipment and procedures)
- Reviewing individual records for community-acquired infections that may be reportable to the health department

## CLINICAL INTEREST BOX 22.9
## Infection control surveillance form

**Site of infection**
Please tick appropriate box.
Please circle relevant symptoms.
State right or left leg, abdominal wound, if applicable.
Include any individual who shows signs of infection (pain, heat, redness, swelling, wound discharge) as well as any person who is being treated for an infection with antibiotics.
**Has this infection occurred within 30 days after the operative procedure? Y ☐ N ☐**
**Wound** (location) ☐

_____
(Inflammation, pain, swelling, purulent discharge, temperature > 38°C)
**Urinary tract** ☐
(Pain, frequency, temperature, MSU taken)
**Phlebitis** ☐

_____
(Pain, swelling, purulent ooze at IV site)
**Bacteraemia** ☐ (PICC/CVC in situ Y ☐ or N ☐)

_____
PICC/CVC insertion date: _____
(Temperature >38°C, blood cultures taken)
**Neonatal infection** ☐
**Gastroenteritis** ☐

_____
(If you have 2 or more persons with symptoms notify infection control manager immediately)
***Ensure individuals have not had aperients***
(Onset of vomiting, diarrhoea, cramping)
**Multi-resistant organism** (identified) ☐
MRSA ☐
VRE ☐
*Clostridium difficile* ☐
ESBL ☐
Other ☐
Colonised ☐
Infected ☐
**Other type of infection** ☐
**Reported by:** _____ **Date:** _____

*(Modified from NHMRC 2010)*

- Gathering statistics regarding the epidemiology of iatrogenic infections
- Coordinating immunisation programs for staff and maintaining health-screening records
- Conferring with support services such as the housekeeping department within the facility.

The infection prevention and control nurse is responsible for reviewing laboratory and radiology reports, case notes, autopsy reports and documentation of staff infections, and for reporting all relevant information to the infection prevention and control committee. The committee authorises the distribution of data to relevant people within the establishment.

### Evaluating the efficacy of nursing measures

The infection control nurse and the committee perform an important role in surveillance and monitoring of infections in healthcare settings but it is the role of every nurse to ensure infection rates are kept to a minimum. Continuous evaluation determines the efficacy of nursing work and identifies if and when infection prevention and control strategies need to be increased or modified. The success of the infection control program is determined by whether or not the goals for reducing or preventing infection have been met by the nursing interventions implemented. Signs that indicate success include:

- No local signs of infection around portals of entry (e.g. wounds, IV or wound-drain insertion sites, gastrostomy or jejunostomy feeding tubes)
- Susceptible individuals do not develop signs or symptoms of respiratory, blood stream, urinary tract or other infections (e.g. individuals who have had surgery recover and are discharged without contracting healthcare-associated infections)
- Signs of infection are detected at a very early stage, indicating that nurses are efficient in assessing and monitoring individuals under their care
- Outbreaks of infection in a healthcare setting are identified at a very early stage, indicating that nursing documentation and reporting of signs and symptoms of all infections is prompt, clear and there is minimal to no cross-transmission of infection and outbreaks are contained.

## Summary

This chapter provides information about the chain of infection, the way infections develop and are transmitted, the ways the body defends against them and why some individuals are more susceptible to infection than others. It provides the EN with information about how to practise nursing in a way that incorporates standard and transmission-based precautions and the prevention and control strategies recommended by the NHMRC, the *Australian Guidelines for the Prevention and Control of Infection in Healthcare* (2010). Infection prevention and control principles are applicable to every area of nursing practice and is everybody's responsibility. The principles and practices covered in this chapter provide nurses with the essential information to ensure that they protect themselves, individuals under their care and other healthcare workers from pathogenic microorganisms.

## Review Questions

1. Provide six (6) examples or occasions when healthcare workers and allied healthcare workers must perform hand hygiene to prevent cross-infection.
2. Describe the body's natural defences against infection.
3. What is meant by 'normal flora'?
4. Identify the differences between inflammation and infection.
5. Provide three (3) examples of how pathogens are transmitted.
6. Explain the difference between non-specific and specific immunity.
7. List five (5) factors that influence susceptibility to infection in a person.
8. What is meant by the terms 'healthcare-associated infection (HAI)' and 'iatrogenic infection'?
9. Can a reusable medical device or monitoring equipment be disinfected or sterilised for use on another person if not cleaned first? Explain the difference between disinfection and sterilisation.
10. How would you explain the terms 'standard precautions' and 'transmission-based precautions'?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Maintenance of health: hygiene and comfort care

*Lindsay Bava*

CHAPTER 23

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- State the significance of personal hygiene to the maintenance of health
- Identify factors that influence hygiene practices
- Identify complications that may result if personal hygiene is neglected
- Perform nursing procedures for individual hygiene accurately and safely
- Identify the factors that may interfere with individual comfort
- Identify the importance of a well-made bed and comfortable positioning of individuals to the promotion of health and wellbeing
- Apply appropriate principles to select supplementary equipment used in conjunction with bed making
- Apply appropriate principles when planning and implementing measures to promote comfort
- Describe the positions that individuals may be required to assume in bed
- Apply decision-making frameworks when determining hygiene and comfort care for individuals

## KEY TERMS

alopecia
gingivitis
halitosis
making an occupied bed
operation bed
pediculosis
personal hygiene
supplementary equipment
surgical/post-anaesthetic bed
unoccupied bed

## CHAPTER FOCUS

Hygiene is the science of health. It has also been described as the self-care by which people maintain cleanliness that is conducive to the preservation of health. Personal hygiene includes activities such as bathing, toileting, general body hygiene and grooming (Parker 2012). Hygiene helps the individual to maintain a positive body image and helps protect the body against disease such as infection.

Comfort is often associated with compassionate care and many nursing interventions are implemented to provide comfort (Bourgeois & Van der Riet 2012). Comfort is subjective and may also be described as a feeling of ease or well-being; for people to feel comfortable their physiological, psychological and spiritual needs must be met. This chapter introduces the nurse to the knowledge and skills required to assist an individual with their hygiene and physical comfort needs.

## LIVED EXPERIENCE

Joan remembers a time she was recovering from a serious anaphylactic reaction to penicillin in hospital. A nurse was caring for her and moved to rearrange her pillows and change her linen that was soiled. Softly, and while still listening to Joan's feelings of discomfort, the nurse took the pillow, changed the linen, fluffed it up and gently replaced it. Joan instantly felt more comfortable. When thanked, the nurse dismissed it as being nothing extraordinary. Nonetheless, those simple duties, such as bed making, listening, shifting an individual in bed, realigning pillows and touching an individual's hand brought a profound change in Joan's comfort levels when she was so unwell.

**Joan aged 68 years, day 2 following a serious anaphylactic reaction to penicillin**

Many factors influence whether or not an individual is comfortable; they relate to physical, emotional and spiritual needs being met. To most people, physical comfort means being clean, dry, warm and free of hunger and pain. Emotional comfort relates more to being relatively free from stress and feeling satisfied with interpersonal relationships; in particular, people are more likely to be emotionally content when they feel loved and are able to love others. Spiritual comfort is connected to a sense of purpose and satisfaction in life that may or may not be entwined with religious meaning. The nurse considers all these interrelated elements when caring for an individual's comfort. This chapter discusses the physical elements of comfort, specifically in relation to hygiene care and moving and positioning an individual. Management of pain is discussed in depth in Chapter 33. (Information about assisting an individual with stress and spiritual comfort is provided in Chapters 27 and 39.)

## FACTORS AFFECTING PERSONAL HYGIENE

**Personal hygiene** refers to the measures people take to keep their bodies clean. Neglect of personal hygiene can have a detrimental effect on physical and psychological health and the comfort of an individual. Many factors influence people with regard to personal hygiene practices. It is important for nurses to appreciate that emphasis on cleanliness varies according to an individual's personal preference, culture, religious values and lifestyle. Other factors that may affect an individual's hygiene practices include:

- Stage of development
- Level of independence
- Physical and intellectual capabilities
- Emotional state
- Economic status
- Knowledge of the significance of hygiene
- Availability of facilities (e.g. water)
- Environment or climate.

Nurses should respect individual preferences and cultural norms and, whenever possible, enable an individual to follow their usual routine of personal cleansing (Berman et al 2015). For example, if an individual prefers to shower in the evening rather than the morning, or to shower every second day, these practices are best continued. Maintaining routine and normality can help limit the stress during times of illness.

Many individuals will be able to attend to their own hygiene, while others will require partial or total assistance from the nurse. Some individuals, for example those who are unconscious, will be unable to participate in planning their own hygiene care. In these instances, it is the responsibility of the nurse to ensure that suitable nursing care plans are devised to meet hygiene needs. Assessing an individual's abilities to care for their own hygiene needs safely and effectively includes identifying factors such as loss of balance, poor vision, decreased sense of touch or limitations in mobility. In the case of some older people with dementia, the ability to remember, plan and carry out self-care activities will need to be assessed. It is important for the nurse to recognise that an inability to care for personal hygiene needs without assistance and the lack of privacy that accompanies intervention by another person can be very embarrassing for the individual. The associated loss of independence can have a negative impact on the individual's feelings of self-worth; they may feel that they are a burden to the nurses. A calm, sensitive, caring and professional approach can help reduce these feelings. Wherever care is provided, the nurse's role is to ensure

that the individual maintains high standards of personal hygiene for efficient body function and sense of wellbeing. It is important for the nurse to be aware of the function and care requirements of areas such as the skin, hair, mouth, eyes, nose, ears and nails to help individuals maintain high standards of personal hygiene in each of these areas. Assisting with hygiene provides an ideal opportunity for the nurse to observe and assess the individual for any abnormalities or changes in health status. It also provides a time to talk informally and privately together, which can provide the nurse with insights about the individual's psychological and spiritual wellbeing. The nurse must, on every occasion, seek the consent of the individual before starting to provide any personal care and assistance.

### Cultural considerations

An individual's cultural beliefs and personal values may influence hygiene care. People from diverse cultural backgrounds follow different self-care practices. In many cultural groups in Australia, it is common to bathe or shower daily, whereas in some other cultural groups it is customary to bathe completely only once a week (Berman et al 2015).

Culture plays a role not only in hygiene practices and preferences but also in sensitivity to personal space; for example, some Chinese people may view tasks associated with closeness and touch as being offensive or impolite (Crisp et al 2013). The nurse should ask the individual what would make them feel most comfortable during a bath. Perhaps they would prefer only a partial bath from the nurse, with a family member assisting with the bathing of more private body parts. The individual may also want to defer part of the hygiene. If, in the nurse's judgment, hygiene is critical to prevent problems, such as skin breakdown, the nurse must try to understand the individual's concerns then help them understand the reason for accepting the nurse's intervention. The nurse can play a very important role, particularly when caring for individuals in rural settings, poor individuals and older adults, in being able to screen for abnormalities such as dental decay and referring dental problems to a dental professional.

Hair care may also be important to people from other cultures. When caring for individuals from different cultures, it is important to learn as much as possible from them or their family about preferred hair care practices. Cultural preferences may also affect how hair is combed and styled (Crisp et al 2013).

## SKIN AND SKIN CARE

The skin is the largest organ of the body. It is a semi-permeable layer that protects underlying tissues and organs from injury or invasion by microorganisms. It is waterproof, controls the rate at which water is lost from the body by evaporation, helps regulate body temperature and produces keratin, melanin, sweat and sebum. The skin also plays an important role in perception of sensation through the sensory nerve endings it contains, which are sensitive to touch, pressure, pain and temperature (Crisp et al 2013). See Chapters 29 and 34 for more information about the skin and sensory abilities.

If the skin is not washed regularly dirt, sebum, dried sweat and dead skin cells collect, providing an ideal medium for the growth of bacteria and fungi. Bacteria decompose the dirt and dried sweat producing an unpleasant body odour, and infections such as boils are more likely if the skin is not cleansed adequately.

Skin undergoes many changes during a person's lifespan and, as a result, care needs may vary according to the individual's age or stage of development. In addition, characteristics of normal skin may vary according to ethnic or racial background. Consequently, replenishing the skin, particularly in older individuals, is essential to prevent skin tears. Skin tears occur due to drying of the skin, skin becoming fragile and hormonal changes causing skin transformation. Best practice standards and literature studies (Skin Tears 2006) demonstrate moisturising of the skin has a direct link to the reduction of the number of skin tears that occur in our elderly individuals.

When moisturising the skin, care must be taken to not further damage the skin with excess force, or with rings and bracelets the nurse may be wearing; all jewellery must be removed. The nurse must also investigate that an individual has no allergies to the moisturiser chosen and that it is clearly documented in the individual's history and plan of care that skin care has occurred.

### Infants

In infancy, the skin is thin and easily blistered or excoriated by friction, acid or alkaline substances. It is very sensitive to heat or cold, so it is vital that the temperature of bath water is tested before bathing; approximately 38°C is recommended as the newborn's skin is prone to irritation (Gunn 2010). Mild, non-irritating soaps or soap-free solutions may be used on the skin and, as the infant has no bladder or bowel control, thorough cleansing of the genital and anal areas is necessary to prevent excoriation. After washing, the infant's skin should be patted dry with a soft towel, paying particular attention to skin creases and folds. Cradle cap is a common form of dermatitis of infants which consists of thick, yellow waxy scales on the scalp, which may occur as a result of an accumulation of sebum. It can usually be prevented by regular gentle washing and drying of the scalp and hair (Barker 2013).

### Adolescents

Adolescence is accompanied by many changes that are due to hormonal activity. Sweating from the axillae usually occurs at this stage and the adolescent may need education concerning the importance of having a regular shower or bath. Education can also include information about the function of deodorant and antiperspirant (Berman et al 2015). Acne is a common problem as sebaceous glands become more active in adolescence. Skin hygiene, together with a balanced diet, is important in preventing secondary skin infections.

## The middle years

Middle age is often associated with further skin changes, particularly during the male climacteric (decreased levels of androgens) or the female menopause—because of a decrease in circulating ovarian hormone levels (primarily oestrogen and progesterone) the skin may become drier and the pubic and axillary hair may become sparse. Some women may experience thinning and dryness of the skin of the external genitalia, which may be accompanied by pruritus (Berman et al 2015). Lubricants are available to reduce any discomfort associated with such changes.

## Older adults

Older age is associated with increasing change in the dermis, with the result that skin is thinner, less elastic and dry. The decreased production of sebum and associated dryness mean that the skin of older people is less able to tolerate soap. To help counteract the dryness, a mild soap or soap-free washing lotion can be used and a moisturising lotion applied after a bath or shower. To prevent skin irritation caused by dry skin some older people choose to change from a daily shower or bath to every second day or less frequently (see Clinical Interest Box 23.1).

## Nursing observations of the skin

The skin should be observed for:

- Colour. Particular note should be taken of any abnormalities such as pallor, jaundice, cyanosis or altered pigmentation. Areas of red, deep pink or mottled skin that do not become paler with fingertip pressure may be a sign that a pressure injury is developing. (See Chapter 29 for information on the development and prevention of pressure injuries.)
- Hydration. Deviations from normal include excessive dryness or oiliness, increased sweating and fluid retention (oedema)
- Texture. The skin may be smooth and supple or contain rough scaly patches. It is also important to observe if the skin appears thin and fragile
- Turgor. Picking up and then releasing a small fold of skin is the simplest way to assess skin turgor. Adequately hydrated skin returns rapidly to its previous state, whereas the skin of an individual who is dehydrated is slow to respond. The skin of an older individual may also resume its shape more slowly because of reduced elasticity
- Lesions. The skin should be observed for the presence of bruises, blisters, inflammation, rashes and localised swellings such as cysts, petechiae, bites, scratch marks or puncture marks.

Abnormalities and changes should be reported and documented and appropriate nursing care implemented in response to nursing observations.

Care of the skin includes maintenance of cleanliness and protection from injury. The skin must be protected against injury by gentle handling and the use of appropriate bed linen and equipment. Cleansing involves the use of soaps and lotions that do not cause irritation or dryness and careful drying of the skin, particularly in folds or creases. If the individual wishes, and it is not contraindicated, deodorants, powders and perfumes may be used to enhance the feeling of freshness and to improve morale. Cleansing of the skin may be achieved by several means and the method selected depends on the individual's level of mobility and independence. Some individuals will be able to have a bath or shower, while more dependent individuals may require a bed or trolley bath. Whichever method of cleansing is used the nurse must ensure the individual's privacy, comfort and safety. It is now sometimes a reality that male and female individuals are accommodated in the same ward or unit area and some even share bathroom and toilet facilities. This can increase the individual's discomfort and concerns about privacy, especially during hygiene and toileting procedures. The nurse will need to be sensitive to the concerns of individuals faced with this situation and reassure them that every effort will be made to maintain their personal privacy (Crisp et al 2013; deWit 2013; Springhouse Staff 2011).

### CLINICAL INTEREST BOX 23.1 Hygiene and the elderly

I have noticed over the last couple of years that my skin feels and looks significantly dry. My local pharmacist recommended that I use a soap-free cleanser in the shower and suggested that I apply moisturiser to the dry, flaky skin after I wash. She also suggested that I shower every second day and just have a quick wash at other times.

**Mrs Anderson, aged 76**

# BATHING AND SHOWERING

An individual may have either a bath or a shower, depending on individual preference and general condition. Both methods of cleansing refresh the individual, stimulate circulation and promote relaxation. They also provide an opportunity for the nurse to observe the condition of the individual's body, including assessment of mobility and strength.

## Nursing observations and assessment

If individuals are able to attend to personal hygiene needs safely and independently, they may be left to bathe in private. It is the responsibility of the nurse to ensure that the bathroom has been prepared for use and that the individual has all the necessary items. The nurse should ensure that the individual knows where the call bell is located and that they know how to use it to call for a nurse.

It is the nurse's responsibility to assess how much assistance a dependent individual requires. Some individuals may require help with transfers, while others will require the nurse

to remain with them throughout the entire procedure. The nurse should remain with, and provide assistance to, any individual who is weak, frail, unsteady or confused. Some individuals may require a shower chair to sit on during the shower. For example, a chair would be helpful for a postoperative individual who can walk to the shower but is at risk of becoming easily fatigued.

## Devices used to assist when bathing and showering

There are several other devices designed to assist the nurse when providing hygiene care for individuals. These include handrails, bath seats, mechanical hoists, mobile baths and shower trolleys.

Handrails fixed to the wall at the side of the bath or shower can be used for support by individuals who are able to stand. Bath benches or seats fit across the top of a bath and allow the individual to shower using a hand-held shower hose.

Lifting devices such as hoists or standing machines may be used to safely transfer non-ambulatory individuals onto a mobile shower chair so that they have the opportunity to shower or bathe. It is generally easier to remove the individual's clothing before the lift and transfer to the bathroom, but being moved around in a lifting device can feel extremely undignified and distressing. It is recommended in the policy of many institutions that hoists and standing machine transfers be used by two nurses to ensure maximum individual safety. For further information regarding safe transfer of individuals, refer to http://www.worksafe.com.au/ or http://www.australia.gov.au/directories/australia/safeworkaustralia. The utmost care must be taken to ensure that the individual's privacy and dignity are maintained, in particular the individual's private body areas must be securely covered from view during transfer to the bathroom. Any individual who requires the use of a mechanical lifting machine must never be left unattended in the device or in the bath. Individuals who may require the use of a mechanical lifter include those who are heavy or extremely weak, frail or helpless.

When individuals require aids in the home, structural alterations to the house may be necessary to facilitate their use. Government-funded care packages sometimes provide for this need. In some situations, nurses teach family members who are providing home-based care for dependent relatives how to use the hoist safely. (See the Australian Department of Health and Ageing at www.health.gov.au.)

Mobile baths are available in some healthcare facilities. A mobile bath can be moved to the individual's bedside. The individual is transferred from the bed into the bath and transported to the bathroom. The bath is filled and the individual bathed in the usual manner.

Shower trolleys are designed for use in the normal shower area. Using a hoist, the individual is positioned onto the trolley and wheeled to the bathroom. The surrounding edge is inflated and converts the trolley into a shallow bath and the nurse washes the individual using the shower hose.

A full explanation about the aid being used, reassurance about its safety and maintaining the individual's personal privacy and dignity during use are important components of reducing stress and embarrassment for the individual. Examples of some aids that are available are illustrated in Figure 23.1.

### CRITICAL THINKING EXERCISE 23.1

Mr Kaur, a 27-year-old Indian man, sustained a fractured tibia and fibula of his right leg as a result of a motorcycle accident. He was taken straight from the accident to the emergency department and then surgery, and has not washed since before the accident. He has arrived on the ward direct from the operating suite, with a plaster cast on the injured leg, and in a considerable amount of pain. What needs to be done to meet his comfort and hygiene needs? What cultural aspects of care should be taken into account?

Key aspects of assisting an individual to bathe or shower are outlined in Clinical Skill 23.1.

## Individuals requiring special consideration

Individuals who are weak, frail, unsteady or confused will require the nurse's assistance to bathe or shower. An individual may feel faint and collapse in the bath or shower. If this occurs the nurse should immediately drain the bath or turn off the shower. Towels should be used to cover the individual for warmth and dignity and extra towels should be placed under the individual's legs and feet to increase venous return. The nurse should summon immediate assistance and remain with the individual, ensuring that the airway is clear. (See Chapter 44 for full emergency care actions in situations in which a person has collapsed.) Case Study 23.1 outlines the hygiene needs of an individual following a cerebrovascular accident (CVA).

Some individuals will require special consideration when bathing or showering; for example, special attention is needed for individuals who have drainage or intravenous (IV) tubing, wound dressings, plaster casts or specific skin disorders. There may also be special needs associated with surgical or other interventions.

### An individual with dementia

Difficulties often arise when bathing individuals who have dementia. The nurse can reduce their discomfort by avoiding running water over their face, maintaining warmth and keeping them covered as much as is practicable. Keeping routines and giving clear, simple instructions, cues or demonstrations, and allowing the individual as much independence as possible will also allay the anxiety associated with bathing (Berman et al 2015). Music, singing or talking during bathing may distract the individual from fretful reactions and improve the experience. It is necessary to check the water temperature prior to washing the individual. The skin of the older person may be more sensitive to temperature

**Figure 23.1** Devices to assist bathing and showering

A: Mechanical lifting device B: Shower chair C: Handrails attached to the walls in the shower and toilet D: Hand-held shower E: Shower trolley

extremes due to deterioration in control mechanisms such as vasodilation and vasoconstriction (Crisp et al 2013).

## An individual with a skin disorder

Soap-free cleansers are best used on individuals with any dryness, erythema or pruritus, with care taken to follow any medically prescribed treatments. Emollient creams or lotions may also need to be applied following bathing. Where the application of medicated creams or lotions is required, gloves should be applied before they are administered because they are absorbed through the skin.

## An individual with an intravenous line

Care is necessary to avoid kinking or dislodging IV tubing and precautions must be taken to prevent the intravenous site from becoming wet. Pumps should be switched to battery mode when the individual is showering. The nurse will need to assist the individual to change their clothing. Remove the individual's gown or pyjamas. If an extremity has reduced mobility or is injured, begin removal from the unaffected side, then lower the IV container or remove from pump and slide gown covering affected arm over tubing and container. Rehang the IV container and check the flow rate or reset the pump rate. Do not disconnect the IV tubing.

## An individual with a urinary catheter or wound drainage tubing

Drainage tubing and the container receiving the drainage fluid must be positioned below the area into which the tubing is inserted in order to promote drainage and to prevent back-flow of fluids into the body. For example, a urinary catheter

## CLINICAL SKILL 23.1 Assisting with a shower or bath

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Personal toiletry items including clothing<br>2–3 bath towels<br>Bathmat<br>Face washers<br>Shower chair or commode<br>Plastic apron and shoe protection<br>Gloves<br>Soiled-linen container |

| **Skill activity** | **Rationale** |
|---|---|
| Review individual's care plan and current treatment orders | Provides information about individual's mobility, cognition, preferences and level and type of assistance required |
| Inform individual of proposed activity, assess for pain, gain consent | Promotes involvement and cooperation, maintains autonomy |
| Assess bathroom and equipment for safety | Maintains safe work environment |
| Ensure bathroom is clean and the floor is dry | Prevents cross-infection and promotes safety |
| Provide a shower chair or commode if needed | Promotes safety |
| Arrange required toiletry items within easy reach | Promotes efficiency and functional independence |
| Offer use of toilet facilities before activity | Promotes comfort |
| Perform hand hygiene | Reduces risk of transmission of microorganisms |
| **Assist with a shower** | |
| During the procedure, encourage individual to participate as able and assist as required. During the procedure, communicate proposed actions to individual to encourage cooperation. | |
| Turn on taps, direct flow away from individual and adjust water temperature | Maintains safety |
| Allow individual to check the water temperature for suitability | Promotes comfort and safety |
| Allow individual to hold shower handle and direct water flow onto own body if able | Promotes functional independence and cooperation |
| Keep flow of warm water across individual's back during procedure | Maintains comfort and warmth |
| Supply soap product and wash cloth to individual and encourage them to wash their own body as able | Promotes self-help skills and functional independence |
| Provide full assistance with washing if required. Wash the body in an efficient manner, starting with the face | Provides support to meet hygiene needs<br>Promotes individual comfort |
| Wash and rinse genital area from front to back | Avoids transmission of microorganism and cross-contamination |
| Dispose of the washcloth used to wash genitals immediately | Maintains hygiene and infection control principles |
| Assist as required with washing hard-to-reach areas such as lower legs, back and hair washing | Provides support to meet hygiene needs |

*Continued*

| CLINICAL SKILL 23.1 Assisting with a shower or bath—cont'd | |
|---|---|
| Apply disposable gloves if skin to mucous membrane contact is likely | Maintains infection control principles |
| Assess individual's skin condition, especially pressure areas over bony prominences | Identifies risks to skin integrity |
| Ensure soap product is completely rinsed from the body, especially under skin folds | Reduces irritants on the skin and helps maintain skin integrity |
| Turn hot tap off first, then cold | Promotes safety |
| Place towel around individual's shoulders and another towel or bathmat under the feet | Promotes comfort and warmth by maintaining body heat |
| Drying, dressing and grooming continued Step 3 | |
| **Assisting with a bath** | |
| Fill the bath with warm water to individual's hip level | Promotes safety. A deep, hot bath may cause vasodilation |
| Assist individual to the bathroom and close the bathroom door | Provides privacy and maintains individual dignity<br>Helps to maintain a comfortable room temperature |
| Assist individual to undress and to climb into bath | Provides support and promote safety |
| Assess level of supervision required and, if safe, leave individual to perform activity, but remain within calling distance of bathroom.<br>During the activity, encourage the individual to participate as able and assist as needed. During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Supply soap and wash cloth and encourage individual to participate | Provides support, promotes self-care skills and functional independence |
| Assist with washing hard-to-reach areas such as lower legs and back | Provides support to meet hygiene needs |
| Provide full assistance with washing if required. Wash the body in an efficient manner, starting with the face | Provides support to meet hygiene needs<br>Promotes individual comfort |
| Dispose of wash cloth used on individual's genitals | Maintains infection control |
| Assess individual's skin condition, especially pressure areas over bony prominences | Identifies risks to skin integrity |
| Ensure soap product is completely rinsed from the body, especially under skin folds | Reduces irritants on the skin and helps maintain skin integrity |
| Drain bath first, then assist individual to climb out of bath | Promotes safety |
| **Assisting with drying, dressing and grooming** | |
| During the activity, encourage the individual to participate as able and assist as needed. During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Sit individual on a chair covered with a towel and place a second towel around shoulders for warmth | Provides comfort and warmth |
| Ensure skin folds and hard to reach areas are completely dried, such as between toes | Maintains skin integrity |
| Apply prescribed creams or treatments such as anti-embolic stockings | Follows treatment orders |
| Assist with dressing as required. Dress injured or affected side first. Assist with zips, buttons or ties/laces | Promotes functional independence |

## CLINICAL SKILL 23.1 Assisting with a shower or bath—cont'd

| | |
|---|---|
| Set up toiletry items and assist with grooming as required, brushing teeth, drying hair, applying make-up, shaving, hearing aids and glasses<br>Dress affected side first | Maintains positive self-image and promotes independence |
| Assist individual to return to bed or chair | Promotes comfort and rest |
| Ensure all individual's requirements are within reach such as call bell, phone, fluids, reading glasses | Promotes independence |
| Collect toiletries from bathroom and return them to individual's bedside locker | Maintains tidy environment and care for individual's personal items |
| Dispose of towels and other linen in the soiled-linen container | Prevents cross-contamination |
| Clean and dry floors, shower chair or bath and leave bathroom door open | Maintains safe environment, infection control and allows ventilation of bathroom |
| Check individual has call bell and other personal items within reach before leaving | Promotes comfort and individual wellbeing |
| Perform hand hygiene | Prevents cross-contamination |
| Documentation is the responsibility of the EN or Registered Nurse and must be completed on behalf of unregulated health workers who may have been delegated the activity. | |
| Document the individual's response to the procedure in the healthcare record, noting the level of participation, changes in skin integrity or individual's condition | Provides clear and up-to-date communication of individual's data between healthcare professionals<br>Maintains legal document of care and interventions provided |
| Update the individual's care plan information on domains related to mobility, activities of daily living (ADLs), skin integrity and hygiene preferences | Allows clear and accurate communication of information about individual's care between nurses |
| Verbally report to Registered Nurse any changes in individual condition that indicate risk for deterioration | Allows for timely review, response and intervention |

*(Australian Commission on Safety and Quality in Healthcare 2015; Joanna Briggs Institute 2013a; 2013b; Nursing and Midwifery Board of Australia 2013; Rebeiro et al 2012; Wilkinson et al 2015)*

## CASE STUDY 23.1

Mrs Joan Bennett is a 68-year-old woman who was admitted to hospital 10 days ago following the sudden onset of left-sided arm and leg weakness. She has been diagnosed as having a right-sided CVA and has moderate weakness down her left side.

Mrs Bennett says that she knows she has had a stroke but insists that she can attend to her own hygiene needs; she prefers to shower daily in the evening when she is at home.

Mrs Bennett is right-handed so is able to assist the nurse with washing herself but she tends to only wash her chest and right leg; she forgets to wash the left side of her body unless prompted to do so by the nurse.

She requires supervision with ambulation as she is unsteady on her feet; the physiotherapist has provided her with a walking frame which she has reluctantly agreed to use. She says she prefers to walk unassisted as she is very independent. She needs to be reminded to walk with supervision as she has been found in the bathroom alone on several occasions attempting to get into the shower. She needs to sit down when showering in order to prevent a fall.

Mrs Bennett also requires assistance with dressing due to her left-sided weakness.

1. What would the nurse need to do to ensure Mrs Bennett's safety during the showering process?
2. What actions would the nurse take to allow Mrs Bennett to remain as independent as possible with her hygiene care?
3. How would the nurse assist Mrs Bennett to be as independent as possible with dressing?
4. Apart from the physiotherapist, which other members of the healthcare team would be involved in the care of Mrs Bennett?
5. What hygiene equipment could the nurse use to assist Mrs Bennett in the shower?

## NURSING CARE PLAN 23.1

**Assessment:** Mrs Joan Bennett is a 68-year-old woman who was admitted to hospital 10 days ago following the sudden onset of left-sided arm and leg weakness. She has been diagnosed as having a right-sided stroke and has moderate weakness down her left side.
**Issue/s to be addressed:** Inability to perform self-care hygiene independently
Skin integrity is maintained.
**Goals:** Mrs Joan Bennett will attend to personal hygiene
Mrs Bennett's skin remains intact.

| Care/Actions | Rationale |
|---|---|
| Assess Mrs Bennett's level of ability to attend to shower or bath to reduce risk of injury to self or others | The direct observation and assessment of Mrs Bennett will assist goal and intervention planning. Ensure appropriate aids and footwear of Mrs Bennett to reduce falls risk |
| Ask Mrs Bennett for input into personal hygiene habits and cultural preferences | Creating opportunities for Mrs Bennett to assist in intervention planning will preserve her self-esteem, prevent helplessness and achieve cultural appropriateness to the activity |
| Individualise the bathing routine based on Mrs Bennett's own history of practices that address skin needs, self-care needs, individual responses to bathing and equipment required | Bathing should not be routinely scheduled with a task focus. Mrs Bennett's input will produce a more positive experience and preserve her dignity |
| Encourage Mrs Bennett to attend to and participate with personal hygiene | This will encourage Mrs Bennett's independence and motivation to self-care |
| Use of Mrs Bennett's personal hygiene aids to assist with personal grooming including hair, teeth/dentures | This will assist Mrs Bennett to attend to her own personal hygiene, decrease the risk of injury and promote safety |
| Refer Mrs Bennett to the allied health team as necessary (e.g. OT, physiotherapist) | This will assist Mrs Bennett to maximise her ability to self-care |
| Promote privacy by closing doors, providing towels and clothes | This will promote privacy and retain Mrs Bennett's dignity |

**Evaluation**

Mrs Bennett's personal hygiene and personal grooming is attended to with an individualised holistic approach.
Mrs Bennett participates in her care which is culturally appropriate and promotes her independence, dignity, self-esteem and privacy.
Mrs Bennett's skin integrity is inspected during her shower and abnormalities reported.
Mrs Bennett's documentation is attended to and allied health staff are notified as required.

bag should not be raised above the level of the individual's bladder.

### An individual with a wound dressing or bandage

The nursing care plan should be checked to determine if the dressing or bandage is to be removed before the bath or shower. If wound dressings or bandages are to remain in position, they must be protected from moisture with a waterproof covering.

### An individual with a plaster cast/splint on a limb

A waterproof cover must be applied securely over the limb to protect the plaster/splint from moisture. Care should be taken to avoid applying tapes or adhesives to the individual's skin.

## Bathing the individual in bed

Individuals who are confined to bed or whose condition does not enable them to have a bath or shower may be provided with equipment for washing in bed, or may be given a bed bath (also referred to as a sponge) by the nurse. If individuals are able to wash unaided, they are provided with all necessary items, the upper bedclothes turned down and a towel placed over them for warmth and privacy. The nurse will need to help with washing and drying the back and any other parts of the body the individual is unable to attend to independently. When the bath is completed and the individual's hair and teeth have been attended to, the nurse remakes the bed.

A complete bed bath involves washing the entire body of an individual in bed. It is performed by the nurse when an individual is unable to wash unaided. Individuals who may require a bed bath include those who have a debilitating illness or are paralysed or unconscious. A bed bath is also frequently needed after surgery. Depending on the individual's level of mobility, either one or two nurses perform the procedure. Healthcare facilities commonly adopt their own specific guidelines concerning how to perform a bed bath. An alternative to the traditional sponge bowl method is the bag bath method (see Clinical Interest Box 23.2).

## CLINICAL INTEREST BOX 23.2 Bag bath method of washing an individual in bed

This method involves the use of a bag containing 10 pre-moistened disposable cloths, each one used for a different area of the individual's body. A bag bath is convenient because it is easy and quick to prepare by warming in the microwave for about 1.5 minutes. After washing, the skin is allowed to air dry so that moisturisers contained in the cloth can remain on the skin. Individuals who have mild–moderate skin conditions have reported improvement with consistent use of this method (Bauer 2013). However, they are an expensive option and are not used as commonly as other methods.

*(Bauer 2013)*

Key aspects related to performing a bed bath or sponge bath:

- Throughout the bed bath the nurse should promote the privacy, safety and comfort of the individual, while ensuring that all hygiene needs are met
- During the bed bath the nurse assesses the status of the individual's skin, hair, nails and level of mobility. The bed bath also provides time to talk with the individual without interruption and it is often during this time that issues of concern are raised
- Individuals should be encouraged to help themselves as much as they are able, to promote independence
- Individuals who have not been bathed in bed before may be embarrassed about the exposure of their bodies and their loss of independence. It is the responsibility of the nurse to demonstrate sensitivity and to ensure adequate privacy throughout the procedure. The individual's privacy and warmth is maintained by exposing only the area that is being washed: this is achieved by using a dry towel to cover other areas of the individual's body
- The nurse who is to perform the bed bath must be aware if there are any limitations of movement or positioning for the individual. For example, individuals who have had a total hip replacement must not lie on the affected side until the surgeon has given their approval and individuals who are experiencing difficulty in breathing may need to remain sitting up throughout the bed bath to prevent further respiratory distress
- During the bed bath, the individual's joints should be put through the full range of motion, unless this is contraindicated. Movement improves circulation, maintains joint mobility and preserves muscle tone
- When dressing an individual who has some impairment of an arm or leg (e.g. paralysis), the affected limb should be placed into the garment first so that maximum use may be made of the flexibility of the unaffected limb
- If an individual is experiencing pain (e.g. after surgery) ensure that prescribed analgesia is given before the bed bath is performed; make sure you allow sufficient time for the analgesia to take effect prior to commencing the procedure
- Ensure that the water is the correct temperature and changed throughout the procedure when it becomes cool, too soapy, dirty or after washing the genital area
- If individuals have a range of movement that permits it, when cleaning nails it may be helpful to place their hands and/or feet in the bowl of water. This is more refreshing for individuals and enables the nails to be cleansed more effectively
- Ensure that all soap is rinsed off the skin, as residual soap may cause dryness
- Special care should be taken to ensure that all skin folds and creases are washed and thoroughly dried; for example, under breasts, in the groin area between the buttocks, between fingers and toes. If these areas are not dried properly the skin may become excoriated and painful
- Throughout the bed bath the individual's skin should be observed for areas of redness, breaks, bruises and other deviations from normal. Deviations should be reported and documented. Nursing measures should be implemented as appropriate
- If the individual has an indwelling urinary catheter or has had certain types of gynaecological surgery, it is important to thoroughly clean the perineal area in order to prevent vaginal or urinary tract infection.

Refer to Clinical Skill 23.2 for information and guidelines on performing a bed bath.

### Perineal care

Many individuals prefer to wash their own perineal area and privacy should be provided for them if they are able to do so. The nurse may provide a degree of privacy by holding the covering towel or sheet up and away from the individual's body, forming a tent while the individual washes their genital area beneath it. If the individual is unable to wash the perineum independently, the nurse is advised to put on gloves and place a waterproof sheet (often referred to as a 'bluey') under the individual to protect the mattress. Only the area to be washed should be exposed. If faecal material is present it should be enclosed in a fold of the bluey or tissue and removed with disposable wipes. The anus and buttocks are then cleansed and dried and the soiled sheet removed and replaced with a clean one. The perineum should be washed and rinsed thoroughly and patted dry. Care should be taken to wash a female individual's perineum from front to back to minimise the risk of contamination from the anal area. Frequent hygiene care may be needed for menstruating women. If needed, a fresh sanitary pad should be put in place at the completion of the perineal wash.

Care should be taken to retract the foreskin of uncircumcised adult males so that the head of the penis can be cleaned effectively. Once the area is cleaned, the foreskin should be

## CLINICAL SKILL 23.2 Performing a bed bath

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Washbasin 2/3 full with warm water<br>2 towels<br>Disposable wipes<br>2 washcloths<br>Disposable gloves<br>Bed linen and soiled-linen container<br>Pyjamas or gown<br>Soiled-linen container<br>**Toiletries items:**<br>Soap product<br>Deodorant<br>Moisturiser, skin lotions or emollients<br>Toothbrush and toothpaste<br>Hair care products<br>Shaving equipment |

| Skill activity | Rationale |
|---|---|
| Review individual's care plan and current treatment orders | Provides information about individual treatment, level of assistance required and equipment/supplies needed |
| Perform hand hygiene | Reduces risk of transmission of microorganisms |
| Inform individual of proposed activity, assess for pain, gain consent to proceed | Promotes individual cooperation and comfort and maintains autonomy |
| Offer the individual use of toilet bedpan or bottle before procedure begins | Promotes comfort |
| Clear over-bed table for use | Prevents cross-infection |
| Collect equipment/supplies and prepare for use | Promotes efficiency |
| Ensure adequate lighting and provide privacy | Maintains individual dignity |
| Check the bed brakes are engaged and adjust the bed to safe working height | Follows safe work practices |
| Lower the head of the bed so the dependent individual is lying flat with one pillow | Promotes comfort |
| Fill bowl two-thirds full with warm water | Promotes safe work practices |
| Untuck, fold and remove upper layers of bed linen and place on a clean, flat surface | Promotes efficiency and maintains infection control |
| Cover individual with a bath sheet or bed sheet and assist the individual to remove clothing | Maintains warmth and maintains dignity |
| **Washing the front of the body**<br>During procedure, communicate proposed actions to individual to encourage cooperation. | |
| **For the individual who requires full assistance**<br>Begin to wash the front of the body starting with face, then the chest and abdomen, arms and hands, legs and feet then the groin | Promotes efficient practice |
| Expose only the body part being washed | Maintains warmth and dignity |
| Place one towel under or across the body part and use the other towel to dry | Protects bed linen from moisture |

| CLINICAL SKILL 23.2 Performing a bed bath—cont'd | |
|---|---|
| Rinse soap product thoroughly from skin before patting dry | Maintains skin integrity |
| Place a towel across the chest and wash the face with the wash cloth without soap products. Take care around the eyes. Clean the ears and neck then dry carefully | Maintains skin integrity |
| Place towel lengthwise under the arm. Use a small amount of soap product on the wash cloth to wash the arm, including the axilla | Maintains skin integrity |
| Use long and firm stokes and move joints through the normal range of motion as tolerated. Rinse and pat dry | Promotes circulation and maintains joint health |
| Wash individual's hand in the bowl of water if able. Take care to stabilise the basin on the bed and allow the individual's hand to rest in the water. Dry well | Promotes comfort |
| Repeat with other arm and hand. Apply deodorant and other creams if required | Promotes efficient work practices |
| Uncover chest and place towel between water basin and individual. Wash chest, taking care to wash and dry thoroughly under women's breasts | Protects bed linen<br>Maintains skin integrity and prevents excoriation |
| Cover the upper body with the bath towel | Maintains warmth and dignity |
| Wash abdomen, rinse and pat dry. Cover with the bath towel | Promotes efficient work practices |
| Check the warmth of the water and replace if cool or dirty | Maintains comfort |
| Repeat washing procedure with legs and feet taking care to dry between toes | Promotes efficient work practices and promotes individual comfort |
| Apply gloves to wash the genitals. Rinse and pat dry, in particular, skin folds | Maintains infection control |
| Change basin water and dispose of wash cloth | Maintains infection control |
| **For the individual who can partially assist**<br>Adjust the head of the bed to semi-recumbent position and place the wash basin within reach | Promotes functional independence |
| Encourage the individual to participate as able<br>Assist to reposition towels and rinse the wash cloth when necessary | Promotes independence and participation |
| **Washing the back and buttocks**<br>During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Assist the individual to roll into a lateral position supported by the bed rail and a second person if required | Provides comfort and maintains safety |
| Keep individual covered with a bath towel and expose back and buttocks. Place towel on mattress and tuck gently against the back and buttocks | Maintains comfort and dignity |
| Wash the back starting at the neck using long firm strokes | Promotes circulation |
| Inspect the skin for signs of pressure or other injury | Maintains skin integrity |

*Continued*

| CLINICAL SKILL 23.2 Performing a bed bath—cont'd | |
|---|---|
| Pat dry thoroughly, especially at the buttocks and skin folds. Apply creams as required | Maintains skin integrity |
| Cover back with towel, ensure individual is comfortable in the lateral position and well supported for the linen change procedure | Promotes comfort and safety |
| Remove water basin and position clean bed linen and soiled-linen container within reach<br>Raise bed rail if moving away from the bed | Promotes safety and efficiency |
| Assist the individual into clean pyjamas or clothing of their choice | Promotes individual comfort |
| Assist the individual into a position of comfort | Promotes individual comfort |
| Lower bed to a safe height for the individual if appropriate | Maintains individual comfort and safety |
| Remove equipment, dispose of soiled supplies | Prevents cross-infection |
| Perform hand hygiene | Prevents cross-infection |
| Check individual has call bell and other personal items within reach before leaving | Promotes comfort and individual wellbeing |
| Document the activity, outcome and the individual's response to the activity in the healthcare record<br>Update the individual's care plan for domains related to mobility, activities of daily living (ADLs), skin integrity and hygiene preferences | Maintains legal document of care and interventions provided<br>Allows clear and accurate communication of information about individual's care between nurses |
| Verbally report to Registered Nurse any observations that may need review or changes in individual condition that indicate risk for deterioration | Facilitates timely response and intervention |
| *(Australian Commission on Safety and Quality in Healthcare 2015; Joanna Briggs Institute 2013a; 2013b; Nursing and Midwifery Board of Australia 2013; Rebeiro et al 2012; Wilkinson et al 2015)* | |

returned to its natural position. The scrotum should be lifted and the area below washed, rinsed and dried thoroughly. Retraction of an infant's or child's foreskin is not recommended. The foreskin is resistive to retraction until separation of the foreskin and glans penis occurs naturally at about age 3–5 years. After this it is recommended that the child's foreskin be checked only very occasionally for retraction. Therefore, under normal circumstances the nurse will not need to retract the foreskin of children during their hygiene care. However, if the tip of a child's penis shows signs of irritation this should be reported and documented.

If there is a urinary catheter in situ, the area around it should be carefully washed with unperfumed soap (or alternative) and water. When the perineal wash is completed the underpad is removed, all washers must be immediately disposed of and the individual made comfortable.

Providing intimate care can cause embarrassment to the nurse and to the individual, but this should never result in personal hygiene being neglected. A professional, dignified and sensitive manner can help with uncomfortable feelings (Crisp et al 2013; deWit 2013).

Many individuals prefer to undertake this task in the supine position, Sims' position or lateral position, depending on the individual's health history and assessment. Please refer to sitting position explanations later in this chapter.

### CRITICAL THINKING EXERCISE 23.2

Mr Jones, 85, has a permanent indwelling catheter for advanced multiple sclerosis. He has also recently been diagnosed with early dementia. He is unable to care for his own personal hygiene now unaided. Discuss the psychological impact of providing perineal care to Mr Jones. List 3 individuals who have special needs for perineal care. Correctly demonstrate the procedure for providing perineal care for the male and female individual.

## Bathing an infant

Bath time should be an enjoyable occasion for the infant and the bath should be completed as quickly and safely as possible

because prolonged exposure may cause the loss of body heat (Berman et al 2015). Preparation for a bath includes:

- Ensuring that the room is warm and draught free
- Assembling all the items required: baby bath half filled with water at 38°C, bath thermometer, two towels, a face washer, cotton wool swabs, a mild, soap-free cleansing lotion, a clean set of clothing and nappies, clean linen for the cot, a receptacle for soiled linen and a gown or apron
- Preparing an area (e.g. place a towel on the bench or table beside the bath) on which the infant can be placed while being undressed, dried and dressed.

The procedure for bathing the infant is as follows:

- Wash hands and put on gown or apron
- Undress the infant, except for the nappy, which is left on
- Wrap the infant in a towel, and wash the face with cotton wool swabs moistened with warm water. Care should be taken to wash the eyes from the inner to the outer canthus (corner) (Burton et al 2013). Items such as cotton swabs should not be inserted into the nose or ears. The inside of the ears should be left alone, but the outer ear should be cleansed with moistened cotton wool. Pat the face gently to dry
- With the infant on the bench, unwrap the towel and remove the nappy. The infant should be washed in a top-to-toe direction, turning the surface of the washcloth as the bath progresses. The genitalia should be washed from front to back to prevent faecal matter from coming into contact with the urethra, as this would risk the onset of a urinary tract infection. A mild soap may be needed for heavily soiled areas. Alkaline soaps should be avoided because they alter the pH of skin. Particular attention should be paid to the skin folds, axillae, groin and between the fingers and toes and under the chin where food accumulates. The infant must always be held firmly but gently with the dominant hand and never left unattended. Lowering the infant slowly into the water avoids startling
- The infant should be allowed some time to splash and kick in the water
- The nurse then lifts the infant from the bath and returns the infant to the prepared bench. The infant is dried quickly but thoroughly. Where skin areas come in contact with each other there is a possibility of chafing, and particular care is needed when drying these areas: the use of baby powder is not recommended because it may irritate the respiratory tract (Leifer 2010)
- The infant is then dressed before becoming cold
- The nurse reports and documents anything of concern relating to the infant.

As the infant grows rapidly in the first 12 months, the procedure is adapted to suit the child's developmental level and as the child grows, most of the actual washing is done in the bath, with the nurse supporting the infant as needed. Infants and young children must never be left unsupervised in a bath. Nurses have an important role in providing support and reassurance for new mothers, particularly when instructing them how to bathe their babies.

## HAIR CARE

Hair care is very personal and the appearance of the hair can indicate a person's general health status (Parker 2012). Hair that is well groomed generally promotes a positive body image. Hair that is not washed and brushed tends to become tangled, greasy and malodorous. The scalp can become encrusted with sebum and dried sweat, which causes a feeling of discomfort. In an attempt to relieve the discomfort the individual may scratch the scalp and cause breaks in the skin that provide a portal of entry for microorganisms.

Hair care includes beard and moustache care as well as shaving, brushing, combing and shampooing head hair. Brushing and combing the hair stimulates scalp circulation, removes dead skin cells and distributes the natural oils that give the hair a healthy sheen (Crisp et al 2013). To brush hair, the nurse parts the hair into several sections. Brushing from the scalp towards the hair ends reduces pulling. Shampooing removes grease, dirt, blood or other substances and prevents an offensive odour. The frequency of hair care depends on the length and texture of the hair, the individual's usual practice and general condition. Hair should be brushed or combed at least twice daily and shampooed according to personal preference or as necessary. Plaiting can help to avoid tangles, but plaits should be unplaited and the hair combed to ensure good hygiene. Plaits that are too tight can lead to discomfort and bald patches.

During long periods of hospitalisation, individuals may desire the services of a hairdresser to cut or style their hair, but hair should not be cut or restyled unless the individual gives permission. Brushes and combs should be washed regularly and never shared between individuals.

### Nursing observations and assessment of the hair and scalp

As part of individual assessment, the nurse should observe for and report any abnormalities such as excessive dryness, hair fragility or dandruff, **alopecia** (hair loss) or pediculosis capitis (head lice). The scalp should be observed for redness, heavy scaling, flaking or lesions. Some individuals will be able to care for their hair independently, while others will require the nurse's assistance. Individuals may have their hair shampooed during a bath or a shower, or it may be done with the individual sitting in front of a sink. If the individual is confined to bed the hair may be washed with the individual in bed or lying on a trolley.

### Washing the individual's hair in bed

Certain devices are available to facilitate hair washing in bed, such as a shampoo tray (Figure 23.2A). If specially designed equipment is not available, a waterproof sheet can be placed under the individual's head and arranged so that the water can drain into a bucket at the side of the bed (Figure 23.2B).

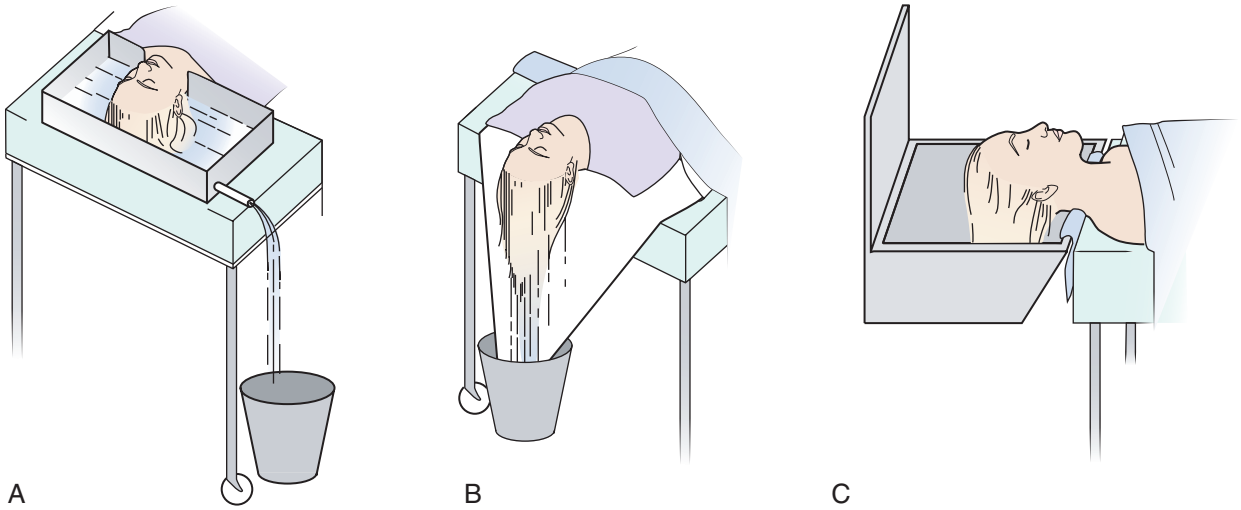

**Figure 23.2** Hair washing in bed

A: Using a shampoo tray B: Hair wash in hospital C: Individual on a trolley for hair wash

Individuals who can be moved from the bed onto a trolley may be wheeled to a sink and positioned so that the neck is supported on a pillow and the head extended over the sink (Figure 23.2C).

The method of giving the individual a shampoo is usually determined by the facilities available and the individual's condition. The basic equipment for shampooing the hair consists of:

- Shampoo of the individual's choice
- Conditioner if desired
- Two bath towels
- One face washer
- Protection for the bed (e.g. a waterproof sheet)
- Warm water (directed with handheld nozzle or jug)
- Brush and comb
- Hair dryer if available
- Shampoo tray or equipment for fashioning a trough
- A receptacle for soiled water.

If an individual is too ill or cannot tolerate a shampoo with water, a dry shampoo may be used. Several commercially prepared substances are available that are applied to the hair then brushed out.

## Management of pediculosis (lice)

**Pediculosis** is a condition in which hair is infested with lice. Lice (or pediculi) are parasitic insects that suck blood from the skin and inject a toxin that causes itching, which may result in excoriation from scratching. The lice lay eggs (or nits) which attach themselves along the shaft of the hair with a cement-like substance that makes removal difficult. Pediculosis can occur wherever there is hair and the three varieties of lice infestation are *pediculi capitis* (head lice) *pediculi corporis* (body lice) and *pediculi pubis* (pubic lice). Signs and symptoms that pediculi have infested the hair include pruritus, excoriation of the skin from scratching and visible lice or nits. The body louse tends to adhere to clothing and may not be evident on the body (Parker 2012). Untreated pediculosis can result in secondary skin infection such as dermatitis. The lice also spread from person to person on clothing, bedding, combs and brushes. It is important to note that pediculosis is not necessarily a sign of poor personal hygiene, as the parasites survive equally well on clean hair. The nits and lice can be destroyed by the use of a prescribed lotion or shampoo. With the available preparations, one single application is often effective. Sometimes a second treatment is recommended about one week later, in case any remaining nits have hatched into lice. The bed linen, personal clothing, hairbrush and comb belonging to the person infested with lice must also be treated to prevent re-infestation. To avoid transmitting the parasites to others, the nurse should wear gloves and perform thorough handwashing after the treatment.

## Shaving

Many men shave every day; if so, this should be continued during illness. Shaving promotes individual comfort by removing whiskers that may itch and irritate the skin. A facial shave should be performed using an electric razor—because the skin can be cut or nicked with a blade razor, an electric one is preferable. If an individual is unable to shave independently the nurse will need to assist or perform the procedure for the individual. Electric razors should be checked for function and cleanliness before use and brushed free of whiskers after use. If the razor head is adjustable the appropriate setting will need to be selected. The nurse proceeds as follows:

- The electric razor is moved in a circular motion, pressed firmly against the skin, and each area of the individual's face shaved until it is smooth
- Short gentle strokes are best around the nose and mouth to avoid irritation of these sensitive areas
- If the individual wishes, aftershave lotion may be applied.

Some females develop a growth of facial hair, and this is usually removed by depilatory creams, tweezers or wax. Shaving should be avoided because the blunt angle of the cut hairs makes the regrowth look heavier.

# EYE, EAR AND NASAL CARE

## Assessment and care of the eyes

The eyes are the organs of sight through which visual information about the environment is transmitted to the brain for interpretation. If the eyes are not cleansed adequately, secretions may accumulate. The conjunctiva of the eyes should be observed for inflammation or pallor, and the sclera observed for signs of jaundice. Any discharge, discomfort or pain and the presence of contact lenses, prostheses or spectacles should be noted. Under normal circumstances the eyes are kept clean by face washing and showering. If the eyes become irritated or infected, some individuals may require extra care, which consists of cleansing, usually with sterile, soft gauze swabs, to remove secretions from the eyelids and to reduce discomfort. As eye bathing/toilet is sometimes required as part of the individual's hygiene needs, guidelines for the procedure are outlined in Clinical Skill 23.3.

When bathing the eyes the nurse uses an aseptic technique to reduce the risk of introducing microorganisms. (See Chapter 22 for information concerning aseptic technique and the prevention and control of infection.) The eyes are always cleansed from the inner to the outer canthus. The procedure must be carefully performed to prevent any injury to the eyes (Figure 23.3).

Individuals who may require special eye care include those whose corneal reflex is impaired, due to altered consciousness

### CLINICAL SKILL 23.3 Performing an eye toilet

**Review and carry out the standard steps for all clinical skills/interventions**

|---|---|
| Ask or assist individual to lie flat if permitted | Facilitates drainage of fluid away from the face |
| Place towel or disposable waterproof sheet under individual's head | Protects pillow and bedding |
| Place kidney dish close to the individual's cheek | Protects individual and bed linen |
| Perform hand hygiene and apply gloves if required | Prevents cross-infection |
| Begin with the less affected or the cleaner of the two eyes | Prevents transmission of microorganisms from an affected eye to an unaffected eye |
| Ask or assist the individual to close the eyelid<br>Use a saline moistened swab to clean eyelid from inner canthus to outer canthus and discard swab in kidney dish | Prevents fluid and debris from entering the nasolacrimal duct |
| Use a new moistened swab for each action and continue to gently swab the eyelid and lashes until clean | Prevents cross-contamination |
| If the top and bottom eyelids or lashes are stuck together, gently swab across the eyelid until the eyelashes are free | Promotes comfort |
| Ask the individual to open the eye or assist individual to open eye if appropriate<br>Use a gauze swab in the hand to gently bring the lower eyelid down | Allows inspection of the eyeball |
| Inspect the eyeball and surrounding tissue and assess for signs of injury, inflammation, debris, foreign body or infection | Identifies risks to individual's eye health |
| Use gauze swab to absorb moisture and dry around the eye | Promotes individual comfort |
| Repeat the procedure for the other eye | Prevents cross-infection to unaffected eye |
| During the procedure, continue to communicate with the individual to facilitate cooperation. | |
| Dry any moisture from the individual's face, remove the towel from under the head | Promotes individual comfort and maintains skin integrity |
| Following the eye toilet, prescribed and non-prescribed drops may need to be instilled or ointments applied<br>Allow appropriate time in between instilling eye drops and applying ointment | Applies individual treatment and care orders for irritation or infection<br>Maximises effectiveness of treatment |
| Assist the individual into a position of comfort | Promotes individual comfort |
| Lower bed to a safe height for the individual if appropriate | Maintains individual comfort and safety |
| Remove equipment, dispose of soiled supplies | Prevents cross-infection |
| Perform hand hygiene | Prevents cross-infection |
| Document the individual response to the procedure and outcome in the individual's healthcare record and care plan | Provides clear and up-to-date communication of the individual's data between healthcare professionals<br>Maintains a legal record of care and interventions provided |
| Verbally report to Registered Nurse any changes in individual condition | Allows for timely review, response and intervention |
| *(Australian Commission on Safety and Quality in Healthcare 2015; Joanna Briggs Institute 2002, updated 2014; 2013c; Nursing and Midwifery Board of Australia 2013; Rebeiro et al 2012)* | |

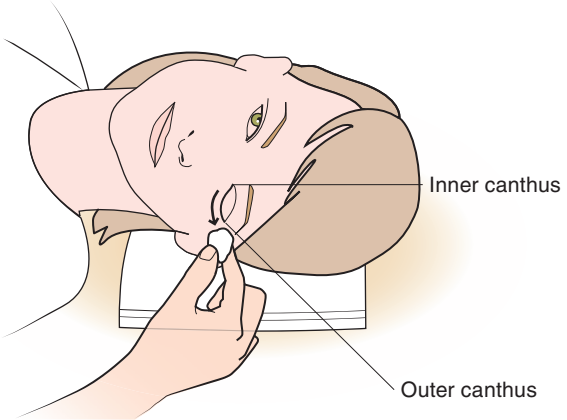

**Figure 23.3** Swabbing the eyes

or facial paralysis and those whose eyes are irritated or infected. Individuals with conjunctivitis, a common condition caused by infection, allergies or irritating substances such as dust or smoke, may also require special eye care.

It should be noted that, provided that the principles of asepsis are maintained, it may not always be necessary to use a sterile dressing pack each time an eye toilet is performed. It is best to consult the policy and procedure/safe operating procedure manuals of individual institutions for appropriate guidelines.

### Assessment and care of the ears

Lack of aural hygiene can lead to an accumulation of dirt and wax, which may result in discomfort and temporary hearing loss. The ears are cleaned as part of normal hygiene practices, for example, during a shower. They should be assessed for any discharge or complaints of tinnitus, discomfort or pain, and the use of a hearing aid should be noted. (See Chapter 34 for relevant information about hearing aids.)

Individuals who are dependent on others for their hygiene needs should have their ears cleansed with the face washer during the shower or bath. If there is an accumulation of debris or wax in the orifice, this should be documented and reported. The nurse should not insert any object, including cotton-tipped applicators, into an individual's ear canal as part of routine hygiene. Applicators may compact the cerumen, making the ear more difficult to clean (deWit 2013). Excessive cerumen or dry wax necessitates ear irrigation. This is undertaken only after examination and authorisation by a medical officer.

### Assessment and care of the nose

Secretions from the mucous membrane that lines the nose may accumulate, causing discomfort and providing a medium for the growth of microorganisms. The nose should be assessed for the presence of any discharge other than the normal mucus secretion, for bleeding, swelling of the mucosa or any obstruction.

Blowing the nose is the most effective way of removing secretions from the nostrils. If individuals are unable to perform this function, as a result of being unconscious or due to presence of an intranasal tube, the nurse may be required to clean the nostrils. This is commonly achieved using small cotton-wool-tipped applicators moistened with a solution such as water or normal saline. An applicator is inserted gently into the nostril, rotated and withdrawn, and the technique is repeated until the nostrils are clean. Sometimes a water-soluble cream is applied around the nostrils to prevent soreness. If an individual has an endotracheal, nasogastric or feeding tube inserted through the nose, any tapes anchoring the tube should be changed at least daily (Crisp et al 2013).

## MOUTH CARE

Poor oral hygiene leads to dental decay and unhealthy mucous membranes, providing a potential source of infection as well as being a source of discomfort for the individual. If food particles are not removed from the mouth and teeth, an unpleasant taste and **halitosis** (bad breath) can result. The mouth should be inspected for obvious dental decay, pallor, inflammation or the presence of ulcers on the mucosa. The lips should be observed for hydration, pallor or cyanosis and the presence of cracks or vesicles. Dentures, partial plates, bridges and crowns should be noted.

### Oral hygiene

Oral hygiene involves measures to keep the mouth and teeth clean and in healthy condition. Care of the mouth includes brushing the teeth, mouth rinses and regular visits to the dentist. The measures necessary to maintain the mouth and teeth in a healthy condition include:

- An adequate fluid intake to stimulate the flow of saliva. Saliva helps maintain a healthy mouth by washing away shed epithelial cells, food debris and microorganisms. Saliva also keeps the mouth lining moist and acts as a mild antiseptic that inhibits the growth of microorganisms, and maintains the pH balance inhibiting the formation of caries (Berman et al 2015)
- A well-balanced diet that provides the tissues with the nutrients necessary for growth and repair. Foods that require chewing stimulate saliva flow as well as blood circulation to the gums and should be included when possible
- Brushing and flossing the teeth to remove plaque and food debris massages the gums, while tongue brushing and cleansing prevent mouth odour and infection
- Rinsing the mouth with alcohol-free mouth washes to remove unpleasant tastes or odours
- Regular visits to the dentist to allow inspection of the teeth for decay, cleaning and treatment of any cavities and other abnormalities.

If oral hygiene is neglected, complications may occur, including:

- Dental decay and halitosis
- Reduced nutrition due to inability to chew and diet restrictions

- Coated tongue and subsequent dulling of taste, which may lead to loss of appetite
- Inflammation of the oral mucosa (stomatitis), inflammation of the tongue (glossitis), inflammation of the gums (**gingivitis**) and periodontitis (inflammation of ligaments, gums and bones supporting the teeth)
- An accumulation of food particles, dead epithelial cells and microorganisms on the teeth, tongue and lips
- The spread of oral infections to other parts of the body such as the parotid glands, eustachian (auditory) tubes and respiratory tract
- Dryness of the mucosa, resulting in cracking or ulcers
- Social isolation.

## At-risk individuals

Individuals with reduced flow of saliva or those who experience difficulty with normal chewing or whose swallowing actions are impaired are particularly prone to developing an unhealthy condition of the mouth. Examples include individuals who:

- Experience dyspnoea, which results in mouth breathing and consequently a dry mouth
- Are febrile or dehydrated
- Are not taking food or fluids orally or whose fluid intake is restricted
- Are receiving certain medications that cause dryness of the mouth
- Have impaired movement of the mouth, such as facial paralysis or surgical immobilisation of the jaw
- Have a nasogastric tube or airway in position, which may irritate or damage the mucosa or lead to an accumulation of debris in the mouth
- Wear partial or full dentures, which allow food particles to accumulate in the mouth
- Are unable to care for their oral hygiene adequately because of their physical or emotional state (Crisp et al 2013; Berman et al 2015).

Individuals who have had chemotherapy or radiotherapy are at risk of developing oral thrush and mucositis. It is, therefore, recommended to clean the mouth using saline or water after every meal (Marrs et al 2012).

## Assisting the individual with oral hygiene

Many individuals are able to attend to their oral hygiene but others may require encouragement and some assistance. The nurse should offer individuals the opportunity to brush their teeth after meals and in the evening. The nurse should ensure that each individual has a toothbrush and toothpaste and should assist them to the bathroom if necessary.

Some individuals with cognitive or memory impairment may need repeated prompting to enable them to complete the task of cleaning their teeth. Individuals may not clean effectively or may refuse to clean their teeth at all; individuals with Alzheimer's or dementia may not understand what it is they are being asked to do. They may get frustrated, irritated, agitated and even aggressive as a result. Sometimes the problem may be resolved by temporarily distracting the individual with another activity and returning later to cleaning the teeth. It may be helpful to follow the routine for cleaning the teeth conducted previously; for example the same time of the day, after breakfast or after getting dressed. It may even help to have a familiar mirror, towel or other object from home. It should be remembered that the individual is not being deliberately difficult; a calm, quiet approach and gentle encouragement is often the key to managing challenging responses. Nurses need to find the key to gaining trust from each person.

For individuals confined to bed, the nurse should provide teeth-cleaning equipment consisting of a toothbrush, toothpaste, a mug of water, a container for used water and a towel. Individuals who are accustomed to using dental floss as part of their normal hygiene should be encouraged to continue the practice. Flossing involves inserting waxed or unwaxed dental floss between the teeth. The motion used to pull floss between teeth removes plaque and tartar from tooth enamel. To prevent bleeding, individuals who are receiving chemotherapy or radiation or are on anticoagulant therapy should use unwaxed floss and avoid flossing near the line of the gum. To aid in cavity prevention, apply toothpaste before flossing, thus allowing fluoride to come in direct contact with tooth surfaces. Flossing once a day is sufficient. Floss holders are available for individuals who have difficulty managing the floss (Crisp et al 2013).

Individuals who are unable to brush their teeth will require the nurse's assistance with this procedure. Individuals are taken to the bathroom, or teeth-cleaning equipment is brought to the bedside. The individual should be assisted into a comfortable sitting position and the clothing protected by a towel. The nurse should apply toothpaste to a dampened toothbrush and gently but thoroughly brush the individual's teeth using an up-and-down movement. Water is provided for the individual to rinse the mouth, and a container is positioned to receive the used rinsing water. The mouth is then rinsed, but leaving some paste helps protect the teeth. Finally the lips are wiped dry, the toothbrush and toothpaste put away and the mug and container removed for cleaning.

Some individuals wear partial or full dentures, which, like natural teeth, require effective care to remove deposits and to prevent mouth odour. Care of dentures involves removing, brushing and rinsing them after meals. If it is the individual's usual practice, dentures may be soaked in a commercial denture cleaner before brushing. All dentures should be removed at night, so the nurse should ensure that they are put in a container labelled with the individual's name and placed in a safe position. Many individuals are very reluctant to be seen without their dentures, so it is important to pull curtains and close doors to provide privacy when necessary. If individuals are not able to care for their dentures independently it is the nurse's responsibility to attend to this.

To remove a partial denture the nurse, wearing disposable gloves, exerts equal pressure on the clips each side of the plate ensuring that pressure is not placed on the borders, because

they may easily bend or break. A full upper denture may be removed by breaking the seal of the denture from the palate. This can be achieved by taking hold of the denture at the front or side with the thumb and index finger. A lower denture is removed by holding it in the centre, and turning it slightly before lifting it out of the mouth. A gauze square may be used to provide a firm grip on the dentures. Dentures should be gently placed in a denture container and taken to the bathroom for cleaning and rinsing. When handling dentures care must be taken to avoid damage.

Before the dentures are replaced, the individual's mouth is rinsed and the gums brushed to remove any debris. When individuals are unable to insert their own dentures the nurse should assist. Moistening the dentures facilitates easier insertion and aids correct positioning into the mouth to keep them firmly in place. Individuals should be encouraged to wear their dentures to facilitate eating and speaking and to prevent changes in the gum line that may affect denture fit.

If normal oral hygiene practices are not possible, the mouth and teeth must be cleaned by other means. Special mouth care is often required if the individual:

- Is unconscious
- Is not taking oral food or fluids
- Experiences any impairment to mouth movement (e.g. facial paralysis)
- Has developed sores inside the mouth
- Has a mouth infection
- Has a very dry mouth (e.g. as a result of mouth breathing, dehydration or the effect of certain medications).

In these instances, the individual's mouth is cleansed either by the use of alcohol-free mouth rinses or by carefully swabbing all areas. The latter procedure is often referred to as a 'mouth toilet'. A variety of substances may be used to clean and refresh the mouth. The nurse should refer to the healthcare facility's policy and procedure/safe operating procedure manual for information on the equipment, substances and method to be used.

Refer to Clinical Skills 23.4 and 23.5 for information and guidelines on assisting with oral hygiene and performing special mouth care (swabbing).

## NAIL CARE

Care of the nails involves keeping them clean, shaped and trimmed. Regular care of the nails is important because dirty fingernails can carry microorganisms which may be transferred to food or passed to other people. People who have dirty nails can also infect themselves by scratching. Many individuals will be able to care for their nails independently, while others will require assistance. For example, individuals who have limbs encased in plaster, are unconscious, confused or vision impaired may need the nurse to assist with nail care.

### Routine nail care

Nails should be kept clean and trimmed according to the policy of the healthcare agency and the individual's personal preference. As part of the policy of many healthcare facilities, a podiatrist is required to perform nail care for individuals. Nails can be kept clean by removing any visible dirt with a blunt instrument such as an orangewood stick. A metal nail file is not used because it can make the nails rough and trap dirt. Some individuals will have their own hand-care products and they should be encouraged to use them after a shower or bath. Nails that are particularly dirty or thickened are easier to attend to if the individual's hands or feet are soaked in warm soapy water for 5–10 minutes before the care begins. Whenever nails are being trimmed, extreme care must be taken to prevent any damage to the nail beds and surrounding tissue.

### At-risk individuals

Individuals who have diabetes or any circulatory disorder that affects the lower limbs are at high risk of infection, which can start easily in a damaged nail bed. It is therefore often the policy of the institution that such individuals have foot and nail care undertaken only by a podiatrist. The podiatrist is also often required to care for the feet of older people whose nails have become thickened and distorted with age or for those with conditions such as corns, calluses or in-growing toenails. Nail clippers are used in preference to scissors for trimming nails. Toenails should be cut straight across. Nails not trimmed in this way tend to grow inwards, creating a risk for pain and infection in the surrounding soft tissue.

### Nursing observations and assessment

While undertaking nail care the nurse observes for:

- Discolouration, such as pallor or cyanosis
- The presence of inflammation around the nail edges
- Signs of brittleness or cracks
- Deviations from normal shape, such as a spoon-shaped or concave appearance.

Pallor or cyanosis of the nails may indicate heart disease, while brittleness and/or a spoon-like shape may indicate the presence of iron-deficiency anaemia. Any change or abnormality should be reported and documented. During nail care, the nurse can take the opportunity to educate individuals, or those who care for them at home, on how best to provide nail care. Education can also include how to inspect the hands and feet for lesions, dryness or signs of inflammation or infection, and the importance of reporting any change or abnormality promptly to the Registered Nurse or medical officer. See Progress Note Example 23.1.

**CRITICAL THINKING EXERCISE 23.3**

Mrs Smith is an 87-year-old woman who has recently had a right-sided CVA and has lost the ability to attend to attend her own foot care. Discuss the rationale for providing foot and nail care to Mrs Smith. List two other types of individuals who need special attention to their feet and nails and the rationale. Describe the procedure in safely performing foot and nail care.

## CLINICAL SKILL 23.4 Assisting with oral hygiene, cleaning teeth and dentures

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Kidney dish or small bowl<br>Warm water for rinsing<br>Soft toothbrush or electric toothbrush<br>Fluoride tooth or denture paste<br>Towel<br>Alcohol-based hand rub<br>PPE: non-sterile gloves and eye protection |

| **Skill activity** | **Rationale** |
|---|---|
| Review individual's care plan and current treatment orders | Provides information about individual treatment, equipment/supplies needed |
| Inform individual of proposed activity, assess for pain, gain consent to proceed | Promotes individual cooperation and comfort and maintains autonomy |
| Position individual seated at the basin or position clean over-bed table in front of individual at a suitable height for use | Promotes functional independence |
| Assist with preparation of items for use: apply toothpaste to brush, place towel over chest or within reach, fill cup with water | Promotes efficiency and functional independence |
| Perform hand hygiene | Prevents cross-infection |
| **Cleaning dentures** | |
| During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Apply non-sterile gloves and eye protection | Prevents cross-infection |
| Ask or assist individual to remove dentures into small bowl or kidney dish | Facilitates cleaning |
| Use a finger to carefully break the suction between the gum and denture at the end of the gum line | Promotes individual comfort and maintains safe work practices |
| Wet toothbrush in water and brush the inner and outer surface of dentures using firm strokes | Ensures efficient cleaning |
| Rinse each denture under running water and ensure all paste is removed from denture surfaces | Promotes individual comfort and maintains oral health |
| Offer individual a cup of clean warm to cool water to rinse and a bowl to spit waste before reinserting dentures | Promotes individual comfort and oral hygiene |
| Allow individual to replace own dentures in mouth if able | Promotes individual comfort and independence |
| **Cleaning teeth** | |
| During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Ask individual to open mouth and briefly inspect teeth and oral cavity for debris. Assist to rinse if necessary | Allows inspection of teeth and oral cavity<br>Removes debris from mouth to facilitate cleaning |
| Gently brush all teeth and gum surfaces using an up and down action or circular motion | Facilitates removal of debris and maintains tooth and gum health |
| Start at the upper back teeth and gently brush the outer surfaces of teeth and gum line towards the front teeth | Removes debris from teeth and gums |

## CLINICAL SKILL 23.4 Assisting with oral hygiene, cleaning teeth and dentures—cont'd

| | |
|---|---|
| Repeat with inner top teeth and gums | Removes debris from teeth and gums |
| Offer water to rinse mouth before continuing to clean outer and inner surfaces of lower teeth and gums | Facilitates removal of tooth paste from mouth |
| Brush chewing surfaces of teeth | Removes debris from teeth and gums |
| Brush surface of tongue if necessary | Promotes individual comfort |
| Offer water to rinse toothpaste from mouth | Promotes individual comfort and maintains oral health |
| Dry around mouth and apply water-based moisturiser to lips | Promotes individual comfort |
| Remove gloves and perform hand hygiene | Prevents cross-infection |
| Assist the individual into a position of comfort | Promotes individual comfort |
| Lower bed to a safe height for the individual if appropriate | Maintains individual comfort and safety |
| Remove equipment, dispose of soiled supplies | Prevents cross-infection |
| Perform hand hygiene | Prevents cross-infection |
| Check individual has call bell and other personal items within reach before leaving | Promotes comfort and individual wellbeing |
| Document the individual's response and outcome of the procedure in the healthcare record<br>Update the individual's care plan for domains related to oral hygiene | Maintains legal document of care and interventions provided<br>Allows clear and accurate communication of information about individual's care between nurses |

## CLINICAL SKILL 23.5 Performing special mouth care

**Review and carry out the standard steps for all clinical skills/interventions**

**NMBA Decision-making Framework considerations:**

1. Am I educated?
2. Am I authorised?
3. Am I competent?

If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator.

**Equipment:**

Kidney dish or similar × 2
Large cotton swab sticks
Cup of warm water
Soft toothbrush or electric toothbrush
Fluoride toothpaste
Chlorhexidine mouthwash
Towel
Disposable waterproof sheet ('bluey')
Pen torch
Tongue depressor
Labelled denture container
Water-based lip moisturiser
Prescribed or non-prescribed medication
Alcohol-based hand rub
PPE: disposable gloves and eye protection
Cleaning solution (alcohol) and wipe for trolley or work surface
Rubbish bag
Suction equipment (with Yankauer or y-suction catheter)

*Continued*

| CLINICAL SKILL 23.5 Performing special mouth care—cont'd | |
|---|---|
| **Skill activity** | **Rationale** |
| Review individual's care plan and current treatment orders | Provides information about individual treatment, equipment/supplies needed |
| Inform individual of proposed activity, assess for pain, gain consent to proceed | Promotes individual cooperation and comfort and maintains autonomy |
| Clean trolley or work surface | Prevents cross-infection |
| Collect equipment/supplies and prepare for use | Promotes efficiency |
| Ensure adequate lighting | Promotes safe practice |
| Provide privacy | Maintains individual dignity |
| Adjust the bed to safe working height | Follows safe work practices |
| Perform hand hygiene | Prevents cross-infection |
| Assist individual into lateral position | Allows secretions to be suctioned from the buccal cavity and protects airway from aspiration |
| Place towel or waterproof sheet under head | Protects pillow and bedding |
| Perform hand hygiene | Maintains infection control principles |
| During procedure, communicate proposed actions to individual to encourage cooperation. | |
| Apply gloves and eye protection | Maintains infection control principles |
| Ask the individual to open the mouth or use the tongue depressor to gently open the mouth<br>Carefully remove dentures or partial denture into kidney dish or denture container | Allows dentures or dental plates to be safely removed |
| Use torch to inspect oral cavity: teeth, gum surfaces, mucous membranes and tongue | Allows for close inspection of oral cavity to identify injury, inflammation or infection, loose teeth and foreign objects |
| Place kidney dish at individual's chin or cheek<br>Place a small amount of toothpaste on the toothbrush or prepare chlorhexidine mouth swabs for use | Protects individual and bedding from secretions |
| Brush or swab teeth and gums using a gentle up-and-down action, beginning with inside back teeth | Removes debris and plaque from teeth and gums |
| Offer water (and straw) to rinse mouth (only if gag reflex is present) and encourage individual to spit into kidney dish if able | Toothpaste and debris should be rinsed from teeth and gum surfaces |
| If individual is unable to rinse and spit, or gag is absent, rinse toothbrush with water and use to remove toothpaste from teeth and gum surfaces<br>Suction secretions from buccal cavity as required | Toothpaste should be removed from teeth and gum surfaces<br>Prevents aspiration of secretions into airway |
| Use toothbrush or mouth swabs to remove coating from tongue if required | Improves oral hygiene |
| Apply prescribed ointments | Completes individual treatment and care orders |
| Clean dentures using toothbrush and toothpaste before rinsing and replacing in the mouth | Promotes oral hygiene and comfort |

| CLINICAL SKILL 23.5 Performing special mouth care—cont'd | |
|---|---|
| Apply a water-based lubricant to the lips | Prevents soreness and cracking |
| Dry moisture from the individual's mouth, remove the towel | Promotes comfort |
| Assist the individual into a position of comfort | Promotes individual comfort |
| Lower bed to a safe height for the individual if appropriate | Maintains individual comfort and safety |
| Remove equipment, dispose of soiled supplies | Prevents cross-infection |
| Perform hand hygiene | Prevents cross-infection |
| Check individual has call bell and other personal items within reach before leaving | Promotes comfort and individual wellbeing |
| Document the individual's response and outcome of the procedure in the healthcare record<br>Update the individual's care plan for domains related to oral hygiene | Maintains legal document of care and interventions provided<br>Allows clear and accurate communication of information about individual's care between nurses |
| Verbally report to Registered Nurse any observations or changes in individual condition that may indicate risk for deterioration | Facilitates timely review, response and intervention |

### PROGRESS NOTE EXAMPLE 23.1

| | |
|---|---|
| 23/12/2014<br>1415 hrs | Nursing: Mrs Bennett ambulated with one nurse to the shower. Required assistance onto the shower chair. Required prompting with showering was able to shower to her right side but required prompting and assisting to attend personal hygiene to left side of her body, including upper extremities but not lower extremities. Excessive fatigue displayed via excessive respirations and increased verbal prompting required. The use of a shower chair was required due to signs and symptoms of excessive fatigue displayed from Mrs Bennett when showering, causing her to become unsteady on her feet. Mrs Bennett is continent of bowel and bladder and was able to request to use the toilet prior to the shower. Skin assessment conducted—warm, moist and intact. Mrs Bennett appeared to have difficulty and became frustrated while putting her socks and shoes on. Referral to OT made today.<br>***S. Bava* (Bava) EN** |

## HYGIENE SUMMARY

Personal hygiene needs must be met to keep the body clean, to maintain healthy functioning and to promote a positive body image. Neglect of personal hygiene needs causes discomfort and may lead to infection and other serious complications. Continuous assessment of the individual's total body is important for planning and implementing appropriate, high-quality nursing care. It is the nurse's responsibility to ensure that all individuals have access to the facilities necessary for meeting their hygiene needs. Dependent individuals require assistance from the nurse in meeting these needs and the nurse should ensure that the individual's dignity, comfort and safety are promoted throughout all hygiene care procedures. The nurse also has an important role to play in educating individuals and those who care for them at home about all aspects of hygiene that promote optimal health.

## PROMOTING COMFORT

Human comfort depends on meeting a wide range and complex interaction of needs. Nutritional, fluid, elimination, oxygen and temperature regulation needs must be met for the human body to function efficiently and comfortably. The nurse's role incorporates monitoring and meeting these needs. In addition, the nurse promotes the comfort of individuals by promoting ease of movement, rest and sleep and freedom

from pain. (See the relevant chapters in Unit 8 for specific information relating to these areas.)

Physical and emotional comfort are interdependent and if either aspect is disrupted, the other is commonly affected. For example, if individuals are experiencing some form of physical discomfort such as pain, they may develop emotional tension and become withdrawn, anxious or depressed. Conversely, an anxious person may develop physical symptoms such as headaches, loss of appetite or gastrointestinal disturbances. Therefore, for individuals to be comfortable, they must be free from physical discomfort and emotional tension. An important nursing responsibility is assessing factors that are interfering with an individual's comfort, then planning and implementing measures that promote their physical and emotional ease. Discomfort can result from stimuli of physical or psychosocial origin. Freedom from anxiety is important in helping the individual to develop a sense of wellbeing and emotional security. To promote the physical comfort of individuals, the nurse should assist in meeting all care needs. This includes ensuring that individuals are wearing comfortable clothing which is suitable for the environment; individuals should be nursed in the most comfortable position possible.

## Clothing and comfort

A person's comfort is enhanced if they are able to wear clothes of their own choice. Many people feel uncomfortable and undignified if they are required to wear clothing such as a hospital gown provided by the healthcare facility. For this reason, individuals returning from surgery or other procedures are changed into their personal attire as soon as their condition allows. Some residents living in aged care facilities or special accommodation do not have adequate clothing of their own. In this case the nurse should ensure that the clothes supplied by the agency are appropriately selected to meet the residents' individual needs. For example, for an older person living in an aged care facility the choice of clothes should be appropriate in terms of age, gender, temperature and other environmental conditions. They should be clean, fit well and, in the case of individuals who are very frail or confused, be easy for them to manage; for example, Velcro fastenings for ease of dressing and toileting.

## Comfort and the environment

A suitable physical environment is one in which there is adequate lighting, fresh air, ventilation, warmth and cleanliness. Depending on the individual's age and physical condition, the room temperature should be maintained between 20°C and 23°C. The acutely ill, infants and older adults may need a warmer room. However, some ill individuals benefit from cooler room temperatures to lower the body's metabolic demands (Crisp et al 2013). Ideally the environment should be free from excessive noise and unpleasant sights and smells. In addition, there should be sufficient space for the individual's personal belongings, and facilities available for visitors. In the case of residents in long-term accommodation the environment should be as home-like as possible, have attractive views to the outside world and an outdoor area that is safe and accessible. Ideally, residents will have a single room. If not, the facility should provide a room where residents can spend private time with visitors if they wish. The environment should also provide a relaxed happy atmosphere and opportunities to enjoy activities that enhance quality of life, such as outings, concerts and games. For those who are able, the environment should provide the chance for residents to participate in simple everyday activities such as watching television, gardening, crafts or cooking. Comfort can be enhanced by promoting a psychological climate in which the individual is encouraged to communicate any fears or anxieties. A physical environment that reduces the individual's privacy and independence is unsuitable and can be a source of stress and discomfort.

## Equipment to promote comfort

### Provision of a comfortable bed

A comfortable position is, to a significant extent, dependent on the individual's bed. The prime objective of bed-making is the promotion of comfort, as a bed that is made incorrectly may disrupt rest and sleep and may be a contributing factor to the development of complications such as pressure injuries (Berman et al 2015). Beds may be made up in a variety of ways to meet the individual's needs and each healthcare facility commonly adopts its own method of bed making. Although the techniques may vary slightly, the **principles of bed making** remain the same.

Various types of bed are available, most of which can be adjusted manually, mechanically or electronically. Most beds can be raised or lowered horizontally and most can also be adjusted to alter the position of the head, foot or centre. Beds are fitted with wheels, which enables them to be moved easily when necessary, and a brake device that prevents inadvertent movement. The nurse should check that the brakes are applied at all times when the bed is stationary. There are several special types of beds, frames and mattresses that are used for particular circumstances.

Frames are available that may be either fitted to the bed or used in place of a more conventional bed. The Balkan frame, for example, is made from wood or metal, extends lengthwise above the bed and may be used in conjunction with traction apparatus. The Bradford frame consists of a metal frame across which canvas slings are stretched, and may be used to nurse a person who has a fracture or disease of the hip or spine. The Stryker frame consists of two canvas-covered frames attached to a metal frame and may be used to facilitate changing the position of a person with a spinal cord injury or paralysis. Figure 23.4 illustrates the Balkan and Stryker bed frames.

Foam mattresses are commonly covered with a waterproof fabric, which facilitates cleaning and therefore helps to prevent cross-infection. Individuals with specific needs, such as those who are more vulnerable to the development of decubitus ulcers, may be nursed on special mattresses. The most commonly used pressure-relieving devices are alternating air mattresses. These devices work by over- and underinflating in

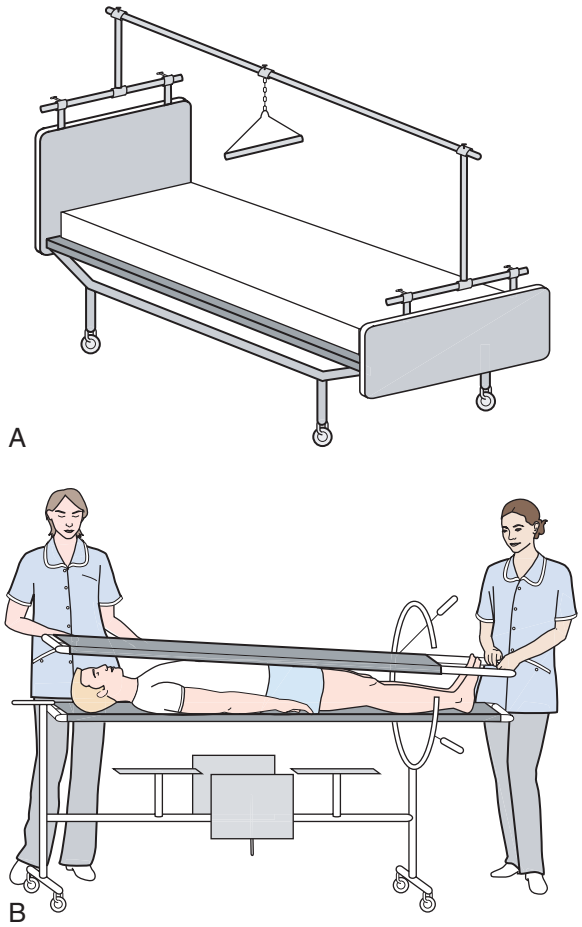

**Figure 23.4** Bed frames and special beds

A: Balkan frame B: Stryker frame. The individual is turned to the prone or supine position. Body alignment is not changed during repositioning

sequence as the individual moves around in the bed (Figure 23.5A). Other less commonly used devices include the gel mattress (Figure 23.5B) and the foam overlay (egg-crate style) mattress (Figure 23.5C). The type of mattress selected must meet the individual's needs, provide comfort and support and should help prevent development of complications.

Pillows are available in a variety of materials, most of which are enclosed in a protective waterproof covering over which a pillowcase is placed. The number of pillows used depends on the needs of the individual, and should be sufficient to provide maximum comfort and support.

Sheets are commonly available in two styles: the long sheet is similar to a conventional single-bed sheet; the draw sheet is a narrow sheet that may be placed across the bottom sheet. Because of their design, draw sheets are easy to replace under an individual without disturbing the other bedclothes. A waterproof sheet may be placed under the draw sheet to protect the bottom sheet against moisture; for example, if an individual is incontinent or is required to use toilet utensils in bed. In some care settings, special reusable incontinence bed protectors with tuck-in flaps are available and may be used instead of a draw sheet. These maintain an

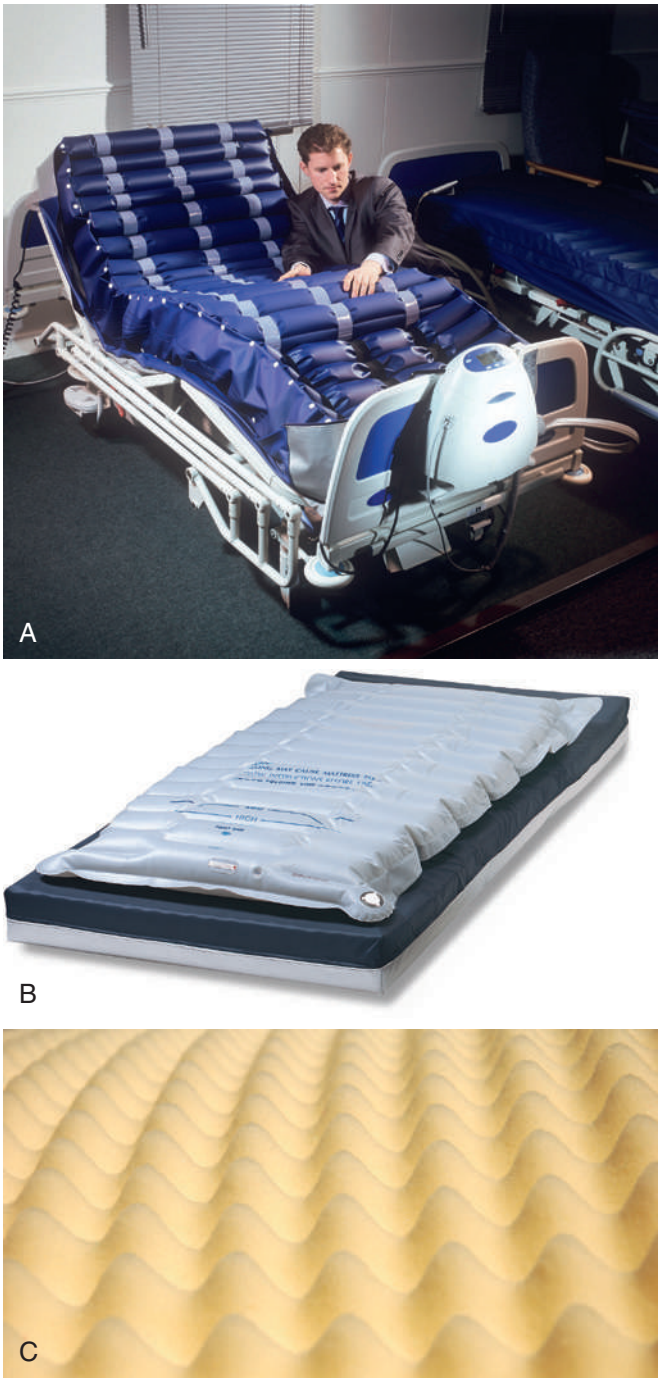

**Figure 23.5** Special mattresses

A: Air mattress B: Gel mattress C: An egg-crate mattress

*(**A**: © Brian Bell/Science Photo Library/Getty Images; **B**: Blue Chip Medical Products, Inc.; **C**: © kanusommer/Shutterstock)*

individual's comfort because they are double or multi-layered and very absorbent. They have an integral waterproof barrier, which means that the side on which the individual lies remains dry. They are commonly referred to as 'Kylie sheets'. Disposable liners are more commonly used these days. Care needs to be taken if an air mattress is in place that sheets are not tucked in, as this interferes with the inflation/deflation.

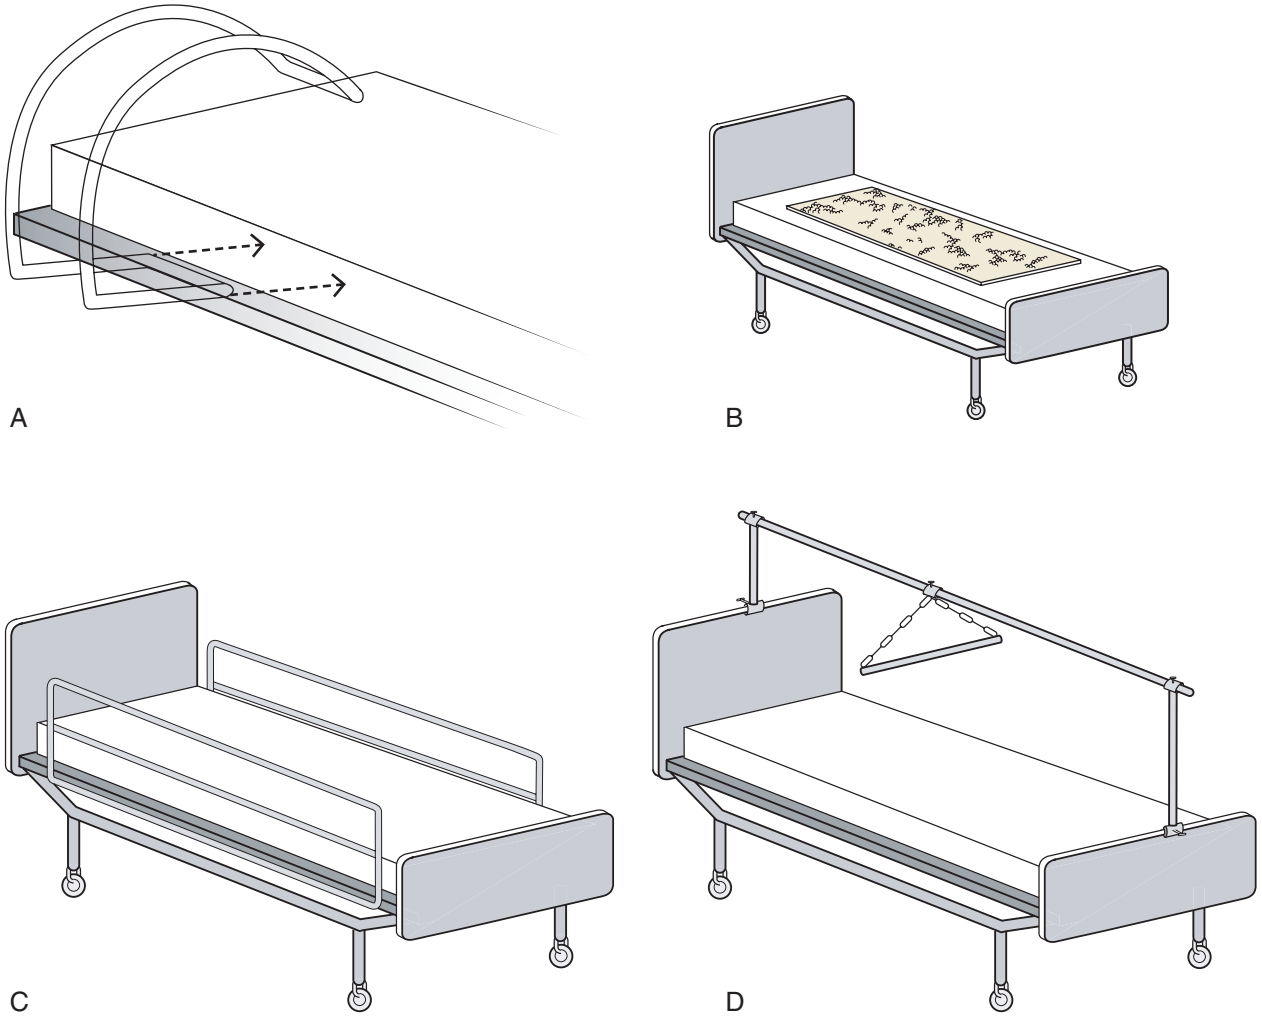

**Figure 23.6** Supplementary equipment used in bed making
A: Bed cradle B: Sheepskin board C: Bed rails D: Overhead trapeze

The frequency with which bed linen is changed depends on the healthcare facility's policy, but any bed clothing that becomes wet, soiled or excessively wrinkled should be replaced promptly to maintain the individual's comfort. Blankets, quilts and bedspreads are available in loosely woven cotton that is easily laundered. Some healthcare facilities may use continental-style quilts in place of blankets and a bedspread.

The use of supplementary items is also an important aspect of nursing care in maintaining comfort.

## Supplementary equipment

A variety of supplementary equipment is available that may be used to enhance comfort, provide added support or promote safety.

*Bed cradle*. A bed cradle is a frame designed to keep the upper bedclothes off all or part of a individual. The cradle may be large enough to extend from one side of the bed to the other, or small enough to place over one leg. The cradle is positioned directly above the area of the individual's body which is to be free of the bedclothes and the top sheet and blankets are brought up over the cradle. A bed cradle may be used for an individual with a burn, an uncovered or painful wound or a plaster cast. The cradle protects the area by elevating the bedclothes, and facilitates observation of the area by the nurse or medical officer (Figure 23.6A).

*Heel or elbow protectors*. Made from sheepskin, foam rubber or inflatable plastic material, these protectors are designed to fit the shape of the heel or elbow (Figure 23.6B). Polyurethane foam dressings may also be used. They are commonly used to prevent the development of decubitus ulcers on these areas, as they reduce friction between the skin and the bed linen.

*Bed rails*. Many beds are fitted with built-in side rails that can be raised (Figure 23.6C). Historically, side rails have been used to prevent individuals, such as those at risk of seizures or who are restless or confused, from falling from the bed. However, bed rails are a form of restraint and, whenever possible, the use of bed rails is replaced by less restrictive, safe alternatives such as the use of very low beds. This change is in line with a policy of careful risk assessment and the use of

the minimal restraint possible for any individual in any situation.

*Trapeze*. An overhead trapeze, monkey bar or hand grip is a swinging bar suspended from an overhead pole, which may be used by an individual to facilitate movement in bed (Figure 23.6D). They should not be used for individuals with upper body or shoulder injuries.

*Rope*. A length of rope or similar material may be attached to the foot of the bed and positioned on top of the quilt. By holding on to the end of the rope, the individual is able to pull themself up into a sitting position.

*Sandbag*. A sandbag is commonly a waterproof bag filled with sand, used to maintain part of the body in alignment; for example, sandbags may be used to immobilise a fractured leg before splinting or surgery.

*Wedge-shaped pillow*. A wedge-shaped pillow is placed between the legs to maintain abduction, for example, after total hip replacement.

The nurse must ensure that any supplementary equipment is positioned and used correctly to promote the individual's comfort and safety.

# BED MAKING

## Making an unoccupied bed

An **unoccupied bed** is the term used to describe a bed that is either temporarily vacated by the individual, for example, during a shower, or a bed that is being made up after an individual's discharge from the healthcare facility. The unoccupied bed can be made up as a 'closed' or an 'open' bed. To make a closed bed, the upper bedding is tucked in at the bottom and sides. To make an open bed, the upper bedding is folded up at the bottom and sides. The advantage of the open style is that the upper bedding can be quickly folded lengthwise, or into a pack to facilitate ease of transferring an individual from a trolley into the bed.

See Clinical Skill 23.6 for the step-by-step guidelines for making an unoccupied bed.

## Key principles related to bed making

- All the equipment such as clean linen and the soiled linen skip should be collected before the procedure is started

### CLINICAL SKILL 23.6 Making an unoccupied bed

| Ensure a chair or clean flat surface is available to place the bed linen to be reused | Prevents cross-infection |
| Move the bedside cabinet and over-bed table away from the bed | Provides safe work space around bed |
| Check the bed brakes are engaged then raise the bed level to a safe working height. Lower head of bed | Follows safe work practices |
| Remove pillowcases and place in soiled-linen container<br>Place pillows on a clean flat surface | Prevents cross-infection |
| Apply disposable gloves and apron if bedding is heavily soiled | Prevents cross-infection |

*Continued*

| CLINICAL SKILL 23.6 Making an unoccupied bed—cont'd | |
|---|---|
| Start at the top (head) of the bed, lift the mattress on one side of the bed and free the bottom sheet | Promotes work efficiency |
| Move down to the end (foot) of the bed, lift the mattress and loosen and untuck each layer at the corner | Facilitates ease of removal |
| If working alone, complete one side of the bed before moving to loosen other side | Promotes efficient work practices |
| Inspect each layer of bed linen for signs of soiling or damage and replace as required | Promotes skin integrity and individual hygiene and comfort |
| Remove each item of upper bed linen separately, fold and place on a clean flat surface | Folding facilitates replacement |
| Take the top hem of bed linen and fold down towards the centre of the bed and repeat with bottom hem | Promotes efficient work practices. Prevents cross-infection |
| From the side of the bed, bring each piece towards the centre and fold bundle again | Promotes efficient work practices. Prevents cross-infection |
| Lift off the bed, holding bundle away from body and place on a clean flat surface | Prevents cross-infection |
| Remove soiled linen by rolling towards the centre of the bed | Prevents cross-infection |
| Lift off bed, holding bundle away from body and place into soiled-linen container | Prevents cross-infection |
| Inspect mattress for signs of damage. Clean and dry if soiled | Prevents cross-infection |
| Remove gloves and perform hand hygiene | Prevents cross-infection |
| If working alone, complete bed making on one side of the bed before moving to complete the other side | Promotes efficient work practices |
| **If reusing bed linen**<br>Place folded bottom sheet in the centre of the mattress<br>Unfold sheet towards each side of the bed then unfold over the edge of mattress<br>Unfold the sheet towards the top and bottom ends of the bed | Bedclothes are easier to adjust or remove if they are replaced and tucked in separately |
| **If using a new sheet**<br>Place folded sheet in the centre of the mattress and unfold sheet along the length of mattress<br>Unfold the sheet across the mattress towards edge of the bed | Promotes efficient work practices |
| Position the sheet so it hangs equally on each side and move the sheet up towards the head of the bed to allow sufficient amount to tuck under mattress | Allows sufficient sheet at each corner to complete triangular folds |
| **Complete a triangular fold**<br>Stand facing the head of the bed, tuck in the sheet at each corner over the top of the mattress and pull tightly under the mattress | Maintains a neat appearance and holds the sheet firmly on the mattress |
| At the side of the bed, pick up the edge of the sheet about 40 cm from head of the bed and lift up onto mattress | Promotes individual comfort and maintains neat appearance |

| CLINICAL SKILL 23.6 Making an unoccupied bed—cont'd | |
|---|---|
| Pull sheet tightly to make a 45-degree angle from the top corner of the mattress | Promotes individual comfort and maintains neat appearance |
| Tuck remaining sheet under the mattress at each side | Promotes individual comfort and maintains neat appearance |
| Bring the triangular fold down over the side of the bed and tuck in tightly under the mattress | Promotes individual comfort and maintains neat appearance |
| Repeat at the foot or end of the bed then tuck in the remaining sheet along the long edge of the bed | Promotes individual comfort and maintains neat appearance |
| If working alone, move to opposite side of bed and begin tucking in the sheet at the head of the bed | Promotes efficient work practices |
| Ensure the sheet is smooth and tucked in tightly | Promotes individual comfort and maintenance of skin integrity |
| Position the waterproof sheet and draw sheet if required across the centre of the bed and tuck in along both sides | Protects the individual and bottom sheet and facilitates ease of removal and replacement if soiled |
| Place top sheet on bed and unfold along length of bed and position evenly over the bed | Allows sufficient amount of sheet to complete triangular folds |
| Bring the top edge of sheet to the level of the bed head | Allows sufficient amount of sheet to fold over and protect the blanket |
| Move to the end of the bed and tuck the sheet tightly under the bottom of the mattress | Promotes individual comfort and maintains neat appearance |
| Tuck the remaining sheet under the mattress using a triangular fold | Promotes individual comfort and maintains neat appearance |
| Place blanket on centre of bed and unfold, position as above and tuck in at the end of the bed using a triangular fold | Promotes individual comfort and maintains neat appearance |
| Move to the head of the bed and fold the blanket down 30 cm<br>Fold top sheet over to cover the blanket | Folded sheet protects the blanket |
| Place bedspread on centre of bed and unfold, ensuring it is evenly positioned on each side and covering the untucked portion of the blanket | Promotes individual comfort and maintains neat appearance |
| Bring top hem of bedspread level with the bed head then tuck in the remainder at the end of the bed using a triangular fold | Promotes individual comfort and maintains neat appearance |
| At the head of the bed, fold excess fabric under and bring neatly to the level of the sheet and blanket | Maintains neat appearance |
| Fold bedding back according to individual's need | Allows easy access for individual to return to bed |
| Replace pillows and arrange according to individual's need, adjust head of bed if required and lower bed level | Promotes individual comfort and safety |
| Reposition bedside cabinet and over-bed table | Allows safe access to individual's items |
| Assist individual to return to bed if needed or leave in a comfortable position with all personal items within reach | Promotes individual safety, wellbeing and functional independence |
| Remove soiled-linen container, perform hand hygiene | Prevents cross-infection |

- Measures should be implemented to prevent cross-infection:
  - the nurse's hands should be washed and dried before and after making the bed
  - it is important to ensure that the hands are washed after removing dirty linen from the bed prior to handling the clean linen
  - all linen should be held away from the body. This limits the risk of contaminating clean linen with any microorganisms on the nurse's clothing. It also limits the risk of contamination of the nurse's clothing with microorganisms from soiled linen
  - bedclothes should not be shaken or flicked, as this permits easy transmission of microorganisms to other people or other surfaces via the airborne route
  - soiled linen should immediately be placed into a soiled-linen skip. It should never be placed on top of clean linen (it may contaminate the clean linen), on the floor (it may collect microorganisms from the floor surface) or anywhere other than in the appropriate designated container
  - beds should not be made while procedures involving the use of sterile equipment are being performed nearby, as disturbed dust particles can travel and contaminate a sterile field. (See Chapter 22 for more information concerning infection prevention and control.)
- The nurse should don gloves to remove any solid faecal matter before placing the soiled linen in the container. Using toilet paper to envelop the faeces, the faecal matter should be placed in a bedpan, covered, taken to the pan room and flushed as normal
- During bed making, the nurse should observe the principles of body mechanics to prevent back strain, including raising the height of the bed
- When positioning the bottom sheet, the nurse should ensure that it is put on with the hem facing down. Sheets must be free from rough areas, wrinkles or creases, to promote comfort and to avoid damage to the individual's skin
- To maintain bedclothes in position, the corners are mitred (Figure 23.7). Mitred corners help to prevent the bedclothes becoming loose and uncomfortable for the individual
- To facilitate efficient bed making, bedclothes to be replaced are folded and placed on a chair. Folding the bedclothes avoids excessive wrinkling and facilitates ease of replacement. Alternatively, the bedclothes may be placed over a 'bed-stripper', which is a frame attached to the foot of the bed. Bedding that is not being replaced is rolled up and placed into the soiled-linen container
- If a waterproof draw sheet is used, it must be completely covered by a cotton draw sheet to prevent it making contact with the individual's skin

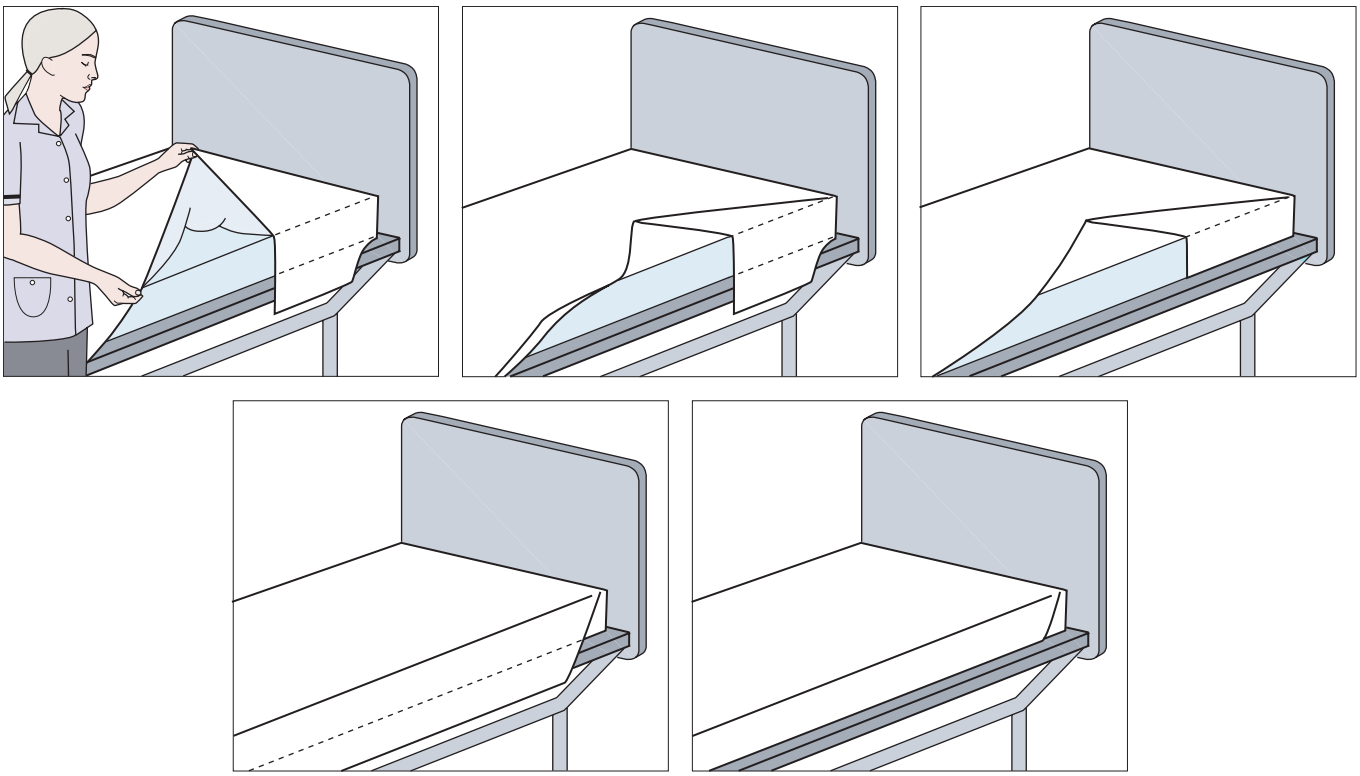

**Figure 23.7** Mitred corners

- A vertical pleat or fold should be made in the upper bedclothes, to provide room for the individual's feet. This technique prevents the bedclothes from pressing down on the feet, which can result in a condition known as foot drop
- When a bed is to be made up after an individual's discharge from the healthcare facility, the entire bed and fittings are cleaned beforehand. The bed should then be allowed to air before being made up with clean bedding.

## Making a surgical/post-anaesthetic bed

An **surgical/post-anaesthetic bed** (Figure 23.8) is a version of an open unoccupied bed and is made up to receive an individual after surgery or anaesthesia. The upper bedding is arranged into a pack, which can be easily removed to facilitate efficient transfer of the individual from a trolley into the bed. Once the individual is in the bed, the upper bedding pack is unfolded and carefully placed over the individual. The suggested procedure for making an **operation bed** is provided in Clinical Skill 23.7. (See Chapter 43 for information concerning other preparations required for receiving postoperative individuals back in their room.)

**Figure 23.8** Operation bed
*(Potter & Perry 2013)*

## Making an occupied bed

The term '**occupied**' is used to describe a bed that is being made while the individual is sitting or lying in it. When making an occupied bed the nurse must be aware of any restrictions in the individual's movement or position, such as a painful wound or a urinary catheter. The nurse should ensure that the individual's safety and comfort are maintained throughout the procedure. In addition to following the key principles relating to making a bed, before starting to make an occupied bed the nurse should:

- Assess the need for assistance. Two or more nurses may be necessary to move the individual safely and painlessly and to complete the procedure quickly to avoid the individual becoming fatigued. The individual must be adequately supported and kept warm during the procedure. Some individuals must be moved keeping the body in total alignment; for example, some individuals with spinal injuries or who have had spinal surgery must avoid twisting. In these circumstances individuals must be log-rolled so that the body is moved as one unit. At least three people are required to log-roll the person and keep their body in alignment. Standing on the side of the bed to which the individual is to be turned, one nurse supports the individual's head, another supports the trunk, while the third nurse supports the legs. Before starting movement, a pillow is placed between the individual's legs. At a given signal, the individual is rolled in one coordinated, smooth movement towards the nurses (Figure 23.9)
- Consider if it is preferable to make the occupied bed from top to bottom, rather than from side to side. It is often easier and less disruptive for an individual (e.g. one who has distressed breathing or a leg in traction) if the nurses adjust the bottom sheet in this manner.

The technique used to make an occupied bed should be one that causes minimal disturbance to the individual.

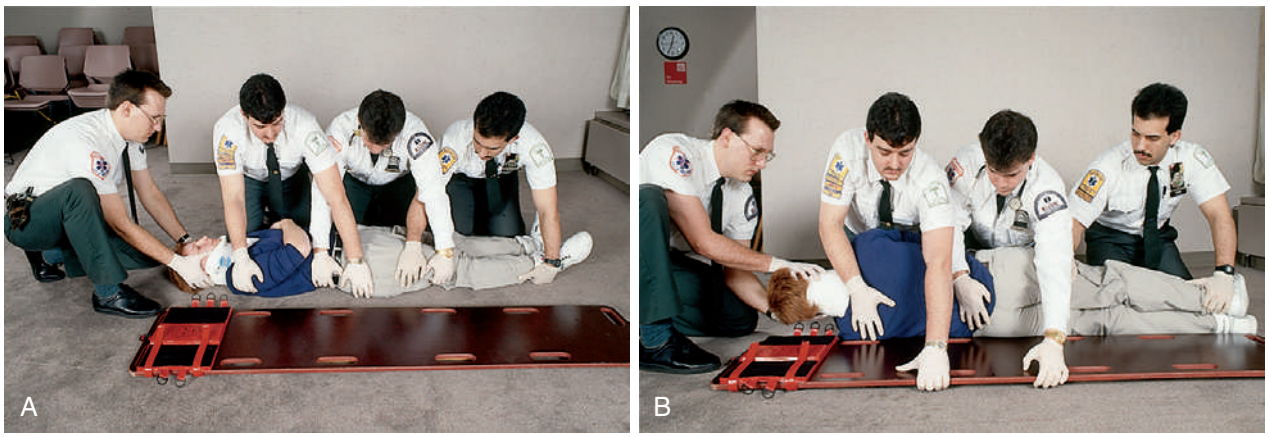

**Figure 23.9** The log-roll method of moving an individual

*(Swartz 2009)*

## CLINICAL SKILL 23.7 Making a theatre bed

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/ clinical facilitator/educator. | Flat sheet × 2<br>Draw sheet (if required)<br>Plastic sheet ('bluey')<br>Pillow case<br>Blanket<br>Bedspread<br>PPE: disposable gloves<br>Soiled-linen container |

| Skill activity | Rationale |
|---|---|
| Perform hand hygiene | Prevents cross-infection |
| Collect clean bed linen and place on a chair or flat surface near the bed<br>Place soiled-linen container near the bed | Facilitates access during the procedure<br>Prevents cross-infection |
| Move the bedside cabinet and over-bed table away from the bed | Provides safe work space around bed |
| Check the bed brakes are engaged then raise the bed level to a safe working height. Lower head of bed | Follows safe work practices |
| Remove pillowcases and place in soiled-linen container<br>Place pillows on a clean flat surface | Prevents cross-infection |
| Apply disposable gloves and apron if bedding is soiled | Prevents cross-infection |
| Start at the top (head) of the the bed, lift the mattress on one side of the bed and untuck the bottom sheet | Promotes work efficiency |
| Move down to the end (foot) of the bed, lift the mattress and loosen and untuck each layer at the corner | Facilitates ease of removal |
| If working alone, complete one side of the bed before moving to loosen other side | Promotes work efficiency |
| Remove each item of soiled linen separately by rolling towards the centre of the bed | Contains debris in linen bundle |
| Lift off bed, hold away from body and place in soiled-linen container | Prevents cross-infection |
| Inspect mattress for signs of soiling or damage. Clean and dry if soiled | Prevents cross-infection and maintains skin integrity |
| Remove gloves and perform hand hygiene | Prevents cross-infection |
| If working alone, complete bed making on one side of bed before moving to complete the other side | Promotes efficient work practices |
| Place folded sheet in the centre of the mattress and unfold sheet along the length of mattress<br>Unfold the sheet across the mattress towards edge of the bed | Promotes efficient work practices |
| Position the sheet so it hangs equally on each side and move the sheet up towards the head of the bed to allow sufficient amount to tuck under mattress | Allows sufficient amount of sheet to complete triangular folds at each corner |
| Stand facing the head of the bed and tuck sheet over the top of the mattress and pull tightly under the mattress | Provides a neat and secure fold for the sheet and promotes individual comfort |
| At the side of the bed, pick up the edge of the sheet about 40 cm from head of the bed and lift up onto mattress | Promotes individual comfort and maintains neat appearance |

| CLINICAL SKILL 23.7 Making a theatre bed—cont'd | |
|---|---|
| Pull sheet tightly to make a 45-degree angle from the top corner of the mattress | Promotes individual comfort and maintains neat appearance |
| Bring the triangular fold down over the side of the bed and tuck in tightly under the mattress | Promotes individual comfort and maintains neat appearance |
| Tuck remaining sheet under the mattress at each side | Promotes individual comfort and maintains neat appearance |
| Repeat at the foot or end of the bed then tuck in the remaining sheet along the long edge of the bed | Promotes individual comfort and maintains neat appearance |
| If working alone, move to opposite side of bed and begin tucking in the sheet at the head of the bed | Promotes efficient work practices |
| Ensure the sheet is smooth and tucked in tightly | Promotes individual comfort and maintenance of skin integrity |
| Position the waterproof sheet and draw sheet if required across the width of the bed according to surgical procedure. For example, place across the middle section of mattress for gynaecological and abdominal surgeries or at the top of the mattress for head and neck surgeries<br>Tuck under mattress on both sides | Protects the individual and bottom sheet and facilitates ease of removal and replacement if soiled |
| Place top sheet on bed and unfold along length of bed and position evenly over the bed | Allows sufficient amount of sheet at each corner to complete a triangular fold |
| Bring the top edge of sheet to the level of the bed head | Allows sufficient amount of sheet to fold over blanket |
| Allow the remaining sheet to hang over the end of the bed without tucking in | Allows sheet to be folded into bundle |
| Place blanket over sheet and bring to the level of the sheet at the top end of the bed and adjust to allow remaining blanket to overhang equally on both sides and over end of bed | Allows blanket to be folded into bundle |
| Place bedspread over blanket as above, if required | Allows bedspread to be folded into bundle |
| Fold bedspread down 30 cm from top. Fold blanket down over the bedspread and fold sheet over the blanket | Prepares bedding for folding into bundle |
| Move to end of the bed and fold the sheet, blanket and bedspread as above | Prepares bedding for folding into bundle |
| Pick up the sheet, blanket and bedspread at each corner and fold towards the middle of the bed making a 45-degree angle fold | Folds bedding into bundle |
| Pick up the point of the sheet, blanket and bedspread from each side of the bed and fold towards the centre of the bed | Folds bedding into bundle |
| Fold each edge of the bundle towards the centre of the bed and then fold one side of the bundle onto the other | Folds bedding into bundle |
| Fold each end of the bundle into the centre and then fold over again | Folds bedding into bundle |
| Place bed linen bundle at the end of the bed or place on a flat clean surface | Facilitates efficient replacement of bed linen |
| Replace pillowcase and place on bed | Promotes individual comfort |
| Perform hand hygiene | Prevents cross-infection |
| *(Australian Commission on Safety and Quality in Healthcare 2015; Joanna Briggs Institute 2013a; Rebeiro et al 2012)* | |

Commonly, the bed is remade after attention to the individual's daily hygiene needs. It may be necessary to make an occupied bed more frequently; for example, if the bedclothes become wet, soiled or disarranged. When possible, two nurses should work together to make the bed, for the promotion of individual comfort and safety. At times it may be necessary for more than two nurses to make an occupied bed; for example, to help when an individual has multiple injuries. The use of a slide sheet is helpful when moving individuals in and around the bed. It reduces the risk of injury to nurses and to individuals.

Making an occupied bed provides the nurse with an ideal opportunity for communicating with and observing the individual. During the procedure the nurse is able to assess certain aspects of the individual's condition, such as emotional state, skin colour, the presence of pain, the ability to move or distress associated with exertion. Observations should be documented and any deviations from normal should be reported immediately to the nurse in charge. When the condition of individuals permits, they may be able to move themselves during bed making, by using an overhead hand grip.

The suggested procedure for making an occupied bed is provided in Clinical Skill 23.8.

## Making a divided bed

A divided bed is sometimes referred to as a split or traction bed. Making a divided bed involves arranging the upper bedding into two sections. This style of bed is commonly used

| CLINICAL SKILL 23.8 Making the occupied bed | |
|---|---|
| **Review and carry out the standard steps for all clinical skills/interventions** | |
| **NMBA Decision-making Framework considerations:**<br>1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | **Equipment:**<br>Flat sheet × 2<br>Draw sheet (if required)<br>Plastic sheet ('bluey')<br>Pillow case<br>Blanket<br>Bedspread<br>PPE: disposable gloves<br>Soiled-linen container |
| **Skill activity** | **Rationale** |
| Prepare equipment and supplies | Promotes efficient work practice |
| Check bed brakes are engaged and raise the bed height | Maintains safe work practices |
| Assist the individual to roll into a lateral position supported by the bed rail and a second person if required | Provides comfort and maintains safety |
| **Change the bed linen** | |
| Start at the top (head) of the bed, lift the mattress on one side of the bed and free the bottom sheet | Promotes work efficiency |
| Move down to the end (foot) of the bed, lift the mattress and loosen and untuck each layer at the corner | Facilitates ease of removal |
| Fan fold or tightly roll sheet towards the centre of the bed and tuck under individual's back and buttocks | Facilitates ease of retrieval by assistant from under the individual |
| Inspect the mattress surface and smooth creases and remove debris | Maintains skin integrity |
| Place clean folded sheet in the centre of the bed. Unfold towards the top and bottom end of the bed | Promotes efficient work practices |
| Unfold half of the length of the sheet towards the edge of the mattress and position to allow a drop of 30 cm at the top, bottom and side edge of sheet | Ensures sheet is evenly positioned on mattress and allows sufficient amount of sheet to complete fold |
| Tuck in sheet at top and bottom using a triangular fold. Tuck in sheet along side of bed. Roll or fan fold excess sheet towards individual's back and tuck under as able | Ensures sheet remains in place and promotes individual's comfort. Maintains neat appearance |

| CLINICAL SKILL 23.8 Making the occupied bed—cont'd | |
|---|---|
| Inform the individual about the need to move over the linen roll and assist as necessary. Support with the side rail as needed | Encourages participation |
| Remove sheet from under individual and place carefully in soiled-linen container. Bring the clean sheet through from under the individual and pull tightly before tucking in at the top and bottom ends and along the side of the bed | Ensures sheet remains in place and promotes individual comfort. Maintains neat appearance |
| Pull bluey/Kylie or draw sheet through from under individual and tuck in firmly under mattress<br>Ensure the surface is free of creases or folds | Protects bottom sheet and mattress. Maintains individual comfort and skin integrity |
| Support individual to roll back to centre of the bed and assist into clean pyjamas or hospital gown | Promotes comfort and individual wellbeing |
| Replace top sheet, blanket and bedspread | Provides warmth and individual comfort |
| Unfold top sheet towards the top and bottom of the bed and fold over the top sheet at the level of the individual's chin to allow at least 30 cm to cover the chest | Promotes efficient work practices |
| Tuck in sheet at end of bed using a triangular fold. Ensure the individual has sufficient room to move feet and toes | Promotes individual comfort and maintains neat appearance.<br>Promotes skin integrity |
| Unfold blanket as above and tuck in using triangular fold at end of bed | Promotes individual comfort and maintains neat appearance |
| Fold blanket 30 cm from top then fold sheet over blanket | Folded sheet protects blanket from soiling. Promotes individual comfort |
| Replace bedspread and tuck in using triangular fold at end of bed | Promotes individual comfort and maintains neat appearance |
| Fold under the top 30 cm of bedspread at the level of the sheet and blanket | Promotes individual comfort and maintains neat appearance |
| Adjust the bedspread along each side of bed to cover the untucked sheet and blanket | Promotes neat appearance |
| Assist the individual into a position of comfort | Promotes individual comfort |
| Lower bed to a safe height for the individual if appropriate | Maintains individual comfort and safety |
| Remove equipment, dispose of soiled supplies | Prevents cross-infection |
| Check individual has call bell and other personal items within reach before leaving | Promotes safety, individual comfort and functional independence |
| Perform hand hygiene | Prevents cross-infection |
| Document the activity, outcome and the individual's response to the activity in the healthcare record | Maintains legal document of care and interventions provided |
| Verbally report to Registered Nurse any observations that may need review or changes in individual condition that indicate risk for deterioration | Facilitates timely response and intervention |
| Perform hand hygiene | Prevents cross-infection |

for an individual who has traction equipment applied to a lower limb. A divided bed allows the leg in traction to be free from the weight of the upper bedding, while the rest of the individual's body is covered. Because the upper bedding is arranged in two sections, the individual's torso and unaffected leg may be kept covered without interference to the traction apparatus. A lightweight cover may be placed over the leg in traction to ensure adequate warmth.

The foot of the bed is elevated to counterbalance the traction and a fracture board is commonly placed under the mattress to provide a firm and supportive surface. A trapeze or overhead bar should be provided to facilitate the individual's movement. When changing or straightening the bottom sheet, it is sometimes easier and less disruptive for the individual in traction if nurses work from the top to the bottom of the bed, rather than from side to side.

Certain adverse effects may be associated with prolonged bed rest and immobility; it is therefore important that the nurse implements preventive measures to reduce such effects.

## COMFORTABLE POSITIONING

Individuals assume, or are assisted into, the position they find the most comfortable, unless a specific posture is indicated for therapeutic reasons. If an individual is able to move without assistance, the nurse should ensure that the bed pillows are positioned for support and comfort and that there are adequate bedclothes. A call bell and the individual's personal requirements (water jug and tissues) should always be within easy reach. A specific position may be necessary to prevent deformities, relieve pressure and strain, to assist circulation or breathing or to enable various examinations or treatments to be performed. Some individuals will be able to assume a position independently, while others will require the nurse's assistance. The nurse should be aware of measures to promote the individual's safety and comfort and should be able to assist an individual into specific positions. Correct positioning can promote comfort, maintain and help restore body functioning and help to prevent the complications associated with bed rest and immobility.

Key aspects related to positioning:

- To minimise the risk of back strain, nurses are advised to observe the principles of body mechanics and the no-lift policy when assisting individuals to move (see Chapter 28)
- The individual should be provided with information about the importance of correct positioning and the reasons why a specific position may be indicated. To provide some exercise and to promote independence the individual should be encouraged to participate in regular changes of position unless active movement is contraindicated
- All parts of the individual's body should be maintained in proper alignment, with equal weight distribution and the joints in a functional or neutral position. Muscle tension and strain are prevented when the joints are maintained in a slightly flexed position
- Adequate support should be provided to maintain the natural curves of the individual's vertebral column
- To promote safety and comfort, adequate assistance should be obtained to move a heavy, very frail or dependent individual. The individual's body should be handled gently to prevent pain or injury. Appropriate lifting devices are used when necessary to assist individuals into position
- Supplementary equipment should be used when needed (e.g. slide sheets, pillows)
- To prevent prolonged pressure on any area of the body, the individual's position should be changed at least every 2 hours. Each time an individual's position is changed, the nurse should observe the status of the individual's skin to detect any signs of the consequences of prolonged pressure
- The individual should be encouraged to participate in some form of exercise unless this is contraindicated. Exercise helps to promote circulation and muscle tone; if the individual is unable to move independently, all joints should be put through the full range of motion
- There are various positions that an individual may assume, or be required to assume.

### Sitting positions

There are three variations of a sitting position:

1. The semi-upright, or semi-Fowler's, position, in which the individual sits supported by pillows, which are placed against the backrest of the bed (Figure 23.10A)

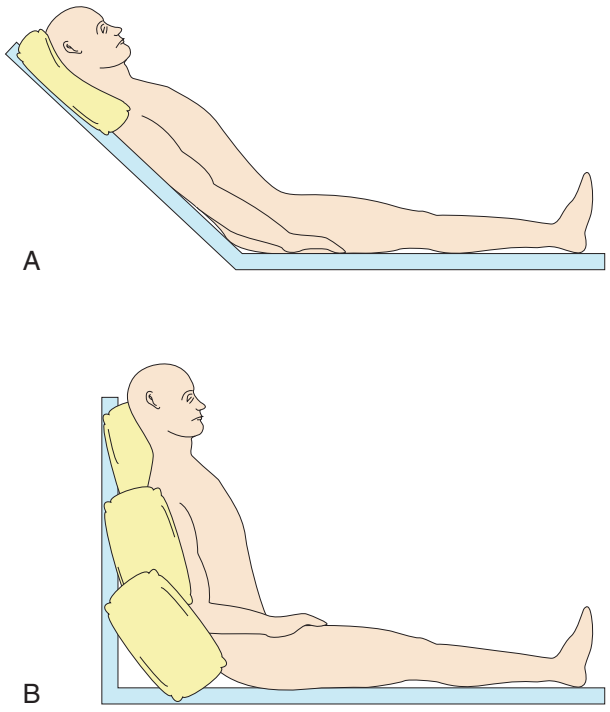

**Figure 23.10** Sitting positions

A: Semi-upright, or semi-Fowler's, position B: Upright, or high Fowler's, position may also be adapted to the orthopnoeic position if the person leans onto an over-bed table

2. The upright or high Fowler's position, in which the individual is in a full sitting position with pillows placed to support the upper body (Figure 23.10B)
3. The orthopnoeic position is an adaptation of the upright or high Fowler's position in which the individual leans onto an over-bed table.

A particular one of these sitting positions may be indicated:

- After abdominal or thoracic surgery. Less tension is exerted on an abdominal wound, therefore comfort is promoted. Drainage by gravity from body cavities is facilitated (e.g. when there has been a drainage tube inserted after surgery)
- To facilitate breathing and reduce dyspnoea. Because the diaphragm is able to flatten, maximal chest expansion is promoted and the risk of lung congestion is decreased. Leaning forwards, as in the orthopnoeic position, helps to increase lung capacity and therefore alleviate distressed breathing
- To facilitate independence, as a sitting position enables the individual to see and participate in ward activities. The activities of daily living (e.g. eating and drinking or using toilet utensils) are also facilitated in this position.

The disadvantages of a sitting position include:

- Difficulty maintaining the position, which may become tiring or uncomfortable
- Difficulty in sleeping
- Prolonged pressure on the buttocks and sacral area, which increases the risk of decubitus ulcers
- Difficulty maintaining a comfortable body temperature; in cold weather it may be hard to bring the bedclothes up to the shoulders, while in hot weather the individual may experience discomfort from the number of pillows required to maintain a sitting position.

## Positions for specific situations

There are a variety of other positions suitable for a range of different circumstances. These include:

- Supine
- Prone
- Lateral
- Sims'
- Coma
- Dorsal/lithotomy
- Genupectoral (knee–chest).

Figure 23.11 illustrates this range of positions.

### Supine position

In a supine position, the individual lies flat on their back with a pillow under their head. Limbs should be positioned in normal alignment. A foot board, firm pillow or other aid may be necessary to maintain the correct position of the feet. A supine position may be indicated:

- To facilitate relaxation of the abdominal muscles (e.g. during medical examination of the abdomen). After abdominal surgery, individuals may be placed in the supine position to relieve tension on the abdominal area
- For several hours after a lumbar puncture. Re-establishment of normal circulation of the cerebrospinal fluid is facilitated, and lying flat helps to prevent a severe headache, which may occur from a change of pressure in cerebrospinal fluid.

The disadvantages of a supine position include:

- Restriction of chest expansion. The lungs are unable to inflate fully, secretions accumulate and congestion of the lungs may occur
- Difficulty may be experienced when toilet utensils are being used. This may lead to incomplete emptying of the bowel or bladder, which may result in constipation or urinary tract infection
- Depression may result from loss of independence and the difficulties associated with activities of living (e.g. eating and drinking). An individual in a supine position may also experience difficulty in seeing, or participating in, ward activities
- Increasing the work of the heart, as lying flat increases venous return (preload).

### Prone position

In a prone position, the individual lies on the abdomen with the head supported on a small pillow and turned to one side. A small pillow may be placed under the abdomen to maintain the natural curve of the spine, or to relieve pressure on the breasts. A pillow may be placed under the ankles to maintain the feet in the correct position and to facilitate slight flexion of the knees (alternatively, the individual may be positioned so that the toes are extended over the end of the mattress.) The individual's arms should be positioned comfortably; for example, flexed beside the head or extended alongside the torso. A prone position may be indicated:

- To relieve pressure on the posterior surface of the body. If an individual has, for example, a burn or decubitus ulcer on the back, a prone position will alleviate pressure on the damaged area and therefore permit healing and relieve pain
- To provide access to the posterior surface of the body for medical examination
- To promote drainage from the respiratory tract. Drainage by gravity is further facilitated when the foot of the bed is elevated.

The disadvantages of a prone position include:

- Restriction of chest expansion. Lung congestion is more probable, as the lungs are unable to inflate fully and secretions accumulate
- Difficulty may be experienced in performing the activities of living; for example, eating, drinking or emptying the bladder or bowel
- Depression from loss of independence and an inability to participate in ward activities.

### Lateral position

In a lateral, or side-lying, position, the individual lies on the side, with the head supported on a pillow. The arms are

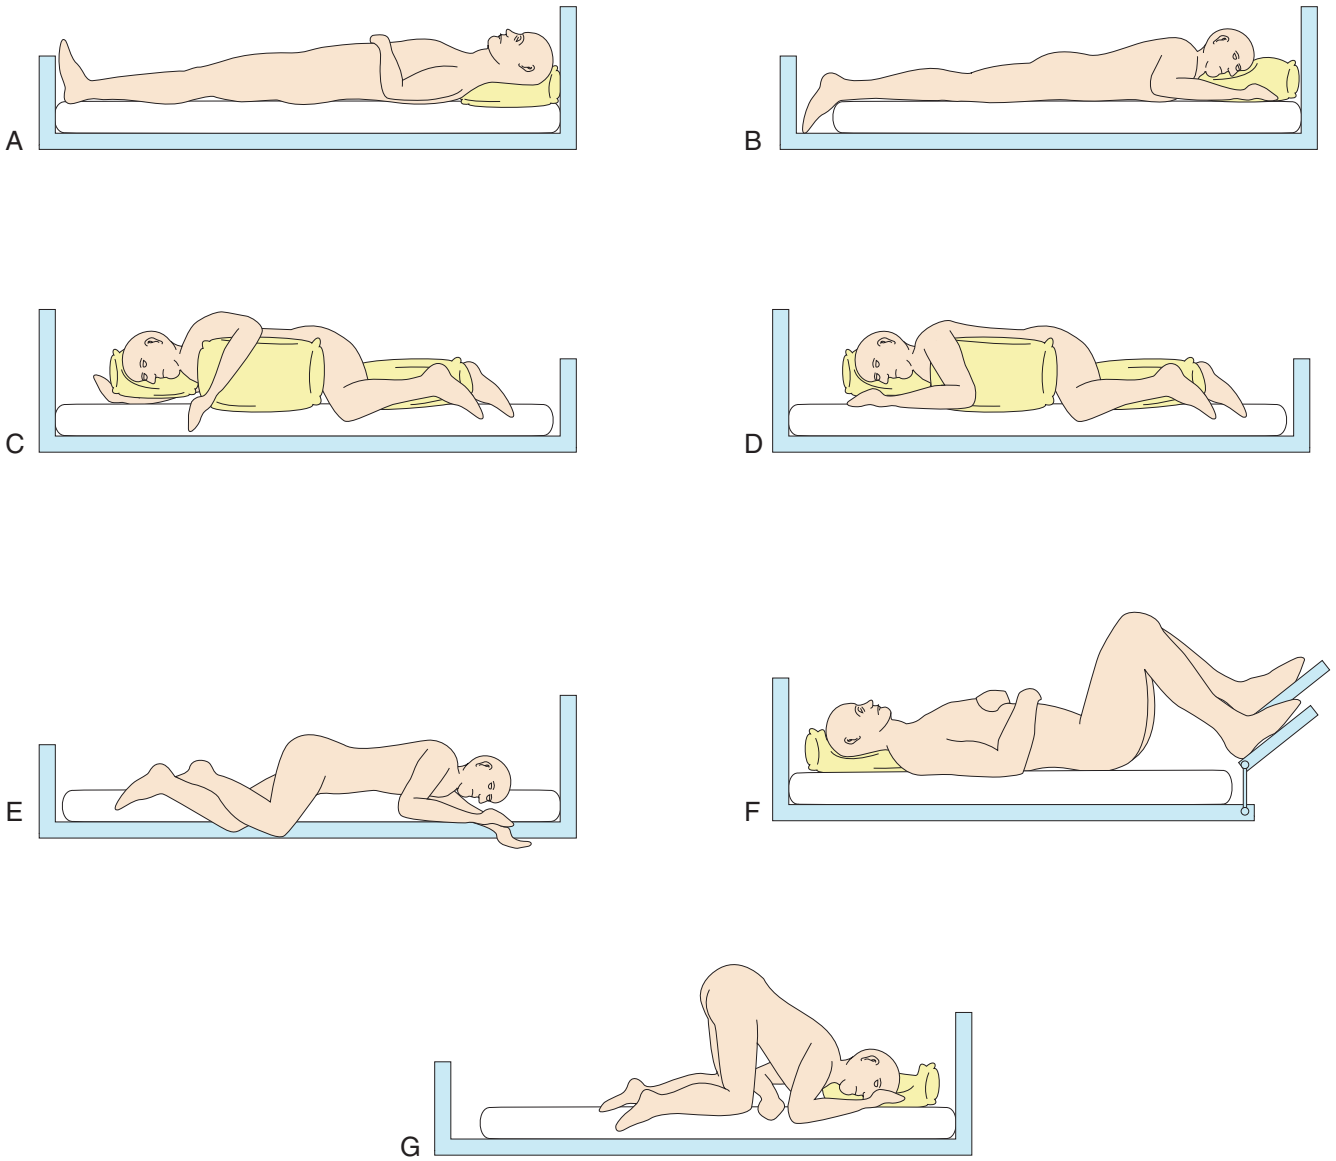

**Figure 23.11** Various positions
A: Supine B: Prone C: Lateral D: Sims' E: Coma F: Dorsal/Lithotomy G: Genupectoral (knee–chest)

placed comfortably in front of the body and, depending on the purpose of the position, the legs may be flexed or extended. If the individual is required to assume a lateral position for a prolonged period, a pillow may be placed along the back to facilitate maintenance of the position. The limbs should not assume a dependent position and may be supported; for example, the upper arm and leg may be flexed and supported on pillows. A lateral position may be adapted for specific purposes; the left lateral position, in which both legs are flexed, is commonly used for examination or treatment involving the rectum. During a lumbar puncture, the individual is positioned laterally with both knees flexed and drawn towards the abdomen, and the head flexed towards the chest. A lateral position may be indicated:

- For treatment or examination involving the rectum (e.g. the insertion of rectal suppositories)
- When a lumbar puncture is being performed. Placing the individual in a lateral position with the spine flexed facilitates entry of the needle between the vertebrae
- To nurse an unconscious individual. A lateral position promotes maintenance of a clear airway by preventing the tongue from falling back and causing obstruction. This position also prevents oral secretions from entering the trachea.

If a lateral position is assumed over a long period, the disadvantages are an increased risk of postural deformities, decubitus ulcers and various other complications associated with the prolonged use of any position.

## Sims' position

In the Sims', or semi-prone, position the individual lies on the side with the upper leg drawn up towards the chest and the buttocks towards the edge of the bed. The lower arm is placed behind the individual, and the upper arm is positioned comfortably in front. The head is supported on a small pillow. Women can adopt this position when having a vaginal examination but the dorsal position is used more commonly for this purpose. The Sims' position is most commonly used for rectal and vaginal examinations and it may also be helpful for women with physical impairments that make the dorsal position uncomfortable or unmanageable (Slater 2012). Some women might find the Sims' position less embarrassing than the dorsal position when a vaginal examination is being performed.

## Coma position

In the coma position, the individual is placed in a position that is basically the Sims' position but without a pillow under the head. Correct positioning of the head is essential to promote a clear airway, and a pillow may impede breathing. A coma position may be indicated temporarily during unconsciousness, such as after an episode of fainting. A clear airway is facilitated with the head on one side, as this prevents the tongue or oral secretions from obstructing the trachea.

If used for an extended time, the disadvantages of the coma position include:

- Restriction of chest expansion. The lungs are unable to inflate fully, secretions accumulate and the risk of lung congestion is increased
- Likely occurrence of postural deformities such as limb contractures. Also, prolonged pressure on the shoulder and arm placed behind the individual may result in damage to the brachial plexus.

Chapter 44 provides information concerning the use of the coma (recovery) position in an emergency situation.

## Dorsal/lithotomy position

In a dorsal/lithotomy position, the individual lies on their back, with knees flexed and apart, and the soles of their feet flat on the bed. Their head is supported on a pillow and their arms are positioned comfortably. A dorsal position may be indicated:

- To introduce a urinary catheter into a female, as the urethral meatus is made visible and accessible
- To perform vaginal examinations or treatments (e.g. insertion of vaginal ointment)
- To administer an enema or rectal suppositories, if the individual is unable to assume a lateral position.

The disadvantage of a dorsal/lithotomy position is that it may be embarrassing for the individual. A lithotomy position may be used during gynaecological surgery or during the birth of a baby.

## Genupectoral position

In the genupectoral or knee–chest position, the individual kneels so that body weight is supported on the knees and chest. The individual is positioned on the knees with the chest resting on the bed and either with the elbows supporting some of the weight, or with the arms extended beyond the head. The head is turned to one side and supported on a pillow. A genupectoral position may be indicated:

- For specific examinations of the lower colon, as the insertion of instruments is facilitated
- During the management of a specific obstetric emergency: if the umbilical cord prolapses, this position prevents the weight of the baby pressing on and obstructing the flow of blood through the cord.

The disadvantages of a genupectoral position include that it is difficult, uncomfortable and embarrassing to maintain; it may result in the person becoming dizzy or faint, and falling.

Whatever position the individual assumes, the nurse should implement measures to promote comfort and safety. Pillows should be arranged for maximum comfort and support and placed so that the individual's head, neck, shoulders and spine are supported at a comfortable angle. The pillow behind the head and neck should be placed so that the individual's head is not pushed forwards. **Supplementary equipment** such as sheepskins may be used to enhance comfort and to relieve pressure. Upper bedclothes should be arranged for maximum covering and warmth and tucked in loosely to allow room for movement. A foot board or firm pillow may be placed in the bed to help sustain the individual's position, and to help maintain the feet in a neutral position. When a person is required to assume a specific position for examination or treatment purposes, the nurse should ensure adequate draping and privacy to reduce embarrassment and promote comfort.

It is also important to ensure that the individual is correctly positioned when sitting in a chair. A variety of chairs is available and a style should be chosen to meet the individual's needs. A chair should be comfortable and support the individual adequately. Specially designed chairs may be indicated for some individuals; a chair with an elevated seat is used after hip surgery, to prevent strain on the joint. When sitting in a chair, the individual's spine and buttocks should be well aligned to the contours of the chair. Both feet should be flat on the floor, or (at times) it may be necessary to support one or both feet on a footstool or chair. Limbs should be supported in a position of comfort with pillows used when necessary; supporting an arm with an intravenous infusion in progress or a plaster cast are two such examples. The individual should be adequately dressed and light coverings should be provided to promote warmth and privacy.

## Summary

It is the role of the nurse to ensure that individuals have their hygiene needs met, are well groomed and, as far as is possible, free of physical discomfort and psychological stress. Nurses must be competent in their responsibilities and practices in assisting individuals with all areas of hygiene, in bed-making procedures and the use of supplementary equipment, and in the correct positioning of individuals to ensure the best possible level of comfort. Ensuring that individuals are clean, fresh and comfortable promotes relaxation, rest and sleep, which are essential for healing and wellness. The nurse who successfully assists individuals to meet all hygiene and comfort needs plays an essential role in promoting their physical and psychological wellbeing.

### DECISION-MAKING FRAMEWORK EXERCISE 23.1

Isobel is a student Enrolled Nurse currently undertaking clinical placement at an aged care facility. She is working alongside a Registered Nurse who is indirectly supervising Isobel during her shift. She is caring for 83-year-old Amy who is scheduled to attend a specialist appointment at the local hospital this morning at 1100 hours. Isobel needs to ensure Amy is ready for her outpatient appointment. It is 0830 hours and Amy has not showered or dressed, nor has she received her medications or breakfast.

Amy has type 2 diabetes. Isobel has completed the morning blood glucose level, which was 4.0 mmol, and has been informed that the transport for Amy will arrive at 1000 hours. Isobel knows that Amy will require her breakfast and medications prior to attending her appointment. However, she also knows that Amy needs to be dressed and packed and ready for her transport for her appointment. Isobel has not completed the medications unit.

Using the decision-making framework:

1. What should Isobel consider when prioritising her tasks for the morning?
2. Does Isobel have the required level of education and supervision to make these decisions?
3. Is prioritising her tasks without direct supervision within Isobel's scope of practice?

## Review Questions

1. List at least four (4) different factors that might influence an individual's hygiene practices.
2. When assessing an individual, what should the nurse observe in relation to the individual's skin, hair, nails, mouth, eyes, ears and nose?
3. List the assessment factors that influence whether an individual can be bathed in bed or showered.
4. What factors must a nurse take into consideration when showering an individual with a urinary catheter, intravenous drip or a plaster cast on a limb?
5. What items would a nurse need to gather when preparing an individual for a bed bath?
6. What would determine the nurse's choice to give an individual special mouth care or a mouth toilet?
7. List at least five (5) infection control principles that should be implemented by the nurse when making a bed.
8. How is the individual positioned when lying in each of the following positions: supine, prone or lateral? Give an example of when each of these positions might be used.
9. How is the individual positioned when sitting in each of the following positions: semi-upright, upright or orthopnoeic? Give an example of when each of these positions might be used.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER

24

# Medication administration and monitoring

*Heather Redmond*

## KEY TERMS

absorption
allergic reaction
biotransformation
chemical name
generic name
trade name
compliance
distribution
drug metabolism
enteral
excretion
first-pass metabolism
intramuscular injection
intravenous injection
medication action
needleless intravenous system
parenteral
pharmacodynamics
pharmacokinetics
pharmacology
poisons Regulations
poisons schedules
protein bound
Quality Use of Medicines (QUM)
subcutaneous injection
therapeutic medication monitoring
topical

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Identify the different formulations of medications
- Identify a medication by generic and trade names
- List the medication administration routes
- Discuss factors affecting medication absorption
- Define 'first-pass metabolism' and discuss its impact on medication dosage
- Discuss the role of plasma proteins in medication distribution
- Compare enzyme induction and enzyme inhibition
- List the organs involved in medication excretion
- Discuss the reasons for therapeutic medication monitoring
- Define medication action, desired outcome, side effects, toxic effects, allergic reaction and medication interactions
- Discuss the legal and other responsibilities of the Enrolled Nurse (EN) regarding medication administration
- Demonstrate an ability to correctly calculate medication dosages for administration
- Demonstrate knowledge of the correct preparation and administration of subcutaneous, intramuscular, intradermal and intravenous injections; topical skin preparations; oral preparations; ophthalmic, otic and nasal drops; vaginal instillations; rectal preparations; and inhalers
- Demonstrate an understanding of the actions of the different medication groups in order to monitor medication effectiveness
- Show an understanding of safe handling of hazardous substances
- Discuss the importance of discharge planning and education in individual compliance with medication therapy

## CHAPTER FOCUS

Medications are an important part of many treatment regimens. It is the most common treatment given in healthcare settings, and as a result a higher incidence of medication errors and adverse medication reactions (ADR) occur (ACSQHC 2013). Administering medication is a nurse's key responsibility and should be treated with the importance it deserves. It is therefore vital for the nurse to have both the knowledge and the skills to administer medications safely and accurately (Brotto 2013). Medication administration offers nurses the opportunity to increase their knowledge and skills, to observe the individual for expected and unexpected actions and to ensure that individuals have been adequately educated about medications. The topics included in this chapter provide the nurse with the foundations to safely and competently administer medications to individuals.

## LIVED EXPERIENCE

Mum lives with us at the moment as she has a lot of health issues. I have been going with her to all her doctors' appointments lately. She sees a cardiologist for her heart failure, her own GP who looks after her diabetes and anything else that crops up, a gastroenterologist for her Crohn's and the oncologist for her chronic leukaemia, so yes, I am worried about all the medications she is on. I know some of the medications she is taking are for side effects she gets from taking other medications. It all gets a bit confusing when I look at all her tablets, as I am sure it is for her. I think, does she really need to take all of these medications, and do the other doctors she sees know what she is taking? Mum doesn't seem to tell them much when she goes to her appointments. I had to point out to one doctor what she was taking, as the doctor didn't know.

**Mary, daughter of Grace, who is 82 years old**

# PHARMACOLOGY

'Pharmakon' is the Greek word for 'drug', and **pharmacology** is the study of the actions, uses and adverse effects of drugs on living systems (Bryant & Knights 2014). Drugs and poisons are controlled substances defined by the *Drugs, Poisons and Controlled Substances Act 1981* and the Drugs, Poisons and Controlled Substances Regulations 2006. The term drugs and poisons are defined together as prescription medicines; pharmacy-only medicines; drugs of dependence; chemicals for household, industrial and chemical use; and veterinary medicines (Bryant & Knights 2014). The definition of a 'drug' is any substance that produces a biological effect when introduced into the body (Rang et al 2012). The term drug can be further divided into medicinal drugs (or medications), which are substances used in the treatment, prevention, diagnostic, curative and health maintenance; and non-medicinal drugs (or social drugs). Social drugs are substances for recreational use and may include caffeine, alcohol, nicotine, cannabis, heroin and cocaine. The distinction between the two is not always clear cut, as some non-medicinal substances can be used in a medicinal way (e.g. caffeine is included in some preparations to treat migraine) and some medicinal substances can be used in non-medicinal ways (e.g. opioid analgesia such as codeine phosphate may be used recreationally for its mind-altering properties). In the general community, however, the term 'drugs' tends to be associated with non-prescription or illicit substances, and 'medications' is the common term used for prescribed drugs that have the intention of producing a therapeutic effect (Rang et al 2012). The term 'poison' as referred to under the definition of drugs, however, is 'any substance that harms the body or causes death' (Bryant & Knights 2014). Medicinal medications given at high doses may also have similar effects to a poison.

Pharmacology can further be subdivided into **pharmacokinetics**, which is the way the body affects the medication during absorption, distribution, metabolism and excretion, and **pharmacodynamics**, which are the effects of the medication on the body (e.g. therapeutic effect and side effects) (Bryant & Knights 2014). Before considering these two areas of pharmacology, it is important to consider the process for naming medication, as well as medication formulations and administration routes.

## Medication names

The nurse should be aware that each medication has various names—chemical, generic and trade (brand or proprietary) names.

The **chemical name** provides an exact description of the medication's chemical composition, which is usually a temporary name until the generic name is assigned (Broyles et al 2013).

The **generic name** is given by the manufacturer who first develops the medication; it is then approved by the medicines regulatory authority (Bryant & Knights 2014). Even generic names are not standardised and nurses should be careful when using textbooks published in countries other than the one where they are practising nursing. Examples of different names used in different countries include adrenaline (Australia) = epinephrine (US), pethidine (Australia) = meperidine (US),

and paracetamol (Australia) = acetaminophen (US). Generic names are always written with a lower-case first letter (Bryant & Knights 2014). Occasionally a medication's generic name may describe its chemical compositions, such as with lithium carbonate or potassium chloride.

Quality Use of Medicines (QUM) recommends that medications be prescribed using the generic rather than trade name (e.g. metronidazole rather than Flagyl); however, Atik (2013) highlighted that not all prescribers adhere to this requirement. Generic prescribing avoids confusion, as some trade names are similar, and may also reduce the cost of the medication for individuals as they can choose a cheaper alternative brand name (Bryant & Knights 2014).

The **trade (brand or proprietary) name** is the name under which a manufacturer markets a medication and is copyrighted to that particular medication. Others are restricted from using the trade name; therefore, there are multiple names for the same generic medication. Examples include the diuretic frusemide, marketed as Urex, Lasix, Frusid and Uremide, and antibacterial agent amoxicillin marketed as Alphamox, Amoxil, Cilamox and Maramox. Trade/brand names are written with an initial upper case letter. Individuals may wish to purchase a cheaper brand and identification of the cheaper medication under a trade name is made easier using the generic name (as costs may vary dramatically between brands). In recent times, the Pharmaceutical Benefits Scheme (PBS) has allowed brand substitution for tablets of the same dose, unless the prescriber has ticked 'brand substitution not permitted' on the prescription form (Bryant & Knights 2014). While brand substitution can save the individual money, it can also cause confusion as the medication may appear different in colour (e.g. 40 mg frusemide tablets can be white (Uremide) or yellow/cream (Lasix)), shape and packaging, which could result in the person taking more than one form of the same medication. When changing medication brands it is important to consider the bioavailability of the new brand compared to what the individual has been taking, as some medications with the same generic name have been shown to have significant differing pharmacological effects (Broyles et al 2013). The prescriber may tick the box on the prescription 'Brand substitution not permitted' if it is known that a different brand name medication with the same generic name has a different chemical composition to other cheaper brand names (Bryant & Knights 2014). See Case Study 24.1 regarding brand substitution.

## Classification

Medications are allocated to a class or category, which have similar characteristics or actions on specific body systems. Antihypotensives have the primary action of reducing blood pressure and are divided into six categories: central and peripheral antiadrenergic agents, beta-adrenergic blockers, vasodilators, ACE inhibitors, angiotensin II antagonists and calcium channel blockers (Tiziani 2013). The medication prescribed will depend on the individual's symptoms and the desired effect, frequency required and cost. A combination of medications in the same class may be chosen to control a person's blood pressure (an ACE inhibitor and a calcium channel blocker; amlodipine and benazepril) or from another medication class (an ACE inhibitor and a diuretic: fosinopril/hydrochlorothiazide) (Tiziani 2013). A medication may also be classified into more than one class; for example, aspirin is classified as an analgesic, antipyretic, anti-inflammatory and anti-platelet (Brotto 2013).

### CASE STUDY 24.1

Mary is a 75-year-old woman who presents to hospital for a hip replacement. She has a history of atrial fibrillation, hypertension, gastro-oesophageal reflux disease and type 2 diabetes, for which she is stable on her current medication regimen. She is a widow and lives with her son. Mary is ambulant and self-caring with no obvious impaired cognitive function. Mary's medications are metformin 500 mg BD (twice daily), glibenclamide 5 mg mane, digoxin 125 micrograms mane, atenolol 50 mg mane, enalapril 5 mg mane, omeprazole 20 mg nocte and warfarin usually 5 mg nocte. Mary states that the last few times she had scripts filled she was asked if she would like the cheaper alternative, when available, and was reassured that some of the actual medicine remains the same. However, warfarin could not be substituted. Mary was happy about the reduced cost of some of the medicines but remains concerned about different brands being effective and safe.

1. When is brand substitution inappropriate? (Give medication- or individual-related reasons.)
2. List some steps you could take to avoid confusing Mary if she changes the brand of her medications now and in the future.

## Quality use of medications

In 1985, the World Health Organization (WHO) called a Conference of Experts on the Rational Use of Drugs as it found that inappropriate prescription and use of medications was occurring globally. WHO called on all healthcare professionals and governments to assist in developing their own National Medicinal Drug Policy (Department of Health 2014). Australia responded to this by instituting the National Medicines Policy (NMP) in 1999. This policy focused on ensuring that health outcomes were improved for all Australians, to be achieved through access to and wise use of medicines (Department of Health and Ageing 1999).

There are four central objectives of the NMP: timely access and cost effective medications for Australians; meeting quality, safety and efficacy in medicine standards; Quality Use of Medicines (QUM); and that a responsible and viable medicines industry is maintained (Department of Health and Ageing 2011). This will ensure that medications that are prescribed, purchased over the counter or complementary are appropriate, safe and effective, and are used to promote the health outcomes of individuals (Brotto 2013).

The NMP definition of **Quality Use of Medicines** (QUM) is that medications are selected wisely; are appropriate, taking into consideration the individual and their health concerns as well as factors such as risks, benefits, alternative therapies, comorbidities, regimen, monitoring and associated costs; and are used safely and effectively to optimise health outcomes. The Australian National Strategy for QUM has set guidelines for the approach and principles required to achieve QUM in Australia. In addition, a QUM Strategic Action Plan was developed from the National Strategy for QUM which is reviewed biannually, and a plan developed to assist all Australian healthcare stakeholders to incorporate QUM strategies into medication practices (Department of Health and Ageing 2002). QUM involves the government and policy makers deciding about the supply of a medicine and the subsidy applied. It is important that the QUM is a team approach encompassing those that prescribe, dispense and administer medicines as well as individuals who take the medicine (Brotto 2013).

## The prescriber's role

Medications are primarily prescribed by a medical officer; however, veterinarians, dentists, pharmacists and nurse practitioners (NPs) can prescribe within a specific scope of practice (Brotto 2013). In addition, hospital policy may allow for Registered Nurses (RNs) to 'nurse initiate' medications from an approved list to certain hospitalised individuals (Brotto 2013). The person prescribing the medication must follow the QUM objectives to ensure the medication is appropriate and safe for the individual taking the medication.

## The pharmacist's role

Pharmaceutical companies make medications in their specific forms, which are ready for dispensing to community and hospital pharmacies. Prescribed medications are prepared and dispensed by the pharmacist for community and hospitalised individuals (Brotto 2013). Compounding pharmacists also make special orders for medications by mixing compounds and/or solutions. Hospital pharmacists may mix up intravenous (IV) additive solutions (e.g. total parental nutrition TPN) for individual medication requirements. When dispensing, the pharmacists needs to ensure that the medication is suitable for the individual, including looking for any contraindications or interactions. The correct labelling of the right dosage and number of tablets is also part of the pharmacist's role. In many acute settings the hospital pharmacist also checks each individual's medication chart to ensure accuracy and the correct medication and dosage is prescribed. Amendments may be made by the pharmacist. Healthcare workers and individuals can access the pharmacist for a valuable resource to provide information relating to the prescribed medication including action, side effects, interactions and incompatibilities (Brotto 2013).

## The nurse's role

Nurses have several roles in prescribing (NP only) and administering medications. Nurses require knowledge of the rationale, as well as the therapeutic and non-therapeutic effects of the prescribed medication, adverse drug reactions (ADRs) and contraindications (Brotto 2013). This enables nurses to ascertain the appropriateness of the medication they are about to deliver and be able to provide individual and/or family education about specific medications and their effects. Administering medications includes the responsibility of assessing individuals prior to administration, following the seven rights, and evaluating the therapeutic effectiveness and outcomes after administration (Brotto 2013).

## The consumer's role

The individual who has been prescribed the medication has a role in adhering to the prescribing regimen, having regular health reviews with the medical officer, and reporting any health concerns and side effects associated with the medication being taken. Information regarding any alternative therapies being used should be discussed, such as naturopathy, homeopathy or over-the-counter medications (OTC) to ensure they do not interact with the prescribed medications being taken.

Medication management in residential aged care facilities (RACF) falls under the *Aged Care Act 1997*, Quality of Care Principles, Residential Care Standards and the Accreditation Standards. The approach in QUM in RACF for the use and management of medications is outlined in *The Guiding Principles for Medication Management in Residential Aged Care Facilities* (2012). The QUM in RACF approach means that suitable medications are chosen which treat illness and maintain health, the necessity of the medication is considered and that medications are used safely and effectively.

Medications accessed OTC are non-prescription medications and are generally used for short-term, self-limiting illnesses such as headache, heartburn and constipation. They also include vitamins, minerals and herbal medications and remedies which, unfortunately, many people consider to be safe because they are natural. However, herbal medications and remedies do interact with prescription medications (e.g. St John's wort interacts with warfarin, increasing warfarin's metabolism and decreasing its therapeutic effect) and non-prescription medications (e.g. aspirin and ibuprofen) can cause gastrointestinal bleeding and must only be taken at recommended doses (Bryant & Knights 2014).

### CRITICAL THINKING EXERCISE 24.1

An 85-year-old woman was admitted to the medical ward after presentation to the emergency department in acute pulmonary oedema. On arrival at the medical ward you are completing her admission and discharge plan when she tells you that when she has something special on in the day she does not take her Lasix as it makes her go to the toilet too often. She had her granddaughter's wedding over the weekend, so had not taken the medication for 3 days. Is this quality use of medications and how would you respond?

## Medication formulations and administration routes

Medications are given by three general methods: **enteral**, **parenteral** and **topical** administration. Enteral administration is when medication enters into the gastrointestinal tract. Parenteral medication administration involves injection into the body tissues. Topical administration includes medication applied to the skin, mucous membranes and intraocularly (Brotto 2013). A single medication may be available in a variety of forms (Table 24.1, Figure 24.1) and administered via several different routes.

Enteral administration of medications include:

- Oral (PO)—the most convenient and least expensive way of administering medications as most are available in oral preparations (Bryant & Knights 2014). Most

**TABLE 24.1 | Medication forms**

| | |
|---|---|
| Capsule | Gelatine container enclosing a medication in liquid, powder or granule form |
| Tablet | A medication mixed with a base compound and compressed into a variety of shapes. Tablets are sometimes coated, which delays release of the medication until the tablet reaches the intestine. Tablets are coated if the medication could cause gastric irritation or if it would be destroyed by gastric juice. Another form of tablet is 'slow release' (or sustained release), which contains a medication that is released over a prolonged period |
| Granules | Small rounded pellets that are usually coated |
| Lozenge | Small tablet containing a medicinal agent in a flavoured fruit or mucilage base, which dissolves in the mouth to release the medication |
| Mixture | Aqueous vehicle in which medications are dissolved or suspended |
| Suspension | Liquid in which insoluble particles of a medication are dispersed |
| Elixir | Sweetened, flavoured alcoholic solution containing a medication |
| Linctus | Sweetened syrup containing a medication |
| Tincture | Alcoholic solution containing a medication |
| Emulsion | Mixture of oil and water containing a medication |
| Syrup | Concentrated sugar solution containing a medication |
| Cachet | Envelope of rice paper that encloses a medication |
| Injection | Sterile aqueous or oily solutions and suspensions containing a medication, which are administered parenterally |
| Suppository | Solid preparation containing a medication, which melts when inserted into the rectum |
| Pessary | Solid preparation containing a medication, which is administered vaginally |
| Drops | Aqueous or oily solution containing a medication. Drops may be instilled into the eye, ear or nose |
| Cream | Aqueous or oily emulsion for topical application |
| Ointment | Semi-solid greasy preparation for topical application |
| Paste | Similar to ointment but contains a high proportion of powders. Pastes have a very stiff consistency and will adhere to lesions at body temperature |
| Liniment | Oily or alcoholic preparation for topical application |
| Paint | Liquid preparation for application to the skin or mucous membranes |
| Lotion | Aqueous, alcoholic or emulsified vehicle for topical application |
| Powder (dusting) | Medicated substance for topical application |

*(Adapted from Bryant & Knights 2014; Broyles et al 2013; Brotto 2013)*

**Figure 24.1** Forms of oral medications
*(Potter et al 2013)*

medications are not absorbed until they reach the small intestine (Rang et al 2012), and effects may not be seen for 30 to 45 minutes after administration. Disadvantages may include slow absorption, irritation to the gastric mucosa, possible unpleasant taste and inability/decreased absorbency in the critically ill (as the gut may not be functioning). This route is not suitable in those who are vomiting or are not able to take oral medications (e.g. unconscious person, child, person with dementia) (Broyles et al 2013). Oral liquid medications are administered via a specialised oral syringe. The oral syringe is orange in colour to differentiate between syringes used for parenteral medication delivery. The tip does not allow for a needle to be attached, therefore ensuring there is no risk of mistakenly administering oral medication via the parenteral route.

- Orogastric/nasogastric/percutaneous endoscopic gastrostomy (OG/NG/PEG)—this route is generally used for oral medications when the individual already has the tube in place for other reasons. (See Chapter 30 for information about nasogastric and PEG tubes.) An orange oral syringe or catheter tip syringe would be used to administer the medication.

Parenteral administration of medications include:

- Intravenous (IV)—medication delivery via the IV route is rapid, as it is administered directly into the blood stream (Rang et al 2012). The IV route may be accessed for therapeutic or diagnostic purposes (e.g. serum blood levels). Nurses may care for individuals receiving IV medication therapy as inpatient or outpatients, or in their homes (Broyles et al 2013). The individual must be observed and assessed more closely to detect ADRs as these may occur more quickly with IV medication administration (Brotto 2013). In preparing and administering IV medication infection control principles are followed, maintaining asepsis and a non-touch technique to prevent infection occurring (Brotto 2013). Advantages include route of choice in an emergency situation, when other routes are not appropriate (e.g. the unconscious person), volume and dosages can be titrated more closely and constant blood levels can be maintained (Rang et al 2012). Disadvantages include increased risk of ADRs, local reactions such as pain/discomfort, irritation, risk of infection, more costly than other routes and unsuitability for self-administration.
- Intramuscular (IM)—the medication is injected into the muscle tissue, from which it is absorbed into the bloodstream. Medication absorption IM is generally fast because of the vascular nature of muscle. However, this can be slowed by the addition of oily substances (termed a depot preparation). IM injection is suitable for medications that are irritating or painful, as this is minimised when the medication is injected into a large muscle (Broyles et al 2013).
- Subcutaneous (subcut)—medications are injected into fatty, subcutaneous tissue underlying the dermis and overlying the muscle. This route is used more frequently than the IM route (Broyles et al 2013). Medication absorption subcutaneously is relatively slower than with IM injection because of the poor blood supply in subcutaneous tissue (Brotto 2013). One advantage of the subcutaneous route is the suitability for medications requiring a slower absorption rate, such as insulin. Disadvantages include unpredictable absorption rates, may cause bruising and only small volumes (≤ 1 mL) can be given (Brotto 2013).
- Intradermal (ID)—medications are administered into the dermis (under the epidermis). Medications are not commonly given via this route. Substances such as local anaesthetics are sometimes administered intradermally and this route is used for allergy testing; for example, Mantoux tests.
- Intrathecal (IT)—injections are given directly into the central nervous system (CNS) via the cerebrospinal fluid, bypassing the blood–brain barrier. (See Chapter 35 for an explanation of the blood–brain barrier.) Epidural injections are given into the space between the arachnoid mater and the dura mater and are often used as regional anaesthetics during surgical procedures involving the pelvic region (Rang et al 2012).
- Intraarticular—injections are given directly into articular joints. Examples include corticosteroids to reduce joint inflammation and radio-opaque contrast to view structures. Disadvantages to this route are that it can be painful and is often required to be done under radiological imaging to ensure that it is administered into the joint cavity.

Topical administration of medications include:

- Cutaneous—application of medication to the skin where a local effect is desired. Preparations include antiseptics, creams and lotions. Some preparations have systemic as well as local effects, as small amounts may be absorbed systemically (Broyles et al 2013).

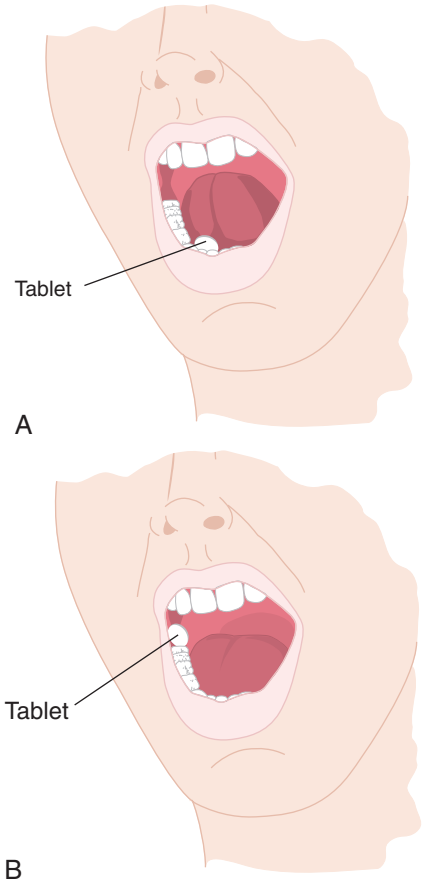

**Figure 24.2** A: Sublingual administration of a tablet B: Buccal administration of a tablet
*(Potter et al 2013)*

- Transdermal—medications given via this route require a steady rate of delivery of the medication over a longer period of time. Transdermal preparations are lipid soluble medications and include hormones, antiemetic agents, antianginal agents and nicotine patches (Rang et al 2012).
- Mucous membranes—some medications administered via this route have both local and systemic effects. Medications designed to be absorbed through the mucous membranes can be administered:
- Sublingually (subling) (Figure 24.2A)—even though medication is placed into the mouth and under the tongue (e.g. sprays, lozenges) the medication is absorbed directly into the systemic circulation and does not pass though the stomach. Any subling or buccal medication swallowed is usually metabolised quickly by gastric acid (Rang et al 2012)
- Buccally (Figure 24.2B) between the inner linings of the cheeks
- Intranasally via aerosol or drops instilled in the nose, where the medication is rapidly absorbed through the vascular network in the nasal tissues
- Rectally (PR), where it may have both local (evacuation suppositories) and systemic (antiemetic) effects (Brotto 2013). Advantages include its suitability in individuals who are nauseous or vomiting, have swallowing problems, are unconscious or have severe inflammatory bowel disease. The slow absorption of anti-inflammatory preparations makes this route ideal for overnight analgesia administration, unlike oral preparations where the effects have often worn off by the following morning. Disadvantages include suppositories causing anal or rectal irritation, especially with prolonged use, self-administration may be difficult for some individuals and the presence of faecal matter in the rectum interferes with medication absorption, making it erratic and unpredictable
- Vaginally (PV)—preparations include pessaries, foams, jellies or creams inserted into the vagina with a special plunger (Brotto 2013). One advantage of this route is that the individual is often able to self-administer. The onset is slow and effects are generally local
- Conjunctivally is the ophthalmic administration of aqueous solutions and ointments into the eyes. The disadvantage of solutions is that corneal contact time is brief, and ointments cause blurred vision (Rang et al 2012).
- Otic—medication is placed into the ear via drops or creams.
- Inhalation—the large surface area and blood flow in the lungs facilitates rapid absorption (Rang et al 2012). Agents given via this route include oxygen, anaesthetic agents, mucolytic agents and bronchodilators. A proportion of inhaled medications will reach the systemic circulation and may cause ADRs (e.g. salbutamol causing tremor) (Rang et al 2012).
- Intraocular—a disc is inserted into the eye much like a contact lens and the medication is released over a period of time.

### CRITICAL THINKING EXERCISE 24.2

A 72-year-old woman, who has been recently diagnosed with throat cancer and is palliative, has been admitted to your ward for implementation of a pain management plan. The medical officer has written up for PRN oxycodone hydrochloride 10 mg oral 4–6 hourly. The patient has difficulty swallowing and is not eating any food. What are other route options for delivery of this medication? What nursing action would you implement?

## PHARMACOKINETICS

Pharmacokinetics is the study of the way the body affects the medication over time and relates to the processes of absorption, distribution, metabolism and excretion. Figure 24.3 simplifies this process.

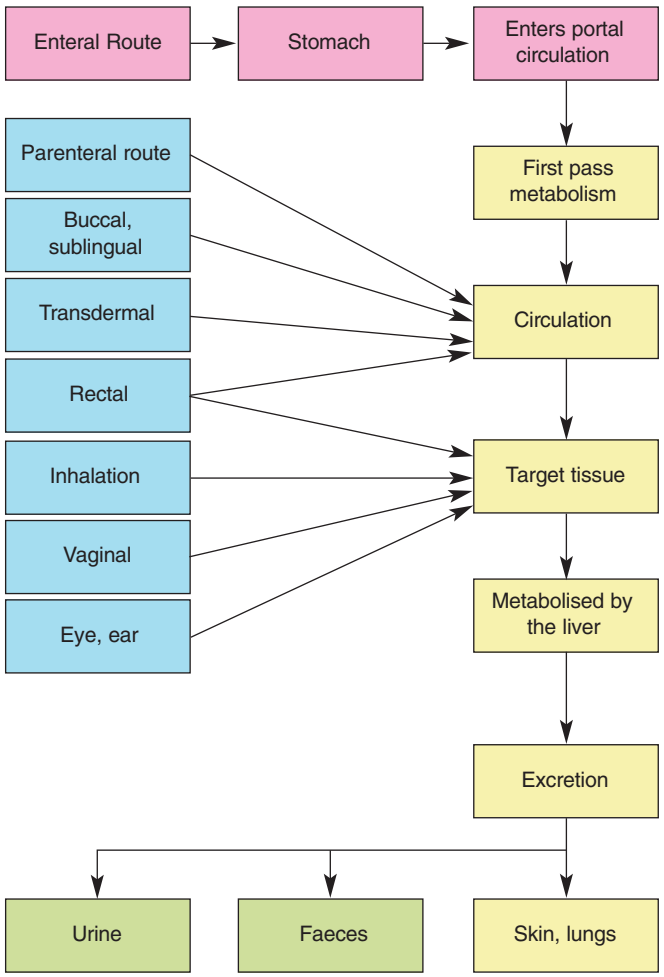

**Figure 24.3** Pharmacokinetics simplified

## Absorption

**Absorption** is the movement of a medication from the site of administration into the bloodstream where it is carried to the site of action (Broyles et al 2013). The rate and amount of medication absorbed depends on different factors including:

- Route of administration: affects the speed with which a medication takes effect. This is important for all medication routes as most medications must enter the blood stream before they exert their action (Rang et al 2012). An oral medication has to undergo absorption in the gastrointestinal tract before it reaches the bloodstream. It is therefore slower acting than if the same medication were given by injection. A medication given by injection bypasses the gastrointestinal tract. The fastest effect for medication occurs via the IV route, because the medication is injected directly into circulating blood.
- Dissolvability of the medication: how fast an oral medication dissolves depends on its form or preparation, as a liquid form will be more readily absorbed than in a tablet or capsule form (Brotto 2013). If the tablet is enteric-coated, it will be prevented from breaking down in the stomach, therefore delaying absorption of the medication until it reaches the intestine (Brotto 2013).
- Food: can delay the passage and therefore absorption of some medications. These medications may need to be administered on an empty stomach or after meals (Broyles et al 2013). Some IM or subcutaneous are suspended in an oily substance or fluid which provides a sustained release of the medication from the site of injection (Broyles et al 2013).
- Degree of blood flow to the area: a medication will be absorbed more rapidly from a highly vascular area (as with IM injections) and less rapidly from poorly vascularised areas (such as fat in subcutaneous injections). In addition, heat or massage can increase the absorption rates of the medication in IM and subcutaneous injections (Broyles et al 2013).
- Solubility of the medication: to be effectively absorbed across the cell membrane, a medication should be lipophilic (fat loving). Acidic medications are readily absorbed in the stomach, while alkaline medications are better absorbed in the intestine. However, because most medications pass rapidly through the stomach, absorption mainly takes place in the intestine (Broyles et al 2013).
- Body surface area: the larger the body surface area the faster the medication will be absorbed. The small intestine has a larger surface area than the stomach and therefore medications will be absorbed at a faster rate (Brotto 2013). Gastric motility plays a large role in the rate of medication absorption; for example, medications can affect motility by increasing (metoclopramide) or decreasing (codeine) the speed of motility and therefore affecting the absorption time of other medications (Rang et al 2012).

## First-pass metabolism

Enteral medications are absorbed from the gastrointestinal tract, enter the hepatic portal system where they reach the liver and either pass through unchanged (in parent form) or are metabolised (Bryant & Knights 2014). During this hepatic **first-pass metabolism**, **biotransformation** occurs where liver enzymes break down the medication, resulting in reduced amounts of the medication entering the systemic circulation (Rang et al 2012). Biotransformation occurs primarily in the liver; however, the lungs, kidneys, blood and small intestine also play a role in metabolising some medications (Brotto 2013). Bioavailability is the percentage of the unchanged medication that reaches the systemic circulation for distribution (Rang et al 2012). Medication delivered via the IV route has 100% bioavailability as it is delivered directly into the blood stream because it bypasses first-pass metabolism. Some medications are better given via the parenteral route as they are almost entirely metabolised by digestive system if given orally. An example of this is glyceryl trinitrate (Anginine), which is used to treat angina pectoris. If given

orally, it is ineffective as it is destroyed by the hepatic first-pass metabolism. Given sublingually, the medication is absorbed through the oral mucous membranes into the blood stream and is able to reach the target organs to exert its therapeutic effect (Rang et al 2012). First-pass metabolism is also the reason why oral doses and parenteral doses are not equal—giving medications via the parenteral route means that smaller doses can be given to achieve the same therapeutic effect.

## Distribution

After the medication has been absorbed into the systemic circulation, it will then be distributed to specific tissues for medication action to occur. The chemical and physical properties of the medication affect the **distribution** rate and delivery of the medication as well as the physical makeup of the individual consuming the medication (Brotto 2013). The blood plasma contains a variety of plasma proteins (e.g. albumin, corticosteroid-binding globulin (CBG) and glycoproteins), which are able to bind to medications to produce a medication–protein complex. Medication molecules are transported in blood either bound to these proteins or freely in the plasma. Molecules that become **protein bound** (i.e. bind loosely to blood proteins) cannot elicit a pharmacological effect; however, there is always some unbound (or free) medication that is available to bind with receptors to exert an effect (Broyles et al 2013). Equilibrium exists between the bound and unbound medication and when the unbound plasma levels of the medication diminish the bound medication is able to be released from the plasma protein and become available to bind with target tissues (Broyles et al 2013).

If an individual has a condition which causes decreased levels of plasma proteins (e.g. liver disease, malnutrition or extensive burns) a greater portion of the medication remains unbound and is available to bind to the tissue, increasing the effects of the medication and therefore requiring a decrease in the dose. Conversely, if there is an increased level of plasma proteins (e.g. in a individual who has multiple myeloma) this will cause more of the medication to be bound, reducing the availability of the medication to bind with receptors. This will decrease the medication's effectiveness, and therefore requires an increase in dose to exert the required effect.

Medications may also compete for the same binding site on the plasma protein when more than one medication is administered concurrently. The medication with the higher affinity (or greater attraction) will be bound and displace the other(s) from the protein-binding site, resulting in an increase in the plasma concentration of the now unbound medication (Broyles et al 2013). For example, aspirin will displace warfarin (an anticoagulant) from the plasma protein, resulting in increased levels of unbound warfarin and potentially increasing the risk of haemorrhage (Broyles et al 2013). The effect is the same as giving an increased dose of the medication.

The blood–brain barrier of the CNS is generally very selective and allows only fat-soluble medications to pass through it (Brotto 2013). However, some conditions alter the permeability of the blood–brain barrier (e.g. meningitis renders the blood–brain barrier permeable to penicillin, which it would otherwise be unable to pass through). The placental barrier is not as effective as the blood brain–barrier, and many fat soluble and non-fat soluble medications are able to cross the placenta to the fetus, potentially causing significant damage, including congenital malformations (Brotto 2013). Unless absolutely necessary, medications should not be taken during pregnancy and especially not during the first trimester, when organ development in the fetus occurs.

## Metabolism

**Drug metabolism** is the process of chemical modification of a drug and is usually carried out by enzymes. For most drugs metabolism results in the formation of a more hydrophilic (water-loving) compound or metabolite so that it can be readily excreted from the body via the kidneys (Bryant & Knights 2014). **Biotransformation** is the process of detoxification, degradation and removal of biologically active chemicals by enzymes (Brotto 2013). This is important in inactivating medication before it accumulates and produces a toxic effect (Broyles et al 2013). These enzymes are primarily produced by the liver; however, some are also found in plasma, lungs, kidneys and intestines in smaller amounts than produced by the liver (Brotto 2013). In some circumstances the amount of enzymes produced can alter, thereby also altering the rate of metabolism. For example, alcohol stimulates production of hepatic enzymes in habitual drinkers, resulting in the alcohol being more rapidly metabolised than in a non-drinker (Broyles et al 2013). Alcohol can also cause the levels of other enzymes involved in medication metabolism to increase, leading to the rapid metabolism of the medication and therefore reducing the therapeutic effect (Broyles et al 2013). Some medications are known enzyme inhibitors and have the opposite effect, causing a decreased synthesis of enzymes, resulting in decreased metabolism and increasing the therapeutic effect. Medications such as cimetidine, erythromycin, allopurinol and metronidazole and foods such as grapefruit juice are enzyme inhibitors (Rang et al 2012).

## Excretion

After metabolism, medications and their metabolites are **excreted** from the body via the kidneys, lungs, exocrine glands (e.g. sweat, saliva, tears, breast milk), liver and/or intestine (Brotto 2013). The kidneys, however, are the main organs for medication excretion. Some medications are excreted in the urine unchanged and others have undergone the process of biotransformation before being excreted (Brotto 2013). If an individual's renal function is impaired, the individual is at risk of medication toxicity due to the medication failing to be excreted as required; this may occur more slowly in the very young and in older people (Bryant & Knights 2014).

The chemical composition of medications determines the organ(s) of excretion; for example, 100% of frusemide, 80% of digoxin and 50% of salbutamol are excreted in the urine. Gaseous compounds such as general anaesthetic agents are expelled via the lungs (Brotto 2013). Alcohol is also partially excreted via the lungs and this is the basis of the police

random breath test to detect drink-drivers. Some medications (e.g. penicillin) are excreted unchanged in the urine, while others must undergo biotransformation in the liver before being excreted by the kidneys. Many medications enter the hepatic circulation to be broken down by the liver, excreted in bile and then into the intestines to be excreted in faeces (Brotto 2013). The liver has a large metabolic capacity so, in people with liver disease, medication elimination is generally not affected until a large portion of the liver's functional capacity is lost. Many medications can enter the mammary glands and be excreted in breast milk, increasing the risk of infants ingesting the excreted medication (Bryant & Knights 2014).

## Importance of therapeutic medication monitoring

Monitoring for a medication's therapeutic effect can be done by observing or measuring the individual for clinical signs and symptoms, including expected outcomes (antihypertensives lowering blood pressure) and ADRs, as well as taking blood samples to ascertain the medication levels in the body (Bryant & Knights 2014). For medications to be therapeutic, certain blood levels need to be reached and maintained. It is therefore a priority that medications are administered on time. To maintain therapeutic levels of a medication the time interval between each medication dosing is important. The subsequent dose is determined by the medication **half-life**, which is the time taken for the medication concentration to be reduced by half from the time it was administered (Brotto 2013). If medications are administered late, the level of the medication in the blood may drop below a therapeutic level; for example, if the level of an antibiotic is too low, it provides an opportunity for microorganisms to multiply and also potentially develop resistance. If the blood levels are too high, toxicity and serious consequences might occur. This also provides the basis for adjusting medication dosages (Bryant & Knights 2014).

The main aim of **therapeutic medication monitoring** is to optimise medication therapy by achieving adequate medication levels while minimising toxicity. This is especially important in individuals at the extremes of age—infants and the older person. Clinical Interest Box 24.1 outlines some signs and symptoms of toxicity commonly seen in older individuals.

Clinical Interest Box 24.2 identifies changes related to ageing that influence pharmacokinetics.

Medication serum blood levels are measured to:

- Individualise the dose to the individual; for example, insulins and warfarin. Insulin, as a hypoglycaemic agent, lowers blood glucose levels and therefore the dose may vary depending on the person's blood glucose levels at the time of administration. Warfarin is an anticoagulant used to manage or prevent the formation of a thrombus (blood clot) and is varied depending on the serum International Normalisation Ratio (INR) result in maintaining the warfarin levels within the therapeutic range (Tiziani 2013). With each of these medications the optimal dose is highly individual, the effects need careful monitoring and the dose may need to be adjusted periodically
- Avoid toxicity; for example, digoxin and vancomycin. Digoxin is a medication that slows the heart rate and strengthens the force of contraction of the heart, increasing cardiac output. Therapeutic levels of digoxin

### CLINICAL INTEREST BOX 24.1 Indicators of medication toxicity in older adults

Skin
- Rashes
- Pruritus
- Urticaria
- Photosensitivity (e.g. abnormal responses to sunlight)

Gastrointestinal tract (GIT)
- Discomfort and pain (e.g. pancreatitis)
- Nausea and vomiting
- Blood in stools or vomitus
- Diarrhoea

Cardiovascular system
- Abnormalities in cardiac rhythm (e.g. palpitations, tachycardia)
- Hypotension or hypertension
- Congestive cardiac failure
- Depression of bone marrow activity (causing anaemia, leucopenia or other abnormalities of the blood)

Central nervous system
- Increasing confusion and irritability
- Alterations in gait (e.g. stumbling)
- Tremors
- Unusual drowsiness or insomnia
- Blurred vision or other vision abnormalities
- Slurred speech
- Ototoxicity (changes in hearing and balance)
- Intolerance to heat or cold (changes in temperature regulation)
- Anticholinergic effects (ranging from dry mouth and hot dry skin to serious mental impairment and seizures)

Renal system
- Electrolyte imbalance
- Urine retention
- Polyuria
- Fluid retention

Respiratory system
- Dyspnoea
- Asthmatic responses

Biliary system
- Jaundice
- Impaired liver function
- Clotting changes

*(Adapted from Touhy & Jett 2012)*

## CLINICAL INTEREST BOX 24.2 Age-related changes that influence pharmacokinetics and pharmacodynamics

Many age-related changes to the body have an impact on the way that a medication may be absorbed, distributed, metabolised and excreted from the body (Broyles et al 2013). Because of these differences, all medication therapy should be given cautiously and monitored carefully in the older individual. Age-related changes that may affect the pharmacokinetics of a medication include:

- Altered nutritional habits and ingestion of non-prescription medications that may alter medication absorption (e.g. ingestion of antacids and laxatives)
- Dry mouth and decreased saliva leading to potential difficulty swallowing oral medications
- Changes in the quantity and quality of digestive enzymes
- Increase in gastric pH
- Decrease in gastric motility
- Decrease in intestinal blood flow
- Delayed gastric emptying
- Decreases in total body water and lean body mass and increase in body fat, which may all lead to an altered distribution of the medication, as well as potential decrease in absorption of transdermal or topical medications
- Decreased levels of plasma proteins and therefore decreased protein binding of medications if malnutrition or acute illness is present
- Changes in liver mass and blood flow leading to reduction in the Phase I metabolism in the liver, involving the microsomal enzymes
- Alteration in bioavailability of medications (e.g. some medications undergoing extensive first-pass metabolism may have significant increase in availability while others may be reduced or decreased, such as ACE inhibitors available as promedications)
- Reduction of the liver's ability to recover from injury such as hepatitis
- Hepatic function may also be affected by severe nutritional deficiencies
- Decreased cardiac output and reserve
- Decreased blood flow to liver and kidneys
- Congestive cardiac failure reduces both the capacity of the liver to metabolise medications as well as the hepatic flow
- Creatinine clearance decreases with age, resulting in a longer half-life of many medications and the subsequent risk of accumulation
- Decreased renal excretion
- Changes in response to medications related to changes in medication concentration (related to above factors)
- Risk of medication interactions is increased
- Decrease in ability to read label correctly

*(Broyles et al 2013; Bryant & Knights 2014; Rang et al 2012)*

are within a very narrow range and can easily reach toxic levels (Bryant & Knights 2014). Blood tests are performed to measure digoxin levels to indicate toxic levels. Symptoms that may indicate toxicity include slow or irregular heartbeat, anorexia, nausea, vomiting, diarrhoea, drowsiness and extreme tiredness, weakness, confusion, abdominal pain, blurred vision or visual disturbances (Tiziani 2013). Vancomycin is a powerful antibiotic reserved for the treatment of severe infections that are not responding to other antibiotics. This medication can produce severe adverse effects that include rash, itching, fever, tachycardia, nausea, vomiting, diarrhoea and, sometimes, hearing loss or kidney damage (Tiziani 2013). Blood levels are taken immediately before the third dose to ensure therapeutic levels are achieved and the dose is adjusted accordingly. If treatment is ongoing serum trough levels need to be repeated as per the hospital protocol
- Ensure therapeutic blood levels are maintained; for example, prophylactic anticonvulsants (antiepileptics) such as phenytoin, sodium valproate and carbamazepine used to manage epileptic (convulsive) seizures
- Check individual compliance/concordance/adherence
- Ensure comorbidities have not altered medication metabolism and excretion as they may have an adverse effect on therapeutic blood levels; for example, renal impairment, hepatic failure, shock, sepsis
- Ensure that concurrent medication administration is not affecting therapeutic levels
- Indicate a need for change of route of administration; for example, from IV or IM to oral administration or change of dosage; to increase, decrease or cease a medication.

# PHARMACODYNAMICS

Pharmacodynamics relates to how a medication acts on the body, including the strength and duration of its effects. Medication actions are similar in all individuals that take the same medication; however, factors such as tachyphylaxis, desensitisation and tolerance can affect the medication action responses (Bryant & Knights 2014). *Tachyphylaxis* and *desensitisation* occur when there is a sudden decrease (over minutes) in the effect of the medication (Rang et al 2012). *Tolerance* occurs when the individual develops a gradual reduction (over weeks and months) in the responsiveness to the medication, rendering the dose inadequate (Bryant & Knights 2014).

## Medication action

The extent of the response to a **medication** depends on its concentration at the site of **action**, and the affinity the medication has with the receptors, which then exert its response (Bryant & Knights 2014). This is linked to the medication dose and the pharmacokinetic processes of absorption, distribution, metabolism and excretion. Other factors that may

influence a person's response to a medication include their age, weight, gender, disease state and route of administration. However, more than any other factor, the route of administration determines the onset of medication effect. Medications that are administered directly into the bloodstream provoke a rapid response, whereas medications administered orally or topically must be absorbed into the bloodstream before they can take effect. Medications act by affecting or controlling changes in biochemical or physiological processes in the body.

Medications produce their actions in one of three ways: altering body fluids, altering cell membranes or interacting with receptor sites. Most medications act at specific cell receptor sites. When a medication binds with a receptor the action is either agonistic (causing an action) or antagonistic (blocking an action) (Bryant & Knights 2014). An agonist will increase or decrease an action on the receptor site similar to the endogenous ligand (the body's own neurotransmitter or hormone), which normally binds with those receptors. An antagonist takes up the receptor sites blocking the endogenous ligand from binding to the receptor sites, therefore blocking or decreasing the cells' response (Bryant & Knights 2014). A specific medication forms a complex with one type of receptor but may in turn produce multiple effects, because those receptor types may be found in other cells of different tissues or organs.

An agonist (medication) binds with cells receptor sites until they become saturated, producing a response. This is termed *maximal efficacy* and increasing the concentration of the medication dose does not increase the response; however, it may increase the risk of side effects (Rang et al 2012). This is why medication potency (dose of medication required to bind to receptors, eliciting the therapeutic effect) needs to be determined, without causing unwanted side effects. When an antagonist binds with receptor sites it blocks the binding of the endogenous agonist, therefore there is no efficacy (Rang et al 2012).

Medication action is either classified as selective or non-selective. Selective medications bind with their target sites producing the intended effects. A 'selective' medication has a preference for a particular receptor and will have little influence at similar receptor sites in other organs (Bryant & Knights 2014). For example, if a selective beta-blocker was chosen, such as metoprolol tartrate, then the beta-1 cells in the myocardium would be targeted, resulting in a lesser effect on the beta-adrenergic receptors in the lungs, decreasing the likelihood of unwanted side effects compared to the non-selective medication.

Non-selective medication will affect tissues or organs for which the effect is unintended (Bryant & Knights 2014). For example, both the heart and lungs have beta-1 and beta-2 adrenergic receptors. For example, sotolol is a non-selective beta-blocker medication (antagonist) which has the intended action of reducing heart rate by blocking the beta-1 cells in the myocardium. This medication will also affect the beta-2 adrenergic receptors in the lungs, causing bronchoconstriction, and the person taking sotolol may develop an unwanted side effect (cough) due to the non-selective characteristics of the medication.

A medication may produce more than one effect:

- The physiological response occurs to the medication, which exerts the expected therapeutic effect.
- **Adverse effects** (also called adverse drug reactions (ADRs)) are undesirable secondary effects, which may be expected (constipation with codeine) or unexpected (cough with beta-blocker). These effects may also be called *side effects* by consumers. ADRs will indicate to the medical officer that treatment may need to be modified or ceased (Brotto 2013). If a patient is having oxycodone for pain and is experiencing nausea, metoclopramide (antiemetic medication) may also need to be prescribed.
- Toxic effects develop after prolonged administration of high doses of medication, or when a medication accumulates in the blood because of impaired metabolism or excretion. Some medications such as digoxin and lithium have a very narrow safety margin and toxicity can occur at recommended or therapeutic doses (Brotto 2013).
- **Allergic reactions** are unpredictable responses to a medication that the body sees as foreign. This stimulates the body to produce antibodies or immunoglobulins that then bind to the antigen (medication) upon a second exposure, triggering an allergic response (Bryant & Knights 2014). Allergic reactions may be mild, such as urticaria (hives) and pruritus (itching), or they may be severe; for example, severe wheezing and respiratory distress, or life-threatening anaphylactic reaction. Some reactions occur within minutes of the medication being given while other allergic reactions may be delayed for hours or days (Brotto 2013).
- Idiosyncratic reactions are those where the individual's body either overreacts or underreacts to a medication, or when the reaction is unusual and there is no known cause (e.g. the antihistamine promethazine (Phenergan) is sometimes used for sedation; however, in some individuals it can cause insomnia and agitation (Brotto 2013)).
- Pharmacogenetic reactions occur because a person may have a genetic trait, which leads to abnormal reactions to medications. For example, malignant hyperthermia is a genetic autosomal disorder which is triggered when general anaesthetics and muscle relaxants are administered, causing a hypermetabolic state to develop that can quickly lead to death. As a result all individuals who undergo a general anaesthesia have their temperatures monitored (Bryant & Knights 2014).
- Medication tolerance may also occur where a person has a decreased response or resistance to a medication over time, necessitating an increase in dosage to achieve the required response (Broyles et al 2013) (e.g. tolerance to glyceryl trinitrate patches if nitrate-free periods are not adhered to).

- Medication-to-medication interactions occur when one medication changes the action of another medication, by either increasing or decreasing its action (Bryant & Knights 2014). A medication interaction may be synergistic (enhances the effects of another medication), antagonistic (opposes the effects of another medication) or additive (where the two medication actions are added together enhancing the effect) (Brotto 2013).

## SAFETY AND LEGAL REQUIREMENTS IN MEDICATION ADMINISTRATION

The National Safety and Quality Health Service (NSQHS) Standards were developed by the Australian Commission on Safety and Quality in Health Care (ACSQHC) to ensure relevant systems are in place to improve the quality of healthcare practices and to protect the public from harm.

Medicines are the most common healthcare treatment that individuals receive, and as a consequence there is a higher incidence of errors and ADRs than with any other health procedure (ACSQHC 2012b; 2015a). The outcomes of these errors and ADRs add a huge cost to the healthcare system, and are largely avoidable (ACSQHC 2012b). **Medication safety** is one of the NSQHS Standards (2012b) and 'describes the systems and strategies to ensure clinicians safely prescribe, dispense and administer appropriate medicines to informed patients' (p. 3). The Standard outlines the standardised and systematic processes to be implemented to prevent common errors occurring and includes improving communication between clinicians and the workforce and patients; utilising technology for recording and transferring information; and improving accessibility of patient data and support for clinical decision making at the point of care.

A range of paper and electronic National Inpatient Medication Charts (NIMC) were introduced in 2006 for all acute facilities, public and private, across Australia with the aim of addressing the ongoing prescription errors in medication charting (Atik 2013) and subsequent administration errors. This was to ensure safe use of medicines; as healthcare professionals moved employment the medication prescribing stayed the same.

The nurse's role in medication administration is a complex one and must take into consideration the NSQHS Standards, organisational policy and procedure guidelines and scope of practice. These practices promote safe and correct medication administration. Accountability and responsibility are paramount in administering medications and the nurse requires knowledge about all medications being administered, including:

- Generic names and classifications
- Indications for use
- Rationale for prescribed medication
- Medication action
- Desired therapeutic effects and possible adverse reactions
- Normal dosage range
- Correct routes of administration
- Seven rights of medication administration
- Safe handling and storage
- Legislation and healthcare facility policies and procedure guidelines.

The nurse also requires certain skills to:

- Administer medications by the various routes
- Calculate the correct amount of medication to administer
- Evaluate the effects of medications
- Educate individuals about medication therapy
- Teach self-administration
- Record the medications administered and the individual's response.

### Legal aspects of medication administration

Registered and Enrolled Nurses are authorised to administer medications under the *Health Practitioner Regulation National Law Act 2009* as well as relevant regulations and legislation in each state and territory. ENs must work under the direction and supervision of the Registered Nurse (RN). In some states and territories unregulated healthcare workers in RACF may administer medications as guided by their training; however, they must administer medications as set down in the legislation and standards (Department of Health and Ageing 2012). Before a medication can be administered safely, the nurse needs to be aware of the legal aspects of medication administration. This includes knowledge of the laws governing the possession, use and dispensation of medications and the guidelines set down by the Nursing and Midwifery Board of Australia (NMBA) and Australian Nursing and Midwifery Advisory Council (ANMAC) on the administration of medications to individuals. It also means observing the employing healthcare facility's work health and safety (WHS) regulations which are designed to promote safe storage, handling and use of medications.

### Nursing competency

The NMBA is one of the national boards of the Australian Health Practitioner Regulation Agency (AHPRA). In 2009 AHPRA made changes to the registration of nurses and as the EN study programs now have a compulsory medication administration competency, the medication endorsement is no longer added to their registration. In order to protect the public, the NMBA has stipulated that ENs must hold a Board-approved competency (accredited by ANMAC) to be able to safely administer medication. Those ENs who have not completed the required competency units to deliver medications will have a notation reading 'Does not hold Board-approved qualifications in administration of medicines' against the individual nurse's name on the register (NMBA 2015). Jurisdictional legislation and policy specifies the routes and schedules of medicines that the Enrolled Nurse (EN) is able to administer and it is therefore of paramount importance that the nurse and employer understand and comply with the medications and poisons legislation and policy.

Furthermore, to administer intravenous medication, the nurse is required to have completed a separate NMBA-approved unit on the administration and monitoring of intravenous medications (NMBA 2015).

Legal Acts concerning drugs and poisons and the subsequent regulatory bodies in each state and territory in Australia deal with the control of all medications, from prescription medication through to agricultural poisons and research medications. The laws and **Regulations** apply to sale, supply, storage, dispensing and labelling. The medications and **poisons schedules** divide medications into groups according to their mode of action, therapeutic use, potency, potential for abuse and addiction and safety. While there is currently no national medicines and poisons schedule in Australia, the recommendations of two expert advisory committees (Advisory Committee on Medicines Scheduling and Advisory Committee on Chemical Scheduling) in the form of the Poisons Standard 2014 (*Standard for the Uniform Scheduling of Medicines and Poisons* (SUSMP 6)) (Table 24.2) are incorporated into the legislation and regulations of each state and territory in Australia (Australian Government, TGA 2015). Aims of this document include promoting uniform scheduling, labelling and controls on availability and use of medicines throughout Australia (Australian Government, TGA 2015). SUSMP applies to all medicines and poisons in Australia.

## Safe administration of medications

Before administering medications in any form or by any route the nurse must check that the individual does not have any medication allergies. The nurse also observes the individual who is starting a new medication for any signs of allergy or adverse reaction, and reports and records such responses promptly to the medical officer and the nurse in charge. If the situation arises that an individual chooses not to take a prescribed medication, this must also be reported and recorded on the individual's medication chart. The principles of asepsis (see Chapter 22) are employed during the preparation and administration of all medications.

To ensure that medications are administered correctly and safely, the nurse must observe the seven rights of medication administration (Brotto 2013).

1. The right medication
2. The right dose
3. The right person
4. The right route
5. The right time
6. The right reason
7. The right documentation.

Before any medication is administered the individual medication chart (Figure 24.4) must be checked thoroughly and systematically to determine the accuracy of the identity of the individual receiving the medication, the name of the medication, the dosage, the route and the date and time for administration of the medication prescribed.

1. **The right medication:** the nurse compares the label of the medication container with the individual medication chart three times:
   1. Before removing the container from the trolley or cupboard
   2. Before removing the medication from the container
   3. Before returning the container to the trolley or cupboard (Brotto 2013).

   Medication sleeves in the prescribed medication box must be removed from the packaging and the medication sleeve checked for the right medication, as potentially wrong sleeves may have been placed in the medication box.
2. **The right dose:** medications are written in SI unit form. Medication calculations and conversions need to be calculated accurately to ensure the individual obtains the correct dose (Brotto 2013). The correct measuring devices such as cups, spoons, syringes or droppers assist in giving the precise ordered dosage (Broyles et al 2013).
3. **The right person:** to identify a person correctly, before a medication is administered, the nurse:
   - Checks the person's ID label on the medication chart against the person's identity bracelet
   - Asks the person to state their full name and date of birth.

   Special care should be taken when identity bracelets are not worn (e.g. in residential care settings) or where the individual is unable to state their own name, because of dementia or mental disturbance, for example. One safety measure that has been implemented in some aged care residential settings is to have a current photograph of each resident that can help with identification.
4. **The right route:** the route is indicated by the prescriber on the medication chart. The nurse administering the medication must assess if this route is suitable for the individual receiving the medication, and if not should consult with the prescriber (Brotto 2013).
5. **The right time:** medications have different administration time periods. Medications may be administered BD (twice a day), TDS (three times a day), QID (four times a day), mane (morning), midday, nocte (night), before food, after food, with food, stat (immediately and once only), PRN (when required) or on an hourly or day basis (e.g. 6 hourly; every 2nd day). When administering medications at any of the times ordered the nurse must be aware of normal medication intervals and any medication to medication interactions so these can be rescheduled and avoided. The nurse must prioritise her daily workload to ensure medications are given at the correct time.
6. **The right reason:** the nurse must understand the rationale for the prescribed medication and what the expected outcomes should be (Broyles et al 2013). The principles of the QUM and whether the individual requires the prescribed medication must also be taken into consideration (Brotto 2013). For example, if an individual who has been admitted for dizziness and hypotension normally takes an antihypotensive, the need for the medication at this point in time must be reviewed.

## TABLE 24.2 | Standard for the Uniform Scheduling of Medicines and Poisons (SUSMP)

| Schedule | Label | Description | Examples |
|---|---|---|---|
| **Unscheduled substances** | | | |
| | — | Unscheduled substances are those not requiring control by scheduling. They are not considered to be poisons. It is important to note that many therapeutic preparations are unscheduled substances and may be purchased in supermarkets and health food stores | Most antacids, laxatives, contact lens products, infant formulas, vitamins, sunscreens, topical antiseptics and many herbal remedies |
| Schedule 1 Poisons | — | This schedule is not currently used. It was formerly used for substances requiring proof of age, identity and the signature of the purchaser. It has been suggested that some complementary and alternative medicines be moved into this Schedule so that they can be subject to control | |
| **Pharmaceutical substances** | | | |
| Schedule 2 Poisons (or Medicinal/ Therapeutic Substances/Poisons/ Products) | Pharmacy medicine | Available to the public only from pharmacies or, where a pharmacy service is unavailable, from persons licensed to sell Schedule 2 poisons. A pharmacist's advice is available if required | Most cough and cold preparations, some antihistamines, mild analgesics, worm tablets, antiangina sprays, anti-inflammatory agents, topical antifungals, histamine $H_2$-receptor antagonists for gastro-oesophageal reflux (small packets) and decongestant eye drops |
| Schedule 3 Poisons (or Medicinal/ Therapeutic/Potent Substances/Poisons/ Products) | Pharmacy only medicine | Only available to the public from a pharmacist or from medical, dental or veterinary practitioners, but without need for a prescription. The safe use of these substances requires professional advice. The storage must not be accessible to the public | Metered-dose bronchodilator asthma aerosols, topical corticosteroids (low-strength preparations, small packs), adrenaline injections (high strength, for anaphylaxis) |
| Schedule 4 Poisons (or Restricted/ Therapeutic Medications/ Substances/Poisons/ Products) | Prescription only medicine or Prescription animal ready | May be used or supplied only under prescription from a medical, dental or veterinary practitioner. Must be stored in a dispensary. In some Australian states and territories, specially qualified nurses (nurse practitioners), optometrists and podiatrists may prescribe a limited range of Schedule 4 medications | Many medications: all new medications, antibiotics, insulins, antidepressants, hormones (including contraceptives), most cardiovascular and central nervous system medications, antineoplastic agents, vaccines, anti-glaucoma eye drops and most injections |
| **Agricultural, domestic and industrial substances** | | | |
| Schedule 5 Poisons (or Domestic/ Household Type Poisons or Hazardous Substances, or Industrial/Agricultural/ Veterinary Products) | Caution | Substances with a low potential for causing harm, which can be minimised by the use of appropriate packaging with simple warnings and safety directions on the label. For sale by a pharmacist, Poisons licence holder or general dealer. Must not be stored or supplied in a drink or food container | Household poisons, ether, naphthalene, petrol, some head lice preparations and borax |

## TABLE 24.2 | Standard for the Uniform Scheduling of Medicines and Poisons (SUSMP)—cont'd

| Schedule | Label | Description | Examples |
|---|---|---|---|
| **Agricultural, domestic and industrial substances** | | | |
| Schedule 6 Poisons (or Domestic/ Industrial/Agricultural and Veterinary Poisons) | Caution or poison (depending whether for internal or external use) | More dangerous chemicals than Schedule 5, with a moderate potential for causing harm. Extra storage and packaging controls and warning labels are required | Household and garden pesticides and solvents, some iodine preparations |
| Schedule 7 Poisons (or Dangerous Agricultural/Industrial Poisons) | Dangerous poison | Substances with a high potential for causing harm at low exposure and which require special precautions during manufacturing, handling, storage or use. A permit is required to buy these chemicals and the purchaser must be over 18 years of age. These poisons should be available only to specialised or authorised users who have the skills necessary to handle them safely. Special Regulations restricting their availability, possession, storage or use may apply | Arsenic, strychnine, cyanide and commercial pesticides |
| **Controlled medications and prohibited substances** | | | |
| Schedule 8 Poisons (or Medications of Addiction/ Dependence or Controlled Medications or Narcotic Substances) | Controlled medication | Substances that may produce addiction or dependence. Possession without authority is illegal. The tightest controls are used to reduce abuse, misuse and dependence. Prescriptions are only valid for 3 months. Medications must be stored in a locked cabinet and records kept for 3 years | Opioids (e.g. morphine, methadone, high-dose codeine) and CNS stimulants (e.g. dexamphetamine) |
| Schedule 9 Poisons | Prohibited substances | Substances for which the manufacture, possession, sale or use is prohibited except in special circumstances. Medications that may be abused or misused and medications possibly required for teaching, research or analytical purposes, but which are too toxic for therapeutic use | Heroin and most recreational medications (except alcohol and tobacco) |
| Schedule 10 APPENDIX C | Substances of such danger to health as to warrant prohibition of sale, supply and use | A list of substances or preparations, the sale, supply or use of which should be prohibited because of their known dangerous properties. | e.g. Coal Tar, Formaldehyde, hydrogen peroxide, lead compounds |

*(Based on content from Australian Government, Department of Health and Ageing, Therapeutic Goods Administration (2015).* Poisons Standard *from the Federal Register of Legislation at 08/04/16. For the latest information on Australian Government law please go to https://www.legislation.gov.au)*

## PROGRESS NOTE EXAMPLE 24.1

| | |
|---|---|
| 30/04/2015<br>2100 hours | Nursing: Mr George was admitted to the medical ward at 1630 hrs for observation and medication management. Mr George presented to the casualty department with his wife at 0940 this morning after experiencing central chest pain radiating into his jaw. Pain was described as 7/10. ECG and bloods attended. Chest pain resolved with 3 × 600 micrograms of Anginine subling. ECG showed ischaemia, which resolved when he became pain free. Troponin was negative and other bloods NAD. Mr George was pain free on arrival to the ward and no further chest pain this shift. Admission and discharge plan completed. Mr George has a past history of hypertension, osteoarthritis in his lower back and hyperlipidaemia. Vital signs T 36.7°C, RR 18, HR 42 and BP 95/57. Reviewed by medical officer who withheld the evening dose of metoprolol. To be reviewed prior to morning dose. Urinalysis NAD. Referral to cardiac nurse completed. Education commenced for Unstable Angina and education information pack given. Subcut enoxaparin and oral medications given as per order. For fasting bloods in the morning LFTs, FBE, U&Es, & Troponin. Referral for angiogram is being organised by senior medical officer, awaiting call back from angiogram clinic.<br>***H. Redmond*** **(Redmond) EN** |

7. **The right documentation:** the medication chart must be completed accurately by the prescriber, and it is the nurse's responsibility to check the chart for errors and report to the prescriber before administering the medication. The ACSQHC (2011) released a document in 2006 outlining nationally accepted terminology, abbreviations and symbols that are to be used in Australian hospitals in the documentation process in prescribing and administering medicines. The nurse must document accurately and in a timely manner the date and time of medication administration. If missed it may be determined the person has not been given their dosage and there is a risk of a medication error with a second dose being given. If for any reason the medication is not given, this needs to be recorded on the medication chart with the appropriate symbol as indicated on the NIMC and then recorded in the progress notes. The medical officer will also need to be informed to complete a review. See Progress Note Example 24.1.

Most medication errors occur when a nurse fails to follow the recommended safety guidelines, or when the nurse is distracted while preparing or administering medications. The most frequent type of medication errors reported are omission or overdose (particularly analgesics or anticoagulants), which typically occur at the morning and evening medication administration times (Roughead & Semple 2008). To prevent medication administration errors the nurse must:

- Be proficient with the seven rights
- Ensure the accuracy of the prescribed medication order
- Check the date and time to be given
- Read medication labels carefully
- Be aware that many medications have similar names
- Check the expiry date on the medication label
- Check the decimal point on prescriptions and medication container labels
- Not administer a medication if the prescription or medication label is illegible (or if the nurse has any doubt at all about the order)
- Be proficient in calculating medication dosages using correct formulas
- Use administration equipment (e.g. a medicine glass or syringe) with distinct markings
- Not administer any medication prepared by another person; the nurse preparing the medication must be the nurse administering the medication
- Not prepare medications in advance of the prescribed time for administration
- Not prepare more than one person's medication at the same time (e.g. DDAs)
- Not leave prepared medications (e.g. a loaded syringe, transdermal patch or oral medication in a medicine cup) unattended in the medication room, on the medication trolley or at the person's bedside and, most importantly,
- Give full attention to the task.

### CRITICAL THINKING EXERCISE 24.3

You are working in a residential aged care facility. The shift is very busy and the RN you are working with has asked you to check some DDAs for patients requiring oxycodone. When you arrive at the DDA cupboard she tells you that she will also take out another resident's DDA, MS Contin, to save time due to the shift being busy.

What safety issues may arise from checking out two DDA medications at the same time? What is your response?

## Errors in administration

Errors in medication administration occur from failure to follow correct processes in prescribing, dispensing and administration. Information to prevent errors in administration is provided throughout this chapter and focuses on the NSQHS standards and ACSQHC recommendations discussed previously, and is also listed in Clinical Interest Box 24.3. Each healthcare facility has its own protocol for monitoring and

## CLINICAL INTEREST BOX 24.3 Safe medication management guidelines

- All medications must be kept in a locked cupboard or medication trolley, the key of which is kept by an RN at all times. Some preparations (e.g. suppositories, vaccines, thyroxine and insulin) require refrigeration and are stored in a lockable refrigerator. Nothing else should be stored in this refrigerator. Medications or preparations for external use are stored apart from those intended for internal use.
- Medications of addiction (e.g. Schedule 8 or other medications of addiction such as benzodiazepines or panadeine forte) are kept in a separate locked cupboard that is firmly fixed to a wall or floor, within a locked room. The key is kept in the possession of an RN at all times.
- A register must be maintained of all medications of addiction, and the records must contain full details of all receipt of medications and all disposal of medications, whether by administration to a individual, return to the pharmacy department or discarded by any other means. The nurse who administers the medication and the nurse who checks the medication both sign their names in the register.
- Healthcare facilities implement a protocol that conforms to the relevant state or territory Regulations whereby certain medications (usually medications of addiction such as morphine) are checked at the change of shift (e.g. every 8 hours). Two nurses, one of whom should be an RN who has worked the current shift, and one RN from the following shift count the medications together and document their findings in a register. The number of medications in the containers is compared with the number of medications already recorded in the register. Both nurses sign the register to indicate that the count is correct. If the count is not correct, the healthcare facility protocol should be followed.
- Medications of addiction and restricted substances can only be supplied by the pharmacist with a written order by a medical officer or dentist.
- A qualified pharmacist has complete responsibility for all containers issued from the pharmacy department. No one else is permitted to supply a medication, label a container, alter the wording on a label or transfer the contents of one container to another.
- There should be a written medical officer's order for all medications administered to individuals. Verbal orders, including telephone orders, are open to misinterpretation. A written prescription must contain the date of prescribing, the individual's full name, the name and dosage of the medication, the route of administration, the frequency of administration and the signature of the medical officer who is writing the prescription. If the nurse has any doubt about the meaning of an order, the medical officer must be contacted immediately for clarification (before the medication is administered).
- The nurse administering the medication must check the accuracy of the medication order prior to administration and if there are any discrepancies then the order needs to be reviewed by the original prescriber.
- An RN must check every dose of medication to be administered by an undergraduate student nurse. Nursing regulations dictate that an RN must accompany student nurses during administration of a medication. Any medication that requires the process of double checking with another RN must also be done when a student nurse is administering the medication.
- A nurse should administer only a medication that has been prepared personally; for example, the nurse should not administer any medication that has been prepared by someone else and not witnessed personally (Brotto 2013).
- The nurse who administers a medication to be taken orally must remain with the individual until the medication has been swallowed.
- If the nurse is checking a medication that is to be administered by another nurse (e.g. a medication of addiction or intravenous antibiotic), in addition to the safety measures already stated, the checker must observe the dose being measured, reconstituted and drawn up, and then witness the medication being administered via any route (Brotto 2013).
- After administering any medication the nurse records it immediately on the appropriate medication chart. Prompt recording prevents errors. Details recorded on the individual's medication chart include the name of the medication, dosage, route and exact time of administration. The nurse who administers the medication must sign the record sheet (Broyles et al 2013).

recording medication errors, and the nurse must understand and adhere to that protocol.

If the nurse makes a medication error (e.g. administering the wrong medication or dose, or via the wrong route, or to the wrong individual) or identifies an error made by another nurse, the correct reporting processes must be followed, from reporting to the nurse in charge to documenting the incident. In medication administration the nurse accepts responsibility to ensure the individual's safety is maintained and that the individual is not harmed by the nurse's actions (Brotto 2013). The nurse has a professional and ethical responsibility for reporting any error, no matter how minor or trivial it may seem at the time (Brotto 2013). Measures to counteract the effects of the error may be necessary, such as administering an antidote (with a medical officer's order) or monitoring the medication's effects over time. The reporting process

provides an objective analysis of why the medication error occurred and is a means for the facility's quality assurance personnel to monitor such events and to implement measures to prevent recurrence. The medication error, measures taken and outcomes should also be recorded in the individual's medical notes (see Chapter 18 for information on nursing documentation).

### Medical abbreviations

When writing prescriptions, the medical officer frequently uses abbreviations that are derived from Latin. From 2008, standard prescribing terminology, abbreviations and symbols have been introduced in an attempt to reduce the number of associated errors. Abbreviations are also used when referring to strength of medications such as grams (g) and milligrams (mg). For example, the abbreviation for micrograms using the Greek letter μ (mu) (i.e μg) is not recommended, nor is mcg, as these may lead to errors; microg is the preferred and recommended abbreviation, or the whole word (microgram) should be written. Other error-prone abbreviations and symbols which should be avoided include IU (international units—can be mistaken for IV), IVI (intravenous injection—mistaken for IV 1) and qd (every day—mistaken as QID (four times daily). 6/24 can be interpreted as every 6 hours or 6 times in 24 hours; therefore 6 hourly should be written so there is no confusion (ACSQHC 2011).

## SYSTEMS OF MEASUREMENT

To promote accurate and safe administration of medications, the nurse must understand the system of weights and measures used in prescriptions and correctly calculate dosages (Brotto 2013). The metric system is the standard system used for measurement in all medication administrations. The metric system is based on the International System of Units (SI units) where decimals are used to write measurement for length, mass, time, temperature and amount of substance (Bryant & Knights 2014).

### SI units

Commonly used SI units in medication administration are mass (kilograms (kg)), volume (litres (L)), time (min) and amount molecules of a substance (mole (mol)). These basic units can be multiplied or divided by 1000 to form secondary units (Bryant & Knights 2014).

Measures of mass commonly used are:

- grams (g): 1000 g = 1 kg
- milligrams (mg): 1000 mg = 1 g
- micrograms (microg): 1000 microg = 1 mg.

Measures of volume commonly used are:

- millilitres (mL): 1000 mL = 1 L
- microlitres (microL) 1000 microL = 1 mL

Measures of amount of substance are:

- millimoles per litre 1000 mmol/L = 1 mol

The mole is the molecular weight of a substance expressed in grams (Bryant & Knights 2014). The strength of a pharmaceutical preparation used in electrolyte replacement therapy is normally expressed in millimoles per given volume of solution (e.g. mmol/L). Millimoles are also used to express the concentration of substances other than electrolytes and are used widely in laboratories; for example, in haematology reports (cholesterol 5.2 mmol/L).

It is important to note that units are not capitalised (e.g. kilogram, not Kilogram) except for litres (L); full stops should not be used in unit abbreviations (e.g. mL, not m.L or mL.); quantities less than 1 should have a zero to the left of the decimal point to avoid potential errors (e.g. 0.35 mg, not .35 mg) and abbreviations should not be plural (e.g. 100 mL, not 100 mLs). A trailing zero should not be added after the decimal point (e.g. 1.0 mg) as it may be mistaken as 10 mg if the decimal point is not seen (Bryant & Knights 2014).

### Medication calculations

Competence in calculating the required dose of prescribed medications is an important factor in preventing an administration error. The nurse must understand basic mathematical skills in order to be able to accurately calculate dosages, using the correct formulas based on the form of medication and route of administration, as well as mixing medications (Bryant & Knights 2014).

#### Conversions

Medications are not always supplied in the order of measure in which they are prescribed. Nurses are required to convert the available units of volume and weight to the ordered dosages. This is a systematic process. To convert an SI unit of mass the dose is divided or multiplied by 1000 to change to the next SI mass unit (see Figure 24.5). For example, to change milligrams to grams, divide the dose by 1000, which involves moving the decimal point three places to the left:

The medication ceftriaxone comes in 1.2 g and the order written is for 800 mg

$$1.2\text{ g} \times 1000 = 1200\text{ mg} \quad 1.2\text{ g} = 1200\text{ mg}$$

To convert litres to millilitres, multiply by 1000, or move the decimal point three places to the right:

$$0.6\text{ L} \times 1000 = 600\text{ mL} \quad 0.6\text{ L} = 600\text{ mL}$$

These converted SI can then be used to calculate the required medication dosage.

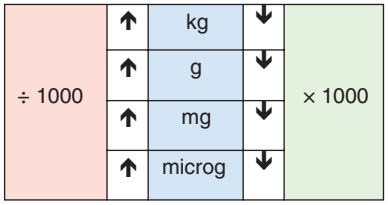

**Figure 24.5** Medication calculation conversion table for mass

## Calculating dosages

Although the introduction of unit doses and prepared solutions has meant that the need for nurses to undertake calculations has decreased, there are certain situations where the nurse will need to perform basic calculations for administration of medications, fluids and other pharmaceutical products. The calculation of dosages must be performed with total accuracy and therefore the nurse must be competent in dealing with decimals, fractions, percentages, ratios and proportions. If any doubt exists, it is important that the nurse double check all calculations with another health professional, such as another nurse, medical officer or pharmacist.

Formulae for calculating medication doses include:

### Liquid medications

$$\frac{\text{Stock required}}{\text{Stock strength}} \times \text{Volume} = \text{volume to be administered}$$

**Example**. A medical officer prescribes fentanyl 100 micrograms intramuscularly (IM). The medication in stock is available in ampoules containing 50 micrograms per mL.

$$\text{Dose required} = 100 \text{ micrograms}$$

$$\text{Stock strength} = 50 \text{ micrograms/mL}$$

$$\text{Volume in stock strength} = 1 \text{ mL}$$

$$\frac{100}{50} \times 1 = 2 \text{ mL} = \text{volume to be administered}$$

### Solid medications

$$\frac{\text{Stock required}}{\text{Stock strength}} = \text{amount to be administered}$$

**Example**. A medical officer prescribes morphine 15 mg orally. The medication in stock is available as tablets containing 30 mg.

$$\text{Dose required} = 15 \text{ mg}$$

$$\text{Stock strength} = 30 \text{ mg}$$

$$\frac{15 \text{ mg}}{30 \text{ mg}} = 0.5 \text{ tablet} = \text{amount to be administered}$$

### Medications measured in units

$$\frac{\text{Stock required}}{\text{Stock strength}} \times \text{Volume} = \text{volume to be administered}$$

**Example**. A medical officer prescribes insulin 10 units subcutaneous (subcut). The insulin is available in 100 units per mL. An insulin syringe must be used to administer all insulin, which is marked in units/mL

$$\text{Number of units required} = 10$$

$$\text{Number of units in stock solution} = 100$$

$$\text{Volume in stock strength} = 1 \text{ mL}$$

$$\frac{10 \text{ units}}{100 \text{ units}} \times 1 \text{ units/mL} = 0.1 \text{ unit}$$

## Calculation of paediatric dosages

Children do not always metabolise medications in the same way as adults, due to a greater body water content and immaturity of their liver and kidneys. In addition children's recommended dosages are not always standard (Broyles et al 2013). In most cases the prescriber will calculate the dose based on weight or weight and height (body surface area (BSA)) before ordering the medication. Clinical Interest Box 24.4 provides interventions to assist the nurse with administering medications to infants and children.

Dosages based on weight use kilograms of body weight per kilogram recommendations to arrive at the approximate and safe dose.

$$\frac{\text{mg/kg}}{\text{Stock Strength}} = \text{tablets to be administered}$$

or for liquids

$$\frac{\text{mg/kg}}{\text{Stock Strength}} \times \text{Vol} = \text{Volume to be administered}$$

**Example**. A medical officer prescribes benzylpenicillin sodium (penicillin G) to be given IV 6 hourly for a 6-year-old child who weighs 18 kg. The recommended dose of penicillin G is 60 mg/kg/dose every 6 hours.

$$\text{Dose required} = 60 \text{ mg/kg}$$

$$\text{Stock strength} = 1200 \text{ mg}$$

$$\text{Child's weight} = 18 \text{ kg}$$

$$\frac{60 \text{ mg} \times 18 \text{ kg}}{1200 \text{ mg}} \times 20 \text{ mL} = 18 \text{ mL} = \text{Vol to be administered}$$

The most accurate way of calculating paediatric dosages is based on BSA. The BSA is calculated using the child's height and weight and a nomogram (see Figure 24.6) and is an indicator of metabolic mass. It is used to calculate correct dosages for paediatric dosages and for cytotoxic medications. A nomogram is used to make the calculation easier. There are 3 columns to the nomogram: Height, Weight and the SA (surface Area). The individual's height is marked on the chart (first column) and then weight (third column) and a line is drawn between these two crossing over the SA (middle) column and the point at which it crosses the SA column is the BSA used in the calculation (Broyles et al 2013).

It should be noted that preparing medications for infants and children requires additional skills. Nurses caring for children are recommended to consult paediatric textbooks for more information. These provide general guidelines concerning administering medications to infants and children.

## CLINICAL INTEREST BOX 24.4 Interventions to assist the nurse with medication delivery for infants and children

For oral medications these interventions may assist the child in taking the oral medication:

- Where possible use liquid rather than tablet form as children find it difficult to swallow tablets
- Offer a pleasant-tasting drink or treat after medication is swallowed as this will remove the unpleasant after-taste and makes compliance/concordance/adherence more likely with next dose
- Mix medication with a tiny amount of pleasant-tasting substance, such as honey (unless contraindicated by pharmacist) to help persuade a reluctant child to take medication
- Avoid mixing the medication with food. If the child does not eat the food the whole dose will not be delivered. This will also prevent food aversion
- Use an oral medication syringe to draw up and deliver liquid medications inside the mouth between the cheek and the gums.

For IM or subcut injections:

- Ensure that a large well-developed muscle is chosen for the intramuscular injection to avoid pain and bruising
- Ask a parent or guardian to be present to assist in decreasing the child's anxiety
- The parent or guardian may need to assist in holding the child
- Use distraction techniques such as a toy or talking reassuringly to the child.

For IV infusion:

- Every child must be weighed before IVT commences and then daily
- Serum electrolytes and glucose must be checked before IVT commences and again within 24 hours if IVT continues
- An inline burette must be used
- IVT is delivered through a volumetric pump
- The IV cannula site is observed every hour when IV therapy is in progress to monitor for extravasation or infiltration
- An accurate fluid balance chart is maintained, documenting input, ongoing losses and urine output.

*(Brotto 2013; The Children's Hospital Westmead 2015)*

## Intravenous administration calculations

There are several methods used to infuse IV fluids and medications directly into the blood stream: gravity feed line, volumetric pump, syringe driver and syringe. With the **gravity feed** line the IV fluid passes from an IV infusion bag into a drip chamber. The drip chamber is designed to allow a fixed number of drops per mL to be delivered, which is controlled by a roller clamp, allowing the nurse to adjust the flow rate.

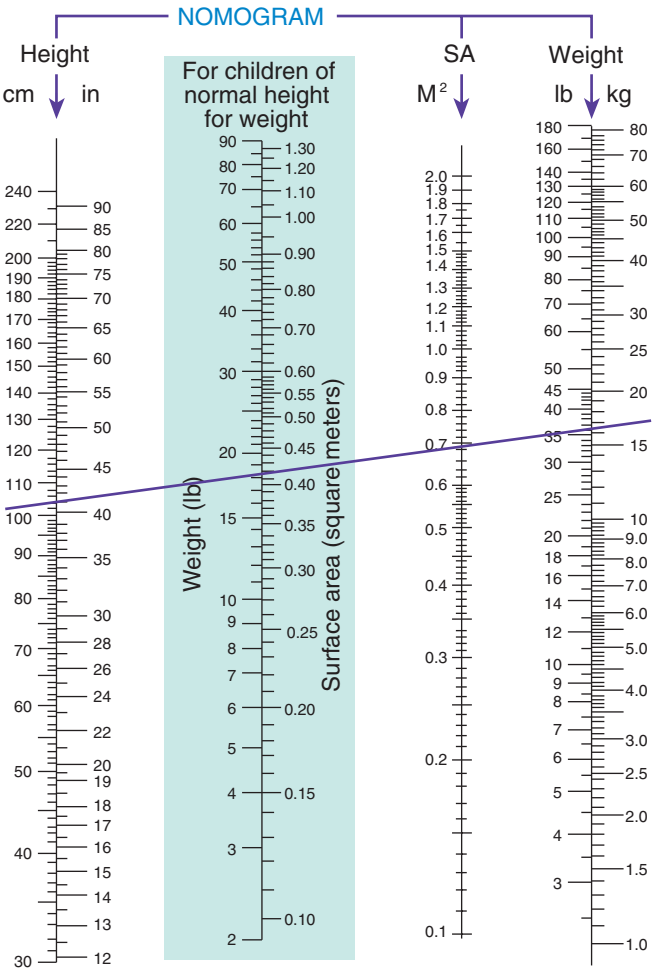

**Figure 24.6** Nomogram
*(Kliegman et al 2011)*

A **volumetric infusion pump** is able to be programmed to maintain an accurate flow rate; however, it should still be checked at regular intervals. A **syringe driver** allows for medications to be administered in smaller amounts of fluid into an IV cannula or a subcutaneous butterfly, which is delivered in minute doses (e.g. insulin or morphine). A single syringe can be attached to the IV cannula directly and a volume of fluid or medication is delivered as a push, either slowly or quickly over a period of time (e.g. sodium chloride 0.9% flush). The calculation of the volume to be infused and delivery rate may vary depending on the device used. The *Australian Injectable Drugs Handbook* by The Society of Hospital Pharmacists of Australia (2014) gives the recommended mixing volumes, type of fluid and rates that certain medications should be administered over and *must be checked prior to every IV medication calculation and administration*. Hospital procedure guidelines also guide the nurse regarding the delivery method and also must be reviewed prior to delivery.

### Calculation of intravenous infusion rate

Volumetric pump rates are calculated in mL/hour or mL/min.

mL/hour is calculated by dividing the total infusion volume by the total infusion time in hours.

$$\frac{\text{Volume to be infused}}{\text{Time (hours)}} = \text{rate mL/hour}$$

**Example**. A medical officer orders sodium chloride 0.9% (normal saline) 1 L to be delivered over 24 hours via an infusion pump.

$$\text{Volume to be delivered} = 1\text{ L} = 1000\text{ mL}$$

$$\text{Time} = 8\text{ hours}$$

$$\frac{1000\text{ mL}}{8} = 125\text{ mL/hour}$$

The rate on the volumetric pump is set at 125 mL/hour and the volume to be infused is set at 1000 mL.

Calculating mL/min is done by dividing the volume to be infused by the minutes then multiplying by 60, which converts the volume to be infused from minutes to hours.

$$\frac{\text{Volume to be infused}}{\text{Time (minutes)}} \times 60 = \text{rate mL/hour}$$

**Example**. A medical officer has ordered 500 mg of IV metronidazole to be delivered over 40 minutes. The stock is metronidazole 500 mg in 100 mL.

$$\text{Volume to be delivered} = 100\text{ mL}$$

$$\text{Time} = 40\text{ minutes}$$

$$\frac{100\text{ mL}}{40\text{ min}} \times 60 = 150\text{ mL/hr} = \text{rate mL/hour}$$

### Gravity feed IV delivery

The number of drops delivered per millilitre of solution varies with different brands and types of infusion sets. This rate is called the drip or drop factor and is usually printed on the back of the package. In Australia, the macrodrops IV infusion sets most commonly used are those with a 20 drops/mL drip chamber. The drip chamber for microdrip is 60 drops/mL.

The nurse will be required to closely regulate the drops per minute to ensure that the total prescribed volume will be delivered in the required time. Drops per minute are calculated using the following formula:

$$\frac{\text{Volume to be infused}}{\text{hours}} \times \frac{\text{drops per mL}}{\text{min}} = \text{rate drops/min}$$

**Example**. A medical officer orders sodium chloride 0.9% 1 L to be delivered over 8 hours. The IV infusion drip chamber delivers 20 drops/mL.

$$\text{Volume to be delivered (mL)} = 1\text{ L} = 1000\text{ mL}$$

$$\text{Drops/mL} = 20\text{ drops}$$

$$\text{Time} = 8 \times 60\text{ (to convert hours to minutes)}$$

$$\frac{1000\text{ mL}}{8} \times \frac{20}{60} = 41\text{ drops/min}$$

When delivering a fluid or medication via a gravity feed line over less than an hour the time in hours is not factored into the equation as only the minutes are used in the calculation.

$$\frac{\text{Volume to be infused}}{\text{min}} \times \text{drops/mL} = \text{rate drops/min}$$

**Example**. A patient is to receive 1 g of IV Cefazolin added to 50 mL of sodium chloride 0.9% and delivered over 25 minutes. The IV giving set delivers 20 drops/mL.

$$\text{Volume to be infused} = 50\text{ mL}$$

$$\text{Time} = 25\text{ min}$$

$$\frac{50\text{ mL}}{25} \times 20\text{ drops/mL} = 40\text{ drops/min}$$

## ADMINISTERING MEDICATIONS

The medication administration route will depend on the rationale for prescription, type and form of medication, medication properties and the desired therapeutic effect (Brotto 2013). The nurse should assess the individual prior to medication administration and collaborate with the medical officer if the prescribed route is not suitable (Broyles et al 2013).

### Administering enteral medications

#### Oral route

The oral route is the most common route by which medications are administered. Oral medications may be presented in solid (tablets, capsules or powder) or liquid (solution, elixir or suspension) form (Bryant & Knights 2014). Oral medications may be contraindicated in individuals who are unconscious, unable to swallow or unable to retain the medication in the stomach (vomiting, gastric drainage, fasting) (Brotto 2013). Before administering any oral medication the nurse must ascertain if any individuals have a nil by mouth status, such as individuals who are to have certain tests or surgery. The nurse must know whether solid medications are to be swallowed whole, chewed or sucked, and whether the medication can be crushed for administration. The nurse will need to consult *Do Not Rush to Crush* published by The Society of Hospital Pharmacists of Australia (2015) to ascertain if certain medications may or may not be crushed prior to administration. Most medications in tablet and capsule form should be swallowed with at least 100 mL of water (Brotto 2013). Powdered medications and some medications in granule form are mixed with a liquid before administration. Enteric-coated or sustained-release preparations must never be crushed, chewed or opened and must be swallowed whole. Enteric coatings are used to:

- Protect the medication from being metabolised by gastric acids
- Protect the stomach from medication that may cause gastric irritation and side effects such as nausea and vomiting
- Cause a delayed release of the medication allowing it to reach the small intestines where it will be absorbed (Bryant & Knights 2014).

Suggested guidelines for safely administering oral medications are provided in Clinical Skill 24.1. Effervescent powders and tablets should be taken immediately after dissolving. All liquid preparations should be shaken before they are poured. Any mixture that stains the teeth should be taken through a straw, and the individual should rinse out the mouth after each dose.

In certain circumstances oral medications may be administered through a nasogastric or PEG tube. Clinical Skill 24.2 provides guidelines to ensure safe administration of medications via a nasogastric or PEG tube. More information about nasogastric and PEG tubes can be found in Chapter 30. Administering medication via a nasogastric or PEG tube is the main reason that tubes become blocked, so nurses must ensure that flushing is thorough and that they never mix medications together to instil via a feeding tube because this causes the clumping responsible for blocking the tube (deWit & Williams 2014). The pharmacist or *Do Not Rush to Crush* should be consulted before crushing any tablets and administering them orally or via a nasogastric or PEG tube. It is often the case that the medication is manufactured and available in a preferable formulation; for example, liquid instead of a solid form.

For oral medication administration the equipment required includes:

- The medication chart
- Medicine receptacle
- Prescribed medication
- Glass of water or thickened fluids as required
- Drinking straw or spoon if necessary
- Oral medication syringe (if required); specific oral liquid medication syringe must be used for all oral liquid medication administration only.

**CRITICAL THINKING EXERCISE 24.4**

Describe the nursing actions if an individual prescribed medication is unable to take it (e.g. is 'nil orally') or is refusing to take the medications.

## Oral mucosal absorption

Some medications are administered by buccal or sublingual application, for the purpose of being absorbed directly into the systemic circulation through the oral mucosa (Broyles et al 2013). These routes are indicated for medications that tend to be destroyed by gastric juice, or those that are rapidly detoxified by the liver. Buccal tablets or wafers are placed in the space between the upper molar teeth and gums. Individuals should be advised to alternate cheeks with each administration to prevent mucosal irritation occurring. Sublingual tablets are placed under the tongue. Both forms remain in place while they dissolve. The individual should be advised not to chew or swallow such tablets or drink fluids until the medication has fully dissolved (Brotto 2013).

## Rectal instillation

Medication may be given rectally in the form of suppositories or retention enemas. The rectal route may be used for a local effect such as evacuation suppositories, or a systemic effect such as analgesia or antiemetic. If individuals are vomiting or unconscious the rectal route may be an option for medication delivery. Some individuals may be able to insert suppositories without assistance of a nurse, avoiding embarrassment, and others will require the nurse to administer the suppository. The individual is placed in the left lateral position and the suppository or enema is inserted past the internal anal sphincter (Brotto 2013). This prevents the medication being expelled. Suppositories have a rounded end to prevent trauma to the rectum upon insertion (Brotto 2013). The nurse should be aware of the different types of suppositories and enemas available. Evacuant suppositories prescribed to promote a bowel action are composed of various substances, such as glycerine, and act by softening and lubricating the faeces to facilitate easier passage and excretion, or by increasing

## CLINICAL SKILL 24.1 Administering oral medications

**Review and carry out the standard steps for all clinical skills/interventions**

**NMBA Decision-making Framework considerations:**

1. Am I educated?
2. Am I authorised?
3. Am I competent?

If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator

**Equipment:**

Medication chart/order
Prescribed medication
Disposable medication cups
Glass of water, juice or preferred liquid
Straw (if required)
Medication cutting device (if required)
Clean pill crusher (if required)
Liquid measure or oral/enteral syringe
Resource material (e.g. MIMS)

## CLINICAL SKILL 24.1 Administering oral medications—cont'd

| Skill activity | Rationale |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Assess the individual's ability to receive the medication via this route | If the individual is nauseous they may not tolerate medication given via this route. Some individuals may require their medication to be crushed |
| Consider any medication administration requirements such as whether the medication must be given with food | Failure to administer the medication according to the guidelines may impact on its effectiveness |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Promotes correct and safe administration of the medication<br>Confirms the individual's identity |
| Perform any necessary assessments related to the medication such as BP, apical pulse, respiratory rate (RR) | Apical pulse should be performed before administering digoxin; RR checked before opioid (narcotic) analgesics; BP checked before antihypertensives. If any abnormalities are found the nurse should not administer medication and should contact nurse in charge and medical officer |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered<br>Prevents preparation errors |
| **Solid dose forms** | |
| Calculate the number of tablets to be given. Ensure you double check the medication calculation | Ensures correct dose is given and reduces the risk of error |
| Tip the required number of tablets or capsules into the lid of the container and transfer into the medicine cup. Do not touch the medication with your bare hands | Maintains cleanliness of medications and prevents cross-infection |
| Some individuals may require their medication to be crushed. Crush medications using the pill crusher if required (Note: not all solid medications can be crushed. The nurse must use an appropriate resource to determine if a particular medication can be crushed) | Some medications cannot be crushed. Crushing these medications can alter their effectiveness |

*Continued*

## CLINICAL SKILL 24.1 Administering oral medications—cont'd

| Liquid dose forms | |
|---|---|
| Calculate the amount of liquid medication to be given (if necessary). Ensure you double check the medication calculation | Ensures correct dose is given and reduces the risk of error |
| Shake bottle thoroughly (unless contraindicated) | Promotes mixing of the contents and a uniform distribution of the medication in the liquid |
| Hold the bottle with the label against the palm of the hand | Mixture will be poured away from the label, to avoid smearing of the label |
| Remove bottle cap and place it upside down | Prevents contamination of the inside of the cap |
| Hold the medicine cup at eye level and pour the prescribed dose (marking on the cup should be even with the fluid level at the base of the meniscus), or withdraw the required dose from the container using an approved oral/enteral syringe. Discard any excess | Ensures accuracy of measurement<br>Note that parenteral syringes should not be used for administration or administration of doses |
| Check the label of the container again | Reading the label again reduces risk of errors |
| Explain the purpose of the medication and its action | Understanding improves compliance with medication therapy |
| Assist the individual into a sitting (preferred) or side-lying position when possible | Prevents aspiration during swallowing |
| Administer the medication. Individual may self-administer, assist as required. Offer the individual a glass of water, unless this is contraindicated. Advise individual to take a few sips of water before placing medication in the mouth | Solid forms of medication are swallowed more easily in a moistened mouth and by swallowing with liquids |
| Remain with the individual until the medication is swallowed. Never leave medication unattended at the bedside or on the medication trolley | The nurse assumes responsibility for ensuring that the individual receives the prescribed medication. Other individuals may access the medications if left at the bedside |
| Give individual any special instructions related to medications, such as sitting upright for 30 minutes after ingestion | Prevents side effects such as oesophageal ulceration |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Record and report immediately if medication is unable to be administered (e.g. the individual refuses medication, is vomiting, is absent); medication not available; health status has changed (hypotensive when on antihypertensives) | Reason can be reviewed by medical officer as required. Document in healthcare record |
| Monitor individual for therapeutic effect of the medication (if applicable) | Ensures medication is achieving the desired effect. |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |

peristalsis through the irritation of intestinal sensory nerve endings. Suggested guidelines for administering rectal suppositories are presented in Clinical Skill 24.3.

The equipment required includes:

- Medication chart
- Prescribed suppository/suppositories
- Non-sterile gloves
- A small disposable sheet to protect bed linen
- Water-soluble lubricant
- Waste receptacle for used articles
- Appropriate toilet facilities (e.g. bedpan, toilet paper)
- Soap, face washer and towel for hygiene after bowel motion or insertion of suppository.

## Administering parenteral medications

### Injections

Nurses commonly administer medications by parenteral injection through the subcutaneous, IM or IV routes. Medications are given by injection for a variety of reasons, including:

- Inability to be absorbed when given orally (e.g. aminoglycoside antibacterial agents)
- Destroyed by digestive juices (e.g. insulin)
- Rapid onset of action may be required
- Very precise control over dosage may be needed
- Inability of the individual to take medications orally.

The administration of an injection is an invasive procedure that must be performed using aseptic non-touch technique (ANTT) as there is a risk of infection when a needle pierces the skin. Infection is prevented by hand hygiene, aseptic technique when preparing the solution and in administration of the injection, and by preparing the skin prior to the injection (Broyles et al 2013). Principles of ANTT (see Chapter 22) are used when preparing for and administering parenteral medications.

A variety of syringes and needles are available, and are single use and disposable. Syringes are available in a range of sizes, varying in capacity from 1 to 50 mL. A syringe consists of a cylindrical barrel with a tip designed to fit the hub of a needle, and a close-fitting plunger (Figure 24.7). The syringe tip is either straight where the needle slides firmly over, or a luer lock where the needle is screwed securely into place. The barrel of the syringe is calibrated into millilitres and tenths of a millilitre or, in the case of an insulin syringe, into units. Selecting an appropriate syringe size depends mainly on the prescribed route, and amount of medication to be administered. Generally a 2–3 mL sized syringe is adequate for subcutaneous, IM and some IV injections.

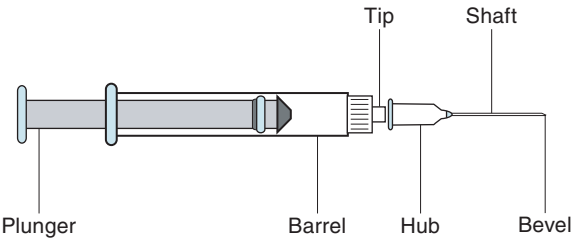

**Figure 24.7** Components of a needle and syringe *(Potter et al 2013)*

Needles are available in various lengths and gauges, with different sized bevels. A needle has three parts (Figure 24.7): the hub, which fits onto the tip of a syringe, the shaft and the bevel tip. Needle gauge is determined by the lumen of the needle: as the diameter of the lumen increases, the gauge number decreases. For example, a 16-gauge needle is substantially larger in diameter than a 22-gauge needle.

Selecting an appropriate needle depends mainly on the prescribed route, viscosity of the medication and the individual's body size and amount of fat. Subcutaneous injections are generally given through a small-diameter needle (e.g. 25-gauge) while IM injections usually require a 21–23-gauge needle. **Intravenous injections** are generally administered through a needleless system. There are specially designed needles that contain a sheath that slide down and cover the needle and tip, to prevent needlestick injury, after the injection has been given (Brotto 2013).

## CLINICAL SKILL 24.3 Inserting a rectal suppository or disposable enema

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Enema/suppository<br>Lubricant<br>Waterproof sheet<br>Gloves<br>Resource material (e.g. MIMS) |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Confirms the individual's identity and reduces risk of allergic reaction<br>Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart | Ensures the correct medication is being administered. Prevents preparation errors |
| Place the individual in a left lateral position with the right leg flexed | Anatomical site of the lower colon means that this position is the most effective for the introduction and retention of suppositories |
| Ensure that the person is adequately covered, with only the buttocks exposed | Promotes warmth and comfort |
| Perform hand hygiene and follow infection control procedures. Put on non-sterile gloves | Prevents cross-infection |
| Lubricate finger of glove and suppository/enema nozzle | Facilitates insertion of suppository/enema |
| Gently insert the suppository/enema by directing it with the finger, through the anus about 10 cm into the rectum | Suppository/enema must pass the internal anal sphincter and come in contact with rectal mucosa |
| During insertion, encourage the individual to take deep breaths through the mouth | Helps to relax the anal sphincters |
| Ask the individual to remain on their side or supine for at least 5 minutes. Encourage the individual to retain the suppository/enema for the correct length of time. A suppository administered to cause a bowel action should be retained for at least 20 minutes. An enema will be held for the time stated on the manufacturer's instructions | Individual must be aware whether the suppository/enema is to be retained to allow any medication to be dissipated, or whether to expect a bowel action. Suppositories/enemas to promote a bowel action must be retained long enough to be effective |

| CLINICAL SKILL 24.3 Inserting a rectal suppository or disposable enema—cont'd | |
|---|---|
| Ensure the individual has easy access to toilet facilities and the signal device (e.g. nurse call bell) | Reduces anxiety related to accidental expulsion of the suppository or faeces |
| Dispose of used equipment appropriately, remove gloves and perform hand hygiene | Prevents cross-infection |
| If a bowel action results, the faeces are observed and the observations reported and documented | Helps to assess the effectiveness of the treatment and detects any abnormalities |
| Attend to the individual's hygiene and position | Helps promote comfort |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2014f; 2014g)* | |

Medication for injections may be presented in sterile ampoules, vials, IV medication bags or bottles (Figure 24.8). Prepared IV medications are premixed in bags in a suitable IV fluid, and will need an IV line connected to it for administration. An ampoule is made of clear glass or plastic, with a constricted neck that must be snapped off to allow access to the medication. Ampoules contain volumes from 0.2 mL to 20 mL or more. A vial is a single-dose glass container with a rubber seal at the top, which is protected by a metal cap until it is ready for use. Vials contain medications in either liquid or powder form, requiring reconstitution prior to administration. Sterile water labelled 'water for injection' and sodium chloride 0.9% are commonly used as diluents to dissolve medications in powder form. The *Australian Injectable Drugs Handbook* specifies type and volume of diluent to use, as well as any other recommendations for administration (e.g. compatibilities, how fast to administer). These instructions must be consulted before the preparation and administration of any parenteral medication. Table 24.3 illustrates the procedure for the preparation of medications from ampoules and vials.

Some medications are available in disposable, single-dose pre-filled syringes and may not need calculations to prepare dose of the medication. It may be necessary to advance the plunger a small way to expel some medication if the dose ordered is less than that in the syringe or to prime the needle (e.g. insulin pen). The nurse must still follow correct checking procedure including name, strength, expiry date and volume of the medication. Particular care is needed because many pre-filled syringes look the same but contain very different medications. Some emergency medications (e.g. adrenaline) are available in an injection system that requires the plunger in a standard syringe to be screwed into the end of a pre-filled vial with an inbuilt needle. After use the whole injection unit is discarded into the appropriate sharps safe container. This device is designed to minimise the risk of needlestick injury (Brotto 2013).

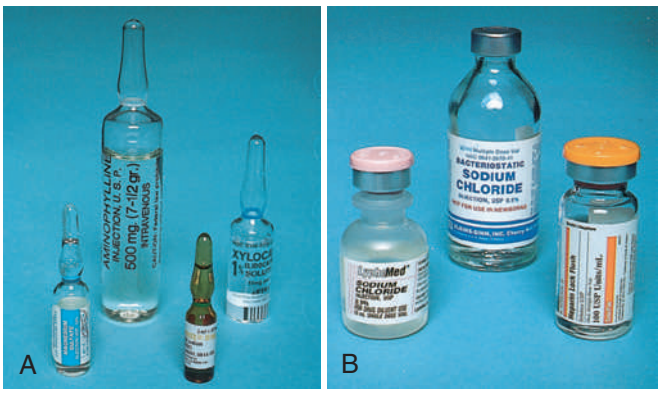

**Figure 24.8** A: Medication in ampoules. B: Medication in vials *(Potter et al 2013)*

**TABLE 24.3 | Preparation of medications from ampoules and vials**

| Ampoules | Vials |
|---|---|
| Rotate the ampoule or tap the top lightly with a finger to dislodge any fluid above the neck of the ampoule | Remove the metal cap to expose the rubber seal |
| Face the dot on the tip of the ampoule away from the body. Gently tilt the tip towards the body and snap away from the body. The tip should easily snap off. If resistance is felt use an ampoule snap device or place a gauze square around the neck of the ampoule to protect the fingers as the glass is snapped | Wipe the surface of the seal with an alcohol swab, to remove any dust or grease |
| Snap the neck in a direction away from the hands, to prevent shattering the glass towards the fingers or face | To prepare a powdered medication, assemble needle and syringe and draw up the amount of diluent recommended on the label of the vial or in the manufacturer's information, and gently inject into the vial. Gently shake or roll the vial between the hands to dissolve the powder |
| Assemble needle and syringe. Remove needle cover<br>Use a blunt filter needle (if available) to draw up medication from a glass ampoule. Filter drawing up needles prevent micro glass particles from entering the syringe and thus avoids injection of these particles into the individual. | Before drawing up the solution, assemble the needle and syringe and remove the needle cover. Draw back on the plunger to draw air into the syringe, equivalent to the volume of medication to be aspirated |
| Insert the needle (attached to the syringe) into the centre of the ampoule opening, being careful not to touch the needle on the rim of the ampoule, to prevent needle contamination | With bevel pointing up, insert the tip of the needle through the centre of the rubber seal |
| Aspirate the medication by pulling back on the syringe. Keep the needle tip below the surface of the medication to prevent aspiration of air bubbles | Inject the air from the syringe into the vial. Hold the plunger, as it may be forced backwards by air pressure within the vial |
| To expel air bubbles from the syringe, remove the needle from the ampoule and hold syringe with the needle pointing up. Draw back slightly on the plunger and then push the plunger up to eject the air (but avoid dispersing medication into the environment). Holding the syringe and needle upright, tap the syringe barrel to dislodge remaining air bubbles. It is important to expel air bubbles because if air is injected it may gain entry to the bloodstream and block a blood vessel | Holding the syringe and plunger, invert the vial. Hold the vial in the non-dominant hand<br>Allow air pressure to gradually fill the syringe with medication. Ensure to keep the tip of the needle below fluid level. Pull back slightly on the plunger to keep the needle tip below the water level<br>Remove the needle from the vial by pulling back on the barrel of the syringe<br>Tap the syringe barrel to remove any air bubbles |
| Remove the drawing-up needle from the syringe before administering the medication via the IV needleless system | Remove the drawing-up needle from the syringe before administering the medication via the IV needleless system |

*Adapted from Brotto (2013)*

## Parenteral fluids

Parenteral fluids correct imbalances in individuals and the IV fluid ordered will be determined by the illness and its effect on the fluid balance status of the individual. IV fluids are divided into isotonic, hypotonic and hypertonic fluids (Wotton 2013). The osmolarity of a fluid is determined by the concentration of solutes (primarily sodium) in a litre of fluid (mOsm/L). Body fluids have an osmolarity of 280–296 mOsm/L. Isotonic fluids have a similar osmolarity as blood and are primarily used to increase the volume of the intravascular space, in the presence of dehydration (from ongoing fluid losses such as vomiting and diarrhoea), hypovolaemia (blood loss) and hypernatraemia (high sodium) (Phillips & Gorski 2014). Isotonic fluids will not cause fluid shifts between the intracellular and extracellular compartments and any isotonic fluids administered IV will remain in the intravascular compartment (Phillips & Gorski 2014). Therefore, the nurse will need to monitor the individual for signs and symptoms of fluid overload (pulmonary and peripheral oedema) especially if they have other comorbidities such as congestive heart failure or hypertension (Wotton 2013). Daily weighs are a good measure of acute body fluid gain,

and should be measured in individuals where there is risk of fluid volume overload.

Hypotonic fluids have an osmolarity less than blood (<250 mOsm/L), and will cause a fluid shift from the intravascular compartments into the intracellular compartment, restoring fluid levels to cells (Phillips & Gorski 2014). Hypotonic fluids are used to treat conditions such as hypertonic dehydration and diabetic ketoacidosis. The individual receiving hypertonic fluids will need to be monitored closely as the fluid shift from the intravascular compartment may cause insufficient fluid in the blood vessels and lead to circulatory collapse.

The osmolarity of hypertonic fluids (>375 mOsm/L) is greater than that of body fluids and will cause a fluid shift from the intracellular space to the extracellular compartment, and is mainly used to treat conditions such as shock (Phillips & Gorski 2014). Individuals will need to be monitored for fluid overload (Wotton 2013).

Potassium chloride (KCl) is a common premixed additive with another IV fluid. The writing on the bags containing the IV solution and the KCl is red, as an alert that the fluid contains potassium. Fluid boluses must not be given from IV fluids containing KCl, as it can be fatal (Wotton 2013). Many hospital facilities now have protocols that individuals going to theatre must not have IV fluid running that has the additive KCl in case they need to have a rapid bolus while having surgery.

Parenteral fluid replacement includes crystalloid fluids (IV fluid and electrolyte replacement) and colloid fluids (blood and blood products) (see Table 24.4). Crystalloids are used to correct and prevent fluid loss as well as correcting electrolyte balances (Wotton 2013). Crystalloids, once mixed with the blood, are able to disperse through the intracellular and extracellular compartments through osmosis without changing the osmolarity of the body's fluids in these compartments (Phillips & Gorski 2014).

Colloids are essentially a hypertonic fluid that contains proteins and starches and once infused normally remain in the intravascular space. These proteins cause an increase in the osmolarity of blood and draw fluid into the blood vessels expanding the volume of the plasma. Colloids are also called volume expanders and include products such as Albumin, Dextran and Mannitol (Phillips & Gorski 2014).

**TABLE 24.4 | Common intravenous fluid types**

| Crystalloids solutions | Therapeutic use |
|---|---|
| 5% Glucose | Provides calories and free water, diluent for IV medications, treatment for hyperkalaemia and dehydration |
| 0.9% Sodium chloride | Replaces electrolytes, hyponatraemia, DKA, flush pre- and post-IV medication delivery and access devices, extracellular fluid replacement, irrigation of wounds |
| Hartmanns | Dehydration, hypovolaemia, extracellular fluid replacement, shock |
| **Colloid solutions** | |
| 20% Albumin | Extremely low albumin in the critically ill, burns, ascites in liver cirrhosis, haemodialysis |
| Dextran | Plasma expander, fluid replacement, perioperative shock, haemorrhage, trauma, |
| Gelofusine | Plasma expander, fluid or blood loss, perioperative shock, haemorrhage, trauma |

*Adapted from Broyles et al (2013); Phillips & Gorski (2014)*

## Injection sites

**Subcutaneous injection** involves injecting medication into the loose connective tissue under the dermis (Brotto 2013). Small volumes of medication that will not damage subcutaneous tissue are administered by this route and must be water soluble (Brotto 2013). Subcutaneous sites that are commonly used include the upper lateral aspect (middle third) of the upper arm, the upper anterior thighs, the abdomen below the costal margins to the iliac crests and the upper ventro or dorsogluteal region (Figure 24.9) (Broyles et al 2013). These injection sites are generally free from bony prominences and large underlying muscles or nerves; the nurse must also assess the skin to avoid skin lesions (Brotto 2013). Subcutaneous injections are administered with the needle inserted at an angle of 45 degrees or 90 degrees (Figure 24.10), depending on the size of the needle used and the amount of adipose tissue on the individual (Broyles et al 2013). An elderly person with minimal subcutaneous tissue should have the needle inserted on a 45-degree angle. Figure 24.11 illustrates

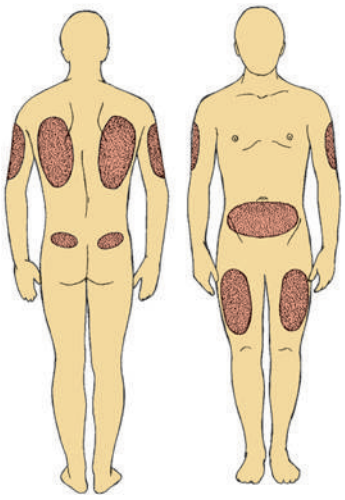

**Figure 24.9** Common sites for subcutaneous injections *(Brotto 2013)*

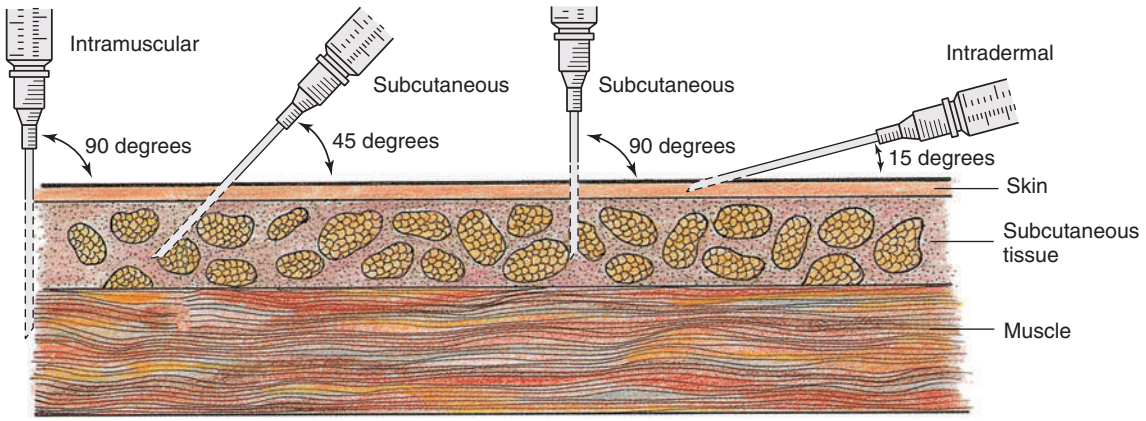

**Figure 24.10** Comparison of angles of insertion for A: subcutaneous injections (45 and 90 degrees), B: intramuscular injections (90 degrees), C: intradermal injections
*(Brotto 2013)*

**Figure 24.11** Administering a subcutaneous injection in the abdomen
*(Potter et al 2013)*

the most common site for administration of subcutaneous injections.

**Intramuscular (IM) injections** involve injecting medication into deep muscle tissue. Muscle is less sensitive to irritating or viscous medications, and specific volumes for each IM muscle site can be injected into muscle without causing severe discomfort. IM injections are administered with the needle inserted at an angle of 90 degrees (Figure 24.10). Any medication given IM or IV must be mixed and administered as per the guidelines outlined in the *Australian Injectable Drugs Handbook* and/or hospital procedural guidelines. These *must be checked prior to IM or IV medication calculation and administration.* The recommended volumes for injecting into specific muscle sites are a maximum of 4 mL for ventrogluteal and 5 mL for vastus lateralis, and up to a maximum of 2 mL for the deltoid muscle (Brotto 2013). Smaller volumes are recommended for elderly or frail individuals, or those with less developed muscle mass or children. The sites chosen are areas where there is minimal risk of the needle penetrating a large blood vessel, nerve or bone.

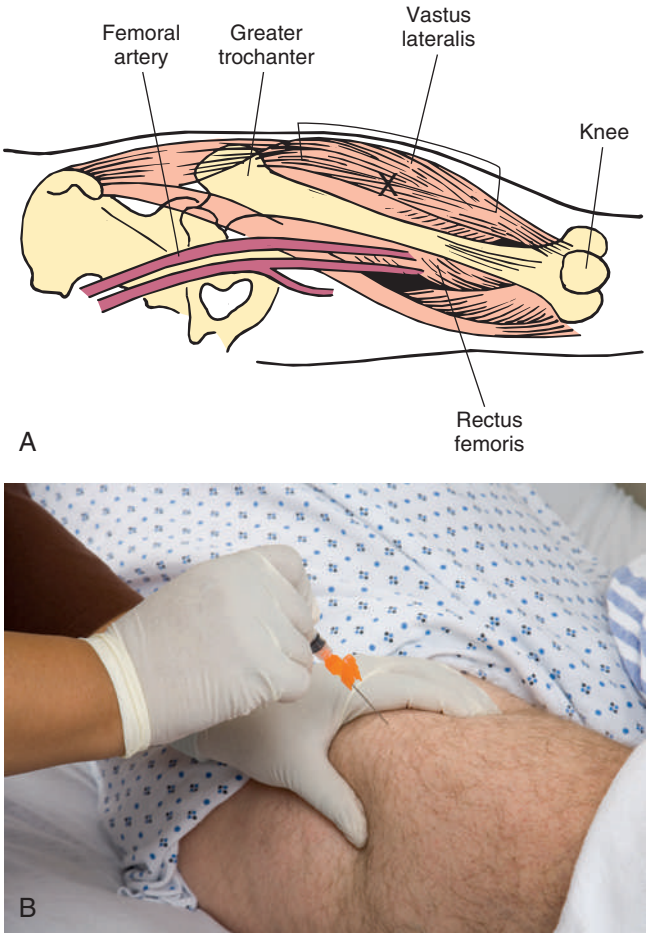

**Figure 24.12** A: Landmark for IM injection vastus lateralis region. B: Injection location vastus lateralis muscle
*(Potter et al 2013)*

The IM injection is always aspirated (syringe is drawn back 0.5 mL) after the needle is inserted into the muscle but before injection of vthe medication, to ascertain that the needle has not entered a blood vessel. Intramuscular sites and their anatomical locations commonly used are the vastus lateralis muscle (Figure 24.12), located at the middle third of

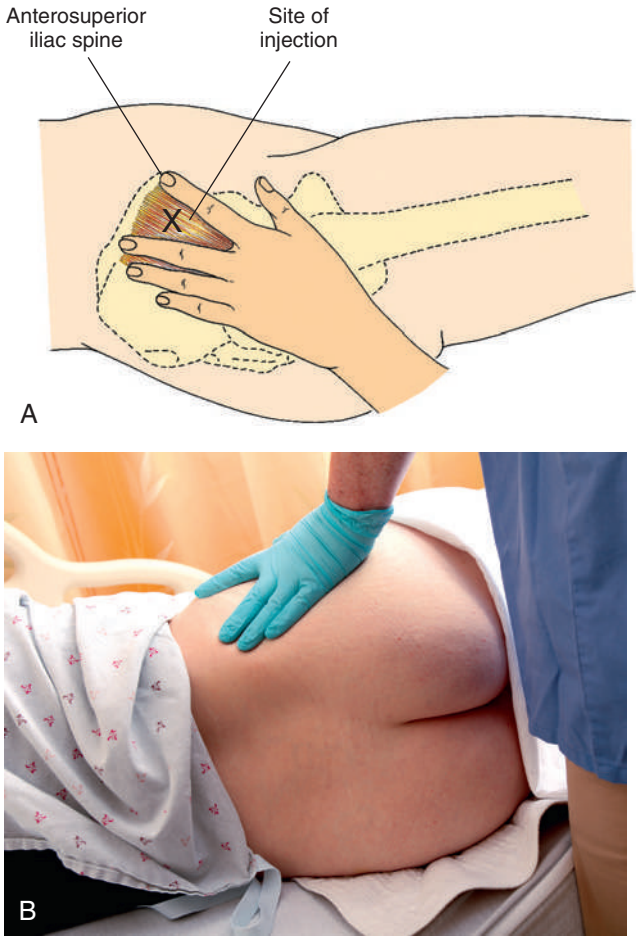

**Figure 24.13** A: Landmark for IM injection ventrogluteal region. B: Injection location ventrogluteal muscle
*(Potter et al 2013)*

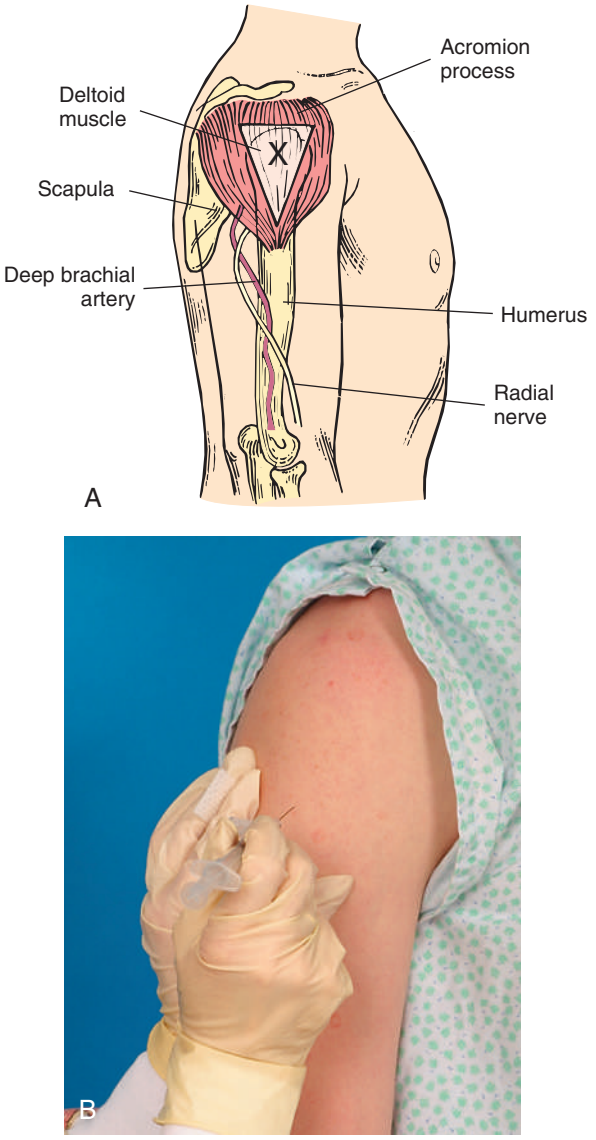

**Figure 24.14** A: Landmark for IM injection deltoid region. B: Injection location deltoid muscle
*(Potter et al 2013)*

the anterior lateral aspect of the thigh; ventrogluteal region (Figure 24.13) where the injection occurs into the gluteus medius muscle located between the greater trochanter and the iliac spine; and deltoid muscle (Figure 24.14) located at the upper outer aspect (middle third) of the upper arm (Brotto 2013). The injection site for ventrogluteal is located midway between greater trochanter and the hip. The ventrogluteal site is the preferred site for intramuscular injections because it does not contain large blood vessels or nerves, is sealed off by bone, contains less fat than the buttock area and has the greatest thickness of gluteal muscle (Brotto 2013; Berman et al 2015). The heel of the hand is placed over the person's greater trochanter, and then the anterior superior iliac spine is palpated with the index finger. The middle finger is widened from the index finger, making a space pointing towards the iliac crest. The injection site is located in the space between the index finger and middle finger (Figure 24.13).

The Z-track method of injection (Figure 24.15) is a technique used when irritating preparations such as iron are given IM. A new needle is attached to the syringe after preparing the medication so that no solution remains on the outside of the needle. The skin and subcutaneous tissue are drawn to one side with the non-dominant hand, the needle is then inserted and medication injected. After removal of the needle the skin is released to close the injection track, preventing the viscous medication seeping into the subcutaneous tissue (Broyles et al 2013). This promotes absorption of the medication at the site and also prevents skin staining and pain. The Z-track method of injection deposits medication into the muscle without tracking residual medication through sensitive tissues.

**Intravenous (IV) injection** involves delivering medication or fluid directly into a vein. It is accessed by a **needleless intravenous system.** Needleless IV systems administer medications or fluids through an IV access device without using a needle. Blunt filter needles may be used for drawing up sterile solutions from ampoules and the needleless ports are then accessed with the hub of the syringe only. Needleless systems are commonly used in acute healthcare settings, and are important in preventing the risk of needlestick injuries in

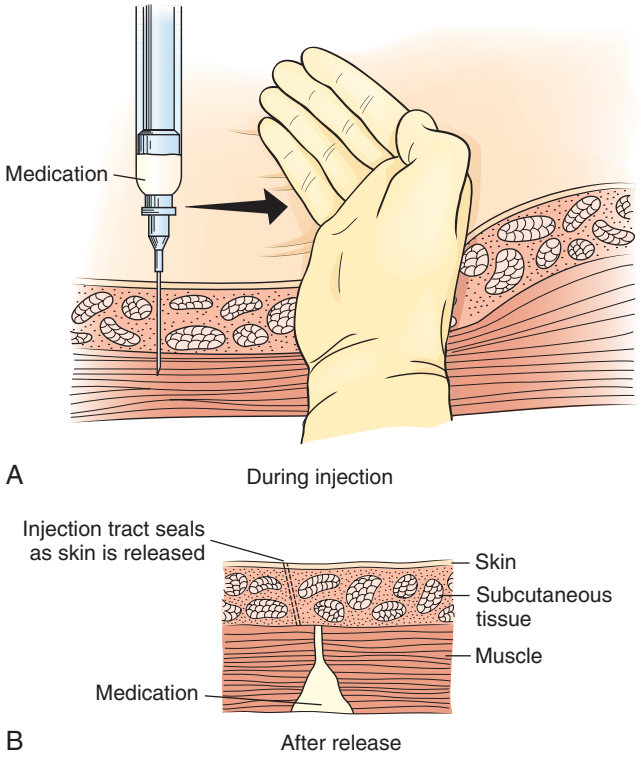

**Figure 24.15** Z-track injection: A: pulling overlying skin down before IM injection and B: releasing after injection to prevent tracking of medication into sensitive tissue *(Potter et al 2013)*

the workplace, as injuries occur with attempts to recap needles, mishandling of needles and syringes, and when needles are left at bedsides (Broyles et al 2013).

### Promoting safety and comfort

To ensure correct subcutaneous or IM administration of an injectable medication and to minimise the individual's discomfort, the nurse should:

- Position the individual comfortably to reduce muscular tension
- Use a sharp needle in the smallest suitable length and gauge
- Select the correct injection site, using anatomical landmarks
- Sites should be rotated to minimise discomfort and tissue damage and aid absorption. This may be achieved by asking the individual the site of the last injection and/or documenting the site in the individual's clinical notes or care plan or on the medication chart
- Insert the needle smoothly and quickly
- Securely hold the syringe steady while the needle remains in the tissues
- Aspirate the syringe in IM injections only before injecting the medication, to check that the needle has not entered an artery or vein
- Remove the needle and press on, or gently massage, the area for several seconds after administration, unless contraindicated
- Dispose of the needle directly into a sharps container to prevent needlestick injuries
- Assess the injection sites ensuring they are free of any bruising, hardness, signs of inflammation or other abnormality.

Suggested guidelines for administering subcutaneous and intramuscular injections are outlined in Clinical Skill 24.4. The equipment required includes:

- Medication chart
- Kidney dish
- Syringe, selected according to the volume of medication to be administered
- Needles, selected according to the route and body size of the individual
- Alcohol swabs
- Prescribed medication in ampoule or vial
- Cotton swab for applying pressure to the site
- Non-sterile gloves
- Sharps receptacle for immediate disposal.

Nurses must be aware of their responsibilities and limitations to their scope of practice in relation to the law and Acts as stipulated by government bodies in each of the states and territories in Australia. They must also practise according to organisational policy and procedural guidelines of the employing hospital or other agency regarding the administration of IV medications.

## Administering fluids and medications via the intravenous route

IV therapy is frequently prescribed for individuals requiring restorative, replacement, maintenance and medication treatment (Broyles et al 2013). The nurse requires knowledge regarding the IV fluids and medications to be administered, rationale for IV therapy, and of the fluid and electrolyte balance of the individual receiving the treatment (Broyles et al 2013). In addition the nurse requires the skills to assist with the establishment of the IV therapy, prepare the equipment required and manage the IV therapy once established. (See Clinical Skills 24.5 and 24.6.) Most organisations require all IV fluid and medications diluted in fluids to be administered through a volumetric pump.

IV medication or fluids need to be administered over a certain time period as giving IV fluids or medication too fast or too slowly can cause serious adverse reactions. The *Australian Injectable Drugs Handbook* gives the recommended times over which individual medications should be administered.

IV fluids and medications may be administered in a number of different ways (see Clinical Skill 24.7), including:

- Large or small volume infusions—IV fluids are available in a variety of fluid types and volumes in 50, 100, 250, 500 and 1000 mL bags. Medications can be added to a compatible fluid and specific volumes for administration. IV fluids may be administered at a rate to keep vein open (TKVO) in instances where IV access is not stable and to preserve the patency of the

## CLINICAL SKILL 24.4 Administering subcutaneous and intramuscular injections

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Prescribed medication<br>Syringe<br>23G needle (for IM injections)<br>25G needle (for subcut injections)<br>Antiseptic swab<br>Sterile gauze<br>Injection tray<br>Sharps container<br>Gloves<br>Resource material (e.g. MIMS) |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Understanding improves compliance/concordance/adherence with medication therapy<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Promotes correct and safe administration of the medication<br>Confirms the individual's identity and reduces risk of allergic reaction |
| Gain the assistance of another nurse if the individual is a child, or an adult who is restless or irrational or may need assistance with positioning | Promotes safety during administration |
| Perform hand hygiene and follow infection control/ANTT procedures. | Prevents cross-infection |
| Calculate the correct dose and prepare the medication according to Table 24.3: Preparation of medications from ampoules and vials<br>Check the label and expiry date. Have two nurses check (one must be a Registered Nurse) according to safe administration guidelines and the facility/organisation policy<br>Compare the medication container with the order on the medication chart | Promotes safety during administration<br>Ensures the correct medication is being administered. Prevents preparation errors |

*Continued*

| CLINICAL SKILL 24.4 Administering subcutaneous and intramuscular injections—cont'd | |
|---|---|
| Select an appropriate injection site and assist the individual into a comfortable position. Select a site that has not been used frequently. If possible, ask the individual the site of the last injection | Appropriate site selection aids absorption, reduces likelihood or injury and discomfort. Rotating sites minimises tissue damage<br>Comfort promotes relaxation and helps to reduce anxiety |
| Locate the site using anatomical landmarks. Check site for any masses, lumps, signs of infection, scars or skin lesions | Insertion of medication into the correct site avoids injury to underlying structures. Masses, scars, etc will interfere with medication absorption |
| Cleanse the site with an antiseptic swab and allow to dry. For subcutaneous injection, follow facility/organisation policy regarding skin cleansing | Removes microorganisms from the skin |
| Put on gloves. Remove the needle cap and hold the syringe in the dominant hand. Hold the individual's skin between the thumb and forefinger and either pull it taut or pinch<br>it up | A needle penetrates tight skin more easily than it does loose skin. Pinching the skin up may be necessary when an subcut injection is given to an obese individual, or when an IM injection is given to an individual with small muscle mass |
| Insert the needle quickly and firmly, at a 45° or 90° angle for subcutaneous injection, and at a 90° angle for IM injection | Quick, firm insertion minimises anxiety and discomfort |
| For an IM injection slowly pull back on the plunger. If blood appears in the syringe, the needle is withdrawn and the injection repeated at another site, using a fresh dose, syringe and needle (this does not need to be performed for a subcut injection) | Muscles are more vascular than subcut tissue. Checks whether needle has penetrated a blood vessel |
| Inject the medication slowly. After injection pause for at least 5 seconds before withdrawing the needle | Slow injection reduces tissue trauma and pain<br>Pausing permits dispersal of the medication |
| Withdraw needle at same angle of insertion while applying gauze gently over the injection site | Support of tissues minimises discomfort as the needle is withdrawn<br>Use of alcohol swab may cause discomfort |
| Activate the needle safety guard (if used) or dispose of syringe without recapping into proper receptacle | Recapping used needles may result in a needlestick injury |
| Apply pressure with sterile gauze if bleeding occurs. Do not massage | Use of alcohol swab may cause discomfort. Massage may cause bleeding, increase the absorption rate, damage underlying tissue |
| Assist the individual into a comfortable position | Promotes comfort |
| Discard syringe and needle into an appropriately labelled rigid-walled sharps container without recapping the needle | Proper disposal prevents sharps injury to personnel or visitors |
| Remove gloves and perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart, including the site of injection | Prompt documentation prevents errors. Sites should be rotated for long-term therapy such as insulin, as repeatedly using the same site leads to thickening of skin and tissue atrophy |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is effective/appropriate for the individual |

## CLINICAL SKILL 24.4 Administering subcutaneous and intramuscular injections—cont'd

| | |
|---|---|
| Monitor individual for any adverse effects to the medication. Report any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |

## CLINICAL SKILL 24.6 Intravenous management

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Intravenous fluid orders<br>IV infusion pump<br>FBC<br>IV cannula care plan |
| **Skill activity** | **Rationale** |
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check all allergies including latex or tape | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Reduces risk of allergic reaction |

## CLINICAL SKILL 24.6 Intravenous management—cont'd

| | |
|---|---|
| Explain the procedure to the individual in relation to the following assessments:<br>Local—check the IV insertion site for any redness/pallor, temperature (hot or cold), pain/discomfort, swelling (infiltration or extravasation) or bleeding; check the patency of the IV cannula; check IV line<br>Ask individual to report any pain or discomfort<br>Systemic assessment—check for any signs of circulatory overload, fluid volume deficit, signs of infection/ septicaemia or pulmonary air embolism | Alleviates anxiety<br>Ensures cooperation and allows for consent for procedure<br>Understanding improves compliance/concordance/ adherence with therapy<br>Abides by legal and ethical guidelines as well as organisation policies and procedures<br>Pain or burning may be an early sign of phlebitis |
| Calculate flow rate and ensure the rate compares with the correct fluid order<br>Check the fluid bag for expiry date, colour and leakage | Ensures safe administration of IV fluid<br>Prevents circulatory overload |
| An individual with IV therapy may need assistance with changing into different clothing, ambulating and hygiene. Be careful not to disconnect the IV tubing<br>Ensure care is taken when assisting them and explain the reason for care when doing any of the above in order to maintain IV access | Educates individual about importance of maintaining IV access and the risks associated with poor management<br>Ensures safety with IV management<br>Prevents complications |
| Monitor IV infusion every hour as per facility/organisation policy. Assess IV patency, rate of flow and response to treatment | Prevents complications related to delivery of IV fluid and early detection of inflammation or tissue damage |
| Change IV fluid as ordered ensuring that correct checking procedures are in place as per policy and procedure<br>Complete FBC as per policy and procedure<br>Document IV management in health record and other forms as required:<br>• signs IV fluid chart, records date and time infusion commenced, completes and attaches change of IV line label to IV tubing<br>• condition each shift, any complications such as infection, injury or loss of patency | Maintains IV access and maintenance<br>Ensures individual is receiving recommended therapy as ordered<br>Prevents complications and monitors status |
| Discontinue IV therapy and remove IV cannula when:<br>there is a medical order (verbal or written)<br>complications have arisen (as mentioned above) and these have been discussed with a Registered Nurse or medical officer (see Clinical Skill 24.8)<br>Document date and time of removal, condition of site at time of removal and whether cannula and tip were complete and intact (see Clinical Skill 24.8) | IV cannulas are inserted to administer medications and/or fluids |
| Communicate abnormal findings to the Registered Nurse/ medical officer<br>Report to oncoming nursing staff: type of fluid, flow rate, condition of cannula site, any side effects | Alerts staff of IV cannula/fluid administration<br>Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Phillips & Gorski 2014; Centers for Disease Control and Prevention 2011)* | |

## CLINICAL SKILL 24.7 Administration of intravenous (IV) medications: infusion and bolus

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication orders, IV fluid, medication, diluent, IV infusion set, burette, syringe and needleless device for administration and vial access (if applicable), IV additive label, IV line label, antiseptic swabs, disposable gloves, IV pump and fluid balance chart (FBC), injection tray<br>Resource material (e.g. MIMS, Injectable Drugs Handbook) |

| **Skill activity** | **Rationale** |
|---|---|
| **General procedures for administration of all IV medications** | |
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions<br>Collect all necessary information about the medication, including action, purpose, normal dose, side effects, any special administration information and compatibility of fluids and medication | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Understanding improves compliance/concordance/adherence with medication therapy<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction.<br>Promotes correct and safe administration of the drug and enables the nurse to monitor the therapeutic effects of the medication |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth.<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Promotes correct and safe administration of the medication<br>Confirms the individual's identity and reduces risk of allergic reaction |
| Perform hand hygiene and follow infection control/ANTT procedures | Prevents cross-infection |
| Calculate the correct dose and prepare the medication according to Table 24.3: Preparation of medications from ampoules and vials<br>Check the label and expiry date. Have two nurses check (one must be a Registered Nurse) according to safe administration guidelines and the facility/organisation policy<br>Compare the medication container with the order on the medication chart | Promotes safety during administration<br>Ensures the correct medication is being administered<br>Prevents preparation errors |
| Check cannula insertion site for any signs of redness, warmth, swelling, pain or tenderness on palpation<br>Assess the patency of the cannula as per facility/organisation policy | Ensures safe administration of medication into venous system rather than into surrounding tissues |

| CLINICAL SKILL 24.7 Administration of intravenous (IV) medications: infusion and bolus—cont'd | |
|---|---|
| If necessary, check vital signs before, during and after infusion of medication as recommended and/or as per policy and procedure | Allows nurse to monitor individual's response to medication<br>Ensures safety of the individual during the administration of the medication |
| Perform hand hygiene and follow infection control/ANTT procedures. Put on disposable gloves | Prevents cross-infection |
| Safely dispose of equipment into the correct disposal unit after use | Prevents accidental needlestick injuries (if needle used) and disposes of waste correctly as per policy and procedure |
| Record medication administration promptly on medication/infusion administration sheet | Prevents medication errors from occurring; for example, dose being duplicated |
| Record volume of fluid in medication bag (used for piggyback/tandem administration) or burette on intake/output form | Prevents circulatory overload |
| Observe closely and report any adverse reactions to medical officer and/or nurse in charge; document in individual's progress notes | Allows medical officer to stop or change medication promptly if an adverse reaction occurs, and to treat the symptoms of an adverse reaction |
| **Large volume infusions (e.g. potassium chloride, vitamins)** | |
| Before adding medication, ensure that it is compatible with the IV fluid | Prevents chemical reaction occurring, which may result in clouding or crystallisation of the IV fluid |
| Perform hand hygiene<br>Vigorously rub injection port with alcohol swab and allow to dry | Prevents introduction of microorganisms and cross-infection |
| Insert the needle, needleless adaptor or syringe and add required medication to the IV infusion bag via the medication injection port, which should have a rubber stopper at end. Do not select port used for IV tubing | Correct addition prevents infection, as medication port is self-sealing to prevent the introduction of microorganisms |
| After withdrawing syringe, gently mix contents of infusion | Ensures even distribution of medication throughout the infusion fluid |
| Complete an IV medication additive label, with details of medication added to fluid, date, time and nurses' signatures | Informs all staff of the contents of the infusion |
| Attach and prime labelled IV tubing. Ensure infusion rate is correct. A volumetric pump or burette may be added (according to facility/organisation policy) | Prevents circulatory overload<br>Ensures correct and safe administration of infusion |
| **Intravenous bolus via IV cannula/IV line** | |
| As well as preparing medication, prepare two syringes with 5–10 mL of normal saline each, for flushing the cannula/line before and after medication administration | Prevents blockage of line and ensures medication has been injected completely, and prevents chemical irritation to the vein |
| Take equipment to the individual in injection tray ensuring all sharps contained/capped correctly<br>Select injection port closest to individual | Ensures correct transporting of equipment and abides by infection control/ANTT procedures.<br>Allows for easier aspiration for blood return to check placement |

*Continued*

| CLINICAL SKILL 24.7 Administration of intravenous (IV) medications: infusion and bolus—cont'd | |
|---|---|
| Perform hand hygiene<br>Vigorously rub the cannula bung/injection port with alcohol swab and allow to dry | Prevents risk of cross contamination and the introduction of microorganisms |
| Connect syringe containing normal saline to IV line or IV bung/smart site by either inserting needle into injection port (needle system) or removing cap of needleless injection port and connecting syringe tip directly | Allows for access |
| If IV line in situ, occlude infusion line above port by pinching tubing. Gently pull back on syringe plunger to aspirate blood | Checks position of cannula, prevents back-flow into IV line and ensures medication to be administered is into venous system |
| Slowly inject 2 mL of normal saline for a short line. Longer lines may need 2–5 mL of normal saline | Clears reservoir of blood and checks patency of access port |
| Inject medication slowly over several minutes (or as directed by manufacturer's information), continuing to occlude tubing above port if applicable | Ensures medication is given at the correct rate. Rapid administration may cause pain or phlebitis or be fatal |
| Withdraw syringe and flush with 2 mL of normal saline for a short line. Longer lines may need 5–10 mL to allow for medication clearance | Flushes medication properly into the venous system preventing chemical irritation |
| Release tubing and regulate infusion rate if necessary | Occluding tubing may affect the infusion rate<br>Ensures the return to the original infusion rate as ordered |
| Vigorously rub the injection port with alcohol swab and allow to dry and if the port was capped, replace cap | Prevents introduction of microorganisms |
| **Piggyback/tandem infusion** | |
| Perform hand hygiene<br>Connect infusion tubing to medication bag using aseptic technique and allow solution to fill tubing | Prevents the introduction of microorganisms and cross-infection<br>Tubing should be filled with solution and free of air to prevent air embolus |
| Hang medication bag and connect tubing to infusion port (e.g. stopcock, needleless system, tubing port) on the primary infusion line after having vigorously rubbed the port with alcohol swab and allowed alcohol to dry | Prevents introduction of microorganisms |
| Infuse medication as per manufacturer's recommendations and/or an intravenous drug administration book<br>Regulate flow rate using regulator clamp | Ensures medication is administered at the correct rate to maintain therapeutic levels and prevent toxicity or adverse reactions |
| When completed, remove and discard secondary infusion bag in a safe and appropriate manner<br>Connect compatible IV fluid to flush medication, then remove secondary line from the primary line<br>Return to primary infusion rate | Ensures complete infusion of medication<br>Ensures the return to the original infusion rate as ordered |
| Ensure primary infusion is running at the correct rate | Secondary infusion may have interfered with the flow of the primary infusion<br>To prevent circulatory overload |

## CLINICAL SKILL 24.7 Administration of intravenous (IV) medications: infusion and bolus—cont'd

| Burette | |
|---|---|
| Perform hand hygiene<br>Fill burette with desired amount of fluid from infusion bag as per the recommendations listed in the manufacturer's guidelines and/or an intravenous drug administration book | Prevents cross-infection<br>Ensures correct amount of diluent for the safe administration of the medication<br>Prevents the risk of circulatory overload<br>Prevents toxicity |
| Clean injection port on top of burette with alcohol swab and allow alcohol to dry | Prevents introduction of microorganisms |
| Inject medication into port and gently mix with fluid in burette | Ensures even distribution of medication throughout fluid |
| Regulate infusion rate to allow medication to infuse at the required rate as per the recommendations listed in the manufacturer's guidelines and/or an intravenous drug administration book | Ensures medication is administered at the correct rate to maintain therapeutic levels and prevent toxicity or adverse reactions |
| Label burette with medication administration label containing name of medication, total volume, time of starting administration, individual details and checking staff signature/initials | Ensures all staff are aware of medication infusion occurring; prevents other medication being added to burette at same time<br>Abides by policy and procedure |
| When infusion is complete, fill burette to desired flush and infuse over the same rate medication administered (ensure flush is enough to completely infuse total medication through the IV giving set)<br>Once complete remove label from burette and return infusion to previous rate | Ensures medication infused correctly and totally in order to allow for therapeutic levels and ensure no crystallisation of fluid occurs<br>Alerts staff that medication infusion is complete |
| If more than one medication is to be administered, ensure that burette and line are 'flushed' in between the medications, and wait the recommended time between the administration of medication as per the recommendations listed in the manufacturer's guidelines and/or an intravenous drug administration book | Prevents incompatible medications coming into contact with each other<br>Ensures that medication actions are adhered to and therapeutic outcomes are optimal |
| Record each medication administered on the medication chart | Prompt documentation prevents errors. Sites should be rotated for long-term therapy such as insulin, as repeatedly using same site leads to thickening of skin and tissue atrophy |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is effective/appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Phillips & Gorski 2014; Centers for Disease Control and Prevention 2011; Berman et al 2015; Tollefson et al 2016)* | |

cannula. They are often administered at small rates (e.g. 10 mL/hour). Large volume infusions are where fluids or medications are delivered in 500–1000 mL bags, and as any medication added to these volumes is not concentrated it is less likely ADRs will occur (Brotto 2013). Small volume infusions are mixed in 50–100 mL bags and given intermittently over a shorter period of time.

- IV bolus—a volume of fluid or medication that may be given quickly over a short time period or as an IV push. A bolus is a prescribed volume delivered from an already existing IV infusion (250 mL over 15 minutes) or by syringe into an IV access port. Some medications that may be given as a push include opioids, antiemetics or antibiotics. Prior to administration of a bolus the patency of the IV cannula must be ascertained to ensure medication enters the vein and not surrounding tissue (Brotto 2013).
- Intermittent IV infusions—as a mixture in a small volume (e.g. 50–100 mL) of compatible fluid in a secondary fluid container separate from the primary infusion.

The two most commonly used additive or secondary setups are:

- The piggyback or add-a-line infusion (Figure 24.16)
- The burette (volume-control administration set) (Figure 24.17).

Both are acceptable procedures for intermittent medications to be administered.

**Figure 24.16** Add-a-line/piggyback setup
*(Potter et al 2013)*

The individual will already have an existing infusion line or an intermittent venous access port. The advantages of the intermittent venous access port include increased mobility, comfort and safety, and the nurse not needing to monitor flow rates on an ongoing basis. Many acute healthcare facilities now have pumps preprogrammed with medication dosages and delivery rates to minimise the risk of medication administration errors.

## Medication administration

Medication administered intravenously gives an immediate response, and allows more control over the rate of medication being delivered, either as a bolus or by diluting it in IV

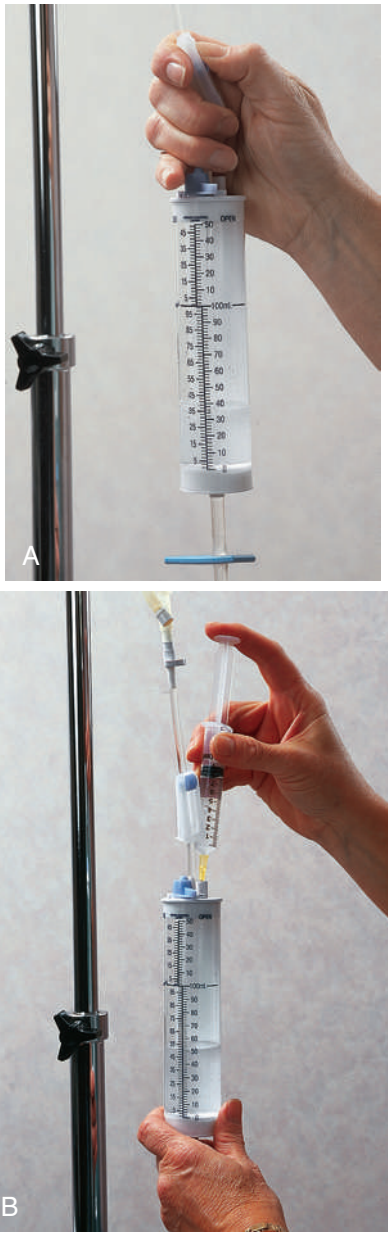

**Figure 24.17** A, B: Burette delivery
*(Brotto 2013)*

solution and giving it intermittently or over a longer time frame (Phillips & Gorski 2014). Immediate adverse reactions and incompatibilities can also occur (Amero et al 2010).

IV medications are often delivered concurrently with other IV fluids or medications and the nurse preparing the fluid or medication must ensure all fluids or medications being delivered are compatible. For the medication to be mixed successfully the diluent and the medication must be compatible (Amero et al 2010). Incompatibility occurs when fluids or medication alter the action of other medications they are mixed with. These are classified as physical, chemical or therapeutic incompatibilities (Phillips & Gorski 2014).

Physical incompatibilities occur when mixing a medication with a fluid or another medication, causing insolubility (where the medication does not dissolve completely in the fluid) (Phillips & Gorski 2014). Cloudiness, colour change or gas bubbles are a sign that there is an incompatibility (Broyles et al 2013). Chemical incompatibility is where the pH is altered by mixing incompatible medications or fluids together, resulting in instability of one or both of the medications (Phillips & Gorski 2014). This can occur when acid or alkaline medications and solutions are mixed (Amero et al 2010). Therapeutic incompatibility is where the individual suffers an ADR when two or more medications are given concurrently, resulting in a decreased or increased therapeutic response (Phillips & Gorski 2014). Medication incompatibilities are outlined in the *Australian Injectable Drugs Handbook* (The Society of Hospital Pharmacists of Australia 2014), and these must be identified prior to mixing medications and fluids to ensure an incompatibility reaction does not occur. The nurse must observe the mixed medication while preparing and prior to administration of the medication, and if any changes in the solution have occurred the medication must not be administered (Broyles et al 2013).

In preparing medications for IV administration the nurse must ensure that the medication solution being mixed or added to a fluid flask is adequately mixed. Inadequately mixed medications can mean the individual inadvertently receives a bolus of the medication (especially if the medication is dense and settles to the base of the fluid flask), which can result in serious ADRs (Phillips & Gorski 2014). If the individual receiving the IV medication complains of pain, burning or stinging in the arm, this is a warning that the concentration of the medication is irritating the vein wall. The concentration of the fluid may need to be altered by mixing in a larger volume of fluid or a slowing of the delivery rate, after review by the medical officer.

### Complications of IV therapy

In the delivery of IV fluids and medications it is the nurse's responsibility to assess and monitor the individual for complications. Complications occur either locally or systemically. Local complications are most common and result from adverse medication reactions or trauma at the IV cannula site (Phillips & Gorski 2014). See Table 24.5 for a list of common local IV therapy complications and clinical manifestations. Systemic complications are less common; however, when they occur they can be life-threatening (Phillips & Gorski 2014). Early detection is required to prevent complications becoming more severe; therefore, any change in the individual's health status while receiving IV fluids or medication must be reported immediately to the nurse in charge. (See Clinical Skill 24.8.)

## Administering topical medication

Topical medications are applied locally to the skin or mucous membranes such as the ear, eye, vagina, rectum and nose. They can be in the form of lotions, pastes, creams, pessaries, powder, oil or ointments.

### Skin applications

Topical preparations such as those used in the treatment of dermatological conditions may be formulated as an ointment, lotion, cream, jelly, powder, paint, paste or spray (Broyles et al 2013). Medications may be applied to the skin by painting, spreading or spraying medication over an area, applying moist dressings or by soaking body parts in a solution. Medications applied to the skin generally have a local effect; however, traces of some medications may be absorbed transdermally into the blood stream (e.g. cortisone). To avoid medication being absorbed through the skin of the hands, the nurse should wear non-sterile gloves for protection or use an applicator during administration of topical medications (Brotto 2013). To prevent accumulation, any residual medication on the skin should be removed before reapplication. In addition, removal of residual medication allows the nurse to assess the application site for any irritation. When applying a prescribed topical preparation, the manufacturer's directions must be followed. (See Clinical Skill 24.9.)

### Applying transdermal medications

Certain medications can be applied to the skin to supply medications directly into the bloodstream for prolonged systemic effect. The medications are applied via an adhesive patch or disc which releases a known amount of medication per time (e.g. 5 mg over 24 hours). Transdermal medications include glyceryl trinitrate (known as nitroglycerine in the US) (to relieve angina pectoris), nicotine (for nicotine withdrawal) and oestrogen (for hormone replacement therapy). Medications administered transdermally bypass the liver and therefore first-pass metabolism.

Adhesive patches or discs which are applied to the skin are composed of an adhesive layer, a rate-limiting membrane, a medication reservoir and a waterproof external layer. The discs are applied to a dry, clean, hairless area of the body. The waterproof external layer enables the individual to shower or bathe without adversely affecting the medication's action. Medications applied in this manner can exert their effects for as long as 72 hours. Education should include the correct application of the transdermal patch or disc (including the removal of the old disc), the frequency of application, the need to rotate application sites to prevent skin irritation occurring, correct storage of the discs, the need to wash the hands after application and correct disposal of the discs after

## TABLE 24.5 | Common complications of IV therapy and clinical manifestations

| Local complications | Clinical manifestations |
|---|---|
| **Infiltration**<br>The IV cannula becomes dislodged from the vein or passes through the wall of the vein. Infusion fluid enters into the surrounding tissue. Often caused by poorly secured cannulas | Oedema surrounding the cannula site, cool to touch, pale skin, infusion slows and pinkish coloured blood on draw back |
| **Thrombosis**<br>A blood clot forms in the vein at the tip of the cannula causing an obstruction in the cannula. Do not force the flush as this can dislodge the clot into the systemic circulation | Cannula does not flush, infusion does not flow and there is pain at site |
| **Extravasation**<br>Vesicant medication enters into the surrounding tissue. This may be caused by a dislodged cannula, increased pressure or irritation of the vesicant fluid on the vein wall, or vein wall being punctured on insertion of the cannula | Site pain and tenderness, oedema, paleness around insertion site, burning sensation and slow or stopped infusion. |
| **Phlebitis**<br>Inflammation of the vein may be caused by irritating medications or fluids, or from the cannula irritating the vein wall | Local erythema, heat, swelling, cording, infusion rate slowed or stopped, and pyrexia |
| **Haematoma**<br>Infiltration of blood into the tissues commonly caused by trauma to the vein wall on insertion of the cannula | Ecchymosis at the insertion site and surrounding tissue, swelling and discomfort |
| **Systemic complications** | **Clinical manifestations** |
| **Peripheral oedema**<br>Caused by infusion of excessive IV fluid or given too rapidly, failure to monitor the person's fluid balance status in a person with renal or cardiovascular compromise. Excess fluid causes pressure in the intravascular space causing it to leak into dependent limbs (legs) | Pitting oedema and pallor in lower extremities that can progress to abdomen, weight gain over short period, taut skin, indentation from pressure of socks and clothing |
| **Acute pulmonary oedema**<br>Caused by infusion of excessive IV fluid or given too rapidly, failure to monitor the person's fluid balance status, in a person with renal or cardiovascular compromise. Excess fluid causes pressure in the intravascular space, causing pressure in the pulmonary capillaries as fluid passes into the alveoli, causing pulmonary oedema. This is a life-threatening condition and an emergency call (MET or code blue) should be made | Shortness of breath, cyanosis around lips and mouth, decreasing oxygen saturations, restlessness, cough, pink frothy sputum, crackles to lung bases on auscultation, weight gain over short period |
| **Speed shock**<br>When the IV fluid or medication is delivered too quickly | Dizziness, hypotension, headache, flushing of the face, chest tightness, may progress further to circulatory shock |
| **Septicaemia**<br>Microorganisms enter the systemic circulation through poor aseptic procedure during insertion and in accessing the cannula | Pyrexia, diaphoresis, diarrhoea, nausea and vomiting, abdominal pain, tachycardia and hypotension |
| **Air embolism**<br>Rare but lethal. Air enters the cannula and the systemic circulation. Occurs when air is present in the IV line from poor priming or changing an IV bag without checking for air in the line | Dizziness, dyspnoea, cyanosis, cough and expiratory wheeze, hypotension and chest pain, confusion, coma |

## CLINICAL SKILL 24.8 Removal of intravenous cannula

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable gloves, dressing pack/sterile gauze (as per facility/organisation policy), injection tray, antiseptic solution/swab (as per facility/organisation policy) and tape |
| **Skill activity** | **Rationale** |
| Check/confirm the medical order for removal of the IV cannula<br>(If removal required due to complications from the IV therapy refer to the Registered Nurse and the facility/organisation policies) | Abides by policy and procedure, and medical order |
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check all allergies including latex or tape | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Understanding improves compliance/concordance/adherence with therapy<br>Promotes participation in care and understanding of health status<br>Reduces risk of allergic reaction |
| Perform hand hygiene and don gloves<br>Follow infection control/ANTT procedures | Prevents cross-infection and abides by infection prevention policy |
| Gently remove tapes securing the IV and the occlusive dressing ensuring no pulling of excess hair<br>Use scissors to cut away hair if required | Decreases discomfort and helps prevent complications to the surrounding skin |
| Once tapes and dressing removed, clean with normal saline chlorhexidine according to facility/organisation policy and allow to dry. Place sterile gauze over insertion site (do not press) and gently remove cannula along the line of the vein<br>Place gauze and a strip of tape over site ensuring adequate pressure until there is no further bleeding from site<br>Inspect the PIVC for completeness | Prevents the introduction of microorganisms<br>Prevents a haematoma or injury to the vein post removal<br>Ensures whole cannula was removed and none left behind |
| Place all discarded equipment in injection tray and dispose in the required waste receptacle.<br>Perform hand hygiene and document removal of IV cannula. Document date and time of removal, condition of site at time of removal and whether cannula and tip were complete and intact.<br>Communicate abnormal findings to the Registered Nurse/medical officer | Abides by infection prevention policies<br>Abides by facility/organisation policies<br>Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |

*(ACSQHC 2012c; 2015b; Phillips & Gorski 2014; Centers for Disease Control and Prevention 2011)*

## CLINICAL SKILL 24.9 Administration of a topical medication

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Prescribed medication<br>Gloves<br>Resource material (e.g. MIMS) |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth.<br>Check the name of medication, dose, route, time of last administration and frequency of administration. The nurse should also identify the site the topical medication needs to be applied | Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered<br>Prevents preparation errors |
| Perform hand hygiene and follow infection control procedures. Put on gloves | Prevents cross-infection. Wearing gloves prevents the nurse absorbing the medication through their skin |
| Apply the required amount of topical medication onto the individual's skin | The amount of topical medication applied depends on the type of medication being applied. For example, if applying a corticosteroid the fingertip unit is used as guide to determine how much product to apply. Other treatments such as emollients may require more generous application of the product |
| Remove gloves, perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |

| CLINICAL SKILL 24.9 Administration of a topical medication—cont'd | |
|---|---|
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2015a; Lawton 2013)* | |

use. Education should particularly stress the importance of keeping the discs out of reach of children. Gloves should be worn and hands washed immediately after applying the discs to avoid the nurse absorbing any of the medication transdermally through the hands (Brotto 2013). (See Clinical Skill 24.10.)

## Instilling eye drops and ointments

Eye drops or ointments prescribed may include those that treat infection, dilate or constrict the pupil, act as a local anaesthetic, stain the cornea, reduce inflammation or reduce intraocular pressure. Key aspects regarding the use of ophthalmic medications include checking the:

- Name, strength and amount of drops or ointment to be instilled
- Frequency and time of last administration
- Eye into which the eye medication is to be instilled (i.e. left, right or both eyes)
- Expiry date on the container, and discarding the medication if the expiry date has passed. Eye drops tend to have a short use-by date after opening, therefore the date is written on the container the day it is opened so the discard date can be observed.

Eye drops are supplied in a squeeze bottle with a nozzle top through which the drops are delivered. To prevent cross-infection a separate container of drops or ointment is supplied for each individual. Single-dose packaging is preferred, as contamination of the medication is likely to occur if a container such as a dropper bottle is used repeatedly. Guidelines for instilling eye drops and ointment are presented in Clinical Skill 24.11.

The equipment required comprises:

- Medication chart
- Non-sterile gloves
- Prescribed drops or ointment
- Normal saline (if required)
- Two or three gauze swabs to cleanse eye prior to instillation
- Rubbish bag for used swabs
- Sterile eye pad and tape if required.

## Instilling ear drops

Ear drops prescribed may include those that treat infection or soften wax. The ear drops must be at room temperature when instilling, as the inner ear is sensitive to temperature extremes, and cold fluids can provoke vertigo or nausea (Brotto 2013). Guidelines for instilling ear drops are presented in Clinical Skill 24.12. The equipment required comprises:

- Medication chart
- Non-sterile gloves
- Prescribed drops, warmed to body temperature
- Two or three cotton wool swabs
- Cotton-tipped buds (if required)
- Rubbish bag for used swabs.

## Inserting vaginal medications

Vaginal medications are available as creams, jellies, ointments or pessaries (Broyles et al 2013). Pessaries and creams are generally administered with an inserter or applicator, allowing the medication to be placed high in the vaginal vault for maximum effect. Vaginal pessaries are presented in conical, oval or cylindrical shapes and are supplied in individual foil or plastic wrappers. Vaginal anti-infective medications are prescribed to treat vaginal infections, and vaginal hormone preparations are prescribed to treat conditions such as senile vaginitis. Unlike the rectum, the vagina does not have a sphincter and therefore the pessaries and creams, when they melt as they warm to body temperature, may run out (Brotto 2013). To help avoid this, vaginal preparations should be instilled at night whenever possible, when the individual is in bed ready for sleep. Sanitary pads are recommended to prevent staining or soiling of underwear. The use of tampons is not recommended.

Individuals who require vaginal medication may prefer to self-administer to avoid embarrassment and should be provided the privacy to do so (Brotto 2013). The nurse may be required to perform the technique or to instruct the individual in how to insert vaginal medications. A suggested procedure is outlined in Clinical Skill 24.13.

*Text continued on page 616*

## CLINICAL SKILL 24.10 Applying transdermal medications

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Prescribed medication<br>Resource material (e.g. MIMS)<br>Gloves |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual compared to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Confirms the individual's identity and reduces risk of allergic reaction<br>Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered<br>Prevents preparation errors |
| Perform hand hygiene and follow infection control procedures. Don non-sterile gloves | Prevents cross-infection<br>Prevents nurse absorbing medication if medication is touched |
| Inspect the skin to ensure that it is intact<br>Rotate site | Broken skin can affect the medication's absorption<br>Reduces irritation. Increased absorption may occur if applied to the same site |
| Ensure that any old patches that are in situ are removed before applying another patch. Patches that contain narcotic agents must be folded with adhesive sides sticking together and disposed of in a sharps container | Ensures the individual receives the correct dose of the medication<br>Ensures that these patches cannot be inappropriately used by another individual |
| Write the date and time on the patch<br>Remove the adhesive backing and apply the patch onto a dry, hairless area of the individual's skin. The patch cannot be cut into smaller pieces | It can be clearly seen when the patch was applied<br>Cutting the patch into smaller pieces can affect the dose of the medication that the individual receives |
| Remove gloves. Perform hand hygiene and follow infection control procedures | Prevents cross-infection |

| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment.<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Understanding improves compliance/concordance/adherence with medication therapy<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose (number of drops), route (including whether medication will be administered to right or left eye or both), time of last administration and frequency of administration | Promotes correct and safe administration of the medication<br>Confirms the individual's identity |

*Continued*

| CLINICAL SKILL 24.11 Instilling eye drops or ointment—cont'd | |
|---|---|
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date<br>Check the date that the container was opened<br>Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Promotes correct and safe administration of the medication<br>Out-of-date medication may be ineffective. Some eye drops must be discarded 30 days after opening the container |
| Assist the individual to a position with the head tilted well back (if possible) | Facilitates correct instillation of medication |
| Perform hand hygiene and follow infection control procedures. Put on non-sterile gloves | Prevents cross-infection |
| If eye contains any discharge or crusting, it should be cleaned with normal saline and gauze swabs before instilling drops or ointment | Discharge or crusting prevents adequate absorption of medication |
| Gently pull down the lower lid to form a pouch | Facilitates correct instillation of medication |
| Remove the cap of the container and hold the dropper or tube slightly away from the eye | Avoids contacting any part of the eye and contaminating the nozzle |
| If drops are being instilled, the prescribed number is dropped into the pouch of the lower lid. 5 minutes should be left between administering multiple eye drops | Medications should be instilled correctly (e.g. into the pouch of the lower lid and not directly onto the eyeball)<br>If eye drops are administered too quickly the previous eye drops may be washed away and not absorbed |
| Advise the individual to close their eyes for 60 seconds after the drops have been administered | This prevents the drops running into the nose and being swallowed |
| If ointment is being instilled, the eye drops should be administered first | Ointment waterproofs the eye |
| The initial 1.25 cm of the ointment is discarded onto a swab. Directing the nozzle of the tube near the lid, a ribbon of ointment is squeezed along the rim of the lower lid | Reduces the risk of instilling contaminated ointment |
| Request the individual to close the eyelid gently. Wipe away any excess with a gauze swab. Request that the individual blink gently several times | Facilitates even distribution of the medication over the eye's surface |
| Apply an eye pad if required (see Clinical Skill 16.1) | A pad may be prescribed for comfort or protection |
| Assist the individual into a comfortable position | Promotes comfort |
| Remove non-sterile gloves, perform hand hygiene | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable). Record appearance of eye in medical record | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |

## CLINICAL SKILL 24.12 Instilling ear drops

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Ear drops<br>Cotton balls<br>Cotton-tipped applicator<br>Resource material (e.g. MIMS) |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration. The nurse should also identify the site the topical medication needs to be applied | Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Check the date that the container was opened<br>Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered. Prevents preparation errors<br>Out of date medication may be ineffective. Some ear drops must be discarded 30 days after opening the container |
| Assist the individual to lie on the side opposite to the affected ear side | Facilitates instillation of the drops into the ear |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Inspect the ear for any wax or drainage. Wipe out gently using a cotton bud, ensuring that wax is not forced inwards | Any occlusion will prevent drops from being evenly distributed |
| Gently pull the auricle up and back. For a child under 3 years, the earlobe is pulled down and back | Straightens the ear canal |
| Ensure that the drops are at room temperature. Instil the prescribed number of drops so that they fall against the sides of the canal and not on the tympanic membrane | Cold drops may cause vertigo and nausea. Avoids discomfort |
| Gently massage or apply pressure to the projection in front of the meatus (the tragus) | Ensures that the drops flow into the canal |

*Continued*

## CLINICAL SKILL 24.12 Instilling ear drops—cont'd

| | |
|---|---|
| Wipe the outer ear free of excess drops | Promotes comfort |
| If prescribed, place a cotton wool swab loosely into the meatus, or instruct the individual to lie with affected ear upwards for 10 minutes | Prevents the medication from leaking out |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer. | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2015b)* | |

## CLINICAL SKILL 24.13 Administration of a vaginal medication

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication order/chart<br>Medication<br>Applicator<br>Gloves<br>Tissues<br>Perineal pad<br>Lubricant for a suppository/pessary<br>Resource material (e.g. MIMS) |
| **Skill activity** | **Rationale** |
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment | Ensures consent<br>Ensures efficiency |
| Ensure therapeutic interaction | Reduces the incidence of performing an activity on the incorrect individual |
| Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status |
| Ask the individual to empty their bladder | Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction<br>If the bladder is empty the individual may have less discomfort. Voiding after the medication is administered may result in the medication not being retained |

| CLINICAL SKILL 24.13 Administration of a vaginal medication—cont'd | |
|---|---|
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Confirms the individual's identity and reduces risk of allergic reaction<br>Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered. Prevents preparation errors |
| Ensure privacy and assist the individual into the dorsal recumbent position, with legs flexed and extended apart | Privacy reduces embarrassment. Position provides easy access to and adequate exposure of the vaginal canal |
| Perform hand hygiene and follow infection control procedures. Put on non-sterile gloves | Prevents cross-infection |
| Attach the applicator to the tube of cream or place the pessary in the applicator. Apply lubricant to the applicator | Promotes correct and safe administration of the medication. Lubrication facilitates insertion |
| Gently retract the labial folds | Exposes the vaginal orifice |
| Insert the applicator into the vagina in an upwards and backwards direction, about 7.5 cm. Push the plunger to deposit the medication | Proper placement ensures equal distribution of medication along the walls of the vaginal cavity |
| Withdraw the applicator, wipe any residual cream from the labia and apply a perineal pad | Promotes comfort; perineal pad prevents staining of clothing |
| Encourage the individual to remain in the recumbent position for at least 10 minutes after administration | Allows medication to melt and be absorbed into the vaginal mucosa. The vagina has no sphincters and the medications may not be retained if the individual stands immediately after administration. Medication given via the vaginal route is best administered at night for this reason |
| Wash applicator in warm soapy water, rinse and dry. The applicator is stored for future use by that individual only. Remove gloves. Perform hand hygiene | Prevents cross-infection |
| Record administration on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2014h)* | |

The equipment required comprises:

- Medication chart and medication chart
- Prescribed pessaries or cream
- Inserter or applicator
- A small disposable sheet to protect bed linen
- Non-sterile gloves
- Receiver (e.g. paper bag) for used articles
- Perineal pad.

## Administering medications by inhalation

Medications can be inhaled to produce a local or systemic effect via the respiratory tract by steam inhalation, nebuliser, atomiser or aerosol spray. Most commonly, medications are delivered to the lungs' membranes as sprays from pressurised aerosol dispensers, or as dry powder from an inhaler (Brotto 2013).

Aerosol inhalers are widely used to administer bronchodilators for the management of asthma, chronic obstructive pulmonary disease or bronchitis. The medication and its inert propellant are maintained under pressure in a small canister. When the valve is activated, a measured quantity of propellant carrying the medication is released through the mouthpiece. It is important that the individual is instructed in the correct technique on inhaler use, otherwise the medication will be deposited on the tongue and not into the airways. A spacer is recommended to be used to ensure maximal benefit from inhalation, and can be particularly beneficial for young children or individuals who find it difficult to manage aerosol inhalation (Brotto 2013). The bronchodilator is released into the plastic spacing device and then inhaled. It is also useful if an individual is unable to coordinate aerosol inhalation. In the use of an inhaler the mouth is placed over the mouthpiece, the individual inhales through the device causing medication particles (in powder form) to be drawn into the respiratory tract. If two inhalers are to be used, the bronchodilator medications should be given before the other medication to open the airways, allowing the second medication to enter more easily to exert a maximal effect. If steroids are used the mouth must be rinsed post dose to prevent fungal infections.

A nebuliser adds moisture and/or medications to inspired air, using the aerosol principle. Nebulisation is often used for administering bronchodilators or mucolytic agents. A high-pressure gas source (air or oxygen) is used to draw up the medication from a chamber creating a mist, which the individual inhales. Small-volume nebulisers are generally used for administering medications. These medications come prepared in 0.9% sodium chloride in plastic vials and are emptied into the aerosol chamber. To prevent cross-infection, each individual should be provided with their own nebuliser and mask for use on repeated occasions. The mask and nebuliser should be cleaned at regular intervals and disposed of when treatment is discontinued or the individual is discharged. (See Clinical Skill 24.14.)

A suggested procedure for using a hand-held inhaler is outlined in Clinical Skill 24.15. The equipment required comprises the medication chart, the prescribed medication, inhaler and the spacer if required.

## Administering medication by intranasal absorption

Medications may be administered intranasally via aerosol or drops instilled in the nose. The medication is rapidly absorbed through the vascular network in the nasal tissues. They may

### CLINICAL SKILL 24.14 Administration of a medication via nebuliser

**Review and carry out the standard steps for all clinical skills/interventions**

| NMBA Decision-making Framework considerations: | Equipment: |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. |---|---|
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Confirms the individual's identity and reduces risk of allergic reaction<br>Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered. Prevents preparation errors |
| Assist the individual into a semi- or high-Fowler's position | Position facilitates entry of the medication into the respiratory tract |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Attach the oxygen tubing to the oxygen or air outlet | Nebuliser can be administered using the air or the oxygen outlet. Individuals with airway disease should not be given high doses of oxygen |
| Open the nebuliser and add the medication that is to be administered to the nebuliser bowl | |
| Attach the nebuliser mask to the oxygen tubing. Turn the oxygen/air on to 6–8 L/min and check that mist is coming from the nebuliser mask | Setting the oxygen/air delivery to 6 L/min ensures that the medication is nebulised |
| Remove mask once medication has been delivered | Mist will no longer come from the mask once the medication has been delivered |
| Dispose of or clean mask as per facility policy | It is imperative that the nurse adheres to the facility policy in regards to the use of nebuliser masks |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |

## CLINICAL SKILL 24.15 Use of a hand held inhaler and spacer

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medication chart/order<br>Hand-held inhaler<br>Spacer<br>Resource material (e.g. MIMS) |

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration | Confirms the individual's identity and reduces risk of allergic reaction.<br>Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered. Prevents preparation errors |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Assist the individual into a semi- or high-Fowler's position | Position facilitates entry of the medication into the respiratory tract |
| Load the inhaler with the canister of medication. Remove the mouthpiece cap. Shake the inhaler | Prepares the inhaler for administration of the medication |
| Attach the mouthpiece of the inhaler into the spacer | The use of a spacer is recommended to ensure more of the medication is delivered into the respiratory tract |
| Instruct the individual to place the mouthpiece of the spacer well into the mouth, close the lips firmly around it and tilt the head back slightly | Tight seal is necessary to prevent the escape of medication into the air |
| Advise the individual to start to breathe in through the mouth and to press the canister to deliver one puff of medication. Inform the individual to breathe in and out for 4 breaths | Ensures the whole dose is delivered into the respiratory tract |

| CLINICAL SKILL 24.15 Use of a hand held inhaler and spacer—cont'd | |
|---|---|
| The technique is repeated if necessary until the prescribed dose has been inhaled or a different inhaler is also required. Time between inhalations depends on which medications are being inhaled | Time between inhalations allows deeper penetration of the second inhalation |
| Clean mouthpiece and spacer after each use with mild soap and water. Replace the cap on the mouthpiece | Prevents contamination of mouthpiece |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Encourage the individual to rinse their mouth after administration | Prevents hoarseness, irritated sore throat or oropharyngeal candidiasis |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2013e)* | |

be used to loosen secretions or treat infections of the nasal cavity or sinuses. Repeated use may lead to nasal irritation or a rebound effect (an increase in nasal congestion). If excess nasal decongestant is swallowed, systemic effects may also develop. It is usually easier for the individual to self-administer sprays. They are positioned in a supine position with the head tilted back (see Clinical Skill 24.16).

## MONITORING THE EFFECTS OF MEDICATIONS

The nurse plays a vital role in monitoring the effects of prescribed medications. Evaluating the individual's response is essential and the nurse is required to assess, report and record all responses to medication. This includes the desired therapeutic effects and any adverse reactions. To monitor the effects of any medication the nurse must first have a clear understanding of the purpose of the medication and its desired effects. Table 24.6 lists the major classes of common medication and their actions, and provides the nurse with a guide to the expected effects of various groups of medications. For example, the nurse needs to be aware that an analgesic medication is administered for the purpose of alleviating pain, an anti-inflammatory medication to relieve inflammation and an antipyretic to lower body temperature. Assessment and documentation should therefore indicate whether or not the medication has successfully achieved the desired therapeutic effect; for example, if the pain has been successfully relieved by the analgesic.

Whenever medication of any sort is administered there is always a possibility that side effects or adverse reactions may occur. Adverse reactions to a medication may be due to overdose, idiosyncrasy, toxic effects, allergy or medication interactions (Brotto 2013). Early detection of the manifestations of an adverse reaction and immediate, factual and concise reporting of these manifestations allows prompt action to be taken. Manifestations of an adverse reaction will depend on the type of medication administered and on each individual. It is important for the nurse to refer to either the manufacturer's information or a reliable textbook to have all of the information concerning possible adverse reactions. The nurse must be informed and knowledgeable about every medication before it is administered and document and report any adverse or side effect immediately to the nurse in charge and medical officer.

| **Skill activity** | **Rationale** |
|---|---|
| Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure/medication, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status on the medication chart and with the individual; compare to the medication ordered; check for medication interactions | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Determines if medication should be given and reduces risk of allergic reaction |
| Verify the indication for the medication | It is important that the nurse understands why the individual is receiving this medication |
| Ensure the correct medication is given by checking the 'seven rights'. Check the medication chart for the individual's name, date of birth and UR number. Check this against the individual's identity band/photo identification (if used) and ask them to state their full name and date of birth<br>Check the name of medication, dose, route, time of last administration and frequency of administration. The nurse should also identify the site the medication needs to be applied | Promotes correct and safe administration of the medication |
| Prepare the individual's medication by first reading the name of medication on the container and the expiry date. Check the date that the container was opened<br>Compare the medication container with the order on the medication chart. Recheck the medication container before returning it to the drawer | Ensures the correct medication is being administered. Prevents preparation errors<br>Out of date medication may be ineffective. Some ear drops must be discarded 30 days after opening the container |
| Ask the individual to gently blow their nose | Clear the nasal passages of mucus that may inhibit absorption of the medication |
| Assist the individual into an appropriate position: supine with head tilted back | Facilitates administration of the medication |
| Perform hand hygiene and follow infection control procedures. Determine if gloves are required for this procedure | Prevents cross-infection. Gloves may be required depending on the risk of exposure to nasal secretions |
| Instil the nasal medication aiming for the midline of the nose<br>Drops: hold the dropper 1 cm above the nares and instil the prescribed number of drops<br>Pressurised container: hold the spray container just into the nostril and press down as the individual slowly breathes in<br>Pump bottle: squeeze the pump as the individual inhales | Promotes correct administration of the medication |

| CLINICAL SKILL 24.16 Administering nasal sprays and drops—cont'd | |
|---|---|
| Use tissues to wipe away any excess fluid and advise the individual to not blow their nose and to remain in the supine position for a few minutes | Promotes absorption of the medication |
| Remove gloves (if used), perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Record each medication administered on the medication chart | Prompt documentation prevents errors |
| Report immediately if the individual refuses medication | Refusal to take medication should be documented on medication chart |
| Monitor individual for medication effectiveness (if applicable) | Ensures medication regimen is appropriate for the individual |
| Monitor individual for any adverse effects to the medication. Report and document any significant deviations to Registered Nurse/medical officer | Any adverse effects can be managed promptly |
| Safe medication management guidelines, outlined in Clinical Interest Box 24.3, should be incorporated into relevant aspects of this procedure and the nurse must act only within the laws, facility/organisation policy and scope of practice, which govern nursing practice. | |
| *(ACSQHC 2012c; 2015b; Joanna Briggs Institute 2014d; 2014e)* | |

**TABLE 24.6 | Major actions of common medication classes**

| Medication class | Action |
|---|---|
| **Medications acting on the cardiovascular system** | |
| Antianginal agents | Relax smooth muscle and reduce myocardial oxygen demand, thereby reducing angina |
| Antihypertensive agents | Reduce high blood pressure |
| Antiarrhythmic agents | Prevent, alleviate or correct cardiac arrhythmias |
| Antiplatelet agents | Decrease platelet aggregation to prevent thrombus formation |
| Cardiac glycosides | Increase force of myocardial contraction |
| Diuretics | Promote the formation and secretion of urine |
| Fibrinolytic agents | Activate the endogenous fibrinolytic system to dissolve intravascular blood clots |
| Lipid-regulating agents | Reduce blood cholesterol level |
| Vasodilators | Dilate blood vessels, improving circulation |
| **Medications acting on the respiratory system** | |
| Antiasthma agents | Prevent asthma symptoms |
| Bronchodilators | Relax bronchiole smooth muscle to relieve bronchospasm and improve ventilation |
| Cough suppressants; expectorants and mucolytics | Depress the cough centre in the medulla oblongata; break up mucus, enabling expectoration |

*Continued*

**TABLE 24.6 | Major actions of common medication classes—cont'd**

| Medication class | Action |
|---|---|
| **Medications acting on the nervous system** | |
| Analgesics | Alter the perception of pain |
| Antianxiety agents | Prevent or relieve anxiety |
| Antidepressants | Prevent or relieve depression |
| Antiepileptics | Also called anticonvulsants. Prevent or reduce the severity of epileptic seizures |
| Antimigraine agents | Prevent or relieve migraine headaches |
| Antimuscarinic agents | Also known as anticholinergics. Inhibit the transmission of parasympathetic nerve impulses, resulting in reduced muscle spasm, decreased secretion of sweat, saliva and nasal, bronchial and gastrointestinal secretions |
| Antipsychotic agents | Counteract or reduce symptoms of psychosis |
| Dopaminergic agents | Either stimulate dopamine receptors or replenish supply of dopamine. Commonly used in the treatment of Parkinson's disease |
| General anaesthetics | Used to induce and maintain anaesthesia during surgery |
| Local anaesthetics | Block nerve conduction |
| Muscle relaxants | Reduce contractility of muscle fibres, thereby reducing muscle spasm |
| Neuromuscular-blocking agents | Have an action at the muscle receptor end-plate and are used as an adjunct to general anaesthetics to relax muscle |
| Opioid analgesics | Alter perception of pain, induce euphoria, depress respiratory and cough reflexes |
| Parasympathomimetic agents | Central nervous system stimulants. Either mimic action of acetylcholine or block acetylcholine breakdown at receptor sites, thereby increasing total amount of acetylcholine |
| Sedatives and hypnotics | Depress the central nervous system |
| Stimulants | Excite the central nervous system |
| Sympathomimetic agents | Mimic noradrenaline and have effects including cardiac stimulation and relaxation of bronchial smooth muscle |
| **Medications acting on the endocrine system** | |
| Antidiabetic agents | Regulate the metabolism of glucose |
| Antithyroid agents | Inhibit synthesis of thyroid hormone (thyroxine) |
| Calcium-regulating agents | Lower blood calcium levels |
| Corticosteroids | Hormones that influence or control key processes in the body, including carbohydrate and protein metabolism, electrolyte and water balance |
| Hypothalamic and pituitary hormones | Used as replacement therapy |
| Thyroid agents | Replace thyroid hormones |

**TABLE 24.6 | Major actions of common medication classes—cont'd**

| Medication class | Action |
|---|---|
| **Medications acting on the gastrointestinal tract** | |
| Anorectic and weight loss agents | Suppress hunger sensation |
| Antacids | Neutralise gastric acidity and reduce pepsin activity |
| Antidiarrhoeal agents | Relieve diarrhoea |
| Antiemetics | Prevent and relieve nausea and vomiting |
| Antiulcer agents | Assist in the healing of gastric and duodenal ulcers |
| Laxatives | Promote peristalsis and evacuation of the bowel by increasing the bulk of faeces by softening the stool or by lubricating the intestinal wall |
| Prostaglandins | Inhibit gastric secretion |
| Topical rectal agents | Reduce pain associated with haemorrhoids |
| **Medications acting on the urinary system** | |
| Bladder function disorder agents | Treat disorders of the bladder to re-establish normal bladder function |
| Diuretics | Promote the formation and secretion of urine |
| **Medications acting on the reproductive system** | |
| Androgens | Control development of and maintenance of male sex organs and male secondary sex characteristics |
| Erectile dysfunction agents | Treats erectile dysfunction by promoting blood flow |
| Oestrogens | Control development and maintenance of female sex organs, secondary sexual characteristics and mammary glands |
| Prostaglandins | May cause contraction or relaxation of smooth muscle in blood vessels, bronchi, uterus or gastrointestinal tract |
| Progestogens | Convert the endometrial proliferative phase to the secretory phase in preparation for a fertilised ovum |
| Sex hormones | Sex hormones are prescribed for a variety of reasons, including the development or control of male or female sex organs and secondary sex characteristics. Common uses include oral contraceptives, hormone replacement medications to treat primary amenorrhoea, delayed onset of puberty or to relieve the symptoms of menopause. Sex hormones may also be used therapeutically to treat osteoporosis, to promote sex drive and fertility and in treatment related to breast or prostatic cancer.<br>The sex hormones include anabolic steroids, androgens, antiandrogens, oestrogens and progesterones |

*Continued*

**TABLE 24.6 | Major actions of common medication classes—cont'd**

| Medication class | Action |
|---|---|
| **Medications acting on the musculoskeletal system** | |
| Analgesics | Prevent and reduce pain |
| Non-steroidal anti-inflammatory medications (NSAIDs) | Reduce inflammation |
| Disease-modifying antirheumatic medications (DMARDs) | Treat rheumatoid arthritis |
| Antigout agents | Reduce pain and inflammation associated with gout or alter production or distribution of uric acid |
| Muscle relaxants | Reduce contractility of muscle fibres, reducing muscle spasm |
| **Medications acting on the immune system** | |
| Antihistamines | Reduce the effects of histamine released from cells |
| Corticosteroids | Hormones that influence or control key processes in the body, including carbohydrate and protein metabolism, electrolyte and water balance |
| Immunomodifiers | Modify the immune system |
| Vaccines, immunoglobulins and antisera | Vaccines induce a specific active artificial immunity. Antisera contain antibodies (immunoglobulins) against a specific disease to confer passive immunity |
| **Medications acting on the blood** | |
| Anticoagulants | Prevent or delay the coagulation of blood |
| Antiplatelet agents | Decrease platelet aggregation to prevent thrombus formation |
| Fibrinolytic agents | Activate the endogenous fibrinolytic system to dissolve intravascular blood clots |
| Haemostatics | Treat or prevent haemorrhage by inhibiting fibrin clot breakdown |
| Lipid-regulating agents | Reduce blood cholesterol level |
| Vasodilators | Dilate blood vessels, improving circulation |
| **Medications acting on the skin** | |
| Dermatological agents | Prevent or treat skin infections; cleansers; moisturising agents; sunscreen agents; topical anaesthetics; topical analgesics |
| **Anti-infective agents** | |
| Anthelmintics | Treat worm infestations |
| Antibacterial agents | Inhibit the growth of or destroy bacteria |
| Antifungal agents | Inhibit the growth of or destroy fungal infections |
| Antimalarial agents | Prevent or treat malaria |
| Antimycobacterial agents | Treat tuberculosis and Hansen's disease (leprosy) |

**TABLE 24.6 | Major actions of common medication classes—cont'd**

| Medication class | Action |
|---|---|
| **Medications acting on the cardiovascular system** | |
| Antiprotozoal agents | Treat protozoal infections |
| Antiviral agents | Prevent or treat viral infections |
| **Medications used in neoplastic disorders** | |
| Antineoplastic agents | Also called cytotoxics. Prevent the proliferation of malignant cells by attacking them at various stages of the cell cycle |
| Corticosteroids | Hormones that influence or control key processes in the body, including carbohydrate and protein metabolism, electrolyte and water balance |
| Immunomodifiers | Modify the immune system |

*(Adapted from Tiziani 2013; Bryant & Knights 2014)*

## SAFE HANDLING OF HAZARDOUS SUBSTANCES

Cytotoxic agents can be absorbed through the skin of people handling cytotoxic medication or bodily fluids from a person who has taken the medication (Bryant & Knights 2014). Cytotoxic medications (used in chemotherapy) may be prescribed in the treatment of malignant disease to inhibit the growth of malignant cells, and may be administered orally, IV or by regional perfusion. As cytotoxic agents are harmful to normal as well as malignant cells, extreme care is required during their preparation and administration.

Although the EN may not be required to administer cytotoxic medications, they may nonetheless assist in the care of an individual receiving chemotherapy increasing, the risk of exposure. It is essential therefore that the nurse is aware of, and understands, the related safety guidelines. Clear guidelines, which are developed by health authorities and are available in healthcare facilities, set down procedures to be followed in the preparation and administration of cytotoxic agents (Bryant & Knights 2014). In addition, the guidelines specify how to deal with spillages, extravasation (leakage of antineoplastic agents into the individual's subcutaneous tissues) and the safe disposal of used equipment and the individual's body wastes (Bryant & Knights 2014). Nurses who are pregnant must avoid contact with any cytotoxic agent, especially during the first trimester, when fetal organs are developing.

A material safety data sheet (MSDS) should be available with every hazardous substance used in a healthcare facility. It is the primary source of safety information provided for people using hazardous substances in the workplace. It provides essential information, direct from the manufacturer, about what to do in the event of leakage, spillage or any type of accident or incident involving the chemical (Worksafe Victoria nd). See Chapter 22 for more information about cleaning and spills.

## SAFE STORAGE, ADMINISTRATION AND DISPOSAL OF MEDICATIONS

Safety precautions with medications in the healthcare facility include:

- Locking the area in which medications are stored, to make them inaccessible to unauthorised persons
- Schedule 8 medications are to be stored in a lockable cupboard or safe, affixed to the wall or floor in a locked room
- Recognising that the pharmacist is responsible for the contents of most medical substances supplied
- Recognising that only the pharmacist may attach or alter a label, fill a container or transfer medication from one container to another. If a label on a container is illegible, the container must be returned to the pharmacist for clarification
- All unused medications are returned to the pharmacy department for correct disposal
- Observing the safety precautions for prescribing, preparation and administration of all medications.

## MEDICATIONS AND THE OLDER ADULT

Older adults are at particular risk of developing ADRs by prescribed medications, as they take more prescribed and OTC medications than any other age group, take multiple medications and their increased age alters the rate at which medications are absorbed, metabolised and excreted from the

body (Bryant & Knights 2014). Toxicity can occur as a result, and can be exacerbated as body weight is often lost as people age, resulting in altered distribution of medications around the body, and the need for a lower dose than has been prescribed (Bryant & Knights 2014). The elderly are also admitted to hospital with ADRs more often than younger adults (Bryant & Knights 2014).

As older adults generally consume more prescription and over-the-counter medications than any other age group they frequently take a combination of many different medications on a daily basis. Sometimes older people are referred to medical specialists and therefore may be prescribed medications by more than one doctor (Bryant & Knights 2014). This results in what is known as polypharmacy, a potentially dangerous indiscriminate use of multiple medications at the same time (Bryant & Knights 2014). Nurses can help prevent poisoning by prescribed medications in older adults by keeping these factors in mind, and actively:

- Observing for and promptly reporting any signs of toxicity; for example, tinnitus, gastric disturbance, mental status changes, visual disorders
- Advocating for frequent reviews of individual medication regimens
- Encouraging older individuals to ask questions of the medical officer, Registered Nurse (RN) or pharmacist about prescribed and non-prescribed herbal or other medications
- Encouraging older people to discuss with the medical officer the possibility of withdrawing medications that may no longer be essential
- Ensuring that non-pharmacological approaches are considered whenever appropriate
- Checking that the individual has understood instructions about taking medications and, if necessary, seeking the help of an RN to clarify instructions.
- Review serum blood of renal and liver functions to ascertain if metabolism and excretion of certain medications may be affected
- Review serum levels of medications to ensure the medications are within the required therapeutic range
- Checking for medication interactions.

ENs can participate in medication-related interventions only under the supervision of the Registered Nurse (RN) within their scope of practice, and in accordance with the code of practice in the state or territory in which they work.

## MEDICATIONS AND THE CHILD

Many medications that have been proven to be safe and effective in adults may not be for children (Bryant & Knights 2014). Standard medication dosages for children often do not exist and therefore the dosage will be calculated based on the weight or the BSA of the child (Bryant & Knights 2014). As children have a higher ratio of body water (75%) than adults (50–60%) and also less body fat than adults, some water-soluble medications need to be given at a higher rate (Bryant & Knights 2014). However, according to the *Australia Medicines Handbook 2010* if the calculated dose based on weight or the BSA is greater than the adult dose then the adult dose should be given. Review Critical Thinking Exercise 24.5 on different dosages of medication for children compared to the average adult.

**CRITICAL THINKING EXERCISE 24.5**

Children and the elderly may be prescribed dosages of medications that are different from the 'average' adult. What are the reasons for this? Outline nursing actions that could assist these groups in receiving the correct medications in the correct dosage.

IV medication and fluid administration in children require accurate prescribing and close monitoring, especially IV fluids as more ADRs occur with IV fluids than any other individual medication (The Royal Children's Hospital nd). See Clinical Interest Box 24.4 for requirements for interventions when administering IV medications to an infant or child.

## CONTINUATION OF MEDICATION REGIMEN AFTER DISCHARGE

It is important that individuals have the correct information to enable them to engage in self-care activities and maintain compliance with the prescribed medication regimen (Broyles et al 2013). The nurse must assess the individual's ability and readiness to absorb information, and ensure that it is geared towards the individual's level of understanding (Broyles et al 2013). See Nursing Care Plan 24.1.

Before discharge from a healthcare facility with medications, the nurse must ensure that the individual:

- Is able to demonstrate safe self-medication techniques after being adequately instructed
- Understands the medication regimen, including the purpose of the prescribed medications, the frequency of administration and any contraindications
- Understands the importance of any related blood tests
- Understands the importance of not stopping medications abruptly without first discussing the matter with the general practitioner or other medical officer
- Is advised to consult the medical officer about any untoward effects from the medication
- Understands the importance of notifying other health professionals about the medication regimen; for example, the visiting community health nurse
- Understands the reasons for not sharing medications with others
- Knows how to store the medications correctly and safely
- Has the contact numbers for emergency services (e.g. ambulance service and Poisons Information Centre) readily at hand (e.g. kept close to the telephone)
- Knows how to discard out-of-date or unwanted medications safely

## NURSING CARE PLAN 24.1

**Assessment:** Mr Albert George is a 73-year-old man who presented to the casualty department this morning experiencing central chest pain radiating into his jaw, after walking his dog in the park. His ECG showed T wave inversion and troponin levels after 6 hours were negative. Vital signs within normal limits. After review by the medical officer it was determined that Mr George has Unstable Angina and was admitted to the medical ward for observation and medication management. Mr George has a past history of hyperlipidaemia, osteoarthritis and hypertension. He currently takes atorvastatin 20 mg mane, Panadol osteo TDS and perindopril 2.5 mg mane. The medical officer has commenced him on enoxaparin 1 mg/kg subcutaneous BD, metoprolol 25 mg oral BD, Anginine 300 microg subling PRN as per protocol and increased his atorvastatin to 40 mg oral mane. He is scheduled for a repeat ECG, fasting bloods and troponin in the morning.
**Issue/s to be addressed:** Knowledge deficit regarding new medication regimen.
**Goal/s:** Mr George will demonstrate ability to follow newly prescribed medication regimen by discharge date.
Mr George will understand rationale for new medication management in relation to Unstable Angina within 2 days.
Mr George will understand and verbalise rationale for PRN administration of Anginine within 2 days.

| Care/Actions | Rationale |
|---|---|
| Assess Mr George's readiness and ability to absorb information | Learning best occurs when the person is able to focus and understand information given. Some individuals are prepared and once they are diagnosed are ready for information; however, others need time to absorb the new diagnosis and will want to wait (Gulanick & Myers 2014) |
| Assess hearing, sight, comprehension and cognition | Cognitive impairments can interfere with learning as well as physical limitations (impaired hearing or vision, or poor hand coordination) so correct tools to assist learning can be used (Gulanick & Myers 2014) |
| Provide information in simple terms at the level of the individual | Person will be able to understand terminology |
| Provide information to support self-regulation and self-management (Gulanick & Myers 2014) | Gives the person the tools to be able to self-manage and know when to seek support (Gulanick & Myers 2014) |
| Refer to pharmacist for information on new medications | Gives the person the most current information |
| Provide pharmacy information sheet on individual medications | Gives the person an easy reference tool showing when and what medications need to be taken |
| Instruct on correct dosage and times of new medications | Allows person to self-manage medication regimen |
| Instruct on correct dosage, administration, storage, use-by date and common side effects (headache and dizziness) for PRN Anginine (Broyles et al 2013) | Provides information to ensure Anginine medication is taken correctly and is discarded 90 days after opening to ensure medication effectiveness (Broyles et al 2013) |
| Provide fridge magnet for Anginine regimen; Rest, ½ Anginine sublingual until medication has dissolved and every 5 minutes × 3 till pain resolves. Call 000 if pain persists | Provides quick and easy access to information so when chest pain is experienced the correct regimen is followed |
| Encourage Mr George to ask questions | Provides clarification and assists with learning (Gulanick & Myers 2014) |

**Evaluation**

Mr George states the rationale for taking his newly prescribed medication.
Mr George states the process for taking the new medications at the required time and correct dose.
Mr George is able to recall the process for taking Anginine for when he is experiencing chest pain, according to protocol.

- Knows how to dispose of used syringes and needles safely if used
- Has been provided with written instruction on each medication
- Has had instruction from the pharmacist for any new medications or changes to medication regimen.

Alternatively, if the individual is unable to complete the above, a family member or friend should be instructed in the safe administration of the medication, covering all the points listed. Another alternative is a visiting district or community nurse, who may be required to call on the individual at home and assist in the administration or monitoring of the medication therapy. The nurse may also be able to gain an understanding of any difficulties the individual is experiencing, offer information that may help the individual deal with them, and monitor **compliance**/concordance/adherence with the medical officer's directions (Broyles et al 2013). Sometimes individuals do not comply/adhere with the prescribed medication regimen after they return home. There are a variety of reasons why this may occur (Clinical Interest Box 24.5).

## CLINICAL INTEREST BOX 24.5 Issues with non-compliance/ concordance/adherence with medication regimens

How many of us have been guilty of not completing a course of antibiotics because we 'feel better' or forget to take them and decide we are better anyway, or keep a few of those antibiotics for the next time it happens, to save going to the medical officer again? Non-compliance/concordance/adherence with medication therapy can be both deliberate and unintentional. Some reasons for non-compliance/concordance/adherence with medication therapy are that individuals:

- Do not understand the information given to them regarding illness and medication regimen
- Disregard the information given to them, perhaps because they do not believe in, or have a fear of, using medications or believe another sort of remedy is more likely to be effective. Attitudes and beliefs about medications can be influenced by cultural background and past experiences with medications
- Alter the medication regimen to fit with lifestyle; for example, only eating meals twice a day so only taking a medication twice a day instead of as ordered; that is, three times a day with meals
- Decrease dose or stop medication because of adverse effects
- Take double doses to make up for missed doses
- Stop medication because there is no change in condition ('It isn't doing me any good')
- Find them too expensive
- Perceive that they do not need them anymore
- Receive unclear directions (given in a rush, too much jargon, given rapidly in English when English is not the first language of the individual)
- Have problems with changing routine; for example, their medication routine differs from their previous regimen
- Have difficulty implementing the regimen; for example, multiple medications to be taken at several different times of the day
- Simply forget to take them.
- Too many medications to take

Several nursing interventions may enhance the ability and willingness of individuals to comply with the prescribed medication regimen (see Clinical Interest Box 24.6).

*(Adapted from Broyles et al 2013; Brotto 2013)*

One measure to promote safe medication administration in the home for older individuals, improve adherence to medication regimens and provide professional support is the use of dose administration aids (DAAs) (i.e. blister packs provided by the community pharmacist which contain medications set out in colour-coded packs that separate doses into times and days of the week) (Figure 24.18) (Pharmaceutical Society of Australia 2015). DAAs are commonly used in residential aged care facilities.

**Figure 24.18** Dose administration aid: Webster-pak® colour-coded blister pack

*(Courtesy Manrex Pty Ltd WebsterCare, www.webstercare.com.au)*

When an older individual has visual impairment it will help if instructions for taking the medications are clearly printed in large bold letters. If individuals are confused it may be necessary for the medications to be taken under the supervision of a family member and kept out of reach at other times. Clinical Interest Box 24.6 provides suggestions to help the nurse enhance individual compliance/concordance/adherence with medication regimens after discharge.

### CRITICAL THINKING EXERCISE 24.6

There are many factors that can result in an individual not being compliant/concordant/adherent with medication therapy. Identify the reasons for non-compliance/concordance/adherence. Outline some nursing actions that you could apply before an individual is discharged to reduce the risk of non-compliance/concordance/adherence with medication therapy.

## CLINICAL INTEREST BOX 24.6 Nursing interventions to enhance individual compliance/concordance/adherence with medication regimens after discharge

### Education

- Assess the individual's knowledge base prior to education so they do not tune out because they already know some of the information
- Assess the individual's understanding of English; if they do not understand English, arrange for an interpreter
- Assess the individual's memory and cognitive function for understanding and retention of information
- Assess the individual's level of hearing; for example, hearing aid in place and switched on
- Assess the individual's level of concentration; for example, is not uncomfortable, needing the toilet, in pain, thirsty, hungry or anxious
- Provide a quiet, calm private area so that individual is not distracted while you are providing information and so that the individual's medical condition remains confidential
- Provide verbal and written instructions to the individual and family members when appropriate. Other visual material may be available (video instructions are available for education about certain medications, such as insulin)
- Ascertain the individual's level of understanding by asking them to repeat the instructions back to you. Encourage them to ask any questions they have about the purpose of the medication and when and how to take it. If necessary, arrange for a visiting nurse to check on the individual's ability to cope with more complex medications, such as insulin injections and disposal of sharps. In the home sharps can be safely disposed of in an empty plastic milk container that has a screw top cap and a 1:10 bleach:water solution in the bottom of it. The environmental biohazard waste-management strategies in the local area should be followed when disposing of the full container
- Provide adequate time when educating the individual about medication. Avoid giving instructions just as the individual is ready to leave the hospital. Provide time for individual to practise and demonstrate their ability with devices such as needles and syringes or nebulisers and inhalers.

### Willingness to follow the medication regimen

- Discuss the individual's feelings, attitudes and beliefs about health alteration and the need for the medication prescribed. If the individual indicates an unwillingness to carry out the medication after being provided with reasons to comply, refer this information to the medical officer and nurse in charge. Alternative therapies may be possible
- Discuss how the regimen fits in with the individual's lifestyle and how any adverse effects might cause a problem to planned activities

### Ability to follow the medication regimen

- Ensure that the individual will be able to read labels on medication pots and bottles. If vision is a problem, contact the pharmacy about printing bigger labels or providing additional large print information
- Check that motor skills will allow the individual to successfully use the medication; for example, that they can open the childproof lid on the container or are able to pour out liquid medication or instil their own eye or ear drops
- Evaluate the individual's social situation; for example, is the cost of the medication a problem? Is the individual sufficiently mobile to go to the pharmacist to fill the prescription?

This is certainly not an exhaustive list. Make a list of your own and see how many more actions you can add to it.

*(Adapted from Broyles et al 2013; Brotto 2013)*

## Summary

As part of the holistic care of the individual, the EN may be required to administer and monitor the effects of medications; it is therefore essential to have the necessary knowledge to ensure the safety of all individuals who are receiving medications. Of particular importance is an understanding of the legal responsibilities involved in administering medication. Nurses must be willing to accept that responsibility and work within their scope of practice as dictated by AHPRA and NMBA. To promote accurate and safe medication administration the nurse must understand the system of weights and measures used in prescriptions, know the meanings of abbreviations and be competent in performing the correct calculation of dosages.

The nurse must have a basic understanding of how medications are transported in the body, how they act, how they are metabolised and how they are excreted. Furthermore, it is important to have an understanding of the actions of the various medication groups so that the nurse will know what the desired effects of the medication are and will therefore be able to monitor the individual's reaction more adequately.

*Continued*

Medications are presented in a variety of forms (e.g. tablets, capsules, mixtures and injectable solutions) which are administered via a variety of different routes. The nurse should not only be competent in administering medication via these routes, but also in monitoring both the desired effects and any side effects that may occur.

The nurse must observe the seven rights of medication administration (right medication, right dose, right person, right route, right time, right reason, right documentation) at all times and understand the procedure if a medication error does occur. To maintain a safe working environment it is important that the nurse understands the guidelines regarding safe handling of hazardous substances. The nurse has an important role in ensuring that the individual understands all aspects of any prescribed medication regimen before being discharged from a healthcare facility. Nurses must follow the principles of asepsis during the preparation and administration of medications via any route and must constantly assess and promote the individual's safety and comfort throughout the administration of any medication therapy.

## DECISION-MAKING FRAMEWORK EXERCISE 24.1

You have just been employed in the medical ward as an Enrolled Nurse. You are working on an afternoon shift and one of the people you are assigned to care for is a 57-year-old woman who is in palliative care. She has end-stage ovarian cancer. She has a syringe driver in situ, giving subcutaneous delivery of 120 mg of morphine and 40 mg of metoclopramide over a 24-hour period. You remember learning about syringe drivers when you did the medication unit in your training; however, that was almost 12 months ago. The syringe driver medication is due to be changed on your shift.

1. Using the decision-making framework determine your scope of practice in caring for and monitoring the individual in delivering the medication by the syringe driver.
2. Do you accept responsibility of caring for the lady over the shift?
3. What is your long-term plan to ensure competency?

## Review Questions

1. What are the three different names a medication may have?
2. Name the routes of medication administration that a nurse may use to administer medications.
3. Name the three factors that medication absorption depends on.
4. What is first-pass metabolism?
5. What are the standardised and systematic processes of the Medication Safety Standard to prevent common medication errors from occurring?
6. What is the difference between a 'bound' medication and an 'unbound' medication?
7. Why is therapeutic medication monitoring important?
8. Explain the differences between side effects, toxic effects and allergic reactions.
9. What do the Poisons Act and Poisons Regulations of each state and territory deal with?
10. What are the 'seven rights' the nurse must observe when administering a medication?
11. How does the nurse identify the correct individual?
12. What does the nurse do if there is any doubt about a medication order?
13. What is the procedure to follow if a medication error occurs?
14. Name the common sites for subcutaneous injections.
15. Name the common sites for intramuscular injections.

Calculation exercises

1. Convert the following to milligrams (mg):
   a. 0.75 g
   b. 22.5 g
   c. 0.003 g
2. Convert the following to grams (g)
   a. 7600 mg
   b. 48 mg
   c. 700 mg
3. Convert the following to micrograms (microg)
   a. 0.0625 mg
   b. 0.36 mg
   c. 0.06 mg

4. Convert the following to milligrams (mg)
   a. 56 microg
   b. 4 microg
   c. 354 microg
5. An individual is prescribed 150 mg soluble aspirin orally. Stock on hand is 300 mg strength tablets. How many tablets would you administer?
6. Mr Stewart is ordered 0.125 mg digoxin orally daily. Digoxin tablets are available in 62.5 microg strength. How many tablets should you administer to Mr Stewart?
7. Mr Newton has epilepsy and has been ordered phenobarbitone 140 mg IM stat for seizures. Stock ampoules contain 200 mg/mL. What volume should be administered?
8. Maddy is a 10-month-old infant weighing about 10 kg. She is ordered paracetamol for pain. Stock on hand is 120 mg/5 mL. The dose is weight based at 15 mg/kg. Calculate the dose required.
9. A child is prescribed penicillin syrup 250 mg orally 6 hourly. Penicillin syrup is available as 250 mg/5 mL. Calculate the total amount (in mL) that the child will receive in a 24-hour period.
10. Poppy Koulouris is ordered 500 mL normal saline to be delivered over 24 hours via a gravity feed line.
    a. Calculate the volume of normal saline she will receive per hour.
    b. If the drip chamber delivers 20 drops/mL, what would be the drip rate in drops per minute?
11. If Alex Brown is ordered 1 L of dextrose 5% to be given over 8 hours, what rate would you set the volumetric pump at?
12. Sara Hart has been ordered 500 mL normal saline. The volumetric pump has been set at 25 mL/hour. How long will the fluid last?
13. Calculate the required drip rate in drops per minute (using a drip chamber that delivers 20 drops/mL) if Alice Ball is to have 100 mL normal saline delivered over 1 hour.
14. Mr Lee is critically ill and has two intravenous lines inserted. One line is running at 45 mL/hour, the second at 30 mL/hour. What volume of fluid would Mr Lee receive over 24 hours?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

thrombocyte

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the structure of the respiratory system
- Explain the functions of the respiratory system
- Explain the structures of the cardiovascular system
- Describe the position of the heart and the function of the circulatory system
- State the factors that affect respiratory function
- Describe the major manifestations of respiratory system disorders
- Describe the major manifestations of circulatory system disorders
- Briefly describe the specific disorders of the cardiac and respiratory systems outlined in this chapter
- Assist in planning and implementing nursing care for the person with a cardiac and respiratory system disorder
- Apply relevant principles in the planning and implementation of nursing actions to assist a person receiving oxygen therapy

## CHAPTER FOCUS

The human body relies on oxygen to survive and it is the role of the cardiac and respiratory systems to supply the body's oxygen demands. The two systems work together to achieve and maintain homeostasis. Cardiopulmonary physiology involves the delivery of oxygenated blood from the lungs to the left side of the heart out to the tissues, and deoxygenated blood from the tissues to the right side of the heart out to the pulmonary circulation for re-oxygenation. Blood is oxygenated through the processes of ventilation, perfusion and transport of respiratory gases.

The overall function of the cardiovascular system, which includes the lymphatic system, is to move blood around the body. The heart pumps the blood for circulation around the body through blood vessels. These blood vessels transport oxygen, nutrients and other substances to the cells and transport waste away from the cells. Blood also assists in protecting the body against infection and distributing heat evenly throughout the body, and prevents its own loss by means of a built-in clotting mechanism.

The respiratory system provides the body with the ability to absorb oxygen and excrete carbon dioxide and other waste products from the body. Oxygen from the atmosphere is delivered to the bloodstream and carbon dioxide diffused out from the bloodstream. This is achieved through the capillary alveoli membrane in the lungs.

Ventilation is the method of delivering air into and out of the lungs and is achieved through inhalation and exhalation. Respiration involves both the respiratory and the circulatory system and is the exchange of gases.

An adequate supply of blood is necessary for the normal function of every cell. Homeostasis depends on the ability of the heart to adequately circulate the required volume of blood and oxygen to the tissues. Cells temporarily deprived of blood or oxygen will not function normally, and continued disruption of blood supply causes irreversible damage or cell death. Any disorder that interferes with the distribution or delivery of blood to tissues or the uptake or excretion of gases in respiration is a potential harm to body cells and may have permanent effects on a part, or all, of the body.

The most common complication of a respiratory disorder is carbon dioxide retention. This can be a result of alveolar hypoventilation, or a cardiovascular disorder altering the ventilation or the perfusion of the lungs and other tissues.

Nursing care related to oxygenation requires an understanding of how the three systems work together to achieve oxygenation within the body. Knowledge of how to maintain and restore a clear airway is an essential component to nursing care. This includes measures directed at removing secretions by the use of suction via the nasal, oropharyngeal or endotracheal routes or by tracheostomy. The patency of airways can be assisted by the use of humidification, nebulisation and physiotherapy using isotonic or hypotonic solutions or certain medications. Education is essential to promote exercise, which maintains optimal circulation of blood, and deep breathing and coughing exercises are encouraged to minimise the retention of secretions and secondary infections. Circulation can be assisted by changes in diet, fluid, exercise, medications and positioning.

Although disorders of the cardiovascular and the respiratory system are common in most communities, the incidence of cardiac and respiratory disease is controlled to some extent by: legislation to minimise airborne irritants; immunisation programs; and health education regarding risks such as diet, exercise practices, smoking and alcohol consumption, hypertension and environmental pollution (Nascimento et al 2014).

## LIVED EXPERIENCE

Stewart, a 69-year-old man, was admitted to the ward with exacerbation of his chronic obstructive pulmonary disease (COPD). Initially his observations were stable and he was treated with oxygen therapy at 4 L/min via nasal prongs and oral corticosteroids. He was breathless on exertion and needed help with his ADLs. Throughout my shift I noticed that his oxygen saturations fell into the clinical review zone on the adult observation chart. He also became drowsy. I reported this to my RN who asked the resident doctor to review him.

The doctor did some arterial blood gases which confirmed a rising carbon dioxide ($CO_2$). I was asked to monitor his oxygen saturations, respiratory rate and conscious state hourly. They also gave an additional dose of IV corticosteroid. As the medical team were worried about possible carbon dioxide retention I was instructed to only administer low-flow oxygen (<3 L per minute) and he had his calling criteria altered to accept 88–92% to avoid further $CO_2$ retention. He was starting to improve when I went home at the end of my shift.

**Alexa, Enrolled Nurse**

# STRUCTURE OF THE RESPIRATORY SYSTEM

The function of the respiratory system (Figure 25.1) is to deliver oxygen from the atmosphere to the bloodstream and to deliver carbon dioxide from the bloodstream to the atmosphere. The structures that make up the respiratory tract constitute the means by which this exchange of gases occurs. The respiratory system consists of cavities and conducting airways that begin at the nasal and oral cavity and end at the alveoli, the functional unit of the respiratory system (Berman et al 2015). The larger **airways** are composed of cartilage and

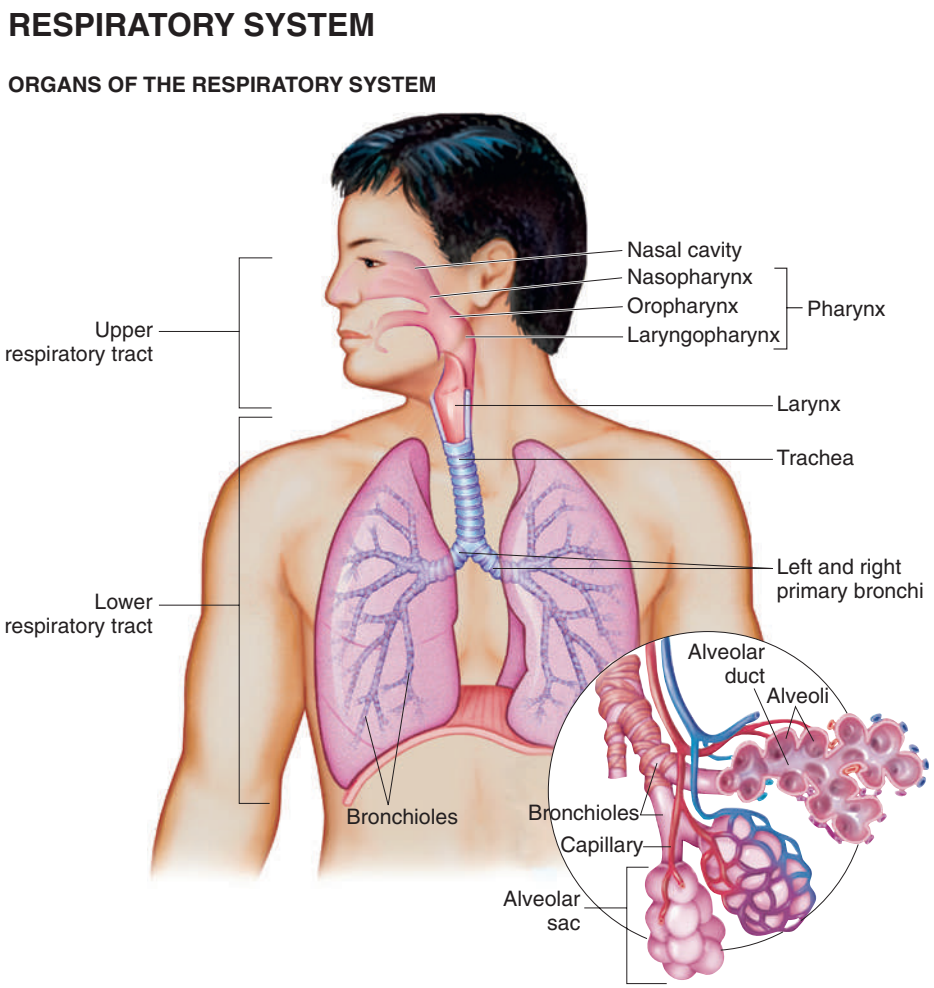

**Figure 25.1** The respiratory tract

*(Thibodeau & Patton 2012, Fig 14-1, p 327)*

smooth muscle that maintain their patency, and are gradually replaced with smooth muscle in the terminal airways, which allows alterations in airway diameter and ventilation. The two lungs are located in the thoracic cavity, encased by a double membrane known as the pleura, and are separated by the mediastinal cavity that contains the heart and great vessels. The thoracic cavity has ribs that aid in ventilation and protect the lungs from damage. The diaphragm and the internal and external intercostal regions are composed of skeletal muscle and constitute the main muscles of ventilation; other muscles are used when required for more forceful inhalation or expiration (Berman et al 2015).

## Upper airways

### Nasal cavities

The nose is a bony cartilaginous structure divided into a right and left nasal cavity by the nasal septum. The anterior portion of the septum is cartilage and the posterior portion is bone, formed by the small thin bone separating the left and right nasal cavity and part of the ethmoid bone. Inside each nostril (nares) is a vestibule lined by skin containing sebaceous and sweat glands and coarse hairs that act as filters. Apart from the vestibules, all other areas of the nasal cavity are lined by mucous membrane. In most of the cavity the membrane is covered by ciliated epithelium with many 'goblet' cells. Mucous cells are also present in the underlying connective tissue. The nose consists of these chambers, with specific structures and cells that have the following functions:

- Hairs and cilia line the nasal cavities and filter foreign particles and pathogens from the inhaled air
- Mucus secreted by the mucosa traps substances in inhaled air, and the cilia move particles of mucus towards the pharynx to be swallowed or expectorated
- Inhaled air is warmed and moistened as it passes over the mucosa. The three nasal turbinate bones in each cavity cause air flow to become turbulent, which enhances contact of air with the mucosa
- Sensory organ for the sense of smell (olfaction) (Marieb & Hoehn 2013).

### Paranasal sinus

A sinus is a cavity within a bone. There are four air-filled paranasal sinuses (Figure 25.2): frontal, maxillary, sphenoid and ethmoid sinuses.

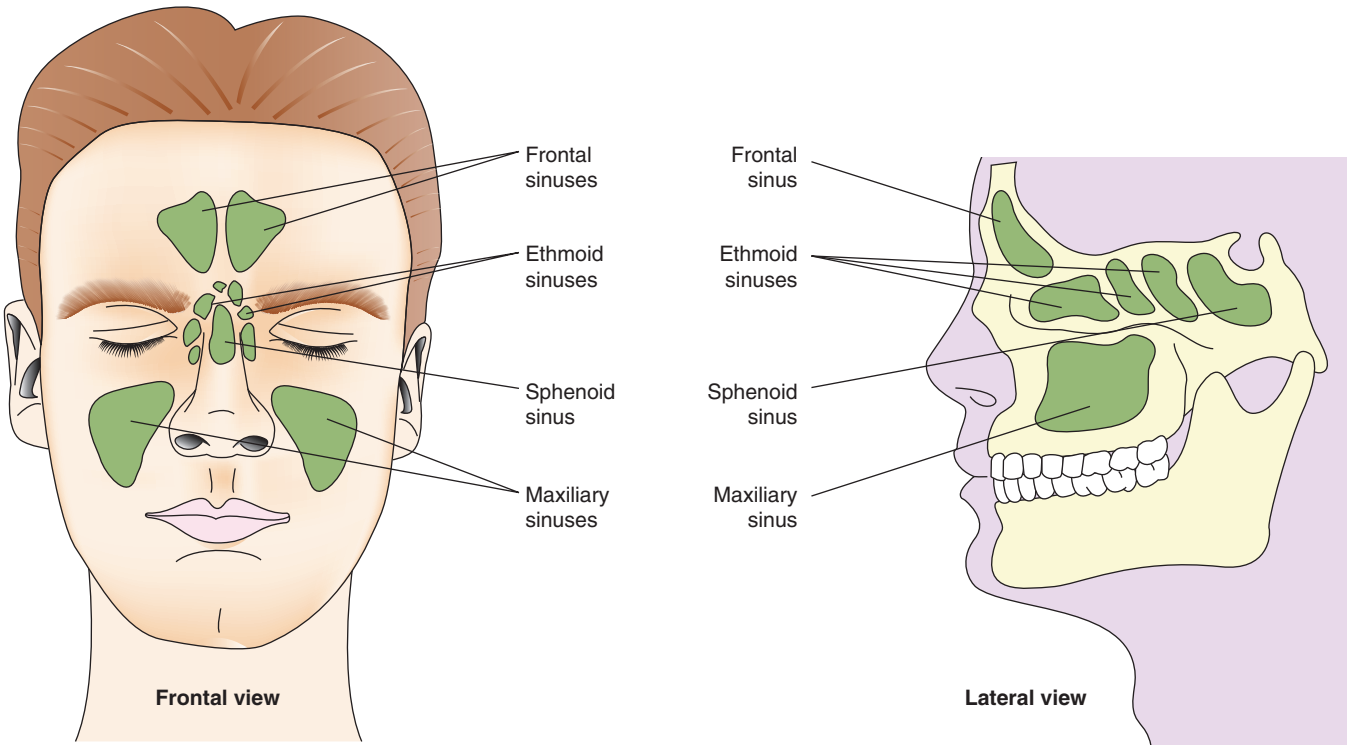

**Figure 25.2** Paranasal sinus

These sinuses are important resonance chambers and aid in voice production (Marieb & Hoehn 2013).

## The pharynx

The pharynx is a muscular tube about 13 cm long, lying in front of the cervical vertebrae and behind the nose, mouth and larynx. It is lined with mucous membrane and has three sections:

***1. Nasopharynx*** The nasopharynx, which is continuous with the nasal cavity above and with the orpharynx below. Its functions include:

- Warming and moistening inhaled air
- Protecting from infection, by patches of lymphoid tissue such as the adenoids
- Equalising pressure in the middle ear with the atmospheric pressure by allowing air to travel along the eustachian tubes to the middle ear.

***2. Oropharynx*** This section lies behind the mouth and is separated from the cavity of the mouth by two folds of mucous membrane (the fauces). Between these folds lie the oral tonsils, which are patches of lymphoid tissue involved in the immune system. The oropharynx provides a common passage for air, food and fluids. The uvula is a muscular projection of the soft palate in the middle of the arch formed by the fauces, and prevents the entry of food and fluid into the nasal cavity (Marieb & Hoehn 2013; Potter et al 2013).

***3. Laryngopharynx*** The laryngopharynx is the section that opens into both the larynx and the oesophagus. It contains the epiglottis (see next section).

## The larynx

The larynx is situated in the upper region of the neck and extends from the pharynx above to the trachea below. It is composed of pieces of cartilage connected by membranes and provides a passageway for air between the pharynx and trachea. As air passes through, it is further moistened, warmed and filtered. The main cartilages that form the larynx are:

- The thyroid cartilage, which is the largest and forms a prominence known as the 'Adam's apple'
- The epiglottis, a leaf-shaped cartilage attached to the upper part of the thyroid cartilage. During swallowing, the larynx rises and the epiglottis covers its opening, directing food and fluid into the oesophagus and preventing entry into the trachea and subsequent aspiration into the lungs
- The pitch of the voice depends on the length and tightness of the cords, and the air sinuses in the skull bones influence the resonance of the voice. The vowels and consonants that make up speech are formed by various positions of the lips and tongue. Speaking requires coordination of the larynx, mouth, lips, tongue, throat, lungs and abdomen (Marieb & Hoehn 2013).

# Lower airway

## The trachea

The trachea is about 12 cm long and lies in front of the oesophagus, extending from the larynx to the mid-thorax, where it divides into a right and a left bronchus. The trachea consists of 15–20 C-shaped rings of cartilage joined by

involuntary muscle and fibrous tissue. Posteriorly the trachea lacks cartilage and is replaced with smooth muscle to enable the oesophagus to expand, while the cartilages maintain the patency of the airway. It thus provides a permanently open passageway for air travelling to and from the lungs. The trachea is lined with ciliated epithelium containing mucus-secreting goblet cells. The cilia sweep the mucus, cell debris and any foreign particles that enter the trachea up into the pharynx to be swallowed or expectorated. During swallowing, the larynx rises and the epiglottis covers its opening, directing food and fluid into the oesophagus and preventing its entry into the trachea and subsequent aspiration into the lungs.

The cricoid cartilage lies below the thyroid cartilage, and is shaped like a wide, banded ring to provide attachments for the various muscles, cartilages and ligaments involved in opening and closing the airway and in speech production. The larynx is lined with mucous membrane, which becomes ciliated in the lower part. In the upper part, two folds of membrane containing embedded fibrous and elastic tissue form the vocal cords. The vocal cords extend from the anterior wall to the posterior wall of the larynx to form the glottis, or voice box, which produces sounds. The nerve supply to the larynx is from the laryngeal and recurrent laryngeal nerves, which are branches of the vagus nerve (Marieb & Hoehn 2013).

***Voice production*** The vocal cords are apart during normal breathing. Contraction of muscles attached to the cords brings them closer together, and expired air is used to cause vibration of the cords. The brain, tongue, lips, nasal cavity and facial muscles all help to convert the resultant sounds into speech. The pitch of the voice depends on the length and tightness of the cords, and the air sinuses in the skull bones influence the resonance of the voice. Speaking requires coordination of the larynx, mouth, lips, tongue, throat, lungs and abdomen.

## Bronchi

At about the middle of the thorax, the trachea divides to form the right and left bronchus. The bronchi enter the lungs; the right bronchus dividing into three, and the left bronchus dividing into two branches. There are three lobes in the right lung and two lobes in the left lung; therefore, one branch of each bronchus enters each lobe. The left bronchus is longer than the right because of the position of the heart. Smooth involuntary muscles surround the airways to allow for alteration in airway diameter (Marieb & Hoehn 2013).

## Bronchioles

Respiratory bronchioles have a dual function: they serve as part of the airways and as part of the alveolar volume (gas exchange) (Broaddus et al 2015). Bronchioles are the smallest branches of the bronchi, and their walls consist of involuntary muscle with elastic fibrous tissue, allowing for expansion and constriction. They divide to form terminal bronchioles that give rise to microscopic alveolar ducts, which terminate in clusters of air sacs called alveoli.

## Lungs

The two lungs lie in the thoracic cavity on either side of the mediastinum. The mediastinal cavity contains the heart, major blood vessels and the oesophagus. The lungs are light and spongy and consist of the bronchioles, alveoli and blood vessels and are supported by areolar tissue. There is also a great deal of elastic tissue to enable the lungs to expand and recoil freely during respiration. The base of each lung rests on the diaphragm and the apex of each extends to just above each clavicle. The right lung has three lobes and is shorter and wider than the left lung, which has two lobes. Each lobe is made up of lobules, each with its own blood, nerve and lymph supply. On the medial side of each lung is a depression called the hilus, through which the bronchi, lymphatic vessels and blood vessels enter and exit (Marieb & Hoehn 2013).

## Alveoli

Alveoli are microscopic air sacs in the lungs. Their walls are composed of one layer of type I, simple squamous epithelial cells, and type II cells that produce surfactant which maintains alveolar expansion by reducing surface tension. Macrophages are present and their role is to phagocytose cell debris and pathogens. The alveoli form a surface area of about 70 $m^2$ for semi-permeable membrane diffusion of gases. The alveoli are surrounded by networks of capillaries, arising from the pulmonary arteries and their tributaries. The function of alveoli is the interchange of oxygen and carbon dioxide between the air in the alveoli and the blood in the capillaries (Figure 25.3).

## Pleura

The pleura (Figure 25.4) comprise a double layer of serous membrane, consisting of the visceral pleura, which adheres to the surface of the lungs, and the parietal pleura, which lines the thoracic cavity and covers the superior surface of the diaphragm. The pleura secrete a thin film of serous fluid, maintained at about 50 mL, which lies between the two

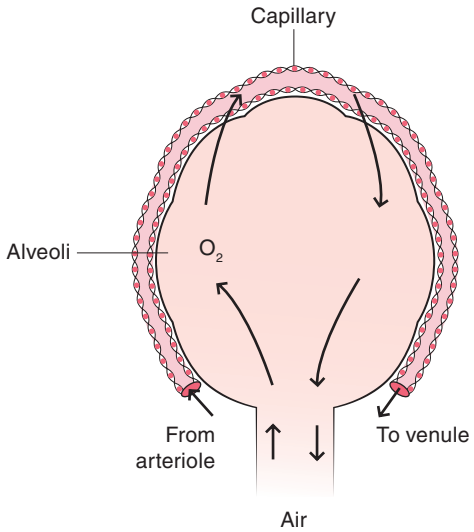

**Figure 25.3** Exchange of gases in the alveoli

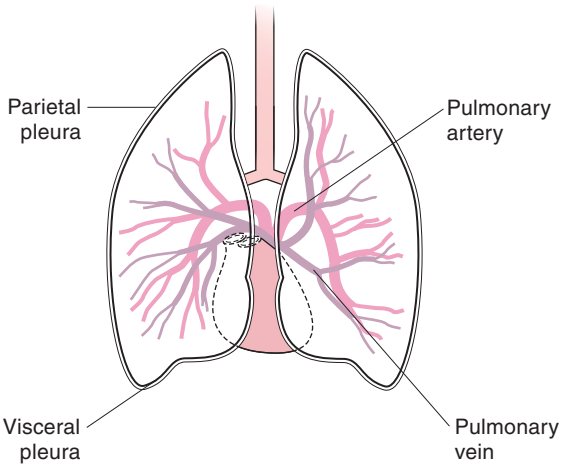

**Figure 25.4** The lungs and the pleura

layers and prevents friction between the surfaces. The pressure within the pleura is 2 mmHg below atmospheric pressure to prevent lung collapse.

### Muscles of ventilation

The main muscles responsible for ventilation are the diaphragm and internal and external intercostal muscles. During difficult or forced breathing, accessory muscles are used, such as the muscles of the neck, thorax (e.g. sternocleidomastoid, anterior serrate, scalene) and abdominal muscles, including the rectus abdominus and transverse abdominus (Marieb & Hoehn 2013).

## SCIENTIFIC PRINCIPLES OF VENTILATION AND RESPIRATION

The major purpose of respiration in to supply oxygen to the body and remove carbon dioxide from the cells. This is accomplished by the process of *ventilation* (movement of air in and out of the lungs), *external respiration* (exchange of gases between the atmosphere and the pulmonary capillaries) and *internal respiration* (exchange of gases between the systematic capillaries and the cell). An understanding of pressure relationships and key principles of respiration will assist in understanding the process of ventilation and respiration (Broaddus et al 2015).

### Pressure

Pressure may be defined as force (or stress) per unit area applied to a surface. The concept of pressure, or force, applies equally to solids, liquids and gases. Described below are some of the principles and concepts relating to pressure that are relevant to nursing.

### Atmospheric pressure

Atmospheric pressure arises by virtue of the weight of the air above the earth. Atmospheric pressure decreases as altitude increases because of the reduced amount of air above. Even at a particular altitude, atmospheric pressure is not constant, but varies according to atmospheric conditions. The total pressure exerted by the atmosphere is about 6.8 kg per 25 $mm^2$ of surface area at sea level. The atmosphere consists principally of nitrogen ($N_2$) 79.03%, oxygen ($O_2$) 20.93% and carbon dioxide ($CO_2$) 0.0004%, which totals 99.9604%. Other gases such as carbon monoxide (CO) are present in minute quantities. Oxygen, a colourless and odourless gas, is essential in sustaining most forms of life.

Water vapour and gases in the atmosphere have weight and, at sea level, exert a pressure defined as 1 atmosphere of pressure ('atmospheric pressure') equivalent to 760 mmHg. The terms negative and positive pressure are used to compare a pressure to normal atmospheric pressure at sea level. Any pressure above normal atmospheric pressure is regarded as a positive pressure, and any pressure below normal atmospheric pressure is regarded as a negative pressure.

The following three laws of physics define the characteristics of gases:

1. Pascal's principle, which states that a confined liquid transmits pressure, applied to it from an external force, equally in all directions
2. Boyle's law, which states that the volume of a given mass of gas is inversely proportional to the pressure to which it is subjected, provided that the temperature remains constant
3. Charles' law, which states that the volume of a given mass of gas is directly proportional to its absolute temperature, provided that the pressure remains constant; for example, as the temperature of a gas is increased (at constant pressure) the gas expands.

The combined effects of atmospheric pressure and the application of the gas laws above provide the basis for the operation of many common devices, and also of the lungs. Boyle's law refers to pressure differentials and is able to be applied to the process of breathing. By changing the volume of the thoracic cavity, the air pressure in the lungs can be made lower or higher than atmospheric pressure, leading to inhalation or exhalation, respectively (Marieb & Hoehn 2013).

### Sensory mechanisms of the respiratory system

Every cell in the human body requires oxygen for normal metabolism and must excrete the metabolic waste product, carbon dioxide. To maintain homeostasis, cells in different locations of the body react to changes in oxygen and $CO_2$ levels. Sensory cells include chemoreceptors, pressorreceptors and baroreceptors.

#### Chemoreceptors

Chemoreceptors are specialised cells located centrally in the upper medulla of the brainstem and peripherally in bodies located in the carotid and aortic arteries. They respond to slight increases in arterial or cerebrospinal fluid $CO_2$ pressure ($P_{CO2}$) and acidity (an increased concentration of hydrogen ($H^+$) ions). Regulation of ventilation depends mainly on the

level of $CO_2$ in the blood. A slight increase in $CO_2$ concentration stimulates chemoreceptors to increase the respiratory rate and depth until the excess $CO_2$ is eliminated. Conversely, a decreased $CO_2$ level slows the ventilatory rate. Oxygen levels are normally sensed by the carotid bodies, which are sensitive to a fall in oxygen concentration of less than 50%. Stimulation of the carotid receptors increases the respiratory rate, the exception being individuals with chronic hypercapnia such as in emphysema.

### Pressorreceptors

Pressorreceptors, or mechanoreceptors, are stretch receptors present in lung tissue and within the thoracic wall. The bronchioles and alveoli also have stretch receptors that respond to extreme over-inflation as well as extreme deflation. When over-inflation occurs, impulses are transmitted from the stretch receptors to the medulla by the vagus nerve, the expiratory centre is activated and exhalation occurs. When extreme deflation occurs impulses from the lungs activate the inspiratory centre, and inhalation occurs.

### Baroreceptors

Baroreceptors are cells sensitive to blood pressure, which normally monitor changes in blood pressure. When blood pressure increases, impulses are sent to the respiratory centres to cause a decrease in respiratory rate. Rate, depth and rhythm of respirations are further affected by reflex responses, chemical signals and voluntary control; for example, during actions such as swallowing, impulses from gustatory centres are conveyed to the respiratory centre, and breathing stops temporarily.

Any abnormal mechanical disturbance, for example, the presence of chemical substances such as cigarette smoke, causes excitement of the lung irritant receptors, which induces hyperventilation and a reflex bronchoconstriction. Information from other parts of the body may also be received by the respiratory centres; for example, a rise in body temperature initiates an increase in the rate of ventilation, while a sudden cooling of the body induces a sudden inhalation followed by hyperventilation.

## The respiratory centres

Respiration is controlled both voluntarily and involuntarily. The automatic control of breathing is regulated by three respiratory centres, known as the medullary centre, located in the medulla oblongata, the apneustic centre in the pons and the pneumotaxic centre in the upper pons of the brainstem. These centres receive stimuli from sensory cells described above, and from each other. Their function is to control the rate, rhythm and depth of ventilation. Impulses travel from the respiratory centres along separate nerves that exit the spinal cord at different levels to separately innervate and control the diaphragm and internal and external intercostal muscles. Impulses are also transmitted to the other centres and cause stimulation of the respiratory muscles via the phrenic nerves, to stimulate the diaphragm to contract, and the intercostal nerves, which stimulate the intercostal muscles.

# VENTILATION AND RESPIRATION

**Respiration** is the term used to describe an interchange of gases. The main purpose of respiration is to supply the body with oxygen and dispose of carbon dioxide. The four processes involved are:

1. Ventilation: movement of air containing different gases into the respiratory tract
2. External respiration: exchange of oxygen and $CO_2$ between the blood and the alveoli (Figure 25.3)
3. Internal respiration: exchange of oxygen and $CO_2$ between the bloodstream and the tissues
4. Cellular respiration: exchange of gases by cells.

## Ventilation

Ventilation has two phases (Figure 25.5): inhalation and exhalation.

### Inhalation

During **inhalation** the diaphragm contracts and flattens, enlarging the thoracic cavity lengthwise, particularly in males. In females normal inhalations occur primarily by contraction of the external intercostal muscles, which raise the ribs and sternum, thus increasing the size of the thoracic cavity from

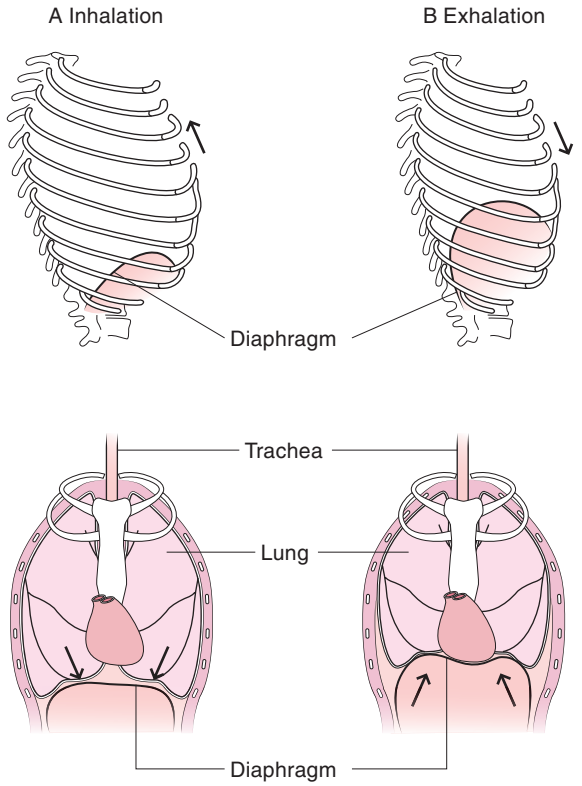

**Figure 25.5** Rib cage and diaphragm positions during breathing

A: At the end of normal inhalation: chest expanded (top left) and diaphragm depressed (bottom left) B: At the end of a normal exhalation: chest depressed (top right) and diaphragm elevated (bottom right)

side to side and front to back. As the chest wall moves up and outwards, the parietal pleura moves with it and, because of the 2 mmHg negative pressure within the pleura, the visceral pleura follows the parietal pleura. This causes stretching of the lungs, which expand to fill the enlarged thorax, and air is pushed into the respiratory passages.

### Exhalation

**Exhalation** is normally a more passive process than inhalation except in exercise and respiratory conditions in which active expiration occurs via internal intercostal and accessory muscles. During exhalation the diaphragm relaxes, thus decreasing the size of the thoracic cavity. The external intercostal muscles also relax, allowing the ribs and sternum to return to their former position, further decreasing the size of the thoracic cavity. The elastic tissue of the lungs allows for recoil, further forcing air out of the respiratory passages.

## Respiration

### External respiration

External respiration is the exchange of gases between air in the alveoli and the blood travelling through the capillaries surrounding the alveoli. Branches of the pulmonary artery bring deoxygenated blood to the capillaries surrounding each alveolus. During **gas exchange**, gases normally diffuse through the semi-permeable walls of the alveoli and capillaries to the area of lowest concentration of each gas, as each gas diffuses independently of other gases, until the pressure is equal on both sides. Thus, oxygen moves from an area of higher concentration in the alveoli to an area of lower concentration in the blood capillaries, while $CO_2$ moves from an area of a higher concentration in blood capillaries to an area of lower concentration in the alveolar air. Pulmonary venules then collect the blood rich in oxygen from the capillaries and unite to form the two pulmonary veins which leave each lung to enter the left atrium of the heart. Table 25.1 illustrates the approximate composition of inspired and expired air.

### Internal respiration

Internal respiration (Figure 25.6) is the exchange of gases between the bloodstream and the tissues. During this exchange, the gases diffuse through the semi-permeable walls of the capillaries to equalise the concentration of gases on both sides. Oxygen moves from the blood into the tissues, down a concentration gradient, to replenish oxygen used in cellular metabolism. Carbon dioxide moves from the tissues into the blood, down a concentration gradient, to rid the tissues of waste produced by cellular metabolism.

**TABLE 25.1 | Composition of inhaled compared with exhaled air**

| | % Oxygen | % Carbon dioxide | % Nitrogen |
|---|---|---|---|
| Inhaled air (atmospheric air) | 20.9 | 0.04 | 79 |
| Exhaled air (alveolar air) | 14.0 | 5.60 | 79 |

*(Soloman 2016)*

### Cellular respiration

The gases that diffuse from the interstitial tissue into cells are used by the cells for metabolism. The metabolism of nutrients uses oxygen and produces $CO_2$, which diffuses from cells into the interstitial tissue. This level of respiration is termed cellular respiration.

## Factors necessary for ventilation and respiration

The passage of oxygen from the atmosphere to the alveoli in the lungs, and the passage of carbon dioxide from the alveoli to the atmosphere, requires an unobstructed airway. In addition, the process of respiration requires:

- Adequate oxygen in the atmosphere
- A patent functioning respiratory tract
- Functioning thoracic muscles and nerves to control the thoracic cage and diaphragm
- Capillaries in close proximity to the cells to allow the exchange of gases
- A functioning cardiovascular system that contains adequate amounts of plasma and normal erythrocytes and haemoglobin to transport the gases (Marieb & Hoehn 2013).

## Transport of oxygen

Oxygen is carried in the blood in two ways:

1. Dissolved in the plasma: only 2–3% of oxygen is carried in this way as oxygen is not very soluble. Oxygen dissolved in plasma is measured as $PaO_2$

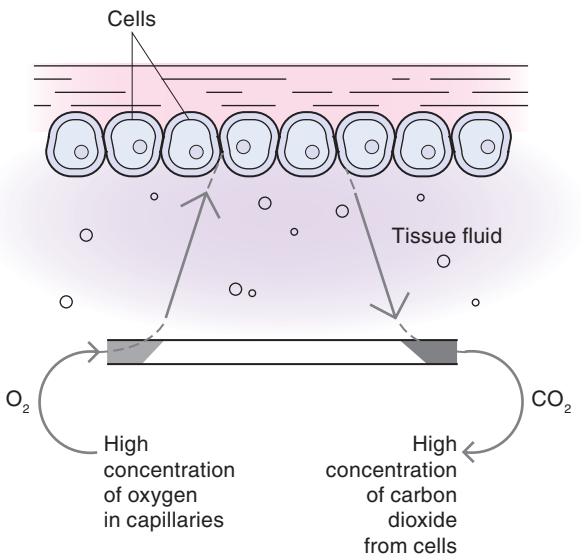

**Figure 25.6** Internal respiration

$$Hb + O_2 = HbO_2$$

(Uncombined or reduced haemoglobin) + oxygen = (oxyhaemoglobin or combined haemoglobin)

**Figure 25.7** Haemoglobin equation

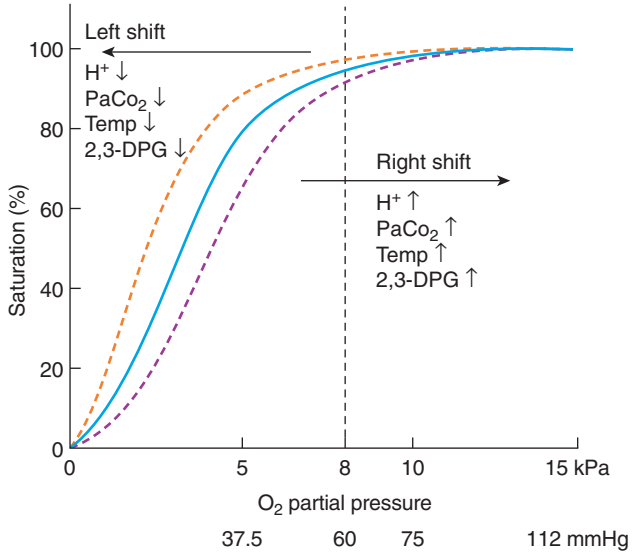

**Figure 25.8** $HbO_2$ dissociation curve

*(Dougherty & Lister 2011:542)*

2. Bound to haemoglobin in the red blood cells: 95–98% of oxygen is carried in this way and is measured by the percentage of oxygen saturated ($SaO_2$).

Haemoglobin is composed of haem (iron) and globulin (protein). Oxygen and haemoglobin combined together form oxyhaemoglobin (Figure 25.7).

Hb that is not combined with oxygen is referred to as reduced haemoglobin. Hb that is completely converted to $HbO_2$ is referred to as fully saturated haemoglobin (Dougherty & Lister 2011). Hb that has a mixture of Hb and $HbO_2$ is referred to as partially saturated haemoglobin. The percentage saturation of haemoglobin is the percentage of $HbO_2$ in the total haemoglobin. The percentage saturation of haemoglobin with oxygen is illustrated in the oxygen–haemoglobin dissociation curve (Figure 25.8).

The bond between haemoglobin and oxygen are affected by various physiological factors that shift the oxygen dissociation curve to the left or to the right. When the $PaO_2$ of blood is high, haemoglobin binds with large amounts of oxygen and is almost fully saturated. When the $PaO_2$ is low, the haemoglobin binds with smaller amounts of oxygen and is partially saturated (Dougherty & Lister 2011).

The assessment of arterial oxygen saturation is commonly performed by using pulse oximetry. This device is non-invasive and can be easily applied by a sensor probe. The principles of pulse oximetry are based on variation in the ratio of the light's absorbance of tissues during systole and diastole (Tin & Lal 2015).

## Factors affecting the release of oxygen from haemoglobin

Several factors affect the amount of oxygen being released from haemoglobin so that the oxygen dissociation curve is said to shift to the left or to the right (Pittman 2013). When a shift occurs to the right there is reduced binding of oxygen to haemoglobin and oxygen is released more easily into the tissues. When a shift occurs to the left there is an increase in the binding of oxygen to the haemoglobin, resulting in oxygen being less easily released into the tissues (Dougherty & Lister 2011). Cellular hypoxia can occur.

### pH

Oxygen is released more readily from haemoglobin in an acid environment. This condition occurs often during an acute illness. During an acute illness an increase in $PaO_2$ is usually present, resulting in a lower pH. This acidic environment allows the oxygen to separate more readily from the haemoglobin allowing the tissues to have more oxygen.

### Temperature

Within limits, the amount of oxygen released from haemoglobin increases as temperature increases, therefore hyperthermia causes a rightward shift while hypothermia causes a leftward shift.

### Organic phosphates

2,3-diphosphoglycerate (DPG) is a primary organic phosphate. It is an intermediate compound formed in red blood cells during the conversion of glycogen to glucose. The production of 2,3-DPG is likely an important adaptive mechanism because the production increases in several conditions where there is diminished peripheral tissue $O_2$ availability, such as hypoxaemia, chronic lung disease, anaemia and congestive heart failure. High levels of 2,3-DPG shift the curve to the right, while low levels of 2,3-DPG cause a leftward shift, seen in states such as septic shock and hypophosphataemia.

### Carbon dioxide excretion

Carbon dioxide is carried through the venous system and breathed out through the lungs. The normal level of carbon dioxide in the blood is 3.5–5.3 kPa. Carbon dioxide has a direct effect on the respiratory centre in the brain. As carbon dioxide levels rise and diffuse from the blood into the cerebrospinal fluid, the $CO_2$ is hydrated and carbonic acid is formed. The role of the respiratory system is to excrete carbonic acid from the lungs during expiration. Carbon dioxide stimulates respiratory rate and so high carbon dioxide levels result in a higher respiration rate.

# STRUCTURE OF THE CARDIOVASCULAR SYSTEM

The structures that make up the **cardiovascular** system are the:

- Heart, which acts as a pump to circulate the blood through the body
- Blood, which carries essential substances to cells and carries wastes away from cells
- Blood vessels, which contain and transport the blood throughout the body
- Lymphatic system, which transports tissue fluid containing electrolytes, proteins and some waste products, recognises and destroys pathogens before they reach the bloodstream and delivers nutrients from the digestive tract into the cardiovascular system.

## The heart

The heart is a hollow, conical muscular organ situated obliquely in the thoracic cavity between the lungs and behind the sternum. One-third of the heart lies to the right, and two-thirds lie to the left of the median plane. Its base is uppermost and points towards the right shoulder, and its apex is below, pointing to the left. The adult heart is about 12 cm × 8 cm × 6 cm and weighs about 300 g.

### Structure of the heart

The heart is divided into a right and a left side by a muscular partition called the septum. Each side is further divided into an upper receiving chamber, the atrium, and a lower distributing chamber, the ventricle (Figure 25.9).

The walls of the heart consist of the pericardium, myocardium and endocardium:

- The pericardium is the outer coat, consisting of two layers of serous membrane. The pericardium secretes a small amount of serous fluid to moisten the surfaces in contact with each other, so that the heart can beat with minimal friction
- The myocardium is the middle muscular layer consisting of cardiac muscle, which is a highly specialised type of muscle tissue present only in the heart. It is of varying thickness, being thicker in both ventricles than in the atria, and thicker in the left ventricle than in the right

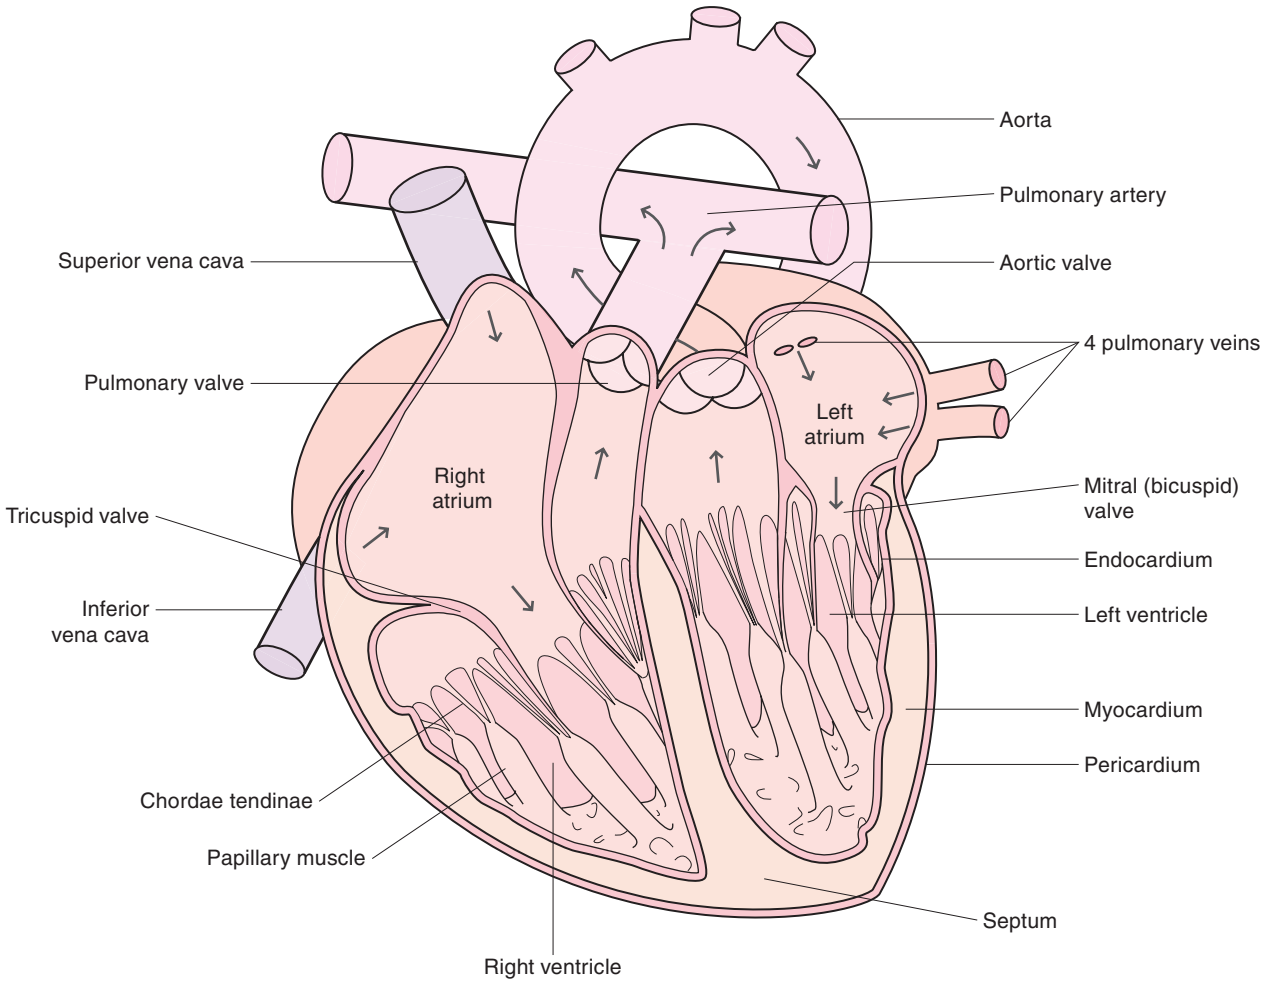

**Figure 25.9** Structure of the heart

- Endocardium is the innermost lining of the heart, and provides a smooth surface for the flow of blood. Folds of endocardium help to form the valves of the heart.

### Valves of the heart

Heart valves consist of flaps of fibrous tissue covered by endocardium, which allow blood to flow in one direction only, thus preventing a backward flow. The valves are the:

- Bicuspid (or mitral) valve, between the left atrium and left ventricle
- Tricuspid valve, between the right atrium and right ventricle
- Aortic valve, between the left ventricle and the aorta
- Pulmonary valve, between the right ventricle and the pulmonary artery.

Fine cords of tendons (chordae tendinae) are attached from the mitral and tricuspid valves to small projections from the muscle walls of the ventricles called papillary muscles. Contraction of the papillary muscles closes the valves, preventing blood from escaping back into the atria.

### Cardiac blood vessels

Several blood vessels either enter or leave the heart. The blood vessels that enter the heart are the:

- Inferior vena cava, which carries deoxygenated blood collected from the lower part of the body to the right atrium
- Superior vena cava, which carries deoxygenated blood collected from the upper part of the body to the right atrium
- Four pulmonary veins, two from each lung, which carry oxygenated blood into the left atrium.

The blood vessels that leave the heart are the aorta, which carries oxygenated blood from the left ventricle for distribution to all the systems and tissues of the body, and the pulmonary artery, which leaves the right ventricle then divides into two branches that carry deoxygenated blood from the heart to each lung. Thus, the right side of the heart deals only with deoxygenated blood, and the left side deals only with oxygenated blood.

### Blood supply to the heart

The heart receives its own supply of blood. As the aorta leaves the heart it gives off two branches called the coronary arteries (right coronary). The coronary arteries divide into smaller and smaller branches, until networks of capillaries are formed in the heart wall. These arteries and their branches supply all parts of the myocardium with blood. Venules collect the deoxygenated blood from the tissues in the heart wall and unite to form a vein (coronary sinus), which opens directly into the right atrium.

### The conducting system of the heart

The heart's conducting system (Figure 25.10) ensures that it contracts in a coordinated and synchronised series of events. The sinoatrial (SA) node is located in the upper part of the right atrium and acts as the pacemaker of the heart, continuously initiating impulses that innervate the rest of the heart. The atrioventricular (AV) node lies in the lower part of the interatrial septum of the heart. The AV node is connected to the bundle of His and is the only natural pathway for the impulse to travel from the atria to the ventricles. The bundle of His divides into the right and left bundle branches, which in turn divide off into tiny fibres termed Purkinje fibres. These fibres rapidly conduct the impulse throughout the myocardium from the apex to the base.

### Functions of the heart

The function of the heart is to act as a pump: it pumps deoxygenated blood to the lungs to excrete carbon dioxide and pick up oxygen, and pumps oxygenated blood to all other parts of the body.

The cardiac cycle is the series of pressure changes, valve actions and electrical potentials that bring about the movement of blood through the heart during one complete heart beat. The cardiac cycle takes about 0.8 of a second and consists of two phases, systole (the contraction phase) and diastole (the relaxation phase). During systole, both atria contract at the same time, emptying their contents into the ventricles. The two ventricles then contract simultaneously, forcing their contents into the aorta and pulmonary artery. Diastole follows after each contraction of the heart.

Cardiac output is the volume of blood pumped out by each ventricle during 1 minute. It is the product of the volume of blood pumped at each beat (stroke volume) and the number of beats during 1 minute (heart rate).

The heartbeat is controlled by the cardioregulatory centre in the central nervous system. The vagus nerve slows it and reduces the force of the beat, while sympathetic nerves quicken the beat and increase its force.

Each cardiac muscle cell is capable of spontaneous, rhythmic self-excitation known as autorhythmia. To be effective as a pump, the action of the whole heart must be coordinated. Coordination of the rhythmic movements is brought about by the specialised cells of the sinoatrial (SA) node (pacemaker).

## Blood

Blood is composed of plasma and formed elements. It is a viscous substance, heavier, thicker and more viscous than water. Despite being a liquid, blood has the unique quality of being able to form solid clots (Rosdahl & Kowalski 2008). Blood composed of a fluid portion (plasma) and formed elements (cells and cell fragments).

Blood is classed as a connective tissue and constitutes about one-twelfth of the weight of the body (Rosdahl & Kowalski 2008). The difference between blood and other connective tissues is that its cells are not fixed but free to move in the liquid portion of the blood, known as plasma (Rosdahl & Kowalski 2008).

Depending on the weight of the individual, the average total volume of blood is about 5–6 L. Blood varies in colour, from bright red when it has a high oxygen content, to dark

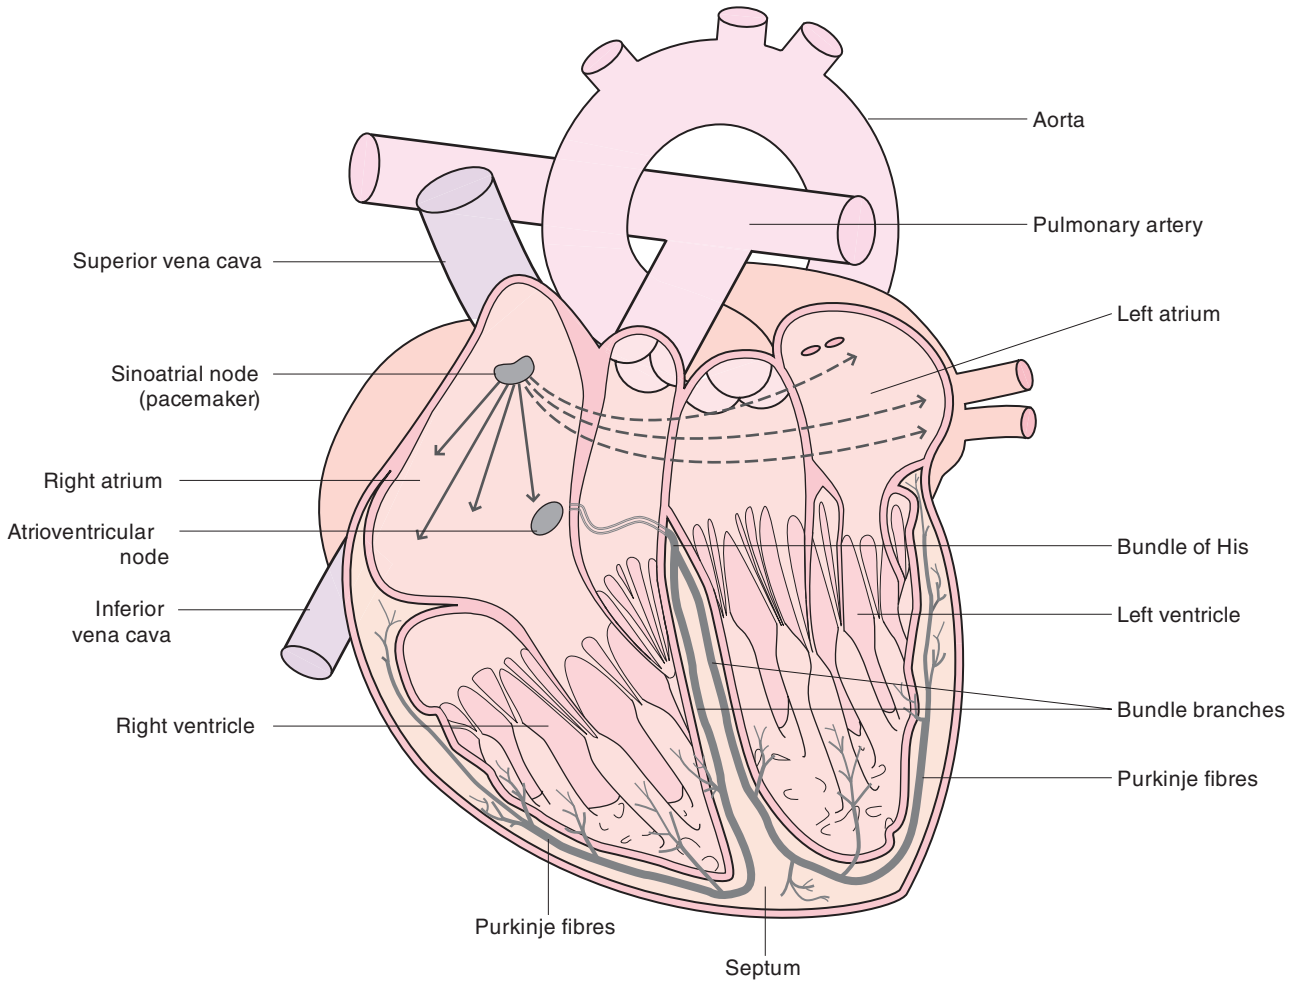

**Figure 25.10** Conduction system of the heart

red when the oxygen content is low. Arterial blood normally has a pH range of 7.35 to 7.45 (Marieb & Hoehn 2013).

## Functions of blood

Blood has the following functions:

- Transporting oxygen, nutrients, water and ions to all tissue cells
- Removing waste materials to excretory organs
- Transporting hormones to cells
- Supplying materials from which cells and glands make their secretions
- Protecting the body against infection by means of the leucocytes and antibodies
- Regulating pH, body temperature and cellular content by distributing heat evenly throughout the body
- Preventing loss of body fluid and blood cells by means of its clotting mechanism (Rosdahl & Kowalski 2008).

## Plasma

Plasma, the fluid part of blood, is a straw-coloured watery fluid in which blood cells are suspended. Plasma forms about 55% of the blood volume and is composed of 90% water (Rosdahl & Kowalski 2008), which is important in the maintenance of all body fluids and in the production of secretions. Plasma contains:

- Proteins: albumin, globulin, fibrinogen, prothrombin and heparin are some of the proteins found in plasma. The liver normally produces proteins, with the exception of serum globulin, which is derived from lymphocytes. Plasma proteins have several important functions: they assist in retaining water in the plasma and interstitial tissue; factors such as prothrombin and fibrinogen are essential for blood clotting; proteins such as heparin help to prevent abnormal clotting of blood in the blood vessels
- Mineral salts: the main mineral salts found in blood plasma are sodium chloride, iodine, potassium, phosphorus, calcium, iron, magnesium and copper. Mineral salts are necessary for the regulation of cellular functioning and electropotentials and maintenance of the blood pH
- Nutrients: those found in blood plasma are numerous and include amino acids, glucose, fatty acids, glycerol and vitamins. They have been reduced to their simplest

form by the digestive processes and absorbed from the alimentary tract into the blood and lymph for circulation to the cells
- Waste products resulting from fat and protein metabolism, including urea, uric acid and creatinine
- Gases, including oxygen, nitrogen and carbon dioxide. Oxygen and nitrogen enter the bloodstream after inhalation of air, and carbon dioxide is an end product of oxidation in the cells
- Hormones: chemical substances secreted directly into the bloodstream by endocrine glands and carried to the areas of the body where they are required to stimulate activity
- Antibodies and antitoxins: complex protein substances produced by the body in response to an invasion by a foreign protein (antigen). They are part of the body's defence mechanism
- Enzymes: produced by the body, which initiate or accelerate chemical reactions (Rosdahl & Kowalski 2008).

## Formed elements

The remaining 45% of blood volume consists of blood cells and fragments suspended in the plasma and is known as formed elements (Rosdahl & Kowalski 2008). The three types of formed elements are erythrocytes, leucocytes and thrombocytes.

***Erythrocytes*** **Erythrocytes** (red cells) are biconcave non-nucleated discs measuring about 7 microns in diameter. In adults, erythrocytes are produced in the red bone marrow of cancellous bone tissue, where they pass through several stages of development (Rosdahl & Kowalski 2008). They begin as large nucleated cells but when mature (after they have produced haemoglobin) they lose the nucleus and are liberated into the circulation. Haemoglobin is a complex protein composed of four different 'haem' chains, each containing a central atom of iron and a globulin protein. It has a strong affinity for both oxygen and carbon monoxide and gives the blood its colour. The normal haemoglobin level is about 14–16 g/100 mL of blood.

The number of erythrocytes is about 5 000 000/mm$^3$ of blood, and their average lifespan is 100–120 days. As their nucleus is absent, they are unable to repair damage and become worn out in circulation, and are destroyed in the spleen and liver. The haemoglobin is split; the liver stores the iron for future use and uses the pigment in the production of bile. The primary function of erythrocytes is to carry oxygen. In the lungs, oxygen combines with haemoglobin to form oxyhaemoglobin, making the blood bright red in colour. As blood circulates through the tissues, the oxygen is released, forming deoxyhaemoglobin, and the blood becomes dark red in colour (Rosdahl & Kowalski 2008).

***Leucocytes*** **Leucocytes** (white cells) measure about 10 microns in diameter. They differ from erythrocytes in that they are larger, possess a nucleus and are less numerous. They also have the power of independent movement, known as diapedis, or emigration, which erythrocytes do not possess. There are two main types of leucocytes: granulocytes and agranular leucocytes (Rosdahl & Kowalski 2008).

**Granulocytes** contain granules of enzymes and are classified as neutrophils, basophils or eosinophils.
- **Neutrophils** are the most numerous of the leucocytes and are important to the body in defence against bacteria, as they have the ability to engulf microorganisims or other foreign particles (phagocytosis) and digest them. Neutrophils also play an important part in the inflammatory response. Injured tissues, and other leucocytes, secrete substances that stimulate the bone marrow to release increased numbers of neutrophils.
- **Basophils** release substances in infected tissue that are toxic to many microorganisms. They also play a part in the allergic response and act to limit the inflammatory response.
- **Eosinophils** are also involved in phagocytosis, as they ingest antigen–antibody complexes and parasites. They also play a role in clot retraction (Rosdahl & Kowalski 2008).
- **Agranular** leucocytes lack granules of enzymes and are classified as monocytes or lymphocytes.
- **Monocytes** have the ability to move into the tissues, where they become macrophages and are capable of phagocytosis. They also secrete a variety of substances involved in the body's defence, and play a role in the immune response.
- **Lymphocytes** are either T lymphocytes or B lymphocytes, both of which divide when stimulated by antigens. T lymphocytes are responsible for cellular immunity, and adhere to cells identified as foreign to the body. They secrete cytotoxic substances that kill the foreign cells. B lymphocytes are involved in humoral immunity, as they produce antibodies and are also responsible for immunoglobulin production. While the lifespan for granular leucocytes is only about 21 days, lymphocytes may survive for up to 100 days.

The total number of leucocytes is about 8000–10 000/mm$^3$ of blood, but this number increases considerably (leucocytosis) when there is any infection in the body. The lifespan of a leucocyte is variable and depends to some extent on the degree of activity.

***Thrombocytes*** **Thrombocytes** (platelets) are the smallest of the formed elements. They are colourless microscopic fragments of the megakaryocyte cell. Measuring about 3 microns in diameter, they do not possess a nucleus. Thrombocytes are produced in the red bone marrow, which is present in cancellous bone tissue. The number of thrombocytes is about 250 000–300 000/mm$^3$ of blood, and the average lifespan of a thrombocyte is 5–9 days. The function of thrombocytes is to play a major role in the clotting of blood to reduce blood loss when a vessel wall is injured. The process involves many substances (clotting factors) which are produced by the liver

and circulate in the plasma, as well as some substances released by the platelets and injured tissues. Normally a blood clot will form within 2–6 minutes after a blood vessel wall has been damaged (Rosdahl & Kowalski 2008).

The mechanism of clotting (haemostasis) involves three phases: vasoconstriction, formation of a temporary platelet plug and formation of a clot. When a small vessel becomes damaged:

- Local vasoconstriction occurs, which reduces blood flow and therefore blood loss
- The vessel wall becomes 'sticky' and platelets adhere to the damaged area
- The platelets release serotonin and adenosine diphosphate (ADP), which attract other thrombocytes, leading to the formation of a temporary platelet plug
- The temporary platelet plug is converted into a clot by the deposition of fibrin, which is formed from fibrinogen. The conversion of fibrinogen to fibrin involves a 'cascade' of reactions that requires a number of plasma factors (numbered I to XIII). A series of reactions culminate in the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin. This conversion requires the presence of platelets, Factor V, Factor X and calcium ions. Vitamin K is also necessary for the conversion of Factors VII, IX and X
- The fibrin forms a meshwork of fibres that traps the erythrocytes and forms the basis of a clot
- The clot plugs the injured blood vessel, drawing the edges together.

The clotting mechanism is a complex one that will not occur if any of the necessary elements are reduced, defective or missing (Marieb & Hoehn 2013).

## Blood group types

Human blood is grouped into four classifications based on immune reactivity. The groups are O, A, B, AB. The Rhesus factor (either negative or positive) is also determined. Eighty-five per cent of the population has Rh antibodies on the surface of the red blood cell (that is, RH positive). The blood of any one group is essentially incompatible with the blood group of another. Therefore blood transfusions should be an exact match to the individual's blood group and Rh factor. When blood transfusions occur with mismatched blood a haemolytic reaction can occur (Daniels & Bromilow 2013). To prevent a mismatch or to recognise a reaction to a transfusion it is important to follow organisational policies and procedures for the preparation, administration and monitoring of individuals undergoing a blood transfusion. See Clinical Skill 25.1 for preparing and monitoring an individual undergoing a blood transfusion.

## Blood vessels

Blood is circulated throughout the body (Figure 25.11) within vessels that form a closed continuous system.

The walls of blood vessels have three layers: an outer coat of fibrous tissue, a thick middle layer of involuntary muscle with elastic fibrous tissue and an inner lining of endothelium to form a smooth surface for contact with blood (Figure 25.12). Blood vessels include the arteries, veins and capillaries.

## Arteries

Arteries carry blood away from the heart (efferent). All arteries carry oxygenated (bright red) blood, with the exception of the two pulmonary arteries which carry deoxygenated (dark red) blood from the heart to the lungs. Arteries vary in size, and large arteries divide to form smaller arteries (Figure 25.13). Further division, or branching, occurs to form the smallest arteries, called arterioles, which divide into capillaries. Arteries and arterioles have the same tissue structure that allows them to stretch and recoil as the heart pumps the blood into them.

## Veins

Veins carry blood towards the heart (afferent). All veins carry deoxygenated (dark red) blood, with the exception of the four pulmonary veins, which carry oxygenated blood from the lungs to the heart. Veins vary in size, and large veins divide

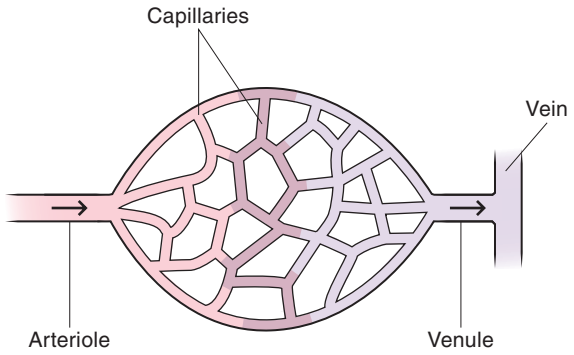

**Figure 25.11** Circulation of blood through the tissues

### DECISION-MAKING FRAMEWORK EXERCISE 25.1

You have been employed as an Enrolled Nurse in a cardiovascular surgical ward for 5 years. On the shift with you tonight there is 1 senior Registered Nurse, 1 recently Registered Nurse and 3 Enrolled Nurses. You have been assigned 3 persons, all are at least 3 days postoperative. During your shift one of your persons requires a blood transfusion.

Using the decision-making framework:

1. Is this within your scope of nursing practice?
2. Are you supported appropriately by other staff members to care for this person?
3. Is this model of care appropriate?
4. What strategies could you consider in this situation?

## CLINICAL SKILL 25.1 Preparing and monitoring an individual undergoing a blood transfusion

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Medical order, fluid order, blood product (packed red cells, whole blood, plasma, platelets, serum albumin, cryoprecipitate), blood infusion giving set, IV pump, fluid balance chart (FBC) and normal saline, transfusion observation form |

| **Skill activity** | **Rationale** |
|---|---|
| Check medical orders/fluid orders to ascertain type, duration and amount of blood product to be administered | Ensures correct product and quantities are given to individual<br>Prevents circulatory overload |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status or previous reactions to blood<br>Verify a signed consent was obtained<br>Instruct the person to report any sudden chills, nausea, dyspnoea, fever, rash, itch, loin/flank pain | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Reduces risk of allergic reaction |
| Measure and record blood pressure and vital signs and record on observation chart pre-transfusion | Provides a baseline of the individual's haemodynamic health status |
| Perform hand hygiene | Prevents cross-infection and contamination of blood and tubing |
| Prepare equipment using aseptic technique: blood infusion line, normal saline (500 mL) and IV pump<br>Prime line with normal saline, including both ports free from air | Prevents the introduction of microorganisms<br>Ensures all equipment ready prior to blood product arriving on ward |
| Establish an IV infusion with normal saline | IV access is established by a medical officer or accredited RN. Normal saline is the solution used during a blood transfusion because it is compatible with blood and does not cause red blood cell lysis |
| Place the equipment in a convenient location near the bedside including:<br>• Equipment for taking vital signs<br>• Blood or blood product (collected from the allocated area within the organisation ensuring it is collected as per policy)<br>• Blood order and requisition form<br>Note: Blood should not exceed the maximum time of 30 minutes away from the fridge; platelets should continue to be agitated by hand prior to administration | Ensures all equipment is at bedside to maximise efficiency, reduces apprehension on the individual's part and increases their confidence in the nurse<br>Abides by facility/organisation policy<br>Reduces the risk of contamination<br>Prevents clumping of platelets |
| Identify the individual and the blood product according to facility/organisation policy<br>Verify the individual's consent (written)<br>Two nurses (one must be a Registered Nurse) check the:<br>• Person's identity according to policy. Check the arm band for name and ID | Two persons check the individual's details and the group and type of blood product to be administered to ensure it matches the order and the correct product is delivered to the correct person<br>Ensures safe administration of the blood product |

## CLINICAL SKILL 25.1 Preparing and monitoring an individual undergoing a blood transfusion—cont'd

| | |
|---|---|
| • Blood product order and requisition form<br>• Information on the blood product and the blood product for evidence of leakage, abnormal colour, clumping<br>• Expiry date<br>Sign the appropriate form/s according to facility/organisation policy<br>Document transfusion on FBC, transfusion form and in healthcare record<br>The two staff members calculate and set the flow rate as prescribed | |
| The blood transfusion must be initiated within 30 minutes from time out of fridge and completed within 4 hours of the product leaving controlled storage (timer often attached)<br>Note: This applies for red cells only | Minimises risk of bacterial infection and contamination |
| Perform hand hygiene and don PPE<br>Initiate the blood transfusion<br>Gently invert the blood product several times<br>Wearing gloves, close clamp on saline infusion and attach blood product to the short tubing on the administrating set using aseptic technique<br>Tip the blood and gently squeeze to fill the filter<br>Place blood on IV stand and open the clamp, squeeze the drip chamber and release it until blood begins to flow | Prevents cross-infection<br>Ensures cells and plasma are mixed<br>Stops the backflow of blood from mixing with the saline<br>Filling the filter prevents air from entering the system<br>Ensures no air bubbles enter the giving set<br>Prevents contamination from microorganisms |
| Remove gloves and perform hand hygiene | Prevents cross-infection |
| Initiate the transfusion slowly (and as per facility/organisation policy)<br>Monitor the person closely (every 5 minutes) for the first 15 minutes after the commencement of the transfusion and ensure close observation throughout the duration of the transfusion. Reassess vital signs after 15 minutes and hourly for the remainder of the transfusion according to facility/organisation policy and individual health status<br>The blood transfusion is completed within 4 hours of the product leaving controlled storage (timer often attached)<br>Note: This applies for red cells only | Most reactions occur within the first 10 minutes. Beginning the transfusion slowly reduces the amount of blood for the system to react against, reducing the severity of the reaction. The rate of the infusion may be increased usually after 15 minutes<br>Vital signs are taken as per facility/organisation guidelines<br>Note: Platelets, plasma (FFP), serum albumin and cryoprecipitate generally do not require regular observations, but refer to facility/organisation policy for further information<br>Minimises risk of bacterial infection and contamination |
| Observe for reactions such as:<br>• Fever, chills, headache, malaise<br>• Flushing of the skin, urticaria, wheezing, itchy rash<br>• Restlessness, anxiety, chest pain, tachypnoea, tachycardia, nausea, shock, haematuria, back pain<br>Stop the blood transfusion if you suspect a reaction<br>Notify RN and medical officer, follow facility/organisation policy<br>Do not discard bag or line, which is returned to blood bank/pathology, and follow blood reaction protocol | Indicates afebrile non-haemolytic or haemolytic reaction or circulatory overload<br>Different actions may be implemented depending on the reaction and medical officer's orders |
| Complete the transfusion<br>Change the giving set as per facility/organisation policy<br>(The individual may require IV frusemide inbetween units, which is often written on the fluid orders) | Ensures individual receives the entire transfusion<br>Decreases risk of bacterial contamination, and retains efficiency of filter<br>Prevents circulatory overload as blood products are colloids (volume expanders) which may lead to pulmonary oedema in patients with cardiac failure |

## CLINICAL SKILL 25.1 Preparing and monitoring an individual undergoing a blood transfusion—cont'd

| | |
|---|---|
| Put on clean PPE and dispose of the blood unit as per facility/organisation policy<br>Remove PPE, perform hand hygiene | Some facilities require all completed blood units (including the giving set) to be returned to blood bank and kept for 24 hours in case of a delayed reaction<br>Others require complete disposal in the infectious waste bin |
| Monitor individual for any adverse effects to the transfusion. Report any significant deviations to Registered Nurse/medical officer<br>Vital signs are often recorded hourly for 4 hours then 4-hourly for 24 hours | Any adverse effects can be managed promptly<br>Individuals can have a delayed reaction to the blood product for up to 24 hours |
| Report and document all relevant information in the healthcare record | Most blood products have a peel-off identification tag that is identical to the blood unit ID number, grouping and Rh factor, so that errors in transcription are avoided. This tab should be removed and placed in the health record as per facility/organisation policy<br>Fractionated plasma products have a batch number sticker on the bottle which is usually peeled off and placed in the health record<br>Medico-legal requirement. Allows for the planning and implementation of care |

*(Australian and New Zealand Society of Blood Transfusion 2011; Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012; 2015; Sparkes et al 2014)*

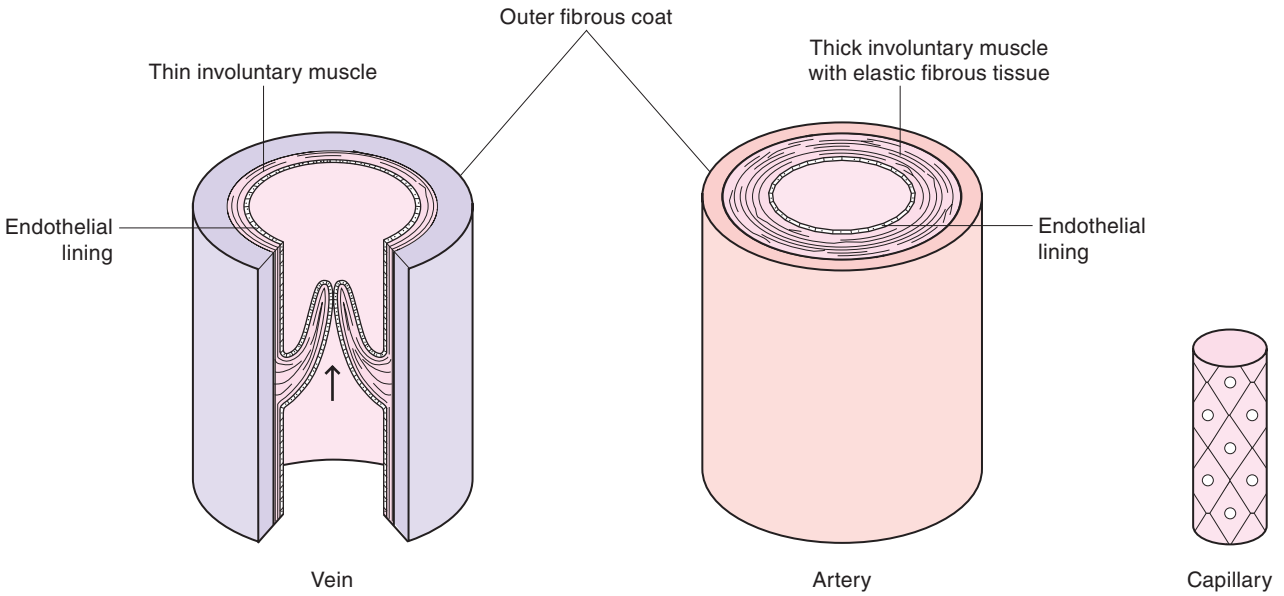

**Figure 25.12** Structure of blood vessels

to form smaller veins. The smallest veins are called venules, which divide into capillaries (Figure 25.13). Venules carry deoxygenated blood away from the capillary beds and unite to form veins. The walls of veins are composed of the same three layers as those of arteries, but the walls are thinner and have less elastic and muscular tissue. Veins join up until the two largest veins are formed—the superior and inferior vena cavae. These two veins empty their contents into the right atrium of the heart.

The larger veins possess pocket-like valves on their inner surfaces. These valves aid the unidirectional flow of blood towards the heart, and prevent a backward flow of blood.

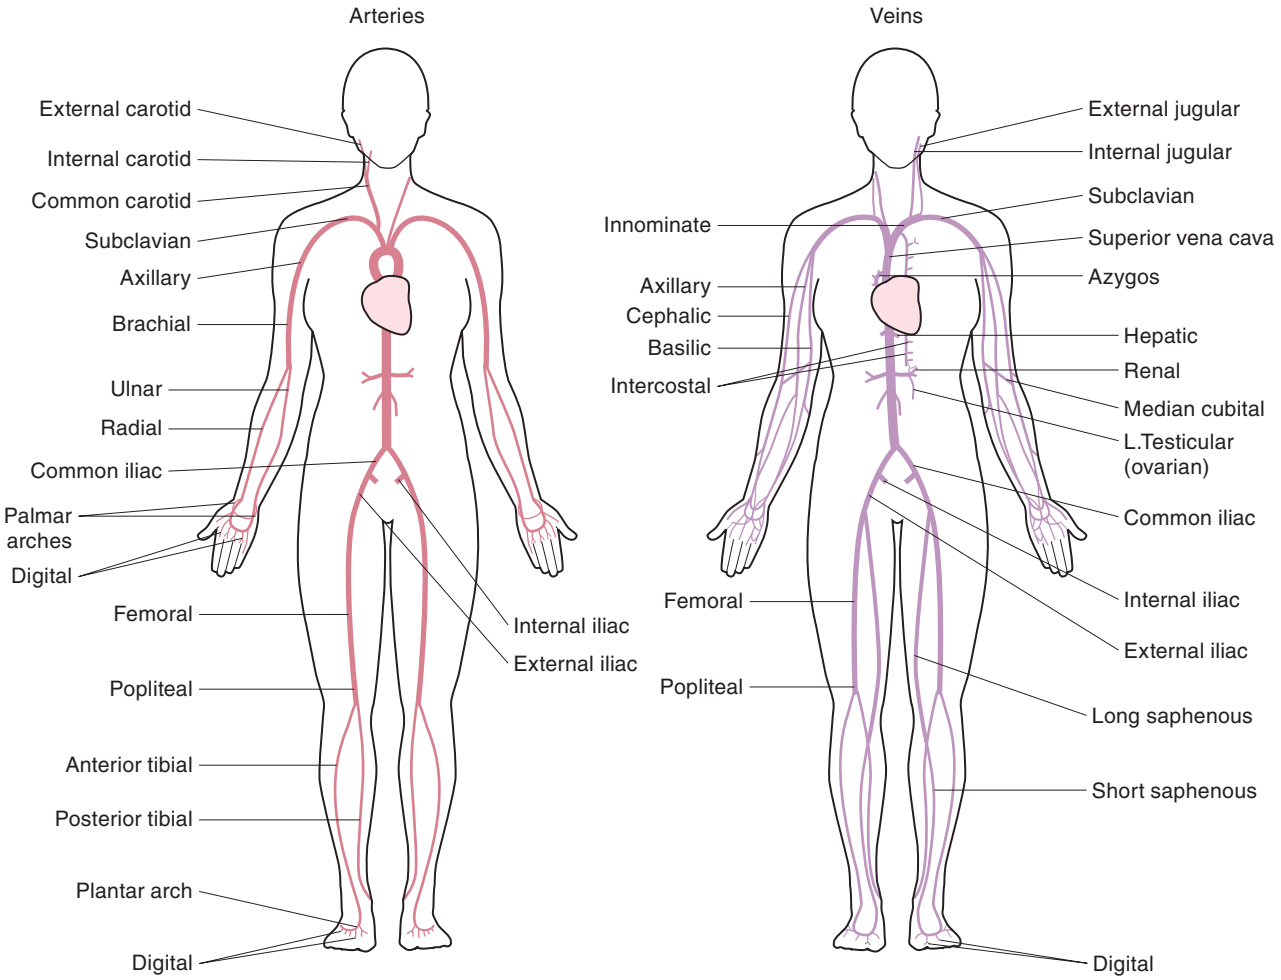

**Figure 25.13** Major arteries and veins

Skeletal muscle activity also helps venous return. As the muscles surrounding the veins contract and relax, the blood is 'milked' through the veins towards the heart.

### Capillaries

Capillaries are microscopic vessels about 5–7 microns in diameter and are composed of a single layer of endothelium, with little surrounding connective tissue. They form closed networks through all tissues and are structurally adapted for their role in the rapid diffusion of substances between the plasma and interstitial fluid. This allows water, oxygen, nutrients and other essential substances to pass rapidly from the blood to the tissue cells, and waste products from the tissue cells pass through the capillary walls to the blood.

### Blood pressure

The term blood pressure refers to the pressure, or force, exerted by blood on the walls of the blood vessels. Pressure is highest in the arteries, which receive blood from the ventricles of the heart at about 120 mmHg. As the vessels divide, their cross-sectional area increases, causing the pressure to progressively reduce so that there is only very slight pressure in the capillaries (about 35 mmHg and 15 mmHg in the venules). Systolic blood pressure is the pressure registered in a large artery as blood is forced out of the ventricle during the contracting period of the cardiac cycle. Diastolic blood pressure is the pressure registered during the relaxing period of the cardiac cycle, when there is no ejection of blood into the arteries. It is therefore lower than the systolic pressure.

## CIRCULATION OF BLOOD

Blood flows continuously around the entire body. The blood vessels (of which there are two circuits—pulmonary and systemic) along with the four chambers of the heart (right and left atrium, right and left ventricle) form this closed circulatory system in which blood flows (Rosdahl & Kowalski 2008). Deoxygenated blood from all body regions is transported via the veins to the superior and inferior vena cavae, which enter the right atrium. The coronary sinus drains venous blood from the myocardium into the right atrium. At first, blood flows passively into the right ventricle as the tricuspid valve is open, then contraction of the right atrium (atrial systole) occurs to empty its entire contents. After the tricuspid valve closes, the right ventricle contracts (ventricular

systole), and blood is ejected through the pulmonary valve into the pulmonary artery.

The pulmonary artery divides into the right pulmonary artery, which carries deoxygenated blood to the right lung and the left pulmonary artery, which carries deoxygenated blood to the left lung. In the lungs, oxygen is exchanged for carbon dioxide from the blood, and the oxygenated blood returns to the left atrium via four pulmonary veins. The left atrium contracts and blood passes through the mitral (bicuspid) valve into the left ventricle. After the mitral valve closes, the left ventricle contracts and blood is ejected into the aorta via the aortic valve. The aorta branches off to supply all areas of the body with oxygenated blood.

## The systemic circulation

The systemic circulation is the distribution of oxygenated blood to all tissues, and the return of deoxygenated blood from all tissues to the heart. When the left ventricle contracts it forces blood into the aorta under pressure. The elastic walls of the aorta distend to receive the blood. When the left ventricle relaxes the walls of the aorta recoil and, with the aortic valve closed, the blood is driven onwards through the aorta. Branches from the aorta also distend and recoil as the blood travels through them, and this wave of distension and recoil is felt as the pulse wherever a superficial artery crosses a hard structure such as a bone.

Arterioles supply networks of capillaries with oxygenated blood, and the hydrostatic pressure behind the blood causes water and other essential substances to be pushed through the capillary walls and wash over the tissue cells to become part of the tissue fluid. Tissue cells allow certain substances they require to enter, and excrete their waste products into the tissue fluid. The pressure within the capillaries will allow only a small amount of the fluid to return through the capillary and venule wall, back into the blood. The remainder of the fluid reaches the blood via the lymphatic system, which is discussed later in this chapter.

### Arteries

The aorta (Figure 25.14) has four sections, each of which has a number of branches. Two coronary arteries to the heart wall branch from the ascending aorta. From the aortic arch branch the left common carotid artery to the head and neck; the left subclavian artery to the left upper limb; and the right innominate artery, which divides into the right common carotid and right subclavian arteries. From the descending thoracic aorta branch the bronchial arteries to the lungs; the oesophageal artery to the oesophagus; and 10 pairs of intercostal arteries to the intercostal muscles. From the abdominal aorta, branch the:

- Phrenic arteries to the diaphragm
- Coeliac trunk, which divides into the gastric artery to the stomach, the hepatic artery to the liver and the splenic artery to the pancreas and spleen
- Superior mesenteric artery to the small intestine
- Renal arteries to the kidneys
- Ovarian or testicular arteries to the ovaries or testes

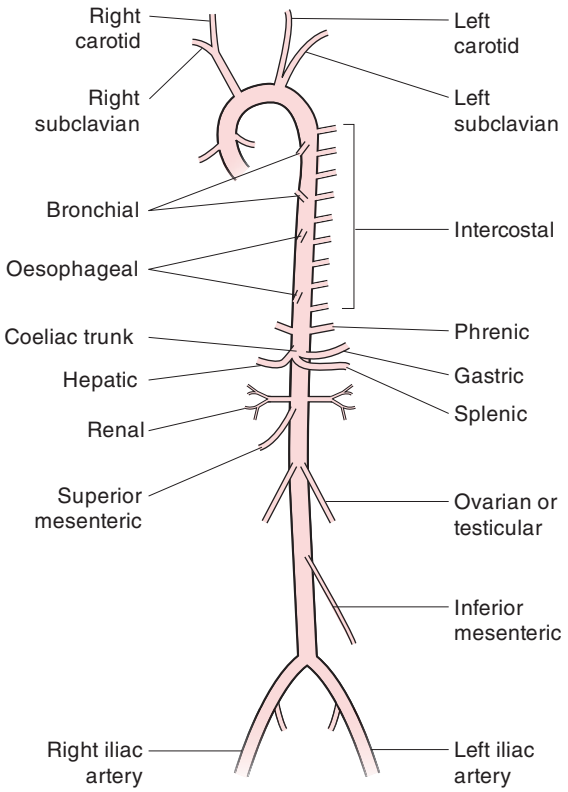

**Figure 25.14** The aorta and its branches

- Inferior mesenteric artery to the large intestine
- Two common iliac arteries to the pelvic organs and the lower limbs.

### Veins

There are two groups of veins: superficial veins, some of which can be seen as bluish lines under the skin; and deep veins, which run beside arteries and often have the same name as the arteries. Veins rely on the squeezing action of skeletal muscles to assist in pushing blood towards the heart, and on respiratory movements, which have a milking effect on the inferior vena cava as it passes through the diaphragm.

## Pulmonary circulation

The pulmonary circulation (Figure 25.15) involves the transport of deoxygenated blood from the heart to the lungs and the return of oxygenated blood from the lungs to the heart. The pulmonary artery leaves the right ventricle and divides into the right and left pulmonary arteries, which carry deoxygenated blood to the lungs. In the lungs, the arteries divide until capillaries are formed. Venules collect the oxygenated blood from the capillaries and unite to form the two pulmonary veins, which leave each lung and enter the left atrium of the heart (Rosdahl & Kowalski 2008).

## Hepatic–portal circulation

The hepatic–portal circulation (Figure 25.16) is a subdivision of the systematic circulation. It is responsible for carrying

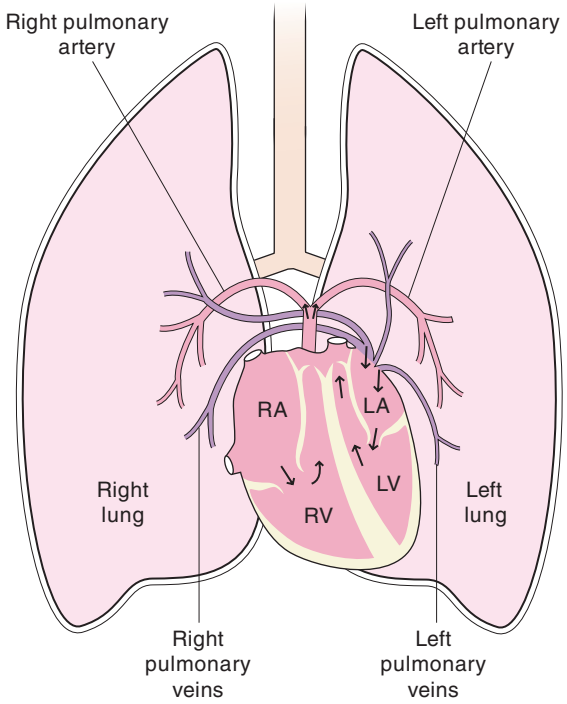

**Figure 25.15** Pulmonary circulation

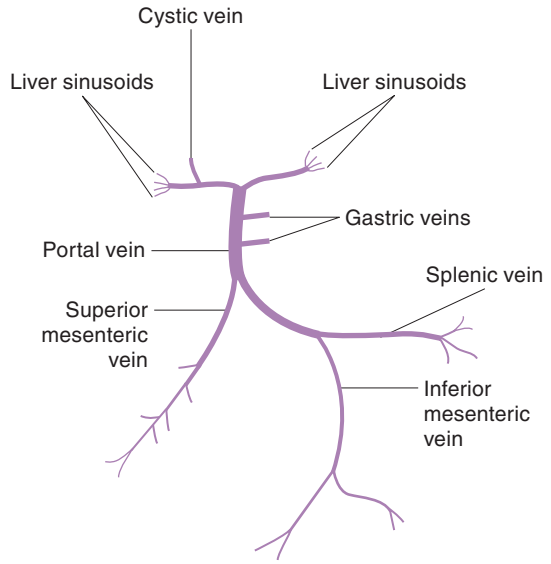

**Figure 25.16** Hepatic–portal circulation

blood that is deoxygenated, but rich in digested nutrients, from some of the abdominal organs to the liver.

The splenic, gastric, inferior and superior mesenteric veins unite to form a large vein called the portal vein, which enters the liver. The liver converts the nutrients brought by the blood into a form to be either used by tissues throughout the body or stored for future use. The liver thus receives blood from two sources: the hepatic artery, which supplies it with oxygenated blood; and the portal vein, carrying deoxygenated blood rich in nutrients. When the oxygen has been extracted from the former and the nutrients from the latter have been processed, the blood leaves via the three hepatic veins (Rosdahl & Kowalski 2008).

## STRUCTURE OF THE LYMPHATIC SYSTEM

The lymphatic system (Figure 25.17) is closely connected with the circulation of blood and consists of an additional set of vessels through which some of the tissue fluid passes before reaching the large veins and entering the blood. Circulation within the lymphatic system is dependent upon the movement of skeletal muscles. Muscular contraction and pressure changes within the thoracic cavity during respiration assist with lymph circulation (Rosdahl & Kowalski 2008). This system consists of lymphatic capillaries, lymphatic vessels, lymphatic nodes and lymphatic ducts. The fluid in the system is called lymph.

The lymphatics serve an important function in preventing oedema, as the tiny vessels collect fluid and proteins from the interstitial spaces and promote their return to the blood

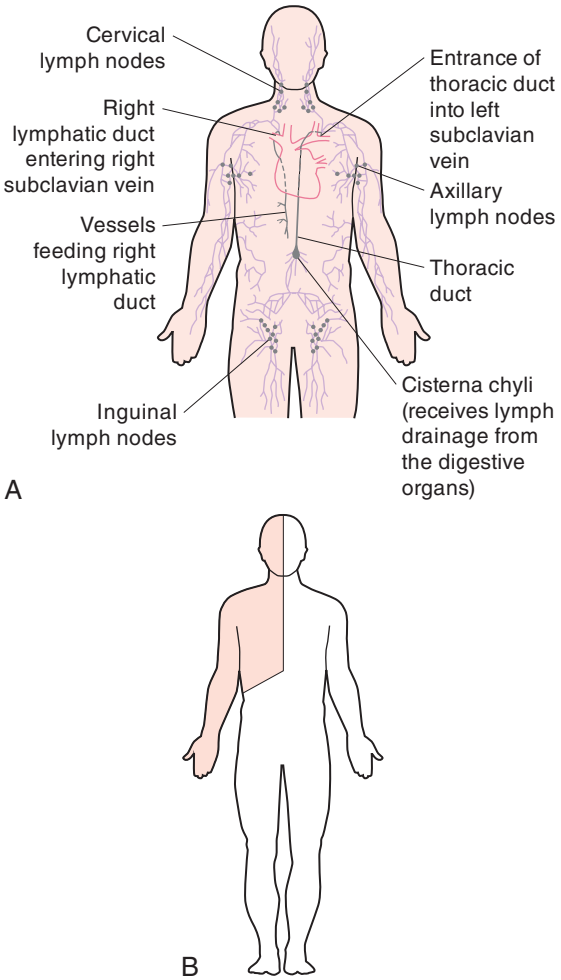

**Figure 25.17** The lymphatic system

A: The distribution of lymphatic vessels and nodes B: Areas drained by the right lymphatic duct (shaded) and the thoracic duct (unshaded)

circulation. They also collect the larger digested fat particles from the digestive system and empty them into the circulation. In addition, the lymphatics play a key role in the body's defence against microorganisms. They collect microorganisms in the interstitial spaces and carry them to the lymph nodes, where the lymphocytes (and macrophages) remove them from the lymph.

## Lymph

When fluid leaks out of the capillaries from the cardiovascular system it accumulates in the tissue spaces. When this fluid is drained from the tissues and collected by the lymphatic system, it is called **lymph** and has a composition similar to the blood plasma. Lymph is normally a colourless fluid, although lymph absorbed from the intestines is saturated with fats and is milky in colour. Lymph travels slowly through the lymphatic system—total lymph flow is about 2–4 L/day.

## Lymphatic capillaries

Lymphatic capillaries are similar in size and structure to blood capillaries. They unite to form larger lymphatic vessels similar in structure to veins and, like veins, they have valves to prevent a backward flow of lymph. All lymphatic vessels pass through one or more lymph nodes. Afferent lymphatic vessels carry lymph to a node. Efferent lymphatic vessels carry lymph away from the node and empty it into the lymphatic ducts.

## Lymph nodes

Lymph nodes are found mainly in groups in many parts of the body, such as the neck, thorax, abdomen, groin and the limbs. Lymphatic nodes vary in size and consist of lymphatic tissue. The functions of lymphatic nodes are to filter and destroy bacteria from the lymph passing through the node; to produce lymphocytes, which are added to the lymph; and to produce antibodies and antitoxins.

## Other areas containing lymphatic tissue

In addition to the nodes already described, lymphatic tissue is found in several other anatomical structures, including the tonsils in the oropharynx, adenoids in the nasopharynx, the appendix attached to the intestines, the thymus gland in the thorax, Peyer's patches in the small intestine and the spleen in the abdomen.

### Tonsils

The tonsils form part of a protective ring of tissue at the entrance to the respiratory and digestive tracts. Lymphatic vessels leave the tonsils and enter the cervical nodes.

### Thymus gland

The thymus gland is a soft grey-pink gland present in the thorax behind the sternum and in front of the heart. It is large in infants and children, reaching its maximum size at puberty. After puberty this gland gradually shrinks, until in adulthood there is only a small piece of tissue left. The thymus gland functions in the production of lymphocytes.

### Spleen

The spleen is a purplish half-moon-shaped organ in the left hypochondriac region of the abdomen. It lies below the diaphragm and behind the lower ribs and is mainly composed of lymphoid tissue enclosed in a fibrous capsule. The functions of the spleen are to:

- Produce lymphocytes, some of which enter the bloodstream to carry out their phagocytic action
- Destroy worn-out erythrocytes, producing bile pigments and iron
- Produce antibodies and antitoxins
- Provide a storage area for erythrocytes needed in emergency situations (if haemorrhage occurs, the spleen vessels contract and empty blood into the circulation in an attempt to restore normal blood volume).

## Lymphatic ducts

The two lymphatic ducts receive the lymph from lymphatic vessels and empty it into the bloodstream via the subclavian vein (Figure 25.17). They are the thoracic duct and the right lymphatic duct.

### Thoracic duct

The thoracic duct, the larger of the two lymphatic ducts, begins in the abdominal cavity at lumbar level as a dilated sac called the cisterna chyli. The duct passes upwards through the aortic opening behind the diaphragm into the thorax, where it empties its contents into the left subclavian vein so that the lymph rejoins the bloodstream. Lymphatic vessels from all parts of the body below the diaphragm, and the left side of the body above the diaphragm, empty their contents into the thoracic duct.

### Right lymphatic duct

The right lymphatic duct is very small (about 1 cm long) and lies in the root of the neck. It receives lymph from the right side of the head and neck, the right side of the thorax and the right upper limb. The right lymphatic duct empties its contents into the right subclavian vein.

# FACTORS AFFECTING THE RESPIRATORY SYSTEM

## Oxygen concentration

Oxygen makes up approximately 21% of the air, which is normally sufficient to meet the needs of the body. A decrease in this amount of oxygen can cause problems. Two instances in which the available oxygen may be deficient are:

- High altitude: the total pressure of all gases in the air decreases as altitude increases. As the total pressure decreases, the oxygen pressure decreases proportionately, and the individual will experience difficulty in maintaining adequate tissue oxygenation (**hypoxia**). Acclimatising is a homeostatic response where initially the ventilatory rate is increased in an

attempt to supply the body with sufficient oxygen, then later the bone marrow is stimulated to increase erythrocyte production (polycythaemia) to carry more oxygen
- Presence of noxious gases: some noxious gases such as carbon monoxide have a higher affinity for haemoglobin than does oxygen, which is displaced by them, causing a reduction in oxygen availability to tissues.

## Regulating mechanisms

Any factor that interferes with the respiratory centres in the brainstem or the nerves that transmit messages to and from them may cause ventilatory difficulties. Respiratory depression can be caused by increased intracranial pressure such as cerebral oedema, due to conditions such as hypercapnia, cerebral bleeds, meningitis, encephalitis, hydrocephalus, tumours, hypoalbuminaemia and keto-acidosis. Clinical Interest Box 25.1 discusses the effect pyrexia (fever) has on oxygen regulation mechanisms. Other factors include certain medications such as analgesics (e.g. morphine), and various anticonvulsant drugs (e.g. clonazepam). Ventilation increases when the pH of the blood is lowered (a respiratory response to rid the body of the excess acid) whereas ventilation decreases when the pH increases (to retain acid). (See respiratory alkalosis and acidosis later in this chapter.)

### CLINICAL INTEREST BOX 25.1 Oxygen requirements and pyrexia

Many respiratory conditions cause pyrexia. Historically individuals have been treated with antipyretics or other methods to cool their skin, such as tepid sponges, fans and removing clothing. Pyrexia is the body's homeostatic mechanism for providing a hostile environment for pathogens and for increasing the immune response. Individuals normally feel hot to touch on the 'up' state of the fever but state that they feel cold, and may shiver, while the 'down' state normally is the reverse.

Cooling an individual's skin may actually increase the pyrexial state, as the body shivers to keep warm. Medical treatment of pyrexia is increasingly aimed at allowing the body's immune system to maintain the pyrexia, without nursing or medical interference, drugs or other care. The pyrexia is still investigated and the cause treated, and antipyretics administered if an individual's other symptoms or past history (e.g. febrile convulsion) deem it safer, or their discomfort may be alleviated by antipyretics.

Most at risk of pyrexial complication are some individuals with congenital or chronic respiratory or cardiac conditions in which they have a diminished 'reserve' or ability for their bodies to supply the extra 10% of oxygen needed per 1°C of body temperature increase. In these individuals not only are antipyretics commonly used but also supplemental oxygen is administered while the pyrexial state exists.

## Exchange of gases during ventilation and respiration

The efficiency of ventilation and respiration can be affected by any factor that interferes with the patency of the respiratory tract or the actions of the ventilatory muscles. For example, an accumulation of secretions may result from respiratory conditions such as asthma, bronchitis or a reduced cough reflex. Ventilations may also be reduced by factors that affect the actions of the ventilatory muscles, such as brainstem or spinal cord injury or motor neuron diseases such as multiple sclerosis or Guillain–Barré syndrome. These conditions can restrict the movements of the diaphragm and/or intercostal muscles. Chest expansion and ventilation can also be affected by deformities of the chest wall or skeleton, such as scoliosis, flail chest (multiple rib fractures causing instability in part of the chest wall and paradoxical breathing movements, the part of the lung underlying the injured area contracts on inspiration and bulges on expiration) and pectus excavatum (a skeletal abnormality of the chest that is characterised by a depressed sternum).

## Diffusion of oxygen and $CO_2$

Any dysfunction of the lungs that affects the alveolar capillary membrane thickness or causes a reduction in their surface area will affect respiratory function. Conditions such as pulmonary oedema, alveolitis, pneumonia or chronic obstructive airways disease may reduce the diffusion of oxygen and $CO_2$. Information on these and other respiratory disorders is provided later in this chapter.

## Transport of oxygen and $CO_2$ to and from the cells

Any condition affecting the efficiency of the heart, blood vessels or blood can interfere with the transportation of oxygen to the cells or $CO_2$ away from the cells. Such conditions include congestive cardiac failure, atherosclerosis, carbon monoxide poisoning and anaemia. Information on these and other cardiovascular disorders is provided later in this chapter.

## Influences on the rate, depth and rhythm of breathing

Several factors influence the characteristics of breathing, such as pyrexia and physical activity. Oxygen requirements are greatest during exertion and least during sleep. The rate and depth of ventilations vary in response to the body's production of $CO_2$; for example, during strenuous exercise the volume of air drawn into the lungs with each breath may be increased from a normal tidal volume of 500 mL to as much as 2300 mL. Changes in mood, emotion and pain may also affect the rate, depth and rhythm of ventilation; for example, the ventilation rate is commonly increased during fear, anxiety or apprehension. Chronic irritation by inhaled irritants such as smoke or dust can also affect breathing and cause short-term effects such as coughing and shortness of breath, or

long-term effects such as severe dyspnoea resulting from emphysema.

### Inadequate ventilation (hypoventilation)

**Hypoventilation** and alveolar hypoventilation is a reduction in the ventilation of the alveoli. The causes are many and varied and include airway obstruction by oedema, inhaled foreign bodies, retained secretions (mucus, casts), polyps, tumours, bronchospasm, emphysema, neuromuscular or skeletal abnormalities and central nervous system disorders. Hypoventilation occurs when the volume of air entering the alveoli is not adequate for the metabolic needs of the body. The reduction in ventilation causes an increase in the partial pressure of $CO_2$ in arterial blood ($PaCO_2$), termed **hypercapnia**, and may also cause **hypoxaemia**, a decrease in the partial pressure of oxygen in arterial blood ($PaO_2$).

### Impaired diffusion

**Diffusion** is the process by which oxygen and $CO_2$ molecules are transported between the alveoli and the capillary network. Diffusion abnormalities can interfere with the passage of oxygen into the blood. Such diffusion abnormalities can result from: a thickening of the alveoli capillary walls, for example, in pulmonary oedema; a reduced amount of functioning lung tissue, such as in emphysema; or fibrosis of the alveolar walls, as seen in alveolitis and pneumonitis.

### Impaired perfusion

Not only is an adequate intake of oxygen by ventilation essential, but for oxygenation of the body tissues to occur, adequate perfusion of lung tissue with blood is essential. Any condition that decreases the circulation of blood to lung tissue may lead to ventilation–perfusion mismatches (V/Q principle) and hypoxaemia. Such conditions include decreased blood volume, pulmonary embolism, cardiac disorders and chronic obstructive pulmonary disease.

In addition to abnormalities of the lungs or respiratory structures, dysfunction of other body systems can adversely affect respiratory function. For example, a disease process that affects the nervous system may adversely affect respirations. When the spinal cord is damaged, the nervous system may greatly impair respiratory function. Cardiovascular dysfunction can affect respiratory function; for example, right-sided heart failure may affect the volume of pulmonary blood circulation. A deformity of the skeletal system, such as scoliosis, may restrict movement of the thoracic cage and thus alter respiratory function. Inadequate lung expansion can also occur after abdominal surgery, as pain in the operation site may inhibit deep breathing and coughing. Not only can abnormalities of other body systems adversely affect the respiratory system, but respiratory abnormalities generally affect all other body systems.

### Additional factors

Numerous other factors can modify the rate and depth of ventilation; for example, involuntary and reflex mechanisms such as exercise, pain, hiccupping, sneezing, sighing and emotions, and conscious voluntary actions such as voluntary breath holding, inhalation and exhalation. Clinical Interest Box 25.2 discusses the alteration to respirations in the older adult. Other factors that affect functioning include:

- Digestive system disorders and diminished appetite, potentiating an alteration in nutritional status
- Changes in renal function, which can affect erythropoietin production
- Osteoporosis
- Circulatory disorders.

These may all combine to affect blood cell production, with subsequent anaemias. In individuals who are more sedentary such combinations of factors and subsequent alveolar hypoventilation increase the risk of primary or secondary infections. To avoid the complications of ageing, all individuals can be educated to:

- Improve their nutritional status, including nutrients and supplementation of additional sources of vitamins as required
- Increase their fluid intake, as permitted
- Perform routine breathing exercises
- Maintain their weight-bearing ability
- Increase their exercise and mobilisation.

## PATHOPHYSIOLOGY RELATED TO THE RESPIRATORY SYSTEM

The signs and symptoms manifested by an individual with a respiratory disorder vary with the location and severity of the disorder. Detailed below are some common clinical features of respiratory disease.

### Chest pain

Disorders of the respiratory system such as pleurisy can result in chest pain. During ventilation, friction occurs between the inflamed pleura. Chest pain may be localised or may be experienced only when the individual breathes deeply, and

#### CLINICAL INTEREST BOX 25.2 Respirations and the older individual

Involutional changes that can occur with increasing age include: loss of elasticity of the lung tissue, costal cartilage calcification, kyphosis, weakening and loss of skeletal muscle fibre, reduction in cilia numbers and beating speed, and thickening of alveolar membranes. These factors and many more diminish the respiratory system's ventilatory capacity and the ability to excrete $CO_2$ and absorb oxygen, increasing the resting respiratory rate from the adult rate of about 20/min to 25/min for an older individual.

*(Williams 2016; Crisp et al 2013)*

can vary from a continuous aching pain to a stabbing knife-like pain. Pain associated with respiratory disorders may be retrosternal, lateral or posterior and is exacerbated by deep inhalation.

## Cough

A cough is a common symptom of many respiratory disorders and may result from irritation or from retained secretions that obstruct some part of the airway. If sputum is swallowed, expectorated or the cough sounds moist, it is described as productive. A non-productive, or dry, cough is one that sounds dry or irritating and no sputum is expectorated or swallowed. Sputum is the result of excessive mucus production and may result from inflammation, infection or congestion.

Haemoptysis (the coughing or expectoration of blood) may occur in some lung diseases. Blood-streaked sputum frequently occurs in some respiratory tract conditions, such as infections (e.g. bronchitis, tuberculosis), pulmonary oedema or bronchogenic carcinoma. The expectoration of bright red or frothy blood indicates a more serious disorder, such as pulmonary embolism or lung abscess.

Voice changes, ranging from hoarseness to aphonia (no speech), may result from numerous causes, including viral upper respiratory tract infections (e.g. laryngitis), vocal cord polyps and laryngeal tumour. Unilateral or bilateral vocal cord paralysis may also result from congenital defects, intubation or other damage to the recurrent nerve; for example, after thyroid or cardiac surgery.

Dyspnoea (difficult or laboured breathing) may result from disorders affecting either the upper or the lower respiratory tract or surrounding structures. Disorders of the upper respiratory tract that may cause dyspnoea include obstruction of the airway by inflammation, a tumour or foreign body. Disorders of the lower respiratory tract that cause dyspnoea include airway inflammations or infections, asthma, pneumonia, pneumonitis, carcinoma of the lung and chronic obstructive pulmonary disease. Any disorder affecting the thorax, such as trauma to the chest wall, commonly causes dyspnoea. Laboured breathing may be accompanied by nasal flaring, the use of the neck and accessory chest muscles and increased ventilation rate.

## Changes in breathing patterns and sounds

Any disorder that affects the respiratory system may produce changes in the pattern of breathing. Examples include **tachypnoea** (increased respiratory rate), **bradypnoea** (decreased respiratory rate) and airway obstruction; for example, due to emphysema, which can result in prolonged forceful **expiration** and pursed-lip breathing. Certain disorders also result in abnormal breathing sounds, such as wheezing or 'grunting' ventilations. Information on abnormal breathing sounds is provided later in this chapter.

## Hypoxia

**Hypoxia** is a deficiency of oxygen in the tissues and may be due to lung disorders that prevent adequate supplies of oxygen from reaching the blood (hypoxaemia). Hypoxia may also be due to hypoventilation, anaemia or impaired tissue utilisation of oxygen. The initial manifestations of hypoxia include tachycardia, tachypnoea, breathlessness, pallor, lethargy or agitation, followed by increasing confusion and deepening cyanosis.

## Thoracic abnormalities

Chronic respiratory system disorders may alter chest configuration; for example, a 'barrel chest' is characteristic of chronic obstructive conditions such as cystic fibrosis and emphysema. Abnormal curvatures of the spine, such as severe scoliosis, and congenital chest deformities such as pigeon chest (Figure 25.18) and pectus excavatum ('funnel chest') (Figure 25.19) may also affect pulmonary ventilation. Asymmetrical chest

**Figure 25.18** Pigeon chest
*(Mir 2003)*

**Figure 25.19** Funnel chest
*(Mir 2003)*

expansion can result from conditions such as flail chest, haemothorax, pneumothorax, retained secretions or inhaled foreign bodies causing atelectasis.

### Other manifestations

Depending on the type and severity of the disorder, other manifestations may be evident. For example, infections of the respiratory tract generally result in pyrexia, headaches, aching muscles and lethargy. Difficulty in swallowing (dysphagia) may be present in disorders such as pharyngitis and tonsillitis. In certain chronic disorders of the respiratory system, clubbing of the fingers (Figure 25.20) may be evident. The distal portions of the fingers are abnormally enlarged by anastamosis of blood vessels in response to peripheral hypoxaemia. The nails have an increased curvature and the angle of the nail bed increases to over 85 degrees.

## SPECIFIC DISORDERS OF THE RESPIRATORY SYSTEM

### Disorders of multiple cause

Certain disorders of the respiratory system have more than one cause and may be related to structural or functional changes, environmental conditions or a combination of factors. It is beyond the scope of this text to provide in-depth information on the various conditions related to the respiratory system. Listed below are some examples of respiratory conditions:

- Rhinitis
- Pleurisy
- Epistaxis
- Sarcoidosis
- Pneumoconioses
- Laryngeal oedema
- Adult respiratory distress syndrome.

**Figure 25.20** Clubbing in a patient with cyanotic congenital heart disease and secondary polycythaemia

Haematology: An Illustrated Colour Text

*Fourth Edition © 2013 Elsevier Ltd*

### Infectious disorders

Infectious disorders can be classed as upper or lower respiratory tract infections. Bacteria or viruses cause infections of the upper respiratory tract while a variety of microorganisms can cause lower respiratory tract infections. For more information review the references and further reading list at the end of this chapter.

Clinical Interest Box 25.3 looks at a viral infection, sudden acute respiratory syndrome (SARS) and Clinical Interest Box 25.4 provides an overview of the Ebola virus. Listed below are some examples of respiratory conditions:

- Sinusitis
- Influenza
- Pharyngitis
- Tonsillitis
- Quinsy
- Laryngitis
- Epiglottitis
- Acute bronchitis
- Pneumonia
- Pertussis
- Croup
- Tuberculosis
- Empyema.

### CLINICAL INTEREST BOX 25.3 Sudden acute respiratory syndrome (SARS)

Sudden acute respiratory syndrome (SARS) first appeared in the southern Chinese province of Guangdong in 2002 and by 2003 had been classified as an epidemic by the World Health Organization (WHO 2004). Symptoms of SARS, which is believed to be spread mainly through droplet infection, include pyrexia, rigors, cough, headache, aches and pains and dyspnoea. These same symptoms are common for many other respiratory infections, making the positive diagnosis difficult (WHO 2004).

The number of deaths to June 2003 was about 800 people worldwide, and the number of people infected since 2002 about 8500. In 2002 and 2003 about 14% of those infected died from SARS, usually 5–6 weeks after becoming ill.

The virus was found to be a coronavirus, and the genome was sequenced in April 2003 by the US Centers for Disease Control and Prevention. After relaxation of SARS infection control measures in Canada, a further outbreak occurred, due probably to transmission by an unrecognised SARS carrier, and affected five individuals in a rehabilitation hospital. As a result, infection control departments worldwide have introduced the most stringent infection control policies for medical and paramedical workers seen to date, to limit the spread of SARS.

*(WHO 2004)*

## CLINICAL INTEREST BOX 25.4 Ebola virus disease

Ebola virus is a serious and severe disease, often fatal in humans. It is transmitted to humans from wild animals and then spreads through human-to-human transmission. There is approximately 50% fatality in those who contract the disease with the fatality rates varying from 25% to 90% in past outbreaks (WHO 2015).

The first ebola virus disease outbreaks occurred in remote villages in Central Africa, near tropical rainforests, but the most recent outbreak in West Africa has involved major urban as well as rural areas. The most severely affected countries are Guinea, Liberia and Sierra Leone. These countries are known to have weak health systems and a lack of human and infrastructural resources (WHO 2015).

The key to controlling outbreaks is community engagement. A multistrategy approach is required and consists of a number of interventions, namely case management, surveillance and contact tracing, a good laboratory service, safe burials and social mobilisation (WHO 2015).

It is essential to implement early supportive care to increase the chance of survival. Supportive care involves rehydration and management of symptoms. As yet there is no licensed treatment proven to neutralise the virus but a range of blood, immunological and drug therapies are under development (WHO 2015). There are currently no licensed Ebola vaccines but two potential candidates are undergoing evaluation (WHO 2015).

### NURSING CARE PLAN 25.1

**Assessment:** Chronic obstructive pulmonary disease (COPD)
**Issue/s to be addressed:** Deficient knowledge on condition, treatment plan and self-management
**Goal/s:** Provide information about disease process/prognosis and treatment regimen

| Care/Actions | Rationale |
|---|---|
| Explain the disease process to the individual | Decreases anxiety and can lead to improved uptake of treatment plan |
| Instruct and demonstrate rationale for deep breathing and coughing exercises | Pursed-lip and abdominal or diaphragmatic breathing exercises strengthen muscles of respiration, help minimise collapse of small airways, and provide the individual with means to control dyspnoea |
| Discuss importance of avoiding people with active respiratory infection | Decreases exposure to and incidence of acquired acute URIs |
| Discuss individual factors that may trigger or aggravate condition (excessively dry air, wind, environmental temperature extremes, pollen, tobacco smoke, aerosol sprays, air pollution) | Environmental factors can induce or aggravate bronchial irritation, leading to increased secretion production and airway blockage |
| Review the harmful effects of smoking, and advise cessation of smoking | Cessation of smoking may slow or halt progression of disease |

**Evaluation**

Increased knowledge and understanding of condition.
Adherence to treatment plan.
Ability to self-manage condition.

## Obstructive disorders

Obstructive disorders are lung diseases that cause a persistent obstruction of bronchial air flow. Airway obstruction can also be due to the inhalation of a foreign body, or one or both bronchi may become obstructed by a benign or malignant tumour. Some of the more common types of airways obstruction are grouped under the heading of chronic obstructive pulmonary disease (COPD) or chronic obstructive airways disease (COAD) (see Nursing Care Plan 25.1). Common forms of COAD include asthma, emphysema, bronchiectasis and chronic bronchitis. Asthma and emphysema are discussed briefly here.

### Asthma

Asthma is a chronic, inflammatory disorder of the airways affecting approximately 300 million people worldwide (GINA 2012). Asthma is manifested by difficulty in breathing caused by generalised narrowing of the airways and is characterised by recurring episodes of paroxysmal dyspnoea, wheezing on expiration, coughing and tenacious, mucoid bronchial secretions. A person having an asthma attack commonly experiences anxiety, diaphoresis, tachycardia and elevated blood pressure. The increased effort of breathing can cause extreme fatigue.

## PROGRESS NOTE EXAMPLE 25.1

| | |
|---|---|
| 01/04/2015<br>1430 hrs | Nursing: Mr Jones reported shortness of breath and difficulty breathing. Upon assessment observations were noted to be BP 140/70, HR 96, RR 22, $SaO_2$ 89% on 4 L/min $O_2$. Salbutamol administered via spacer with effect. Deep breathing and coughing exercises performed. Oxygen saturation levels have improved $SaO_2$ to 96% on 4 L/min. Encourage regular fluids as tolerated, administer antibiotics as ordered.<br>***T. Smith*** **(Smith) EN** |

Episodes of asthma may be precipitated by inhalation or ingestion of allergens or pollutants, infection, or it may be exercise-induced or occur in response to changes in air temperature or emotional stress. The severity and duration of asthma attacks vary; treatment may control the attack rapidly, or the symptoms can become increasingly severe and prolonged.

A severe and prolonged asthma attack that resists treatment is referred to as status asthmaticus (indicated by a $PaCO_2$ of over 50%, or extreme exhaustion). Unless treatment reverses the condition, the individual may develop respiratory failure. An example of an entry in progress notes for a patient with breathing difficulties is shown in Progress Note Example 25.1.

### Emphysema

Emphysema (pulmonary) is a chronically progressive disease characterised by over-distension and destruction of alveolar walls, resulting in a loss of lung elasticity and surface area for diffusion. The predisposing causes are the same as those for chronic bronchitis, with cigarette smoking being the major factor. Initially the peripheral bronchioles become inflamed and the subsequent narrowing of the airways traps air in the alveoli. As the disease progresses the alveolar walls become over-inflated and rupture. Because of loss of lung elasticity the terminal bronchioles tend to collapse prematurely during exhalation, making expulsion of air from the lungs more difficult (Forey et al 2011).

Symptoms of chronic emphysema include shortness of breath, dyspnoea, cyanosis and cough (Forey et al 2011). Individuals will commonly exhale through pursed lips to prolong expiration and reduce the tendency of the airways to collapse. As the disease becomes more severe, they may use their accessory muscles to breathe. The anteroposterior width of the chest usually increases because of expansion of the chest wall and loss of lung elasticity, giving the chest a barrel-shaped appearance. Distension of the neck veins may be present, as may clubbing of the fingers. In advanced emphysema, the person fights for every breath of air (see Case Study 25.1).

### CASE STUDY 25.1

Mr Williams, a 76-year-old chronic smoker diagnosed 30 years prior with emphysema, is a long-term individual in your facility. During the previous 2 days his respiratory effort has increased, and his skin colour, previously pink, has now developed central and peripheral cyanosis that appears to be worsening. He has developed diaphoresis, his blood pressure has increased marginally and he is complaining of a headache.

1. What assessments will you need to undertake?
2. What nursing measures will you implement for Mr Williams?
3. Describe the most appropriate oxygen delivery method and flow rate applicable in this situation and what complications may occur as a result of oxygen therapy.

## Neoplastic disorders

*Benign* or *malignant* neoplasms may affect the upper or lower respiratory tract. Tumours can affect the normal functioning of the respiratory tract and, if malignant, can cause extensive tissue damage by infiltration. The signs and symptoms of neoplastic disease vary depending on the location and extent of the lesion.

*Nasal polyps* are masses of hypertrophied mucosa that commonly form in response to recurrent swelling of the nasal mucosa. Obstruction of the nasal passages develops gradually as the benign polyps multiply and enlarge. The individual experiences difficulty in breathing through the nose, and the voice may have a nasal quality.

*Laryngeal polyps* are growths that arise from the mucous membrane of the vocal cords. The major symptom is hoarseness. Laryngeal polyps are usually benign but they may become malignant.

*Laryngeal carcinoma* is a malignant neoplasm arising from or around the vocal cords. Persistent hoarseness is the major symptom, and heavy cigarette smoking is believed to be a major causative factor. If the lesion is large, dysphagia may be present.

Lung cancer commonly affects a bronchus. It arises from the bronchial epithelium and rapidly invades lung tissue, causing parts of the lung to collapse. It may spread through the lymphatic network and bloodstream to form metastases in other parts of the body, such as the liver, bones or brain. The incidence of lung cancer is related to several factors, the most important being the inhalation of cigarette smoke. Other factors include exposure to atmospheric pollution and occupational pollutants.

Unfortunately, the physical manifestations of lung cancer do not generally appear until the disease is well advanced. Symptoms include persistent cough, dyspnoea, purulent or

blood-streaked sputum, chest pain and repeated attacks of bronchitis or pneumonia. Sometimes the initial symptoms are associated with organs that are the sites of metastasis, such as the liver, bones or brain. Cancer of the lung may also occur secondary to a primary malignant tumour elsewhere in the body, as a result of metastasis.

## Traumatic disorders

Injury to part of the respiratory tract can result from a variety of causes.

### Laryngotracheal trauma

Laryngotracheal trauma can be minor and cause hoarseness and some dysphagia, or it may be severe, as a result of laryngeal or cricoid fracture. In a severe injury, oedema of the larynx may occur and be accompanied by signs of respiratory distress.

### Flail chest

Flail chest occurs when multiple rib fractures result in 'floating' of a segment of the rib cage. As a consequence there may be instability in part of the chest wall and paradoxical breathing. Paradoxical breathing is characterised by the injured chest wall collapsing in during inhalation, and moving out during exhalation. The lung underlying the injury contracts on inhalation and bulges on exhalation. If uncorrected, ventilation is impaired, which may lead to hypoxia and respiratory failure. Manifestations of a flail chest are paradoxical motion of the chest wall during breathing, severe pain, dyspnoea, tachycardia and cyanosis.

### Pneumothorax

Pneumothorax is a collection of air in the pleural space causing the lung on the side of the injury to collapse (MacDuff et al 2010). A pneumothorax may be open or closed. In an open pneumothorax, an injury creates an opening in the chest wall, allowing air to flow into the pleural cavity. In a closed, or spontaneous, pneumothorax, the chest wall is intact and air enters the pleural space from an opening on the surface of the lung.

Depending on the severity, a pneumothorax may cause severe dyspnoea, hypoxaemia, tachypnoea and associated pain, along with ipsilateral diminished chest expansion and breath sounds. There may be subcutaneous emphysema in the neck and upper chest, and a 'sucking' sound may be heard in the region of an open pneumothorax. Tracheal deviation to the contralateral side may be observed in severe cases in some individuals (MacDuff et al 2010).

Tension pneumothorax is a particularly severe form that occurs when air escapes into the pleural cavity. As a result, continuously increasing air pressure in the pleural cavity causes progressive collapse of the lung tissue. Emergency aspiration of air from the pleural cavity is necessary. The presence of severe signs and symptoms of respiratory distress suggests the presence of a tension pneumothorax (MacDuff et al 2010).

**CRITICAL THINKING EXERCISE 25.1**

A 23-year-old male is brought into the emergency department by his friends. His friends state that they were involved in a fight and their friend was stabbed in the chest. The young male appears to be having difficulty breathing. Upon assessment you note that he has a rapid respiratory rate, abnormal breathing movement, shortness of breath and is complaining of chest tightness. What nursing procedures would you implement to alleviate his respiratory distress?

### Haemothorax

Haemothorax is the accumulation of blood in the pleural space, usually as a result of trauma. Manifestations of haemothorax include dyspnoea and chest tightness, and may include signs of hypovolaemia if bleeding continues. If not treated, haemothorax can lead to shock from haemorrhage, and severe pain, or respiratory failure (Patrini et al 2015).

Haemopneumothorax is a collection of air and blood in the pleural cavity. Symptoms include those of both pneumothorax and haemothorax.

# FACTORS AFFECTING THE CARDIOVASCULAR SYSTEM

## Changes in cardiac function

Cardiac failure occurs when the heart is unable to maintain an output of blood sufficient to meet the body's requirements and, as a result, the body tissues may become ischaemic.

Cardiac failure may result from mechanical failure due to disease of valves, obstruction to the blood flow, congenital heart disease, arteriosclerosis or hypertension. Cardiac failure can also occur as a consequence of a disease process, such as cardiomyopathy or myocardial infarction, or as the result of normal ageing. Consequently, the heart's ability to pump blood may be diminished.

When the heart fails to meet the requirements of the body, compensatory mechanisms occur in an attempt to improve cardiac output and to maintain the blood pressure. Compensatory responses include the sympathetic response, the renal response and myocardial hypertrophy. The sympathetic response is stimulated by reduced cardiac output and results in increased heart rate, dilation of the coronary and cerebral arterioles and constriction of the renal and skin arterioles. As a result, essential life functions are maintained. The renal response results in the secretion of substances that stimulate the production of aldosterone, causing vasoconstriction and retention of sodium and water. This response causes an increase in blood volume and peripheral resistance, which increases the workload of the heart.

Myocardial hypertrophy results from prolonged increase in myocardial wall tension and, while this initially maintains cardiac output, eventually cardiac output and tissue perfusion are decreased.

## Changes in the blood vessels

Disturbances in the ability of the arteries to stretch and recoil as blood is pumped from the heart, or changes in the ability of the veins to return the blood to the heart, result in ischaemia of the tissues. The ability of arteries to stretch and recoil may be affected by conditions such as arteriosclerosis, obstruction from inflammation or arterial spasms or from excessive external pressure on an artery. When an artery is narrowed or constricted it is unable to transport sufficient blood to the area it supplies, resulting in ischaemia and possible tissue death (necrosis).

The ability of veins to return blood to the heart may be affected by impaired valves, a sedentary lifestyle, reduced skeletal muscle usage that normally assists venous flow or from excessive external pressure on a vein. When blood flow through a vein is impeded, pooling of blood in the vein occurs. The hydrostatic pressure inside the vein increases and causes oedema in the surrounding tissues. Chronic venous insufficiency can result in thrombophlebitis, stasis cellulitis and stasis ulcers.

The formation of an embolus can cause obstruction of an artery or a vein. The most common embolus is a blood clot (thrombus), although an embolus can also consist of air or fat or foreign bodies. When the thrombus, or part of it, becomes dislodged from the vessel wall it travels in the bloodstream until it reaches a blood vessel that is too narrow for its passage. As a result, blood flow beyond that area is obstructed, and the ultimate consequence may be death of the tissues deprived of adequate oxygen and nutrition.

## Changes in the blood

Haemoglobin in the erythrocytes is responsible for transporting oxygen in the bloodstream. Any condition that affects the normal production or function of erythrocytes may decrease the supply of oxygen to the tissues. Conditions that may impede erythrocyte formation or their ability to carry oxygen include smoking, bone marrow aplasia, metabolic abnormalities, nutritional deficiencies, chronic or acute blood loss, drugs, living at high altitudes, flying, toxins, ionising radiation and genetic abnormalities. Tissue hypoxia results in a compensatory increased production of erythrocytes (polycythaemia), which causes the blood to become viscous and increases the risk of thrombi formation.

Leucocytes protect the body from infection through phagocytosis and the production of antibodies. Any disorder that decreases the production or maturation of leucocytes renders the individual susceptible to overwhelming infection. Conditions that may impede leucocyte production or function include inadequate blood cell production, proliferation of immature leucocytes, viruses, drug reactions, radiation, nutritional deficiencies and bone marrow hypoplasia.

Thrombocytes are necessary for the clotting of blood. Any disorder that impairs thrombocyte production or function renders the individual susceptible to bleeding. A decrease or increase in the formation of thrombocytes generally occurs in association with other disorders. Thrombocytopenia (decrease in thrombocyte number) is commonly due to viral infections but may be idiopathic or may result from bone marrow disease. It may also result from a condition that causes thrombocyte destruction, such as cirrhosis of the liver, or drug toxicity or continued bleeding. Thrombocythaemia (increase in thrombocyte number) is frequently idiopathic, but it may also accompany some disorders such as polycythaemia or chronic myeloid leukaemia.

## Changes in the lymphatic system

The lymphatic system removes fluid and particles from the interstitial spaces, filters the lymph and returns it to the circulation. Impaired lymphatic function may result from obstruction or inflammation of the lymphatic vessels or nodes, or from neoplastic disease. When lymphatic function is impaired, fluid accumulates in the interstitial spaces, and oedema results. As the function of lymphocytes is the key factor in immune responses, diseases of the lymphatic system, such as Hodgkin's disease, may seriously impair the immune processes. The individual with immunodeficiency is vulnerable to infection and other pathological processes that would normally be inhibited by a healthy immune system.

# PATHOSPHYSIOLOGY RELATED TO THE CIRCULATORY SYSTEM

The manifestations of disorders of the circulatory system vary depending on whether the disorder is one that affects the heart, the blood vessels or the blood or blood-forming organs.

## Manifestations of cardiac disorders

### Dyspnoea

Dyspnoea (difficult or laboured breathing) is the most common (and often the earliest) symptom of cardiac disease. Typically the dyspnoea occurs with exertion although, as cardiac disease progresses, the individual may experience dyspnoea at rest. Paroxysmal nocturnal dyspnoea, which is associated with congestive cardiac failure, occurs during sleep; the individual wakes suddenly with difficulty in breathing and a sensation of suffocation.

### Chest pain

Chest pain is one of the most common causes for attending an emergency department and a frequent cause for attending a general practice (Parsonage et al 2013). Chest pain (Table 25.2) may result from myocardial ischaemia or from pericarditis. Chest pain can also be caused by conditions not associated with cardiac disease, such as oesophagitis, reflux, pleurisy, musculoskeletal disorders or stress and anxiety. Missed diagnosis can have adverse outcomes when chest pain assessment is based on clinical features alone (Parsonage et al 2013).

Ischaemic pain is the result of a deficiency of blood to the myocardium, caused by a blocked or constricted coronary blood vessel. Angina (pectoris) is pain that results from

**TABLE 25.2 | Typical patterns of cardiac pain**

| Angina | Myocardial infarction |
|---|---|
| Gradual or sudden onset | Sudden onset |
| Episodic and temporary, usually lasting 3–15 minutes | Lasts longer than 15 minutes |
| Substernal or anterior, not sharply localised. Radiates to back, neck, arms and jaw | Substernal, midline or anterior. Radiates to jaw, neck, back, shoulders or one or both arms |
| Sensation of mild to moderate pressure. Described as tightness, squeezing or crushing | Persistent sensation of severe pressure. Described as crushing, heavy, vice-like, squeezing |
| Precipitated by exertion, stress, ingestion of food, exposure to cold | Not necessarily related to exertion or emotion, and may occur at rest |
| Accompanied by dyspnoea, diaphoresis, nausea, apprehension | Accompanied by nausea, vomiting, dyspnoea, apprehension, diaphoresis, a sensation of 'impending doom', pallor, cold clammy skin |
| Individual keeps still to relieve the pain | Individual moves about in search of a comfortable position |
| Relieved by rest and/or glyceryl trinitrate | Not relieved by rest or glyceryl trinitrate |

diminished supply of oxygen to the heart, and is basically a reversible ischaemic process. Acute myocardial infarction represents the point when ischaemia becomes irreversible; blood flow to part of the heart is inadequate and unrelieved by rest, causing cardiac muscle necrosis (O'Gara et al 2013).

### Palpitations

Palpitations are a sensation of fluttering in the chest or an awareness of the heart's action. The person may describe the heart's action as racing, pounding, stopping or skipping beats. Palpitations may be due to rhythm disturbances such as premature contractions (extra heartbeat), but they can also result from anxiety, stress, caffeine or nicotine, cough and cold medications and fatigue.

### Cough

Cough may be associated with certain cardiovascular and most respiratory diseases. If cardiovascular disease is suspected it may be caused by an accumulation of fluid in the lungs (pulmonary oedema) often made worse at night or when lying in bed.

### Fatigue

Fatigue frequently accompanies cardiac dysfunction and is related to inadequate cardiac output resulting in insufficient blood flow to the brain and skeletal tissues.

### Cyanosis

Cyanosis (blue discolouration of the skin or mucous membranes) appears when haemoglobin oxygen saturation is greatly reduced below 92%. Central cyanosis is evident in all areas of the body, particularly in the lips, mucous membranes and nail beds, whereas peripheral cyanosis is evident mainly in the extremities.

### Syncope

Syncope (transient loss of consciousness) may result when cardiac dysfunction causes an inadequate flow of blood to the brain. Sudden loss of consciousness due to heart block is known as Stokes–Adams syndrome. Heart block is defined as 'impairment of conduction in heart excitation; often applied specifically to atrioventricular heart block' (Hawley et al 2012).

### Oedema

Oedema (local or generalised accumulation of fluid in the tissues) may result from certain cardiac diseases. Peripheral or systemic oedema generally develops from right-sided cardiac failure and is first noticed in the lowest, or dependent, parts of the body, such as the legs, fingers, sacral area, periorbital area, in the abdomen (ascites) and intestines (causing constipation). As venous stasis increases, oedema increases. In left-sided cardiac failure fluid accumulates in the lungs (pulmonary oedema). In advanced cardiac failure total body oedema may develop. The severity of the oedema will depend on the degree to which venous return and/or cardiac output are reduced.

### Pulse abnormalities

Pulse rate, volume or rhythm may be abnormal in the presence of cardiac dysfunction. Tachycardia may accompany cardiac failure, while heart block commonly results in bradycardia. A low cardiac output, and therefore a reduced pulse volume, is associated with cardiac failure and acute myocardial infarction (O'Gara et al 2013). Certain cardiac disorders cause arrhythmias accompanied by an irregular pulse.

## Manifestations of peripheral blood vessel disorders

### Intermittent claudication

Intermittent claudication is cramping pain in a muscle of the leg, brought on by exercise but relieved by rest. Commonly the pain is experienced in the calf muscle during walking and is thought to be due to accumulation of lactic acid in the tissues, rather than to ischaemia of the contracting muscle. Generally, it results from blockage of the superficial femoral artery; for example, due to atherosclerosis.

### Rest pain

Rest pain is leg pain experienced even when resting and occurs when chronic arterial occlusive disease is advanced, or when a vessel is blocked by a thrombus or embolus. As a result, the blood supply to the surrounding tissues is diminished, causing ischaemic pain.

### Pale cold extremities

Pale cold extremities indicate impaired blood flow to the limb. If an artery is suddenly occluded by a thrombus or embolus, there will be numbness and absence of distal pulses as well as coldness and pallor.

### Altered peripheral pulses

Altered peripheral pulses may be present when arterial blood flow is impeded. Diminished or absent pulses suggest partial or total occlusion of an artery; for example, if the popliteal pulse is absent, the superficial femoral artery may be occluded.

### Gangrene

Gangrene, which causes death of tissue, may occur as a result of chronic arterial insufficiency and is the consequence of severe and prolonged ischaemia. Gangrene first develops in the most distal parts of the lower limbs.

### Leg ulcers

Leg ulcers or cellulitis may be present. Chronic occlusion of arterioles and small arteries results in ischaemia, skin breakdown and ulceration. Pooling of venous blood in the tissues of the extremities, for example, as a result of varicose veins, may lead to venous stasis ulcers. Aching or a feeling of fullness or heaviness in the legs is associated with venous insufficiency or valve incompetence. Homans' sign may be positive in the presence of thrombophlebitis. A positive Homans' sign is present when dorsiflexion of the foot (with the knee bent) produces pain in the calf. Tenderness, firmness and swelling in the calf are also suggestive of deep-vein thrombophlebitis.

## Manifestations of blood and blood-forming organ disorders

### Bruising and bleeding

Bruising and bleeding may occur when there is abnormal thrombocyte production or function or reduced levels of clotting factors in the plasma. The appearance of any bruising or haemorrhagic spots in the absence of injury is suggestive of a blood disorder. Types of bruising and bleeding include:

- Purpura: haemorrhagic areas under the skin and in the mucous membranes. If the haemorrhages are small they are termed petechiae; larger purpuric areas are called bruises or ecchymoses
- Petechiae: red-brown pinpoint haemorrhages in the skin. Petechiae can occur over any part of the skin but are most common where pressure has been applied to a body part; seen in meningococcal meningitis and anthrax as well as common viral infections
- Ecchymoses: haemorrhagic spots larger than petechiae. They may be precipitated by an injury or may occur spontaneously
- Gastrointestinal bleeding: which appears as haematemesis and/or melaena and may occur in certain disorders of the blood such as thrombocytopenia, but may also occur as a result of liver failure, oesophageal varices, gastrointestinal ulcerations and drug therapies
- Menorrhagia: which may occur in haemorrhagic disorders as well as gynaecological disorders
- Haematuria: which may occur in haemorrhagic disorders as well as renal disorders
- Neurological changes (e.g. headaches, blurred vision, disorientation or altered consciousness): which may occur if there is bleeding within the central nervous system.

Changes in the skin may accompany disorders of the blood or blood-forming organs. Changes that may occur include pallor, rudor, jaundice, pruritus, thickened nails and ulcerations.

### Fatigue

Fatigue or weakness are common manifestations of many haematological disorders, such as anaemia and leukaemia. An individual with anaemia may also experience shortness of breath, particularly on exertion.

### Enlarged lymph nodes

Enlarged lymph nodes may be present in disorders such as Hodgkin's disease or leukaemia. Pain may be experienced in many haematological disorders; for example, bleeding into a joint may result in joint pain, and bone pain can occur in leukaemia or lymphoma.

# SPECIFIC DISORDERS OF THE CIRCULATORY SYSTEM

Cardiovascular diseases account for approximately one third of mortality worldwide and is responsible for a significant number of disabilities (Nascimento et al 2014). Disorders of the circulatory system may be congenital or due to multiple causes, pathogens or chemicals, or they may be drug related, neoplastic, obstructive, degenerative or the result of trauma. Understanding these conditions and factors that affect the cardiovascular system is imperative to assist with reducing the burden to healthcare these diseases are causing.

It is beyond the scope of this text to provide in-depth information on the various conditions related to the circulatory system. Listed below are some examples of circulatory system conditions.

## Congenital disorders

Congenital disorders are conditions that exist and are which are 'present at and existing from the time of birth' (Hawley et al 2012). These disorders include: ventricular septal defect; atrial septal defect; coarctation of the aorta; patent ductus

arteriosus; tetralogy of Fallot; transposition of the great vessels; thalassaemias (sickle-cell anaemia); and bleeding disorders (haemophilia A, haemophilia B, von Willebrand's disease).

## Disorders of multiple cause

It is beyond the scope of this text to provide in-depth information on the various conditions related to the disorders of multiple causes; only a few of the most common conditions are briefly discussed here.

### Hypertension

Hypertension is strongly associated with increasing rates of cardiovascular disease and is responsible for more death and disease than any other biomedical risk factor (National Heart Foundation of Australia 2010). It is a major risk factor for coronary heart disease and stroke and a contributing factor to the disease progression of chronic heart failure and chronic kidney disease (National Heart Foundation of Australia 2010). Hypertension is frequently asymptomatic until the individual experiences a major problem such as cerebral haemorrhage, renal failure or myocardial infarction. Symptoms that may be due to hypertension include dizziness, chest pain, palpitations, epistaxis, headaches and brief episodes of memory loss (transient ischaemic attacks).

Hypertension should not be diagnosed from one single blood pressure measurement but rather be based upon multiple blood pressure measurements taken on several separate occasions (National Heart Foundation of Australia 2010).

High arterial blood pressure over 135/85 mmHg is generally classified as either primary ('essential') or secondary hypertension. Primary hypertension is the most common form and, while the cause is often unknown, many factors have been implicated as contributing to its development, including high sodium intake, obesity, diabetes, hypercholesterolaemia, genetic factors, alcohol, cigarette smoking and psychosocial factors. Antihypertensive drug therapy may be prescribed to hypertensive persons and evidence shows that these therapies should be implemented in a stepped care approach until target blood pressure levels are achieved (Glynn et al 2010).

Secondary hypertension is caused by either disease or certain medications. Diseases that result in secondary hypertension include those in which renal, vascular, endocrine or neurological mechanisms are involved, such as renal artery stenosis or intercranial lesions. Medications that may lead to secondary hypertension include oral contraceptives, corticosteroids and monoamine oxidase inhibitors. If secondary hypertension is suspected, a specialist referral should be considered (National Heart Foundation of Australia 2010).

Malignant hypertension is the term used to describe primary hypertension when there is a rapid rise of blood pressure to a very high level, such as 250/150 mmHg. It is accompanied by severe headache, visual disturbances and oliguria. If untreated, death may occur rapidly from cardiac or renal failure or cerebrovascular accident.

**CRITICAL THINKING EXERCISE 25.2**

Mrs Phillips, 64, has chronic hypertension. Management of this condition requires her to take one Lasix (frusemide) daily to promote diuresis and limit her daily fluid intake. Mrs Phillips is having difficulty keeping to her limited fluid intake, stating that she feels thirsty. Upon assessment you notice that her lower peripheries are oedematous. Consider what nursing measures you could implement to assist Mrs Phillips.

### Coronary artery (ischaemic heart) disease

This is a disorder in which the arteries that supply blood to the heart muscle become diseased and fail to supply the heart with sufficient blood. Arteriosclerosis is the most common cause of coronary artery disease, causing disturbances of blood flow within the coronary arteries that give rise to altered myocardial perfusion and disruption of the electrical cycle controlling heart rhythm. Atherosclerosis is one type of arteriosclerosis in which narrowing of the arteries occurs as a result of deposits of lipids in and around the smooth muscle, roughening of the endothelial lining and loss of elasticity, with fibrosis and calcification. Eventually the artery becomes occluded, inelastic and incapable of dilating.

Although the precise cause of arteriosclerosis and coronary artery disease is unclear, there is general agreement that many factors contribute to its development, including genetic influences, gender (males are more commonly affected), hypertension, lack of exercise, cigarette smoking, stress, metabolic or endocrine disorders, obesity, diabetes mellitus, hypercholesterolaemia and dietary factors. The dietary factors that are considered to contribute to coronary artery disease are salt, saturated fats and lack of dietary fibre. Coronary artery disease may be asymptomatic until the individual experiences angina or a myocardial infarction, which may result in sudden death.

### Myocardial infarction

Myocardial infarction is the death of part of the myocardium as a result of severe or total deprivation of its blood supply. Blood flow to the myocardium may be obstructed by arteriosclerosis (narrowing or clogging of arteries with deposits of fat, cholesterol and other substances) or by thrombus formation within an atheromatous coronary artery (Nordmann et al 2005). The most common site of infarction is the anterior surface of the left ventricle, resulting from occlusion of the left coronary artery. An infarction may affect some or all of the layers of the heart.

The major complications of a myocardial infarction are left ventricular failure, pericarditis and arrhythmias, which together account for a large percentage of deaths following myocardial infarction. It is generally recognised that the risk of death is greatest in the first few hours after myocardial infarction, with the risk decreasing after that time. Depression is common after recovery from the infarction and can result

in non-compliance with treatment regimens and further infarctions.

A myocardial infarction may be asymptomatic (a silent myocardial infarction). More commonly, it may manifest with pain in the centre of the chest, arms, neck, jaw or back lasting longer than five minutes, pallor, sweating, anxiety, shortness of breath, nausea or vomiting or sudden collapse.

Early and accurate identification as to whether the chest pain is a myocardial infarction event is essential to ensure emergency reperfusion therapy is provided (Parsonage et al 2013). Primary stenting and balloon angioplasty are two methods used to open narrowed or clogged arteries. A systematic review of the evidence found both methods to be equally effective at preventing mortality but the use of stents was associated with fewer arteries needing to be re-cleared (Nordmann et al 2005). Stenting was also found to have a more reduced risk of reinfarction than balloon angioplasty (Nordmann et al 2005).

Other disorders of multiple cause include: arrhythmias, valvular heart disease, heart failure, cardiogenic shock, cardiac arrest, Raynaud's disease, disseminated intravascular coagulation, idiopathic thrombocytopenic purpura, agranulocytosis and Buerger's disease.

### Anaemias

Anaemias are a group of disorders characterised by reduced oxygen-carrying capacity of the blood. Causes of anaemia are numerous and are related to the altered production or destruction of erythrocytes, and to blood loss. Anaemias can thus be classified as due to haematopoietic, haemolytic or haemorrhagic causes.

Aplastic anaemia is caused by injury or destruction of the haematopoietic cells in bone marrow, resulting in reduced or abnormal erythrocyte production. In this disorder the normal haematopoietic tissue is replaced by fatty bone marrow. Aplastic anaemia may be idiopathic or it may be caused by medications, toxic agents, radiation or immunological factors. Manifestations of aplastic anaemia are related to pancytopenia (abnormal depression of the cellular components of blood). They include pallor, tiredness, repeated infections and bleeding tendencies. Bleeding may present as petechiae, ecchymoses, haemorrhage from the mucous membranes, such as the gums, or gastrointestinal haemorrhage.

Pernicious anaemia is characterised by a metabolic defect involving the absence of intrinsic factor, which is secreted by the parietal cells of the gastric mucosa and is essential for vitamin B absorption in the terminal ileum. Pernicious anaemia is thought to result from an autosomal dominant defect. Other causes include gastric cancer, gastrectomy and malabsorption disorders involving the ileum. Manifestations of pernicious anaemia include pallor, tiredness, sore tongue and numbness and tingling in the extremities. Because of vitamin B deficiency, demyelination of nerves and degeneration of nerve tissue occurs, producing neurological effects such as ataxia, altered vision, poor memory, depression and paralysis.

Iron-deficiency anaemia is characterised by small and pale erythrocytes because of reduced haemoglobin concentration. The two most common causes of iron-deficiency anaemia are chronic blood loss and an inadequate dietary intake of iron. Manifestations include pagophagia (craving for ice), pallor, chronic tiredness, tachycardia and shortness of breath on exertion.

Folate deficiency anaemia results from an inadequate dietary intake of folate, a disorder of the small intestine, where folate is absorbed, or from altered metabolism. Manifestations are similar to those associated with pernicious anaemia.

Acute blood-loss anaemia is a condition that results from sudden loss of erythrocytes and, consequently, depletion of haemoglobin and iron. Acute blood-loss anaemia may result from severe trauma, postoperative haemorrhage, invasive neoplasm, ruptured peptic ulcer, ruptured aneurysm or coagulation defects. Acute blood loss itself produces features associated with hypovolaemia and hypoxia, such as pallor, faintness, restlessness, anxiety, hypotension and a weak rapid pulse.

If anaemia is persistent and the individual's haemoglobin levels decrease, the individual may require a transfusion of blood.

## Neoplastic and obstructive disorders

Tumours may occur in any of the chambers of the heart and may affect one or all of the layers of the heart. Secondary metastatic tumours that infiltrate the heart are more common than primary cardiac tumours. Manifestations are related to which part of the heart is affected, and include signs of heart failure, arrhythmias, angina, heart block and infarction. It is beyond the scope of this text to provide in-depth information on the various conditions related to neoplastic and obstructive disorders and only a few of the most common conditions are briefly discussed here.

### Leukaemia

Leukaemia is a neoplastic disorder characterised by an accumulation and proliferation of abnormal cells in the bone marrow. Cells fail to develop and are unable to function normally, and the accumulation of leukaemic cells in the bone marrow prevents normal haematopoiesis. The precise cause of leukaemia is unknown but several factors have been implicated in its development including chromosome abnormality, exposure to radiation from power lines, viruses or chemicals, such as certain weed killers or insecticides. Leukaemia occurs either in acute forms, which involve the proliferation of immature cells, or in chronic forms which involve the proliferation of mature cells. The four most common forms of leukaemia are acute myeloid, chronic myeloid, acute lymphocytic and chronic lymphocytic.

Although manifestations of leukaemia vary according to the particular form of the disorder, there is a similarity in the signs and symptoms, which are related to the lack of normal haematopoiesis in the bone marrow. Bone marrow dysfunction results in:

- Anaemia, which may present as pallor, lethargy and shortness of breath

- Thrombocytopenia, which commonly manifests as petechiae, easy bruising, bleeding gums and haemorrhage (e.g. as occult haematuria)
- Leucopenia, which renders the individual susceptible to recurrent infections. There is generally splenic enlargement, lymphadenopathy and bone pain.

Central nervous system involvement may be present in any of the leukaemias, giving rise to symptoms such as nausea and vomiting, irritability, headache and blurred vision.

### Hodgkin's disease

Hodgkin's disease is a malignant disorder of the lymph node macrophages, characterised by painless and progressive enlargement of the lymph nodes, spleen and other lymphoid tissue. Untreated, Hodgkin's disease metastasises via the lymphatics to sites outside the lymphatic system. The precise cause of the disorder is unknown, but both genetic and environmental factors seem to be implicated in its development. Manifestations of Hodgkin's disease are painless enlargement of the lymph nodes, especially the cervical nodes, pruritus, night sweats, malaise and weight loss. Other symptoms depend on the degree and location of systemic involvement.

Other conditions related to neoplastic and obstructive disorders include: arteriosclerosis obliterans, acute arterial obstruction, thrombophlebitis, chronic venous insufficiency, Burkitt's lymphoma, multiple myeloma and malignant lymphomas.

## Degenerative disorders

### Cardiomyopathy

Cardiomyopathy results from extensive damage to the myocardial muscle fibres, causing hypertrophy of the entire heart, especially of the septum. Although the heart is enlarged, the ventricular chambers are small and are resistant to filling during diastole. Cardiomyopathy leads to congestive cardiac failure, arrhythmias and, frequently, sudden death.

The cause of most cardiomyopathies is unknown but the condition is thought to be genetically transmitted. Some forms of cardiomyopathy result from hypertension, congenital defects and myocardial destruction by toxic, infectious or metabolic agents. The most common manifestation of cardiomyopathy is dyspnoea, as a result of congestive cardiac failure. Angina, fatigue and syncope may occur because of inadequate cardiac output. As cardiac failure progresses, peripheral cyanosis, oedema, liver enlargement and jugular venous distension become evident.

### Aortic aneurysm

Aortic aneurysm is a dilation of the wall of the aorta. There are several types of aneurysm:

- Saccular: an outpouching of one side of the arterial wall
- Fusiform: a spindle-shaped enlargement of the entire circumference of the artery
- Dissecting: a haemorrhagic separation between the medial and internal layers of the artery.

The most common cause of an aneurysm is arteriosclerosis, which weakens the aortic wall and gradually distends the lumen at the weakened area. Other causative factors include congenital defects, infection, hypertension and trauma.

Manifestations of an aortic aneurysm depend on its location, and may not develop until enlargement of the aneurysm exerts pressure on nearby structures. Depending on the location, an aortic aneurysm may manifest as dyspnoea; chest pain; dysphagia; dilated superficial veins on the chest, neck and arms; prominent abdominal pulsation; or dull abdominal or low back pain. A dissecting aneurysm may produce a sudden 'tearing' pain accompanied by pallor, shortness of breath, sweating and syncope. The main complication of an aortic aneurysm is rupture and, without immediate surgical intervention, the individual may bleed to death.

### Varicose veins

Varicose veins are dilated, tortuous branches of the saphenous veins. They result from incompetent valves, which cause a back-flow of venous blood. Varicose veins may result from congenital weakness of the valves, from injury or thrombophlebitis, or from conditions that produce venous stasis, such as pregnancy or occupations that necessitate standing for long periods. Superficial varicose veins may be unsightly but produce no symptoms. Deeper varicose veins may produce mild to severe leg symptoms, such as a feeling of heaviness, cramps, dull aching and discomfort that increases with prolonged standing. Over time, dilation of the veins results in venous stasis, with oedema and changes in skin pigmentation. Visible and palpable protrusions frequently occur along the veins, resulting in disfigurement of the leg(s).

## Infectious and inflammatory disorders

### Pericarditis

Pericarditis (inflammation of the pericardium) may be an acute or chronic condition. Acute pericarditis may be accompanied by a purulent, serous or haemorrhagic exudate, which can produce further complications. Chronic pericarditis is characterised by fibrous pericardial thickening. As well as being caused by infection, pericarditis may result from trauma, radiation, neoplasms, cardiac surgery or myocardial infarction. The prime manifestation is chest pain that increases with deep inhalation, and decreases when the person sits up and leans forward. Other manifestations include dyspnoea and the signs of a systemic infection.

### Myocarditis

Myocarditis (inflammation of the myocardium) may be an acute or chronic condition. Myocarditis may result from viral or bacterial infections, radiation, chemicals or metabolic disorders. Infective myocarditis usually causes non-specific symptoms that reflect a systemic infection. Myocarditis sometimes produces manifestations of severe congestive cardiac failure.

### Endocarditis

Endocarditis (inflammation or infection of the endocardium) may result from invasion by microorganisms or from

non-infective injury to the lining of the heart, or via intravenous (IV) cannulas, dental surgery or any other invasive procedure. Infective endocarditis involves the endocardium of the heart valves more frequently than the endocardium lining the heart chambers. The microorganisms stimulate the deposit of fibrin around them, producing vegetative growth on the endocardium.

Early manifestations are commonly non-specific, and the symptoms of acute endocarditis resemble those associated with influenza: pyrexia, sweats, anorexia, headaches and musculoskeletal aches. If a heart murmur develops, the pulse rate may be rapid and, if vegetations become dislodged, there may be manifestations of embolisation, producing the features of splenic, renal, cerebral, pulmonary or peripheral vascular occlusion.

### Rheumatic heart disease

Rheumatic heart disease refers to the cardiac manifestations of rheumatic fever and includes pericarditis, myocarditis, endocarditis and chronic valvular disease. Rheumatic fever is associated with the type A beta-haemolytic streptococcus and is thought to be immunological in origin. It may be as long as 10 years after an attack of rheumatic fever before signs of heart valve disease become evident. The end result of the disease progression is stenosis of a heart valve, inability of the valve to close properly, or valve incompetence, which leads to regurgitation of blood through the valve during systole. Manifestations of rheumatic heart valve disease depend on the valve affected and on the degree of valve dysfunction. There may be signs of reduced cardiac output, pulmonary congestion, cardiac enlargement, heart failure and the presence of heart murmurs.

### Lymphangitis

Lymphangitis is an acute or chronic inflammation of the lymphatic vessels, which generally results from a streptococcal infection of an extremity. The accompanying lymph node enlargement (lymphadenopathy) may be localised or generalised. Lymphangitis is characterised by red, warm, tender streaks spreading up a limb from a focal point of infection. The regional lymph nodes become enlarged and tender, and the individual experiences pyrexia and malaise.

## RESPIRATORY DIAGNOSTIC TESTS

Certain tests may be used to assist or confirm the diagnosis and severity of respiratory disorders.

### Pulmonary function studies

These studies are used to determine the presence and degree of respiratory dysfunction and are a measure of the functional ability of the lungs. Spirometry or plethysmography is used to assess the individual's lung volume by measuring and recording the volume of inhaled and exhaled air. The values are then compared with the normal values against predicted values for an individual of the same sex, weight, height and age. Table 25.3 lists types of pulmonary function tests and the normal expected values.

### Polysomnography

This test is used to measure upper obstruction and pattern of respirations during sleep, using various pieces of equipment.

### Chest x-ray

A chest x-ray is one of the most common procedures used to evaluate the lungs, and generally involves posterior, anterior and lateral views. Abnormal findings that may be evident on a chest x-ray include areas of density, presence of a mass or accumulation of fluid.

### Ventilation/perfusion scan

A ventilation/perfusion scan involves the administration of a radioactive gas. The radioactive particles are distributed and trapped in the pulmonary capillary bed, and the lung scan produces a visual image of pulmonary blood flow. Tissue that does not pick up the radionuclide will show light coloured area, indicating lack of adequate lung perfusion. Conditions such as pulmonary oedema, lung cancer or COPD may cause abnormal perfusion.

**TABLE 25.3 | Pulmonary function tests**

| Tests | Explanation | Normal value |
|---|---|---|
| Tidal volume | Amount of air inhaled or exhaled during normal breathing | 500 mL |
| Total lung capacity | Total volume of the lungs when maximally inflated | 6000 mL |
| Vital capacity | Total volume of air that can be forcibly exhaled after a maximum inhalation | 3000–6000 mL |
| Functional residual capacity | Amount of air remaining in the lungs after normal exhalation | 2400 mL |
| Inspiratory capacity | Amount of air that can be inhaled after normal exhalation | 3600 mL |
| Expiratory reserve volume | Amount of air that can be exhaled after normal exhalation | 1200 mL |
| Forced expiratory volume (in one second ($FEV_1$)) | Maximal amount of air that can be forcibly exhaled, in one second, after full inhalation | 3000–5000 mL |
| Residual volume | Amount of air remaining in the lungs after a maximal forced exhalation | 1200 mL |

*(Berman et al 2015; Crisp et al 2013)*

### Cultures

A specimen of secretions is obtained, for example, via a nose swab or nasopharyngeal aspirate or throat swab. Care must be taken to ensure that only the back of the throat is swabbed, which represents microorganisms in the respiratory tract. Samples are sent to the laboratory so that any microorganisms present can be identified by use of a special growth medium (the culture). Sensitivity studies may then be done to determine which drug is effective against the specific microorganism.

### Sputum cytology

A specimen of sputum is obtained and sent to the laboratory, where it is examined to detect the presence of pus, pathogenic microorganisms or malignant cells. See Clinical Skill 25.4 and Chapter 22.

### Skin tests

A common skin test performed is the Mantoux test, used in the detection of tuberculosis (TB). A medical officer or registered nurse (RN) qualified in intradermal administration injects intradermally 0.1 mL of solution containing old tuberculin. A positive reaction may be defined as an area of redness or induration of at least 5 mm in diameter appearing within 48–72 hours. The greater the reaction size the greater the exposure to antibodies to the tubercle bacillus.

### Bronchoscopy

Bronchoscopy involves the direct viewing of the trachea and bronchi by means of an instrument called a bronchoscope. A bronchoscopy is used in the diagnosis of respiratory tract disorders and may be used to remove foreign bodies or flush out secretions in the airways and to obtain a specimen of secretions or tissue for microscopic examination.

### Thoracentesis

In thoracentesis the thoracic wall is punctured with a needle to obtain a specimen of pleural fluid for analysis. The procedure may also be performed to relieve pulmonary compression caused by a pleural effusion. A local anaesthetic is injected into the skin before the needle is inserted.

### Arterial blood gas analysis

Blood gas analysis shows how well an individual's lungs are delivering oxygen to the bloodstream and eliminating carbon dioxide. Blood is collected for analysis of pH, $PaCO_2$, $PaO_2$, bicarbonate and base levels.

### Capillary acid–base balance

This analysis is performed by a finger prick. Blood is collected in a glass capillary tube to analyse the acid–base balance and $PCO_2$.

### Other tests

Blood microscopy and culture or viral tests may also be carried out to detect and identify the source of bacterial or viral infections. Other diagnostic tests that may be performed include fluoroscopy, tomography, bronchography and pulmonary angiography.

**CRITICAL THINKING EXERCISE 25.3**

Mr Mula has recently migrated to Australia to join his family. He has presented at the local medical clinic because he has become increasingly tired, has had a persistent cough and has been losing weight without trying. Consider the types of questions that would be important to ask when conducting the nursing history.

## CARDIOVASCULAR DIAGNOSTIC TESTS

Assessment of the individual with a suspected circulatory system disorder, or evaluation of the progress of a disorder, requires that certain cardiovascular tests be performed.

### Assessment of cardiac function

### Electrocardiography (ECG)

Electrocardiography (ECG) (Figure 25.21) provides a graphical record, or trace, that represents the heart's electrical action. Cellular activity of the cardiac muscle generates electrical impulses that flow through the heart. This electrical activity can be measured by a system of electrodes placed at specific points on the body surface (Higgins 2011; Hampton 2013; Perry et al 2012). The ECG displays the electrical activity as waveforms, which are named P, Q, R, S and T waves. The ECG recording illustrates the rate and rhythm of electrical conduction and cardiac contractions through the heart (Higgins 2011; Hampton 2013; Perry et al 2012). Abnormalities indicate enlargement of the chambers, inflammation of the pericardium or damage to the myocardium. Exercise electrocardiography (stress test) measures the cardiovascular effects of controlled physical stress, such as treadmill walking. Ambulatory (Holter) electrocardiography records the heart's electrical activity for a specified time (e.g. 24 hours) as the individual performs their usual activities. See Clinical Skill 25.2 for performing an ECG.

### Echocardiography

Echocardiography is a painless non-invasive test that directs ultra-high-frequency soundwaves through the chest wall into the heart, which then reflects those waves to a transducer and a recording device. As the sound transects the various heart structures, echoes are produced and recorded. Echocardiography evaluates cardiac structure and function and can reveal valve deformities, septal defects, cardiomyopathy and pericardial effusion.

### Nuclear cardiology

Nuclear cardiology involves the use of radioactive tracers to evaluate myocardial blood flow and the status of myocardial cells. An IV injection, for example of the radioisotope thallium-201 or gallium, is administered to the individual while they are exercising, and a scan performed to detect thallium uptake. Healthy myocardial tissue absorbs the radioisotope, but ischaemic or necrotic tissue does not.

## CLINICAL SKILL 25.2 Performing an ECG

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | ECG machine<br>Electrodes<br>Gauze squares/tissues<br>Razor/hair clippers<br>Conduction gel<br>Covering to maintain privacy/modesty |
| **Skill activity** | **Rationale** |
| Confirm request of ECG in healthcare record or verbal request | Safety check that ECG has been requested, and is not performed unnecessarily |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications: check allergy status (adhesives) | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |

## CLINICAL SKILL 25.2 Performing an ECG—cont'd

| | |
|---|---|
| Assist the individual to assume an appropriate position of comfort<br>Ensure individual is pain free, positioned in supine position, head supported. Make note if the person has chest pain<br>Promote independence and involvement if possible<br>Assess the individual's tolerance to procedure<br>Loosen or remove clothing above the waistline<br>Remove jewellery (including piercings)<br>Provision of privacy<br>Note: If the individual has breathing difficulties position in the semi-Fowler's position<br>Obtain additional assistance if required | Ensures individual is comfortable and an accurate ECG can be taken, and helps reduces the amount of artifact<br>Privacy reduces risk of embarrassment as chest is exposed during the procedure<br>Assistance is available when required |
| Perform hand hygiene | Prevents the spread of infection |
| Place the equipment in a convenient location near the bedside. Assemble the required equipment | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Attach limb leads to clean, hair-free sites on arms and legs | Area chosen should be over fleshy, not bony, tissue<br>Skin needs to be clean to ensure the best conduction of electrical impulses. If skin is unclean or wet, use an alcohol swab or soap and water to clean and dry the sites for electrode placement<br>Excess hair is removed as it prevents adequate contact with the skin |
| Determine chest sites and attach electrodes to clean, dry, hair-free sites<br>$V_1$—4th intercostal space, right sternal border<br>$V_2$—4th intercostal space, left sternal border<br>$V_3$—5th intercostal space, left sternal border<br>$V_4$—5th intercostal space, left mid-clavicular line<br>$V_5$—5th intercostal space, left anterior axillary line<br>$V_6$—5th intercostal space, left mid-axillary line | Note: Care must be taken that the electrodes are accurately placed, since errors in diagnosis can occur if the electrodes are incorrectly placed<br>If the individual has large breasts, place under the breasts |
| Attach lead wires to all electrodes | Attaching the electrodes to the leads ensures the electrical activity is conducted to the ECG machine |
| Follow manufacturer's instructions for calibrating and preparing the ECG machine | Machines may be single channel or multichannel. Familiarity with the machine will increase accuracy of recording and decrease individual and nurse stress |
| Ask the individual to relax, refrain from moving and breathe normally. Record ECG and report to experienced RN and medical officer | Lack of experience and ability in interpreting an ECG recording might lead the nurse to overlook changes that are significant. RN can also compare ECG to any previous ECGs |
| Remove electrodes and conduction gel | Increases comfort |
| Clean used equipment and store appropriately | Minimises cross-contamination and stored in correct place for other colleagues to use |
| Make individual comfortable, inform them of how procedure went | Reduces anxiety of individual and supports nurse-to-person relationship |
| Perform hand hygiene | Minimises cross-contamination |

*Continued*

| CLINICAL SKILL 25.2 Performing an ECG—cont'd | |
|---|---|
| Document on ECG (include actual recording, noting name, medical record number, doctor, date and time. Some machines have the ability to program this information so that it is printed out on the ECG recording)<br>Document in the healthcare record<br>Document assessment findings, and/or any abnormalities found<br>Document if individual was pain free or had chest pain during procedure<br>Report the ECG to a Registered Nurses and/or medical officer | Medico-legal requirement. Allows for the planning and implementation of care |
| Reassess individual to make sure no adverse effects from procedure | Ensures individual is comfortable and nil adverse effects have occurred post procedure |
| *(deWit & Williams 2014; Perry et al 2012; Higgins 2011; Kumar 2008; Parsonage et al 2013; O'Gara et al 2013; Hampton 2013; ACSQHC 2012)* | |

### Cardiac catheterisation

Cardiac catheterisation involves the insertion of a catheter into the right or left side of the heart to obtain information on cardiac pressures, cardiac output, oxygenation and heart valve function. The catheter is inserted through a vein in the arm or the groin and advanced into the vena cava; the passage of the catheter is observed on a fluorescent screen and x-ray films are taken. A contrast medium may be injected through the catheter and x-ray films taken (angiography). For coronary angiography, the catheter is advanced into the aortic arch and positioned into a coronary artery; a contrast medium is then injected to outline the coronary arteries as a series of x-ray films is taken.

### Digital subtraction angiography

Digital subtraction angiography is less invasive than conventional angiography and involves injecting contrast dye into the venous system rather than directly into an artery. As the dye circulates through the heart and arterial system, a fluoroscopic image intensifier displays the vessels and focuses the image. A computer then converts the images into numbers. Several vessels can be evaluated with one injection of contrast dye.

### Phonocardiography

Phonocardiography graphically records heart sounds produced as blood flows through the heart and great vessels. Microphones are placed on the chest, usually at the apex and base of the heart, and the sounds are picked up and converted into electrical impulses. The impulses are relayed to a recorder, which provides a graph of the heart sounds in wave form.

### Central venous pressure

The central venous pressure test measures the functioning of the right atrium. A catheter, which is threaded through the subclavian or jugular vein into or near the right atrium, is connected to a manometer. This procedure enables accurate determination of right atrial blood pressure, which reflects right ventricular pressure. This test is also used to assess blood volume.

### Intracardiac pressure monitoring

This test involves the insertion of a balloon-tipped flow-directed catheter, such as the Swan–Ganz catheter, into a large vein and then advancing it until it reaches the right atrium. Once the balloon is inflated, the flow of blood carries the catheter into the pulmonary artery. The procedure permits measurement of both pulmonary artery pressure (PAP) and pulmonary artery wedge pressure (PAWP). In addition, this procedure evaluates pulmonary vascular resistance and tissue oxygenation.

### Blood tests

Blood tests may be performed to measure cardiac enzyme levels, which help to assess myocardial function or cell death. Cardiac enzyme measurements help detect myocardial infarction, evaluate possible causes of chest pain and monitor the severity of myocardial ischaemia.

## Assessment of peripheral blood vessels

### Skin temperature studies

Skin temperature studies may be performed to evaluate skin temperature of the extremities, which helps determine adequacy of blood circulation in arterial disease. Direct skin temperature readings are taken; in arterial disease the temperature in the extremities may be lower than in other body areas. The cold stimulation test may be used to demonstrate Raynaud's syndrome by recording temperature changes in the individual's fingers before and after their submersion in ice water. Normally digital temperature returns to pre-test level

within 15 minutes, but with Raynaud's syndrome return to pre-test level takes longer than 20 minutes.

### Doppler ultrasonography

Doppler ultrasonography involves the transmission of sound waves through the skin, which are reflected from moving blood cells in underlying blood vessels. This test evaluates blood flow in the major veins and arteries in the limbs, and helps to detect peripheral vascular aneurysms and deep vein thrombosis (DVT).

### Arteriography

Arteriography (angiography) is the radiographic examination of one or more arteries after injection of a contrast medium into a major artery, usually the femoral artery. Arteriography can demonstrate blood flow status, collateral circulation, vascular anomaly and tumour and aneurysm formation.

### Lower limb venography

Lower limb venography is the radiographic examination of a vein after an injection of contrast medium and is often used to assess the condition of the deep leg veins. Venography is the definitive test for DVT but may also be used to distinguish clot formation from other forms of venous obstruction or to locate a suitable vein for arterial bypass grafting.

### Impedance plethysmography

Impedance plethysmography is a non-invasive test for measuring venous flow in the limbs and is helpful for detecting DVT. Electrodes are applied to the leg to measure changes in electrical resistance that result from blood volume variations.

## Assessment of haematological status

### Red blood cell (RBC) count

Red blood cell (RBC) (erythrocyte) count is the measurement of the number of erythrocytes found in a microlitre of blood. Together with haematocrit and haemoglobin determinations, this test is most often used to calculate mean corpuscular volume, mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration.

### Haematocrit

Haematocrit is a blood test used to measure the percentage of a given volume of blood occupied by erythrocytes.

### Erythrocyte indices

Erythrocyte indices involve examination of the size, weight and haemoglobin content of the average erythrocyte (mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration).

### Total haemoglobin

Total haemoglobin measures the grams of haemoglobin (Hb) in 100 mL of whole blood.

### Stained red cell examination

Stained red cell examination determines abnormalities in the size, shape or structure of erythrocytes.

### Reticulocyte count

Reticulocyte count measures the number of reticulocytes present in a sample of blood, which is then expressed as a percentage of the total RBC count. (Reticulocytes are immature erythrocytes.)

### Erythrocyte sedimentation rate (ESR)

ESR measures the time required for erythrocytes, in a sample of whole blood, to settle to the bottom of a vertical tube.

### Erythrocyte osmotic fragility

Erythrocyte osmotic fragility measures red cell resistance to haemolysis when exposed to a hypotonic solution.

### White blood cell (WBC) (leucocyte) count

WBC count is the measurement of the number of white cells found in a microlitre of whole blood. A differential WBC count determines the distribution and morphology of the various WBCs and provides more information about the immune system than the WBC count.

### Coagulation

Coagulation function is measured by a wide variety of tests, including:

- Platelet count, which measures the number of circulating thrombocytes (platelets)
- Bleeding time, which measures the duration of bleeding after a standardised skin incision, commonly two small punctures made on the forearm
- Capillary fragility test, which measures the ability of capillaries to remain intact under increased intracapillary pressure. A blood pressure cuff is placed around the upper arm and inflated to midway between the systolic and diastolic pressures. After 5 minutes of sustained pressure, the number of petechiae on a selected area of the forearm are counted
- Clot retraction test, which estimates the quantity and quality of thrombocytes and fibrinogen
- Prothrombin time (PT), which measures the time required for a fibrin clot to form in a citrated plasma sample
- Partial thromboplastin time (PTT), which evaluates the entire coagulation system with the exception of Factors VII and XIII
- Factor VIII activity test, which measures the amount of Factor VIII in the blood and identifies a deficiency of that factor (e.g. as in haemophilia).

## Immunoglobulin studies

Immunoglobulin studies evaluate the amount and types of immunoglobulins present.

### Serum ferritin

Serum ferritin measurements evaluate the amount of iron stored in body tissues.

### Total iron-binding capacity (TIBC)

TIBC measures the amount of available transferrin (a protein that binds with iron) in the blood.

### Sickle-cell test

Sickle-cell test detects the presence of haemoglobin S in suspected sickle-cell anaemia.

### Gastric fluid analysis

Gastric fluid analysis involves measuring the acidity of secretions in the stomach and is used in the diagnosis of pernicious anaemia.

### Bone marrow examination

Bone marrow examination provides information about the character, integrity and production of erythrocytes, leucocytes and thrombocytes in the marrow. Bone marrow can be removed by aspiration or needle biopsy. Aspiration of bone marrow involves the removal of a small amount, generally less than 5 mL. Biopsy, performed under local anaesthesia, is done when a larger amount of bone marrow is required. A needle is inserted through the skin and tissue, for example, over the iliac crest, until it reaches bone. The needle is then directed into the marrow cavity, and a sample of bone marrow is withdrawn.

## Assessment of the lymphatic system

Lymphangiography is the radiographic examination of the lymphatic system after the injection of a contrast medium into a lymphatic vessel in each foot. X-ray films are taken to demonstrate the filling of the lymphatic vessels and, 24 hours later, to visualise the lymph nodes. Clinical Interest Box 25.5 outlines additional nursing assessment of oxygenation status.

# NURSING AN INDIVIDUAL WITH A RESPIRATORY AND/OR CARDIAC SYSTEM DISORDER

A holistic approach to nursing care should be delivered to individuals with a respiratory or cardiac system disorder.

### CLINICAL INTEREST BOX 25.5 Nursing assessment—oxygenation status

- Nursing assessment of oxygenation status includes a history, physical examination and review of relevant diagnostic data
- Nursing assessment should include the individual's perception of the therapy and their health values and cultural beliefs.

*(Berman et al 2015)*

Specific nursing actions and medical management will vary depending on the disorder; however, the main aims of nursing care are to:

- Maintain airway patency
- Maintain fluid and nutritional status
- Facilitate normal and effective breathing
- Promote efficient gas exchange
- Promote comfort and relieve pain
- Provide psychological support
- Maintain skin integrity
- Promote and maintain mobility
- Prevent infection
- Administer prescribed medication
- Provide care before, during and after a diagnostic test.

An individual with a respiratory system disorder will commonly experience problems such as a change in breathing pattern and discomfort associated with breathing. Individuals with cardiac disorders may experience multi-system problems associated with circulation, including pain or discomfort with exercise, difficulty breathing, palpitations and fatigue. Nursing activities include alleviating discomforts associated with exercise and breathing, administering oxygen, positioning, monitoring the individual and their vital signs and helping the individual with cardiovascular and breathing exercises. As well as planning care to meet specific needs, nurses must also consider the individual's other needs, such as nutrition, fluid intake, skin integrity, elimination and the need for comfort (deWit & Williams 2014).

## Promoting a clear airway

One of the most important aspects of care is the maintenance or restoration of a clear airway, which includes measures directed at removing secretions. Commonly an inflammatory respiratory tract disorder results in the production of excessive secretions, made more tenacious by dehydration caused by tachypnoea, mouth breathing and pyrexia. The individual may experience difficulty in maintaining a patent airway; some of the following steps may assist them in expectorating secretions.

## Adequate hydration

Dehydration can make secretions more viscous and difficult to expectorate, so an adequate fluid input is important. Unless contraindicated, the individual should be encouraged to drink at least 2–3 L a day. In certain conditions such as cardiac failure fluid may need to be restricted to 1500 mL or less. The nurse should assess fluid balance by measuring fluid input and output and by observing for signs of oedema. Weighing the individual, for example, each day, is another way of assessing their fluid status. If they are unable to tolerate sufficient fluids orally because of dyspnoea, nausea and/or vomiting or the presence of an oxygen mask that can make drinking more difficult, alternative fluids may be administered by the IV route if necessary.

## Maintaining nutritional status

Commonly an individual with a cardiovascular disorder will be prescribed a diet that aims to reduce serum cholesterol and

triglyceride levels. Sodium intake may also be reduced, for example, in the control and prevention of hypertension. If the individual with either a respiratory or a cardiovascular disorder is obese, a weight-reduction diet is generally prescribed. The diet generally should be low in total fat content, particularly saturated fats, and low in sodium. Kilojoules may be reduced to correct or prevent obesity, and alcohol should be restricted, as it can raise kilojoule intake and serum lipid levels. Beverages and foods containing caffeine should be restricted, as caffeine is a metabolic stimulant that can worsen tachycardia, hypoxaemia and arrhythmias.

In specific blood disorders the individual may be prescribed a diet high in one or more nutrients; for example, a diet high in iron is generally prescribed in the treatment of iron-deficiency anaemia. When a specific diet is prescribed the dietitian consults with the individual to plan the diet and to ensure that they understand any dietary modifications or restrictions.

It is important that nurses are aware of the type of diet that has been prescribed and ensure that the individual receives the correct tray at mealtimes. Nurses encourage the individual to follow the diet and may need to assist at mealtimes, for example, if the individual is unable to eat meals independently. (Information on assisting at mealtime is provided in Chapter 30.)

## Cessation of smoking

If the individual is a smoker, they should be encouraged to stop smoking. Cigarette smoke impairs function of the cilia, and smoking generally aggravates any existing respiratory and cardiac disorder (see Case Study 25.2). Research indicates potential benefits of smoking cessation with advice and/or counselling given by nurses (Rice et al 2013).

## Nebulisation and humidification

As well as drinking adequate fluid, additional fluid may be administered directly into the airways by means of humidifiers, inhalations or nebulisers. Nebulisation or humidification reduces the viscosity of secretions, facilitating easy expectoration. Physiotherapy may be used concurrently. (Information on the use of humidifiers and nebulisers is provided later in this chapter.)

### CASE STUDY 25.2

My dad was a heavy smoker—two packets a day. Then he had a pulmonary embolism (PE) which caused him to collapse 4 days after an emergency appendectomy. Dad spent 7 days in intensive care. Smoking was considered a major cause of the PE. This was such a shock to both Dad and the family that he made the decision to give up smoking. While in hospital Dad was commenced on warfarin and told to wear anti-embolic stockings. He has vowed never to smoke a cigarette again.

1. Describe the purpose of wearing the anti-embolic stockings.
2. Why would warfarin be prescribed?

## Positioning

If an individual with a respiratory condition experiences dyspnoea, they should be assisted into a more upright position. This facilitates alveolar expansion, as gravity allows more blood to perfuse the bases of the lung, improving the ventilation/perfusion (V/Q) ratio. Nurses should ensure that sufficient pillows are placed so that the individual's back, neck, head and arms are well supported, or that the head of the bed is elevated.

## Medication

Medications may be prescribed to reduce pain, loosen secretions, relieve bronchospasm, increase cilia beating speed, combat infection, increase or decrease coughing, relieve pulmonary oedema, alter blood pressure and cholesterol levels or correct arrhythmias. Medications may be given by inhalation, orally or by intramuscular or IV routes. The types of medications prescribed may include analgesics, decongestants, antihistamines, antibiotics, bronchodilators or expectorants. Evidence demonstrates that in the management of acute asthma in both adults and children, the outcomes produced when administering beta$_2$-agonists via nebulisation are no better that when administered via a spacer (Cates et al 2013).

## Oronasopharyngeal suction

If coughing is ineffective in removing secretions, suction may be necessary. Oronasopharyngeal suction removes secretions from the pharynx by means of a suction catheter inserted through the mouth or nostril. This technique is used to maintain a patent airway and is indicated for an individual who is unable to clear their airway effectively with coughing and expectoration.

## Chest physiotherapy

Chest physiotherapy assists the individual to mobilise and eliminate secretions, re-expand airways and alveoli and promotes the efficient use of the muscles of ventilation. Chest physiotherapy includes postural drainage, chest percussion and vibration, coughing and deep-breathing exercises.

### Postural drainage

Postural drainage (Figure 25.22) encourages pulmonary secretions to empty by gravity into the bronchioles, bronchi or trachea, so that they may be expectorated (Potter et al 2013). The individual with a respiratory disorder is assisted to assume positions that promote drainage from the affected parts of the lungs. Effectiveness of the technique largely depends on positioning that allows drainage by gravity. Postural drainage should be avoided immediately before or after meals, to prevent nausea and aspiration of food or vomitus (Potter et al 2013).

| LUNG SEGMENT | POSITION OF PATIENT | LUNG SEGMENT | POSITION OF PATIENT |
|---|---|---|---|
| **Adult** | | | |
| Bilateral  | High-Fowler's | Left lower lobe—lateral segment  | Right side-lying in Trendelenburg's position |
| Apical segments | Sitting on side of bed | Right lower lobe—lateral segment  | Left side-lying in Trendelenburg's position |
| Right upper lobe—anterior segment  | Supine with head elevated | Right lower lobe—posterior segment  | Prone with right side of chest elevated in Trendelenburg's position |
| Left upper lobe—anterior segment  | Supine with head elevated | Right middle lobe—posterior segment | Prone with thorax and abdomen elevated |
| Right upper lobe—posterior segment  | Side-lying with right side of chest elevated on pillows | Both lower lobes—anterior segments  | Supine in Trendelenburg's position |
| Left upper lobe—posterior segment  | Side-lying with left side of chest elevated on pillows | Both lower lobes—posterior segments  | Prone in Trendelenburg's position |
| Right middle lobe—anterior segment  | Three-fourths supine position with dependent lung in Trendelenburg's position | | |
| **Child** | | | |
| Bilateral—apical segments | Sitting on nurse's lap, leaning slightly forwards flexed over pillow | Bilateral lobes—anterior segments  | Lying supine on nurse's lap, back supported with pillow |
| Bilateral—middle anterior segments | Sitting on nurse's lap, leaning against nurse | | |

**Figure 25.22** Postural drainage

*(Potter et al 2013)*

### Percussion and vibration

Percussion and vibration are employed to help loosen respiratory secretions and are commonly used in conjunction with postural drainage. Percussion is performed by rhythmic tapping using cupped hands over the affected segments of the lungs. Care should be afforded to individuals with osteoporosis, fractures or recent surgery. Vibration is performed by placing the hands over the affected area and shaking, so that the chest wall is vibrated while the individual is forcibly exhaling. To ensure sufficient force is being used the individual can be asked to vocalise and a vocal fremitus should be heard.

After postural drainage, percussion and vibration, the individual should be asked to cough to remove the loosened secretions. This is performed by a physiotherapist or allied health assistant. Oral hygiene should be attended to after the procedure because the expectorated secretions may have an offensive taste or odour.

## Promoting comfort and relieving pain

In many disorders of the circulatory system the aim is to increase the individual's activity progressively without pain. Comfort is promoted if the individual is provided with a bed made to meet their specific needs.

The individual may experience pain, for example, as a result of myocardial infarction or peripheral vascular dysfunction, so relief of pain is an important aspect in the promotion of comfort. In certain respiratory conditions such as pleurisy, severe pain may increase on inspiration. The presence of indwelling tubes, wires or cannulas all contribute to further discomfort. Pain-relieving measures such as the administration of adequate analgesic medication are implemented so that the individual is able to rest comfortably, sleep without discomfort and perform the activities of daily living without experiencing pain or significant side effects of the medication. The individual is also advised on what precautions to take to avoid pain, which includes identifying any precipitating factors such as physical exertion or emotional stress. The incidence of pain can generally be reduced by careful planning of activity, modifying risk factors and use of prophylactic measures.

## Providing psychological support

Anxiety and fear are common responses to hospitalisation. An individual who is experiencing a major respiratory or cardio-vascular dysfunction, such as myocardial infarction, pneumonia or blood dyscrasias, often becomes extremely anxious, apprehensive and depressed about dyspnoea, pain, disability, loss of independence and dying. The individual and their significant others may experience great concern about the alterations in lifestyle imposed by their disorder. Nurses provide psychological support by establishing and maintaining a trusting relationship with the individual and their significant others and by encouraging them to express their feelings and concerns. They should be encouraged to discuss any lifestyle adjustments that may be necessary and they should be offered guidance on how to cope with change.

Stress and anxiety can be reduced if the individual's symptoms, such as pain or dyspnoea, are alleviated, and the nurse should try to provide an environment that is as stress-free as possible. The individual should be provided with sufficient information about their illness, as knowledge helps to diminish anxiety and apprehension and assists them to develop effective coping skills. All procedures, treatments and monitoring techniques being implemented are explained so that the individual understands the treatment. The individual should be encouraged to participate in their care as much as possible and, when appropriate, to gradually assume responsibility for self-care to prevent loss of independence. The individual should be informed about support groups and community resources such as rehabilitation classes, which may be helpful after they are discharged from hospital.

## Maintaining skin integrity

An individual with a respiratory, cardiac, peripheral vascular, blood or lymphatic disorder is at risk of impaired skin integrity. Decreased peripheral perfusion and oxygenation can result in skin breakdown. With poor arterial circulation the tissues lack adequate oxygen and nutrients and this can lead to cellulitis, ulcers, poor wound healing and necrosis. Maintenance of skin integrity includes:

- Assessing the skin for any signs of breakdown
- Keeping the skin clean and dry
- Protecting the extremities from exposure to extremes of temperature and from trauma
- Position changes to avoid prolonged pressure on the skin
- The use of accessories (e.g. a sheepskin) to reduce pressure, and promoting mobility.

Preventing skin breakdown includes keeping the feet clean and dry, avoiding rough drying movements, using creams or lotions that prevent drying and cracking, avoiding scratching itchy areas on the legs or feet, providing nail care by a podiatrist and protecting the feet with socks, slippers or well-fitting shoes.

## Promoting and maintaining mobility

Maintenance of mobility is necessary to prevent the complications of immobility, such as decubitus ulcers, venous stasis and pulmonary complications. Problems of immobility should be counteracted with position changes, range-of-motion (ROM) exercises and coughing and deep-breathing exercises. Ambulation of the individual as soon as possible is important to prevent the complications of immobility.

In the initial stages of illness, such as immediately after myocardial infarction, the individual's level of activity may be reduced to a minimum. As their tolerance increases, their level of physical activity gradually increases. The individual should understand the importance of adequate physical exercise, which provides the necessary muscle contraction for movement of arterial blood and lymph to and from the peripheral areas of the body. Exercise or activity programs are generally implemented gradually, and the individual is encouraged to rest after the exercise periods. As the individual's condition

improves, moderate exercise is encouraged as long as pain is not induced.

## Preventing infection

An individual with any of the disorders mentioned previously may be susceptible to infection as a result of nosocomial infections, altered nutritional status, medications such as steroids, invasive procedures and changes in immune status. Measures to prevent infection must be implemented, such as good handwashing techniques, and aseptic techniques for any procedure. Precautions must be taken to prevent damage to the skin or mucous membranes, as injured tissues create a portal for bacterial invasion. If the individual's WBC count is low (leucopenia), it may be necessary to use protective isolation techniques to protect them against infection. The individual must be monitored closely to detect the early manifestations of infection so that appropriate treatment can be prescribed.

## Promoting effective breathing and aeration

In addition to the measures employed to promote a clear airway, other measures may be necessary to maintain adequate ventilation. Breathing exercises may be used by the individual to promote and maintain optimal pulmonary ventilation, and oxygen may be prescribed to supplement that being obtained from the atmosphere.

### Breathing exercises

When respiratory system disorders produce ineffective breathing patterns and inadequate ventilation, the individual may be educated to perform deep-breathing exercises or airway clearance techniques (Osadnik et al 2012).

***Deep breathing*** Deep, or diaphragmatic, breathing uses the diaphragm and abdominal muscles to fully ventilate the lungs. The individual should be assisted into a sitting position to promote optimal alveolar expansion. One hand is placed on the chest and the other hand is placed on the abdomen. If the individual is breathing correctly the hand on the abdomen should rise with inhalation and fall with exhalation; the hand on the chest should remain still. The individual is educated to inhale deeply and slowly, pushing the abdomen out, to promote optimal distribution of air to the alveoli. Individuals may also be educated to exhale through pursed lips, while contracting their abdomen. Exhalation through pursed lips improves ventilation pressures and encourages a slow deep-breathing pattern. Abdominal contraction pushes the diaphragm upwards, exerts pressure on the lungs and helps to empty them.

Breathing exercises are performed according to the individual's condition; for example, short sessions may be indicated if the individual becomes fatigued easily. The duration and frequency with which deep-breathing exercises are performed vary; they may, for example, be performed for 1 minute, with gradual progression to a 10-minute exercise period four times daily.

**Figure 25.23** Spirometry
*(Potter et al 2013)*

***Incentive spirometry/peak flow*** Incentive spirometry (Figure 25.23) uses a breathing device to encourage the individual to achieve maximal ventilation. The device measures peak respiratory flow or respiratory volume, and induces the individual to take a deep breath and hold it for several seconds. Incentive spirometry benefits the individual, as it establishes alveolar hyperinflation for a longer time than is possible with a normal deep breath (Rodman 2014). See Clinical Skill 25.3 for incentive spirometry/peak flow.

### Oxygen therapy

An individual with a respiratory system disorder may be prescribed supplemental oxygen to be administered intermittently or continuously. The administration of oxygen is discussed in more detail later in this chapter.

## Promoting efficient gas exchange

Any disorder of the respiratory system may result in impaired gas exchange. Depending on the extent to which it interferes with ventilation and perfusion, hypercapnia, hypocapnia and/or hypoxaemia may develop. The aim of management of these conditions is to maintain adequate oxygenation and removal of carbon dioxide. In addition to the measures already described, which promote a clear airway and effective breathing, other measures may be necessary, including the insertion of an artificial airway and/or mechanical ventilation. (Information on both these topics is provided later in this chapter.) The nurse must observe the individual for the signs and symptoms of impaired gas exchange (see Table 25.4). Clinical Interest Box 25.6 outlines the cardiopulmonary health promotion for young to older adults.

## CLINICAL SKILL 25.3 Incentive spirometry

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Incentive spirometer<br>Disposable mouthpiece/tube |

| **Skill activity** | **Rationale** |
|---|---|
| Check medical order and reason for incentive spirometry | Ensures indication established for safe intervention and abides by legal and organisation policies and procedures |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Sit individual into an upright position (if able) and lean forwards either on side of the bed or in a chair | Facilitates breathing and lung expansion |
| Instruct the individual to practise inhaling and exhaling 3 times, letting all of their last breath out<br>Ask them to place their lips over the mouthpiece of the spirometer | Enables the person to practise inhaling and exhaling<br>Allows for more accurate results |
| Instruct the individual to inhale slowly (elevating the balls or cylinder) and hold their breath for 2–3 seconds, then exhale slowly | Slow breathing prevents or minimises pain from sudden pressure change in the chest<br>Holding their breath and slowing exhalation helps to maintain maximal inspiration and reduces the risk of progressive collapse of individual alveoli<br>Prevents anxiety |
| Ask the person to remove the mouthpiece, and relax and breathe slowly for a few seconds | Alleviates anxiety and relaxes chest |
| Repeat for a total of 10 times every hour or as indicated by the doctor/physiotherapist<br>If they feel lightheaded or dizzy ask the individual to slow down their breathing and wait longer intervals between cycles<br>Once 10 cycles have been completed ask the individual to cough up and expectorate any sputum<br>Document the results in the healthcare record and report any changes | Allows for chest clearance and proper expansion of the lungs and prevents atelectasis. Coughing can facilitate removal of any secretions<br>Feeling lightheaded and dizzy is a normal reaction; provide reassurance to alleviate anxiety<br>Prevents infection<br>Appropriate care can be planned and implemented |

*(Crisp et al 2013; Rodman 2014; Sydney Cancer Centre: Sydney Gynaecological Oncology Group 2014; ACSQHC 2012; 2015; Sparkes et al 2014)*

**TABLE 25.4 | Impaired gas exchange**

| Condition | Possible cause | Manifestations |
|---|---|---|
| Respiratory acidosis (hypercapnia) | Hypoventilation as a result of chronic obstructive pulmonary disease, pneumonia, drugs or trauma | Flushed warm skin, hypertension, tachycardia, headaches, drowsiness, confusion, irritability, coma |
| Respiratory alkalosis (hypocapnia) | Hyperventilation as a result of acute asthma, cerebral trauma or congestive cardiac failure | Diaphoresis, pallor, tachypnoea, tingling and numbness in the limbs, or around the mouth, carpopedal spasm (tetany) and convulsions |
| Hypoxia | Obstructive lung diseases, and restrictive lung diseases (e.g. chronic bronchitis, emphysema, sarcoidosis) | Pallor or cyanosis, tachypnoea, tachycardia, breathlessness, headaches, irritability, confusion |

**CLINICAL INTEREST BOX 25.6**
**Cardiopulmonary health promotion for young to older adults**

- Maintain ideal body weight
- Eat a low-fat, low-salt, kilojoule-appropriate diet
- Monitor cholesterol and triglyceride levels
- Engage in regular aerobic exercise
- Use stress-reduction techniques
- Be smoke free
- Avoid second-hand smoke and other pollutants
- Use a filter mask when exposed to occupational hazards
- Monitor blood pressure
- Get an annual influenza vaccine if at risk of developing influenza
- Get a pneumococcal vaccine if appropriate
- Reduce exposure to secondary infections

*(Nascimento et al 2014)*

## Specific interventions

Specific nursing interventions relevant to caring for an individual with a respiratory system disorder include:

- Collecting specimens of sputum
- Obtaining nasal or throat swabs
- Administering oxygen
- Suction via the oral, nasal or tracheal routes
- Inhalation therapy.

### Collecting sputum

Sputum is a mucus secretion produced by the mucous membranes that line the respiratory tract. Mucus secretion increases in response to inflammation, infection or congestion. Laboratory examination of sputum may be necessary to determine whether any microorganisms, blood or malignant cells are present. The nurse should observe the sputum, noting the amount, consistency, colour and presence of blood or odour. Sputum is normally clear in colour but may turn white if the individual smokes or has a viral infection; yellow, rust-coloured or green to dark-brown sputum may indicate the presence of an infection. It may be tinged with blood or contain streaks of blood that can suggest inflammations, dryness or infections or conditions such as pulmonary oedema or carcinoma. The consistency varies from watery to mucoid to tenacious.

When a specimen of sputum is required it is best collected early in the morning before any food or fluid is given, as this ensures that there is an accumulation of secretions to be obtained. To avoid the risk of cross-infection with airborne microorganisms the nurse should stand beside rather than in front of an individual when collecting the sputum specimen. Sputum for laboratory testing should be free of saliva and food particles (see Clinical Skill 25.4 for collection of sputum).

### Nasopharyngeal and throat swabs

Laboratory examination of secretions from the nasopharynx or throat may be necessary to determine the presence of pathogenic microorganisms. Collection of a specimen involves swabbing the inflamed tissues and collecting any exudate with a sterile cotton-wool-tipped swab. The nurse should refer to the healthcare institution's policy manual for information about the type of applicator, culture tube and transport medium to use (see Clinical Skill 25.5 for collecting a nasopharyngeal swab).

### Oronasopharyngeal suction

Oronasopharyngeal suction may be required when secretions or foreign substances are causing an obstruction to the individual's airway. Suction is indicated for the individual who is unable to clear the airway effectively with coughing and expectoration, such as the severely debilitated or unconscious individual. The removal of excess secretions and mucus from the airway aids breathing, promotes pulmonary gas exchange and prevents the accumulation of secretions that may cause secondary atelectasis or pneumonia. Suctioning is achieved by means of a catheter, which is introduced through the mouth or nose into the pharynx.

The basic equipment consists of:

- Wall suction or portable suction apparatus
- Collection bottle
- Connecting tubing
- Water suitable for flushing the catheter and tubing in a small container
- Sterile suction catheters

## CLINICAL SKILL 25.4 Collection of sputum

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable gloves<br>Sterile specimen container<br>Tissues<br>Biohazard bag<br>Pathology form—completed by the medical officer<br>Mouth care equipment |
| **Skill activity** | **Rationale** |
| Check the medical officer's orders<br>Check the pathology form ensuring that it is completed and verify details with the individual | Ensures need for the procedure and prevents errors |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Perform hand hygiene and don gloves (other PPE may also be required) | Prevents cross-infection |
| Assist the person to a sitting position<br>Offer mouth care/rinse out the mouth with water<br>Ask the person to start deep breathing and coughing to help facilitate sputum expectoration | Reduces contamination of the specimen with any debris in the mouth<br>Facilitates coughing and expectoration<br>A normal saline nebuliser (if ordered) may be required to help loosen sputum and facilitate expectoration |
| Instruct the person to cough and to expectorate 15 to 30 mL of sputum into a sterile specimen container | A sterile container ensures that the specimen is not contaminated |
| Place the lid on the container, wipe the outside of the container if contaminated, remove gloves/PPE and perform hand hygiene | Prevents cross-infection |
| Ensure that the container is clearly labelled with the relevant information. Dispatch the specimen in a sealed biohazard bag, together with the request form, to the laboratory as soon as possible | Proliferation of microorganisms occurs if the specimen is not dispatched as soon as possible after collection<br>Ensures the correct person's sputum is tested to avoid errors |
| Offer/perform oral hygiene using a mouth swab and/or mouth rinse<br>Document in the individual's healthcare record. Include the amount, colour, consistency, any odour<br>Report findings to Registered Nurse and medical officer | Reduces bad taste or halitosis in mouth<br>Clears the mouth of residual secretions<br>Informs others of which specimen was obtained and when<br>Medico-legal requirement. Allows for the planning and implementation of care |

*(Sparkes et al 2014)*

- Protective glasses
- Disposable gloves
- Tongue depressor.

Suction equipment is usually kept in readiness at the bedside if there is an indication that it may be needed frequently, as an emergency measure or as part of the healthcare institution's policies. In general the pressure is set at 80–120 mmHg for an adult (and considerably lower for a child), depending on the diameter of the catheter and the viscosity of the secretions. The medical officer will prescribe the level of suction to be used. If using the nasal route, suctioning should be alternated between the left and right

## CLINICAL SKILL 25.5 Collecting a nasopharyngeal (nasal) or nasalpharynx (throat) swab

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable gloves<br>Pathology form completed by medical officer<br>Tissues<br>Biohazard bag<br>Normal saline<br>Penlite torch<br>Tongue depressor<br>Throat swab |

| **Skill activity** | **Rationale** |
|---|---|
| Check the medical officer's orders<br>Check the pathology form ensuring that it is completed and verify details with the individual | Ensures need for the procedure and prevents errors |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Inform the individual that they may experience the urge to sneeze or gag during the swabbing. Label the container appropriately<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Assist the person, if possible, to a sitting position | Facilitates collection of the specimen |
| Perform hand hygiene and don gloves/PPE | Prevents cross-infection |
| **For a nasopharyngeal (nose) swab**<br>Request the person to blow their nose<br>If the nasal passage is dry, dip the tip of the swab into the normal saline<br>Request the individual to tilt their head back<br>Insert the swab 2 cm into each nostril, rotating against the anterior nasal mucosa | Clears the nasal passages<br>Prevents trauma<br>Normal saline prevents degradation of viruses or bacteria<br>Facilitates collection of the specimen |
| **For a swab of the nasopharynx (throat)**<br>Request the individual to open their mouth, depress the tongue with a tongue depressor and use a torch to illuminate the throat<br>If the throat is dry dip the tip of the swab into normal saline<br>Ask the person to say 'ah'. Pass the swab over the tonsils, posterior pharyngeal wall and posterior edge of the soft palate | Gentle insertion prevents tissue damage<br>Do not force the swab<br>Facilitates access and visualisation<br>Prevents trauma and facilitates the collection of microorganisms<br>Normal saline prevents degradation of viruses or bacteria<br>Raises the uvula to expose proper site of collection |
| Place the swab in the culture tube/container ensuring the correct medium (viral or bacterial) immediately and close the end of the tube/container<br>Remove and dispose of gloves/PPE and perform hand hygiene | Prevents cross-infection and contamination of the specimen<br>Ensures the correct test is performed to obtain an accurate result |
| Dispatch the specimen in a sealed biohazard bag, together with the request form, to the laboratory as soon as possible. Ensure that the container is clearly labelled with the relevant information<br>Document in the individual's healthcare record and report any findings to the Registered Nurse/medical officer | Proliferation of microorganisms occurs if the specimen is not dispatched and refrigerated as soon as possible after collection<br>Informs others of which specimen was obtained and when<br>Medico-legal requirement. Allows for the planning and implementation of care |

*(ACSQHC 2012; 2015; Sparkes et al 2014)*

nostrils to reduce trauma to the one nostril. It may also be necessary to lubricate the tip of the catheter with a sterile water-soluble lubricant before insertion into the nostril. (See Clinical Interest Box 25.7 and Clinical Skill 25.6.)

## Inhalation therapy

Various forms of inhalation therapy may be prescribed for an individual with a respiratory disorder, including humidified air or oxygen, and nebulised air or oxygen. These can be administered by aerosol devices, electric nebulisers and humidifiers or an intermittent positive-pressure ventilator.

***Electrical humidifiers and nebulisers*** Water vapour may be provided by means of a humidity cot, tent or via a mask or tube attached to the individual. Various electrical devices can provide both humidification and nebulisation, depending on the fitting used. The device has water fed by a sterile container to an electrically warmed core that heats up the fluid contained in it as it passes through a chamber. The warmed water vapour is delivered to the individual via large-bore corrugated tubing and the oxygen concentration can be regulated from room air to 100% oxygen by means of an oxygen venturi-type diluter. The individual inhales the vapour through a nebuliser-type mask.

Nebulisation provides a very visible mist of large water droplets that are delivered into the airways. Nebulisation is used to treat atelectasis and airway infections and to loosen and decrease the viscosity of secretions to facilitate

### CLINICAL INTEREST BOX 25.7 Suctioning and older adults

Older adults often have cardiac and/or pulmonary disease, which increases their susceptibility to hypoxaemia related to suctioning. Watch closely for signs of hypoxaemia. If observed, stop suctioning and hyperoxygenate.

*(Perry et al 2012)*

### CLINICAL SKILL 25.6 Oronasopharyngeal suction

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Suction catheter<br>Suction apparatus<br>Suction tubing<br>Yankauer suction catheter<br>Disposable gloves<br>Oronasopharyngeal tube<br>Sterile water and infectious waste bag<br>Waterproof pad<br>Goggles or face shield (if appropriate) |
| **Skill activity** | **Rationale** |
| Check the medical officer's orders | Ensures need for the procedure and prevents errors |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Perform an assessment of the individual ensuring their vital signs are stable and their oxygen saturations are adequate to allow for the suctioning<br>If possible, position the individual in a sitting position or with the neck extended<br>Place a waterproof pad across individual's chest<br>Remove oxygen mask or nasal cannulae if in situ | Ensures the individual is stable so as to prevent complications<br>A burst of oxygen or normal saline nebuliser may be required prior (if ordered) to help loosen secretions and allow for better clearance of mucus during suctioning<br>Promotes lung expansion and effective coughing. Facilitates catheter insertion<br>Note: If suctioning required due to a mucus plug this will facilitate better oxygen saturations |

*Continued*

| CLINICAL SKILL 25.6 Oronasopharyngeal suction—cont'd | |
|---|---|
| Place the equipment in a convenient location near the bedside. Assemble the required equipment | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene and don gloves. Other PPE may also be required | Prevents cross-infection |
| Attach collection bottle to the suction unit, attach connecting tubing, connector and catheter | Equipment must be assembled and checked for function before the procedure starts |
| Turn on the suction and dip the tip of the catheter into sterile water | Lubricates the catheter to facilitate insertion<br>Prevents the introduction of microorganisms |
| With the suction off (e.g. by using the Y-connector), gently introduce the catheter into the mouth or nostril. If the oral route is used, the individual's tongue may be depressed with a tongue depressor | Suction during insertion may damage the mucosa. Facilitates insertion of the suction catheter<br>Do not put the catheter into the nose and then the mouth, ensure it is cleaned between suctions |
| Ensure that suction pressure is below 120 mmHg. Apply suction as the catheter is withdrawn, rotating the catheter as it is being withdrawn | Pressure above 120 mmHg may damage the mucosa. Rotating motion prevents tissue trauma and obtains maximal volume of secretions<br>Note: Do not force the catheter into the nasal cavity as this can cause trauma<br>When suctioning neonates, infants or children ensure correct measurement is obtained of their nasal cavity to ensure the catheter is not inserted too far, which may cause irreversible damage |
| Apply suction for a maximum of 5–10 second intervals, or less in the young or critically unwell individual, then remove from the airway. Allow the individual time to rest (30 seconds) between suctioning | Suctioning for longer than 10 seconds can cause tissue trauma and hypoxia<br>Allows the individual time to rest and replace oxygen until the next suction |
| If secretions are tenacious, dip the tip of the catheter into the sterile water and apply suction. If a specimen is required for virology or bacterial studies, use of normal saline is recommended | Clears the lumen of catheter<br>Normal saline prevents degradation of viruses or bacteria |
| Repeat the procedure, if necessary, until the mucus obstruction has been removed | Promotes a clear airway |
| After suctioning, instruct the individual (if able) to take several slow deep breaths | Relieves hypoxia and promotes relaxation<br>Facilitates coughing |
| Dip the catheter into the sterile water and apply suction | Clears catheter and connecting tubing<br>Prevents the reintroduction of microorganisms and contamination |
| Discard the catheter, sterile water and gloves. Attend to the rest of the equipment. Perform hand hygiene | Prevents cross-infection |
| Assist the individual into a position of comfort<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Document the time of suctioning, the type and amount of aspirate and the individual's response<br>Report the procedure and any abnormal findings to Registered Nurse/medical officer | Appropriate care can be planned and implemented |

expectoration. It can be delivered through a mask or tracheotomy tube. Humidification provides water vapour in an almost invisible fine mist of small droplets that can travel further into the airways than by nebulisation by virtue of the droplet size and weight. Humidification is used to provide humidity to prevent stasis of mucus, tissue dehydration and to reduce drying, inflammation and irritation of the air passages. These devices provide precise control of oxygen delivery and protection against cross-contamination by means of a sterile pre-filled container of solution, such as sterile water or normal saline.

Other similar devices are used in positive-pressure ventilators, such as Bird or Bennet ventilators, to deliver humidity or medication to an individual on a ventilator or during intermittent positive-pressure breathing therapy. Nurses should know their role and responsibilities regarding inhalation therapy and administration of medications, and should be familiar with the healthcare facility's infection control guidelines. The nurse should check the devices hourly for leaks, cracks and oxygen concentration. Bedding and clothing are changed as soon as they become damp. Care should also be taken to observe the skin surrounding the mask for signs of breakdown.

Mechanical and electrical nebulisers are used to deliver moisture or medication as a fine mist into the airways of individuals with conditions such as asthma or emphysema. Bronchodilators are commonly prescribed in the management of asthma. The devices operate off mains or 12-volt power and are generally used by individuals at home, commonly in individuals with airways disease due to the hypoxic drive effect. Care must be taken to ensure that the device is placed on a stable surface, and regular maintenance of the filters is required.

Gas-driven nebulisers are used with compressed air or oxygen to deliver nebulised vapour or medication. The prescribed solution is inserted into the nebuliser, either alone or together with a prescribed amount of sterile water or saline, and one end of the oxygen tubing is attached to the nebuliser, which is directly connected to a nebuliser mask. The other end of the tubing is attached to an oxygen regulator and then to the pressurised gas source, which is turned on to check for proper misting. To produce particles of the correct size and to better ensure their arrival at the most distal airways, a flow rate of 6–10 L/min is generally recommended. The individual is instructed to breathe deeply, slowly and evenly through the mouthpiece or mask and to hold their breath for 2–3 seconds at the end of inhalation to receive the full benefit of the medication. The individual should be encouraged to cough and expectorate.

Steam inhalations are not generally used because of the risk of burns and the improved effectiveness in providing fluids by other means.

***Mechanical ventilation*** Mechanical ventilation is sometimes indicated for an individual with a respiratory system disorder. Mechanical ventilation artificially assists or controls respiration and it is indicated to correct or prevent gas transport abnormalities. To maintain adequate pulmonary blood gas exchange, an endotracheal or tracheostomy tube is inserted (see below) and connected to the ventilator.

A variety of ventilators are available, which may be one of two main types: pressure controlled or volume controlled. With the pressure-controlled ventilator the gas is delivered to the lungs until a predetermined pressure is reached, then inspiration is terminated. With a volume-controlled ventilator a set volume of gas is delivered with each inspiration. The ventilation rate may be preset, controlled by the individual, or may be a combination of both.

Care of an individual receiving mechanical ventilation should be provided by nursing staff who are qualified and experienced to provide it. An individual who requires mechanical ventilation is generally nursed in an ICU, as they require constant physical attention and emotional support.

## THE INDIVIDUAL WITH AN ARTIFICIAL AIRWAY

The placement of an artificial airway is indicated to relieve obstruction, to facilitate suctioning of the lower respiratory tract, to prevent aspiration or to allow for mechanical ventilation. Artificial airways include the oropharyngeal airway, the endotracheal tube and the tracheostomy tube.

### Oropharyngeal airway

An oropharyngeal airway (Figure 25.24) is a curved rubber or plastic device inserted into the mouth to the posterior pharynx to establish or maintain a patent airway (Potter et al 2013). The airway allows air to pass around and through the tube and facilitates oropharyngeal suctioning. It is used for the short term only, such as in the immediate post-anaesthetic period. If an individual requires respiratory assistance for a longer period, an endotracheal or tracheostomy tube is generally used.

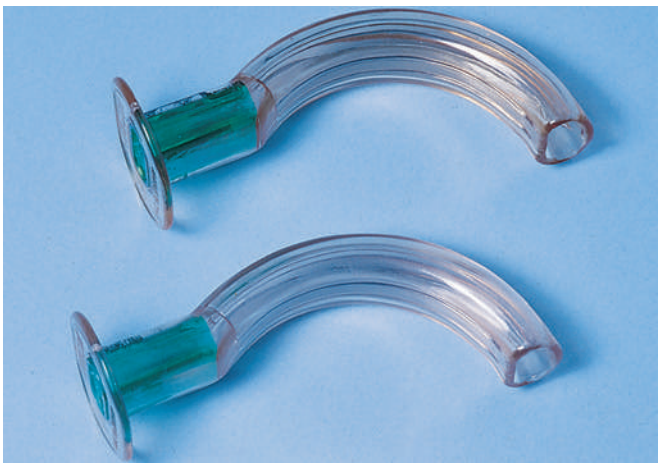

**Figure 25.24** Oropharyngeal airway
*(Potter et al 2013)*

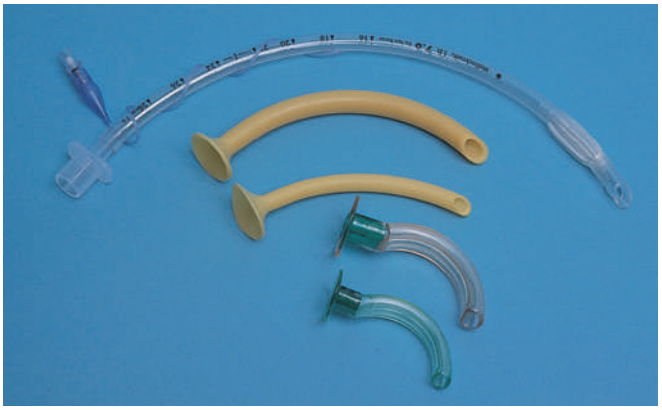

**Figure 25.25** Endotracheal tube (top) compared with nasal and oropharyngeal tubes
*(deWit & Williams 2014)*

**Figure 25.26** Tracheostomy tube
*(Potter et al 2013)*

## Endotracheal tube

An endotracheal tube is a flexible cuffed tube inserted via the mouth or nostril through the larynx into the trachea (Figure 25.25). Endotracheal intubation establishes and maintains a patent airway, prevents aspiration by sealing the trachea off from the digestive tract, facilitates the removal of tracheobronchial secretions and provides a means whereby optimal ventilation can be achieved. Endotracheal intubation may be required in an emergency or may be required for a short or long term.

The tube is inserted by a medical officer, who uses a laryngoscope to visualise the trachea and facilitate the passage of the tube. Most endotracheal tubes in adults have a cuff, which is inflated with air to provide a seal that prevents the leakage of air around the tube when the individual is ventilated. Uncuffed tubes are generally used in infants and children unless there is excessive leakage of air past the tube. To avoid inadvertent removal or displacement of the tube, string and tape may be applied to secure the tube in position. Continuous expert care is required after endotracheal intubation to ensure airway patency and to prevent complications (Pedersen et al 2009). An individual who has been intubated is generally nursed in an ICU and receives constant physical attention and emotional support.

## Tracheostomy

A tracheostomy (Figure 25.26) is a surgical creation of an external opening into the trachea, and may be performed as an emergency temporary measure, a permanent measure or during prolonged mechanical ventilation (Andriolo et al 2015). A tracheostomy tube may be inserted into the tracheostomy to provide a patent airway, prevent aspiration of secretions, allow removal of tracheobronchial secretions by suction and permit the use of a mechanical ventilation device (Dawson 2014). A tracheostomy tube is a short curved tube fitted with a flange that assists in stabilising the tube. Tracheostomy tubes are available in a range of styles, materials and sizes, and some are fitted with an inflatable cuff (Dawson 2014).

# NURSING AN INDIVIDUAL WITH AN ARTIFICIAL AIRWAY

The care of an individual with an artificial airway—whether it has been inserted for a short or long term—involves many physical actions and the provision of emotional support. The main aspects of care include:

- Continued assessment of airway status
- Maintenance of correct cuff pressure to prevent tissue ischaemia and necrosis
- Continued monitoring for complications
- Keeping the tube free of mucus to ensure airway patency
- Preventing infection
- Providing psychological support.

## Nursing a person with a tracheostomy

When caring for a person with a tracheostomy Dawson (2014) describes 12 essential principles of care:

1. Infection control
2. Humidification
3. Cuff management
4. Suctioning
5. Management of the inner cannula
6. Dressings
7. Oral hygiene
8. Communication
9. Swallowing
10. Weaning
11. Decannulation
12. Tube changes.

In the event of an emergency including accidental dislodgement or obstruction of the tube the following should always be available at the bedside (Joanna Briggs Institute 2013):

- Spare sterile tracheostomy tube or inner tube
- Tracheal dilator
- Scissors
- Syringe for a cuffed tube
- Oxygen and sterile 'Y' suction catheters.

A person with an artificial airway will be apprehensive about asphyxiation or choking, which can be further increased by an impaired ability to communicate their needs to others. The individual's ability to effectively remove secretions by coughing may be grossly impaired. When unable to cough or expectorate secretions, suctioning must be performed. In the first few days after the insertion of a tracheostomy tube the procedure is uncomfortable and frightening, and the individual must be provided with an explanation of the suctioning technique before it is performed. The nurse should be aware of their role in, and the regulations and the healthcare facilities, procedures and policies regarding, tracheostomy suctioning. A suggested method of tracheostomy suctioning is outlined in Clinical Skill 25.7.

The basic equipment for tracheostomy suctioning is:

- Sterile 'Y' suction catheters
- Wall or portable suction apparatus

|---|---|
| Remove any humidification (or ventilation) device (i.e. Swedish nose)<br>Inner tube may also need to be removed and cleaned prior to suctioning | Allows access to the tracheostomy tube<br>Prevents a mucus plug from forming and allows for proper removal of secretions |
| Perform hand hygiene and don gloves/PPE | Prevents cross-infection |
| Attach the catheter to the suction tubing and set suction pressure to 80–120 mmHg<br>Catheter size must be smaller than the diameter of the tracheostomy/inner tube | Pressure above 120 mmHg may damage the tracheal mucosa<br>Prevents obstruction of airway |
| Ask the individual to cough and breathe slowly and deeply | Coughing helps loosen secretions, and deep breathing helps to minimise hypoxia |
| If necessary, or prescribed, the individual's lungs are hyper-oxygenated before aspiration | Helps to prevent hypoxia |
| Insert the catheter without suction into the tracheostomy tube just past the correct length of the tracheostomy tube | Prevents hypoxia and tracheal mucosa trauma<br>Suctioning to the xiphoid process can cause trauma and permanent damage to the cartilage, especially in neonates, infants and children; also prevents discomfort |
| Apply suction and withdraw the catheter, rotating it gently. Suction for no longer than 5–10 seconds at a time. Allow the individual to take 4–5 breaths between each aspiration. If secretions are thick, dip the catheter into sterile water and apply suction | Rotating motion avoids tissue trauma<br>Short-term suctioning limits the amount of oxygen removed and prevents hypoxia<br>Helps to clear the lumen of the catheter<br>Note: In neonates and infants do not rotate catheter but simply insert in and out to the required measurement |
| Report immediately if there is any difficulty in inserting the catheter into the tube | The tube may be partially blocked with secretions |
| When suctioning is completed, the individual may need to be hyper-oxygenated again. Replace any humidification device (unless tracheal stoma care/dressing to be performed)<br>Reinsert the clean inner tube<br>Clear suction catheter and tubing with sterile water | Prevents hypoxia and promotes relaxation. Re-establishes delivery of humidity<br>Prevents the reintroduction of microorganisms<br>Note: Suction catheters can be used for up to 24 hours prior to disposal if cleaned thoroughly after use |
| **Tracheal stoma care** | |
| Remove and discard the tracheostomy dressing into a suitable waste receptacle<br>Ensure ties secure around tracheostomy tube | Correct disposal prevents cross-infection and abides by infection prevention policies and procedures<br>Prevents dislodgement of tracheostomy tube |
| Perform hand hygiene<br>Put on sterile gloves<br>For a newly formed stoma, use a sterile drape around the tracheostomy site | Prevents cross-infection<br>Provides a sterile field around the stoma |
| Cleanse the skin around the stoma and the flanges of the tube using gauze and normal saline. Take care not to let normal saline or strands of gauze enter the tube or stoma<br>Use cotton tip applicators dipped in normal saline for hard-to-reach areas of the stoma | Removes accumulated secretions and crusts<br>Prevents aspiration and the risk of infection |

## CLINICAL SKILL 25.7 Tracheostomy suctioning and tracheal stoma care—cont'd

| | |
|---|---|
| Inspect the surrounding area and stoma site for inflammation or skin breakdown<br>Inspect for the formation of a granuloma especially in older tracheostomy stoma sites | Signs of impaired healing or infection require immediate attention<br>Granulomas are generally a collection of macrophages forming a nodular area around the stoma site. These are quite common, especially in older stomas, and can be treated with silver nitrate |
| Apply a sterile tracheostomy dressing using aseptic non-touch technique | Protects the stoma site and reduces transmission of microorganisms |
| Replace the tracheostomy tapes if they are soiled or loose<br>Two people are required to change the tapes (one must be an RN who has achieved competency; the EN would assist with the procedure) | Tracheostomy tube must be secured in position. Soiled tapes predispose the person to infection. Prevents accidental dislodgement of the tube |
| Replace any humidification device (Swedish nose)<br>Change to a new one if the old one soiled | Re-establishes delivery of humidity and helps filter the air to prevent the introduction of microorganisms |
| Remove gloves/PPE, dispose of the equipment appropriately, perform hand hygiene | Prevents cross-infection<br>Abides by infection prevention policies and procedures |
| Assist the individual into a position of comfort.<br>Ask the individual to report any complications during and post procedure (if able) | Promotes rest and relaxation, monitors for adverse effects |
| Document the time of suctioning, the type and amount of aspirate and the individual's response<br>Document and report on the dressing change<br>Report the procedure and any abnormal findings to Registered Nurse/medical officer | Appropriate care can be planned and implemented |

*(Royal Children's Hospital Clinical Practice Guidelines 2014; Joanna Briggs Institute 2014b; Berman et al 2015; Crisp et al 2013; ACSQHC 2012; 2015; Sparkes et al 2014)*

- Connecting tubing
- Disposable gloves
- Container of sterile or tap water for clearing the catheter (depending on the institution's policy)
- Bag or container for contaminated catheters.

Care of the tracheostomy and tracheostomy tube is performed to minimise contamination and to decrease the possibility of obstruction by secretions (Caparros 2014). Tracheostomy care, which is performed using sterile equipment and aseptic technique to prevent infection, involves cleansing of the inner cannula and the area around the stoma. The frequency with which the care is provided may vary depending on the amount of secretions present, and may be as frequent as every half hour to 1 hour or may only be required once every 8 hours.

Some tracheostomy tubes have an inner replaceable tube that can be changed as part of routine daily care (e.g. 4-hourly to daily). It is essential that a spare inner tube is kept close at hand and replaced if the inner tube becomes blocked. The inner tube is cleaned using a suitable solution and dried and made accessible for future use. Many tracheostomy tubes are fitted with an inflatable cuff. Regular deflation of a cuffed tube is performed to prevent tracheal necrosis and stenosis. The frequency and length of time for cuff deflation varies depending on the type of tube used and the condition of the individual.

To prevent the trachea or lower airways from drying and bleeding, a humidification connector, a 'Swedish nose', may be applied. It consists of a single or dual barrel that encloses the tube's orifice; humidity is provided by rolled absorptive paper filters pre-moistened with normal saline. If secretions are present on the outside of the suction catheter, additional sterile saline may be required to be instilled into the tracheostomy tube to loosen secretions and maintain the patency of the tracheostomy tube.

Communication is a significant problem and to alleviate anxiety and apprehension an alternative means of communication should be provided. A pad and pencil should be available, the individual's call bell or buzzer must always be within easy reach and must be answered promptly. If unable to write, the individual can be educated to use a series of gestures or sign language as an alternative method of communicating their needs. Alternatively, for individuals with uncuffed tubes a speaking valve can be employed, or they can be educated

how to cover the tube with their finger to occlude the airway on expiration and allow for limited communication. If the artificial airway is a temporary measure, the individual should be informed that their voice will recover when the tube is removed. Before deflation, the tube and oronasopharynx are aspirated. When the cuff is inflated, only sufficient air is inserted to occlude the escape of air from around the sides of the tube.

The individual should be provided with information about their progress and any procedures that are to be performed. They should be encouraged to participate in their own care as much as possible to reduce any sense of dependency, and the significant others should be involved in the care. The individual may be discharged from hospital with a tracheostomy tube in situ. As soon as possible, they and the significant others are educated in self-care so that they feel comfortable and confident about caring for their tracheostomy. The individual should be provided with information about relevant support groups such as tracheostomy associations that they may wish to contact.

Before the permanent removal of a tracheostomy tube the individual will require sufficient information and emotional support, as they may feel that they will not be able to breathe without the tube. The tube may be removed when the individual is able to maintain independent respiratory function, is able to breathe through the upper respiratory tract and has satisfactory protective reflexes such as the cough reflex.

To prepare the individual for permanent removal of the tracheostomy tube a fenestrated tube may be inserted. This type of tube has an opening in the outer cannula that allows the individual to breathe around as well as through the tube. Thus, they are able to adjust gradually to removal of the tube. Alternatively the tube may be occluded or 'corked' by an adhesive tape to determine the individual's ability to cope without the tube. With uncuffed tubes this is routinely achieved to enhance communication by allowing the individual to occlude the tube with their fingers while speaking. By covering the tube, they may be able to speak, breathe normally through the upper airway and expectorate secretions.

Before the tube is removed, suction is applied to remove tracheal and pharyngeal secretions. The cuff is then deflated and the tube removed. Generally a dry occlusive dressing is placed over the stoma and the individual closely monitored for the first 24 hours. Healing and reduction in the tracheostomy can take 12 months or longer and care must be taken during this time to prevent aspiration and infections. After a period of time, when the individual's airway is stable, the stoma can be surgically sutured together (see Clinical Skill 25.7 for tracheal stoma care).

### Complications of tracheostomy

The insertion of an artificial airway can result in several complications:

- Infection due to altered ciliary function or colonisation of the airway with bacteria
- Tracheal necrosis and stenosis due to excessive pressure on the trachea from the cuff
- Tracheo-oesophageal fistula
- Partial or complete airway obstruction (e.g. due to an accumulation of secretions in the tube)
- Subcutaneous emphysema
- Psychological effects, such as frustration at being unable to communicate as usual.

## THE INDIVIDUAL WITH THORACIC DRAINAGE TUBES

Insertion of chest drainage tubes (Figures 25.27 and 25.28) permits the drainage of air or fluid from the pleural space which, if not removed, alters intrapleural pressure and causes lung collapse (Durai et al 2010). Ventilation is adversely affected by any disruption of the intrapleural pressure, which may be caused by surgery, trauma or pulmonary disease. Insertion of chest tubes drains the excess air or fluid and enables the lungs to function normally (Durai et al 2010).

Chest drainage tubes may be inserted at the time of surgery while an individual is anaesthetised, or they may be inserted using local anaesthetic. Because the procedure is painful, a conscious individual is generally given analgesic medication about 30 minutes before tube insertion. The procedure is performed by a medical officer, using sterile equipment and aseptic technique. The insertion site is selected according to the individual's condition, and one or more tubes may be inserted at the same time. See Clinical Skill 25.8 for care of chest tube/drainage.

### Underwater seal drainage

After insertion the chest tube is connected to a drainage system that permits drainage out of the pleural space and prevents back-flow into that space. The tubing leads to

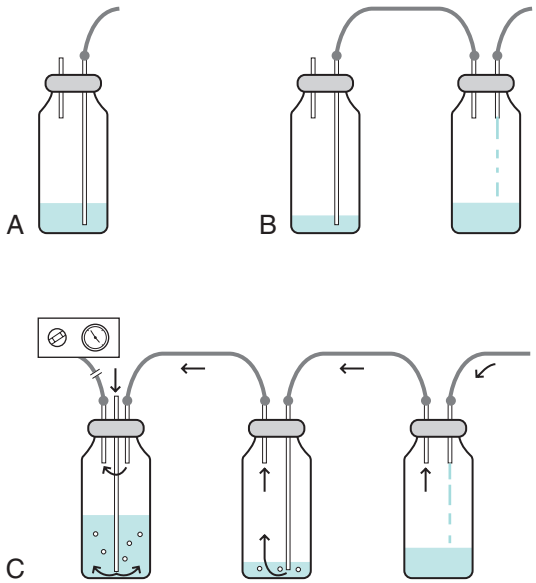

**Figure 25.27** Chest tube drainage A: One-bottle system B: Two-bottle system C: Three-bottle system with suction *(Potter et al 2013)*

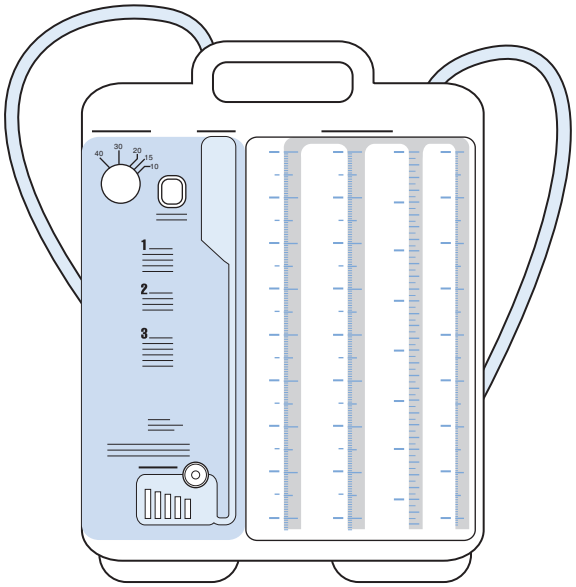

**Figure 25.28** Disposable, commercial chest-drainage system

a collection system positioned well below the level of the individual's chest. This dependent position facilitates the removal of air or fluid from the pleural cavity and prevents backflow. To prevent the entry of air into the pleural cavity the distal end of the tubing is submerged underwater. This provides a closed water-seal drainage system. The depth of water that the tube is placed under determines the water pressure used to create a seal (e.g. 5 cm) and is ordered by a medical officer.

Some commercially available systems of underwater seal drainage (e.g. the Pleur-evac® system) are available already assembled and are disposed of after use. Other types of thoracic drainage systems include the one-, two- or three-bottle systems. The one- and two-bottle systems are primarily gravity systems, which can be provided with suction to facilitate drainage. Such systems provide a water seal and can be connected to suction. A medical officer is required to order the application of suction, which is used to facilitate faster drainage of air or fluids. A low-flow suction regulator device is used to ensure that the suction provides a minimal bubbling effect.

## CLINICAL SKILL 25.8 Care of chest tube/drainage and dressing change

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable and sterile gloves<br>Sterile dressing pack<br>Approved antiseptic solution (2% chlorhexidine gluconate in 70% isopropyl, 10% povidone-iodine or 70% alcohol)<br>Normal saline 0.9%<br>Split dressing/gauze<br>Occlusive dressing<br>Fluid balance chart or chest drain observation chart<br>2 artery forceps |

| **Skill activity** | **Rationale** |
|---|---|
| **Care of chest tube/drainage** | |
| Check the medical officer's orders | Ensures need for the procedure and prevents errors |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment | Ensures consent<br>Ensures efficiency |
| Ensure therapeutic interaction | Reduces the incidence of performing an activity on the incorrect individual |
| Assess for any contraindications | Reduces anxiety/apprehension and gains trust and cooperation |
| Ensure the individual is nursed in a semi-Fowler's or high Fowler's position | Promotes participation in care and understanding of health status |
| Ensure privacy | Ensures correct procedure is about to take place |
| Perform an assessment of the individual ensuring their vital signs are stable and their oxygen saturations are within range as specified by the medical officer | Allows for adequate chest expansion and better respiration. Semi-Fowler's position is preferred for pneumothorax to evacuate air. High-Fowler's is preferred for haemothorax to drain fluid. Reduces anxiety and embarrassment |
| Assess for any pain during inspiration or expiration and/or at the insertion site | Ensures individual is stable so as to prevent any complications |
| Check for bilateral rise and fall of the chest and that there is no respiratory distress | |

## NURSING A PERSON WITH A CHEST DRAIN

The aim of closed-chest underwater seal drainage is to maintain respiratory function and haemodynamic stability by facilitating drainage of air, blood and/or other fluids (Joanna Briggs Institute 2014a). Care of the person includes:

- Nursing them in an upright position when possible, to facilitate optimal lung expansion and to promote drainage by gravity
- Providing adequate explanation and emotional support to reduce anxiety. The individual may tend to restrict their breathing and movement for fear of dislodging the tube, so it is essential to explain that the tube is secured in position with tape and/or sutures
- Administering adequate analgesic medication to decrease discomfort. It may be necessary to administer analgesic medication 30–45 minutes before physiotherapy, to promote pain relief and relaxation
- Encouraging the individual to breathe deeply and cough frequently (e.g. hourly, to help drain the pleural space and expand the lungs)
- Regularly assessing the individual's respiratory status. The individual should be observed for discomfort and any difficulty in breathing, and it is important to observe whether their chest is expanding symmetrically. The ventilations are assessed at regular intervals (e.g. hourly, for rate, rhythm and character)
- Maintaining the water seal and preventing air leakage, which is essential to prevent entry of air into the pleural space. The fluid level in the drainage bottle should be checked frequently (e.g. hourly) and sterile water added if necessary to ensure that the distal end of the water seal tube remains submerged at the ordered level
- Taking precautions to prevent separation of the connections, such as taping the joints and securing the tube to the individual's clothing. Care must be taken to ensure that the underwater seal system remains below the individual's chest to prevent fluid or air re-entering the pleural cavity, which can cause subsequent pneumothorax or empyema

Securing the drainage system to the bed or placing it securely on the floor to protect it from toppling over and from accidental breakage. If the system is accidentally disconnected or broken, air will enter the pleural space and the lungs may collapse. It is general practice to have two chest clamps in plain view at the bedside for any individual with a chest drain; in the event of disconnection, the two clamps are applied immediately to the chest tube, and assistance is summoned immediately.

There is some controversy surrounding this emergency measure, as some authorities believe that clamping a chest tube could result in a tension pneumothorax. It is essential that the nurse be aware of the healthcare institution's measures to be taken should accidental disconnection of the system occur. If a chest tube is accidentally dislodged or falls out, the individual is asked to exhale forcefully and the opening on the skin surface is sealed with an airtight dressing until the tube can be reinserted.

- Maintaining patency of the drainage system, which is essential to facilitate expansion of the lung. The system must be checked hourly for loose connections and for fluctuation in the water-seal bottle. As the individual inhales, the fluid should rise in the water-seal tube, and as they exhale the level should fall back (this is termed 'swinging')

- Ensuring that, if the system is connected to suction, the fluid line in the water-seal tube remains constant. During exhalation, bubbling is normally present in the water-seal bottle. Gently bubbling in a suction control bottle indicates that the correct level of suction has been achieved
- Observing the tubing for, and keeping it free from, kinks. Kinking of the tubing will obstruct the flow of air or fluid. To prevent kinking, or dependent loops of tubing, the tubing should be coiled flat on the bed and may be attached to the edge of the bed with tape and a safety pin. The tubing should fall in a straight line from the coil to the drainage bottle, to facilitate flow. The nurse should ensure that the individual is able to move freely without pulling or lying on the tubing
- Double-clamping the chest tube near the site of insertion when it is necessary to replace a drainage system bottle. The bottle, and, if necessary, the connection tubing, is replaced and the clamps removed. The tubes should not be clamped for longer than 2 minutes, as a tension pneumothorax may result when air or fluid is prevented from escaping. As a safety precaution, two nurses should be present whenever a drainage bottle or system is being replaced
- Protecting the insertion site by an occlusive dressing (e.g. Opsite). Using sterile equipment and aseptic techniques to prevent infection, the dressing is renewed in accordance with the healthcare institution's policy
- Assessing and documenting the colour, volume and type of drainage. Any alteration in the amount, colour or flow of drainage must be reported immediately. Sudden cessation of flow of drainage may indicate a malfunction of the system or disconnection of the tubing. A gradual reduction in flow may indicate occlusion by blood or proteins, that the tube position has moved in the pleural cavity or that the chest has reinflated.

Removal of a chest drain tube is very painful and individuals require adequate analgesia and preparation time (Bauman & Handley 2011). Chest drain removal must be performed by a qualified Registered Nurse or medical officer. Generally the tube is clamped for up to 24 hours before removal, and a chest x-ray is performed immediately beforehand to determine lung expansion. If the individual develops respiratory distress or a pneumothorax, the clamps are removed and the tube left in place. Analgesic medication is usually administered 30–45 minutes before tube removal. The tube is removed swiftly and immediately covered with an occlusive dressing to provide an airtight seal. In some cases the site is closed with purse string sutures that are tightened during removal.

One hour after the removal of the tube an x-ray is taken to ensure that there has been no ingress of air during or after the removal. The insertion site is checked regularly for sounds of air leakage and the individual is observed for manifestations of pneumothorax, infection, subcutaneous emphysema and respiratory distress.

## NURSING PRACTICE AND OXYGEN ADMINISTRATION

Nursing staff must be educated to adequately administer oxygen therapy. Oxygen therapy is the delivery of oxygen to the individual by some device or equipment in concentrations greater than that found in normal room air (room air is 21%). Oxygen therapy is not a cure and does not remove the underlying disease or condition but aims to decrease the workload of the cardiopulmonary system and to protect the individual from tissue hypoxia. Regardless of the mode of delivery the individual must be able to maintain a patent airway, or an artificial airway must be established.

It is important for nursing staff to assess, initiate and monitor oxygen delivery systems within the prescribed parameter. An exception to this would be in an emergency when no individual should be denied adequate oxygenation. In such cases oxygen should be given first and documented later.

### Assessment

An individual's respiratory status is assessed to ascertain whether they are receiving an adequate supply of oxygen and excreting sufficient carbon dioxide to meet their body's needs. A respiratory assessment should consider the following:

- Observing the individual for signs and symptoms of hypoxaemia and respiratory distress
- Identifying any deviations from normal and by assessing their ventilations.

Assessing the respiratory status and identifying any actual or potential problems is assisted by obtaining information from the individual regarding:

- Allergic reactions such as coughing, watery eyes, sneezing or shortness of breath that may occur as a result of exposure to allergens such as dust mites, pet hair or pollen
- Exposure to environmental air pollutants such as chemical wastes, smoke or dust
- History of tobacco and inhaled recreational drugs
- Presence of a cough and the volume, quality and quantity of sputum
- Chest pain.

#### Signs and symptoms of hypoxaemia and respiratory distress

The person should be observed for signs and symptoms of hypoxaemia which is defined as a diminished availability of oxygen to the body tissues. Hypoxaemia may result from disorders that limit the volume of air entering the lungs, or from obstructive lung diseases such as asthma and emphysema. The signs and symptoms of hypoxia and respiratory distress include:

- Cyanosis. Cyanosis is a bluish discolouration of the skin and mucous membranes due to inadequate

oxygenation, and can be either peripheral or central. Peripheral cyanosis results in local vasoconstriction and is usually visible in the nail beds and the lips. Central cyanosis is the result of more severe hypoxia and affects all body organs. It is most visible in highly vascular areas such as the lips, nail beds, tip of the nose, the external ear and the underside of the tongue. In people with naturally dark brown or black skin, cyanosis is most accurately detected by inspecting the mucosa inside the mouth
- Elevated blood pressure and pulse rate
- Shortness of breath (dyspnoea), fatigue and intolerance to exercise
- Abnormal respiratory rate, depth or rhythm
- Sighing, gasping, breath holding
- Flaring of the nares
- Use of accessory muscles during breathing (e.g. substernal recession, tracheal tugging, shoulder shrugging and intercostal muscles during expiration)
- Apprehension, aggression, non-compliance or agitation
- Confusion or reduced level of consciousness
- Visible or excessive perspiration (diaphoresis) (Gillies et al 2012).

### Assessment of an individual with chronic respiratory disorder

A person with a chronic respiratory disorder should also be assessed for a barrel-shaped chest, which is an increase in the anteroposterior diameter of the chest wall, commonly associated with air trapping, as in atelectasis or chronic obstructive airways disease. Individuals with chronic hypoxaemia may experience the same symptoms as above but may have clubbing of the fingers, where the angle of the nail bed increases to over 85 degrees, caused by an increase in capillary numbers to supply poorly perfused tissue, with subsequent increase in size.

## Meeting an individual's need for oxygen

Breathing is an automatic activity, but rate and depth can be changed voluntarily. Normally room air at normal atmospheric pressure, such as at sea level, provides sufficient oxygen to meet metabolic needs of the body. However, admission to hospital, or a respiratory condition, may affect an individual's normal pattern of breathing. For example, if a person has an infection or is apprehensive or anxious, they may experience temporary breathing difficulties. In these instances measures to promote the return of normal breathing are performed. Nurses provide individuals with adequate information to allay some of the anxiety relating to their condition, investigations and hospitalisation. The nurse should also attempt to ensure that the room is ventilated adequately and at a comfortable temperature (deWit & Williams 2014).

Individuals who experience breathing difficulties due to a clinical condition may require assistance to meet any increase in either oxygen demands or carbon dioxide retention. Some methods include, for example, positioning in a more upright position, nebulisation, humidification, physiotherapy (which may include deep-breathing and coughing exercises) and mobilisation. Individuals who suffer from an oxygen deficiency will commonly require administration of oxygen to supplement that being obtained from the atmosphere. See Clinical Skill 25.9: Oxygen therapy—nasal, mask.

## Administering oxygen

To prevent or reverse hypoxia and to improve tissue oxygenation, oxygen may be administered via a number of devices. Oxygen is a drug; it is prescribed by a medical officer who determines the concentration, route and length of time that it is to be administered. To promote the safety and comfort of the individual receiving oxygen therapy, the nurse should be aware of certain principles relevant to the administration of oxygen (deWit & Williams 2014):
- Hypoxaemia can result from insufficient oxygen flow or delivery. Equipment and connections must be checked at regular intervals (e.g. hourly) to ensure that it is functioning properly. If signs or symptoms of hypoxaemia occur they must be reported immediately, as adjustment to the concentration being administered may be necessary, or alternative investigations or treatment implemented
- Although oxygen is not normally combustible, it does support combustion and it is essential to implement safety precautions to reduce the risk of fire. Smoking is prohibited in the vicinity, and measures are taken to prevent sparks, which may be given off by electrical or mechanical items. Inflammable substances such as oil or alcohol should not be used near or on the oxygen equipment
- Administration of any gas can dry and irritate mucous membranes; this is particularly so with nasal prongs. In some healthcare institutions the gas is humidified by passing it through a sterile water humidification system before administration
- Oxygen is colourless and odourless, so accurate gauges on gas cylinders and oxygen concentrators are used to indicate the volume of oxygen remaining or rate of flow. An oxygen regulator limits the flow of the gas. Care must be taken to ensure that connections on the regulator are tight, otherwise a reduced volume or concentration will be administered
- Oxygen toxicity is a hazard with prolonged administration or concentrations over 50%. The individual's capillary, venous or arterial blood gases are commonly measured during oxygen therapy and the concentration of oxygen or method of delivery can be adjusted. Damage and inflammation to airways, blood vessels and nervous tissue may result in acute respiratory distress syndrome (ARDS)
- Nosocomial infections can occur using oxygen therapy, particularly with the use of non-sterile oxygen bubble humidifiers. Masks, tubing, cannulae and catheters are for single individual use and are discarded on discharge. Care must be taken to clean the mask or nebuliser regularly (e.g. every 8 hours).

## CLINICAL SKILL 25.9 Oxygen therapy—nasal, mask

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Oxygen source (wall outlet, cylinder)<br>Flow meter<br>Humidifier and sterile water (if indicated)<br>Oxygen tubing<br>Oxygen delivery system (if $FiO_2$ required)<br>Nasal cannula<br>Oxygen mask (or required mask)<br>Pulse oximeter |
| **Skill activity** | **Rationale** |
| Check the medical officer's orders regarding oxygen therapy for the person and/or inform nurse-in-charge re initiation of oxygen therapy | Ensures need for the procedure and prevents errors<br>Abides by legal parameters and facility/organisation policies |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Perform an assessment of the person ensuring their vital signs and oxygen saturations<br>Assess indications for oxygen requirement:<br>• dyspnoea, tachypnoea, bradypnoea, apnoea<br>• pallor, cyanosis<br>• lethargy or restlessness<br>• use of accessory muscles: nasal flaring, intercostal or sternal recession, tracheal tug | Baseline observations attended to assess for initiation of oxygen therapy<br>Enables safe administration of oxygen therapy |
| Sit person into an upright or semi-Fowler's position (if able) | Facilitates breathing and lung expansion |
| Attach oxygen delivery device to oxygen tubing and attach to oxygen source at prescribed rate. Apply the appropriate delivery device to the individual | Oxygen delivery devices change the amount and the concentration of oxygen being delivered:<br>• Nasal cannulae: 2–4 L/min (26–32%)<br>• Hudson mask: 5–6 L/min (35–50%), 6–10 L/min (50–60%), 10–12 L/min (60–65%)<br>• Non-rebreather: 15 L/min (>60%)<br>• Venturi system (used in high flow oxygen): $FiO_2$ and amount of oxygen determined as per dialled amount<br>Note: High-flow oxygen requires humidification due to drying out oral and nasal mucosa<br>High-flow oxygen can be via the appropriate nasal cannulae or mask |
| Monitor the individual's response to oxygen and their observations as indicated by the medical officer until stable (usually every 15 minutes to hourly)<br>Ensure tubing is not kinked, check mask or cannula stay in correct position<br>Ask the individual to report any complications during and after the procedure, if able | Prevents complications and ensures treatment is working |

| CLINICAL SKILL 25.9 Oxygen therapy—nasal, mask—cont'd | |
|---|---|
| Document in the healthcare record and report any changes to condition | Appropriate care can be planned and implemented |
| Offer/perform oral hygiene using a mouth swab and/or mouth rinse<br>Wash face masks daily with warm soapy water<br>Observe the nares and top of the individual's ears for skin breakdown | Reduces bad taste or halitosis in mouth<br>Provides comfort and maintains moist mucosa<br>Oxygen therapy can dry the nares and the cannula tubing or elastic can cause skin irritation |
| *(Royal Children's Hospital Clinical Practice Guidelines 2013b; Bersten & Soni 2009; Kernick & Margarey 2010; ACSQHC 2012; 2015)* | |

**TABLE 25.5 | Oxygen equipment**

| Type | Oxygen concentration flow rate | Indication |
|---|---|---|
| Nasal cannula/ catheter | $FiO_2$: 24–38%, flow 1–2 L/min<br>$FiO_2$: 30–35%, flow 3–4 L/min<br>$FiO_2$: 38–44%, flow 5–6 L/min | This device is well tolerated by most individuals. The fraction of inspired oxygen varies depending upon the flow of oxygen (L/min) and the rate and depth of the individual's breathing |
| Simple face mask | $FiO_2$: 35–65%, flow 8–12 L/min | High flow of oxygen is required to prevent the rebreathing of carbon dioxide |
| Oxygen mask with reservoir bag (non-rebreather) | $FiO_2$: 60–100%, flow 6–15 L/min | This device allows for a higher $FiO_2$ to be administered. A valve closes during expiration so that exhaled air does not enter the reservoir bag and be rebreathed. Never remove the one-way valve |
| Venturi mask | $FiO_2$: 60–100%, flow 4–15 L/min | This device is one of the most accurate ways to deliver oxygen. Different-sized adapters are used to deliver a fixed or predicted $FiO_2$. It is ideal for $CO_2$ retainers or hypoxic drive individuals |
| Head box | $FiO_2$: 21–100%, low 0.25–3 L/min | A transparent plastic box that fits over the head or shoulders of an infant. The infant can be observed easily, and high concentrations of oxygen can be administered |

The nurse must know how to check that the equipment is functioning correctly and that all connections are secure and do not leak. Cleaning and disposal of equipment is done as per the individual healthcare institution's infection control guidelines.

## Oxygen delivery equipment

Oxygen is often piped to a wall outlet or, less commonly, is supplied via a portable cylinder or oxygen concentrator and may be delivered to the individual via an oxygen regulator using one of several devices. Oxygen is prescribed in litres per minute or in percentage as $FiO_2$ (fraction of inspired oxygen). The mode chosen for the delivery of oxygen is dependent on the individual's clinical condition, concentration of oxygen required, degree of ventilatory support required and the individual's ability to comply with the therapy (see Table 25.5 for description of oxygen delivery equipment and concentration).

### Nasal cannula

A nasal cannula (nasal prongs) (Figure 25.29) is made from a soft plastic material and contains two short prongs that fit into the nostrils. It may be secured in position by an adjustable ring or strap around the back of the head or taped onto the cheeks to prevent dislodgement. Because it does not enclose the nose or mouth, the cannula is comfortable and convenient for the person and there is less risk of aspiration of vomitus than a mask. The cannula is connected to the oxygen supply and the oxygen turned on at a low flow rate, with the flow checked before positioning it in the nares. The prongs are inserted following the natural curve of the nostrils, and the tubes are positioned over each ear and around the back of the head. The ring or strap is adjusted to maintain the position of the prongs, and care is taken to ensure that the strap is not too tight. An over-tight strap can cause pressure on the nostrils, the nose, the upper lip and cheeks. When the cannula has been positioned correctly, the flow of oxygen

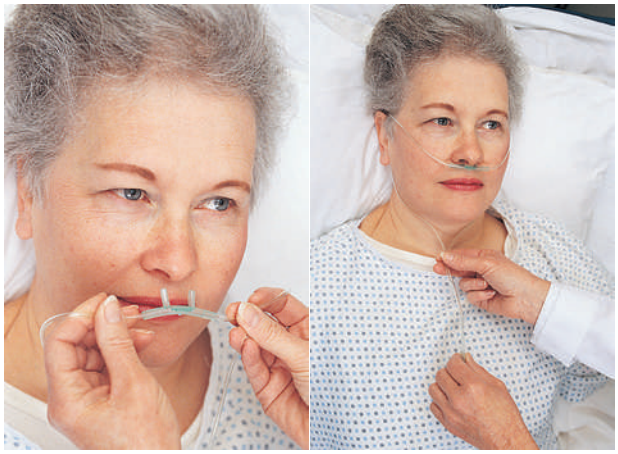

**Figure 25.29** Applying a nasal cannula

*(Potter et al 2013)*

**Figure 25.30** Intranasal oxygen catheter

*(Teleflex, EndoTest, ISIS and Rüsch are trademarks or registered trademarks of Teleflex Incorporated or its affiliates. © 2012 Teleflex Incorporated. All rights reserved.)*

is adjusted to the prescribed rate. Minimum flow is 0.25 L/min to a maximum of 6 L/min, but this will often cause nasal dryness and can be uncomfortable. Flow rates of 1–4 L/min are most commonly used, equating to a concentration of approximately 24–40% oxygen. Higher volumes increase irritation and drying of the nasal mucosa. The oxygen concentration that the individual receives is indeterminable and is reduced if the individual mouth breathes, eats or drinks.

## Nasal catheter

An intranasal oxygen catheter (see the Teleflex® catheter, Figure 25.30) is made from a soft plastic material and contains a series of holes at the distal ends. The approximate length to be inserted is estimated by holding the catheter in a straight line from the tip of the individual's nose to their earlobe, and marking the catheter with an indelible pen to ensure that the insertion length can always be seen. The tip of the catheter may be lubricated with sterile water or a water-soluble lubricant to facilitate insertion. Before insertion, the catheter is connected to the oxygen supply and the oxygen turned on at a low flow rate. As with nasal prongs, oxygen concentration varies with factors such as mouth breathing. The catheter can induce gastric distension if forced into the stomach.

The catheter is gently inserted through one nostril into the nasopharynx to the pre-measured length. Using hypoallergenic tape, the catheter may be secured to the nose or cheek, avoiding traction on the nostril, which could cause skin breakdown. When the catheter has been positioned correctly, the flow of oxygen is adjusted to the prescribed rate. As it is an invasive device, the catheter may cause irritation of the mucosa, so it is usual to remove it after about 8 hours and insert a clean one into the other nostril. Rotating the site reduces the risks of mucous membrane irritation and skin breakdown at the tip of the nose.

## Face mask

Face masks (Figure 25.31) are available in several styles and sizes. They are made from a lightweight vinyl material and are designed to fit over the nose and mouth, secured in position by an elastic band around the head. As the mask covers both the nose and the mouth, it is confining and impedes activities such as eating, drinking and communication as well as potentiating the risk of aspiration of vomitus.

Minimum flow rate for masks is normally 5 L/min, as a lower flow rate is not adequate to clear the mask of exhaled carbon dioxide and can cause hypercapnia ($CO_2$ retention). Depending on the style, a mask can deliver oxygen from 28% at 4 L/min to 100% concentration at higher flow rates. A mask is commonly used when the individual requires higher concentrations and more accurate amounts of oxygen, such as when the individual is mouth breathing, eating, talking or is able to breathe only through the mouth. Oxygen masks are recognisable by the presence of multiple small holes on the sides of the mask, as opposed to nebuliser masks, which have one large-diameter hole each side.

The style and size of a mask is assessed by measuring from the chin to the top of the nose, and an appropriate size is selected. The mask is connected to the oxygen supply via a flexible plastic tube, and the oxygen turned on to check that there are no leaks at a low flow rate. The mask is placed over the nose, mouth and chin, and the elastic strap secured around the back of the head; some masks have pliable metal straps that can be used to mould the mask to the individual's face shape. The strap is adjusted to ensure that the mask is firmly positioned but not uncomfortable, and the flow of oxygen adjusted to the prescribed rate. It is important that the mask fits closely but is not uncomfortable, and the nurse should ensure that there is no leakage of oxygen from the top of the mask. Leakage of oxygen from the top of the mask can flow across the eyes, causing dryness and irritation of the delicate tissues. Masks can create pressure areas on the skin and can be made more comfortable by applying self-adhesive foam to the edges in contact with skin.

***Non-rebreather*** A non-rebreather mask with an oxygen reservoir bag can be used to deliver high concentrations of oxygen to an individual who can breathe spontaneously. A

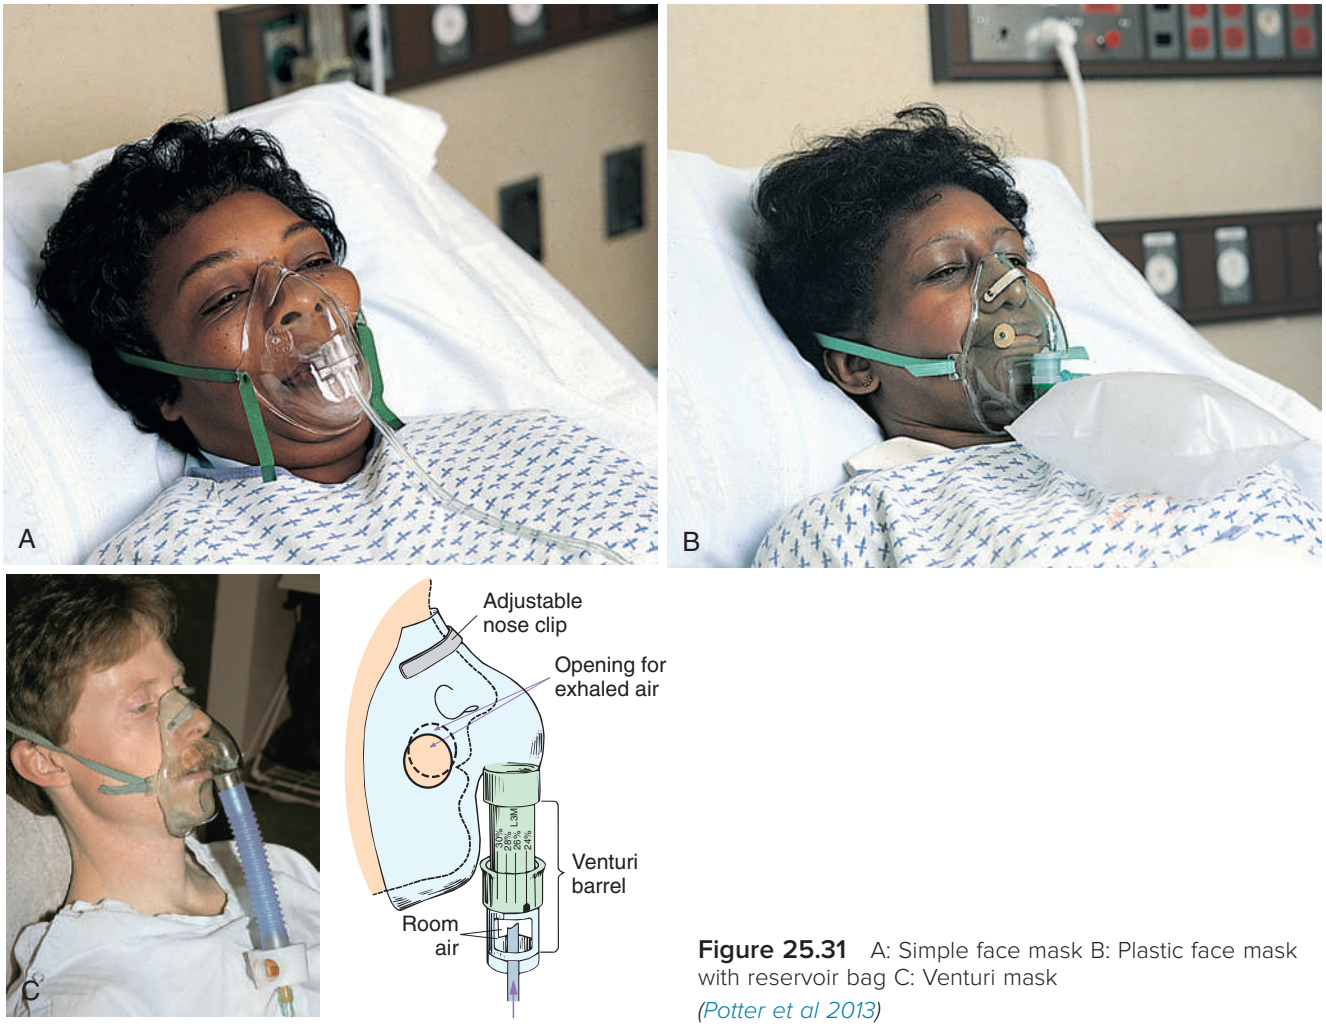

**Figure 25.31** A: Simple face mask B: Plastic face mask with reservoir bag C: Venturi mask
*(Potter et al 2013)*

one-way valve on the mask closes during expiration so that exhaled air does not enter the reservoir bag to be rebreathed. The reservoir bag also helps increase the inspired oxygen concentration by preventing the patient from breathing room air upon inspiration.

***Venturi face mask*** This device mixes oxygen with room air, delivering a predetermined high-flow enriched oxygen concentration. This device is one of the most accurate ways to deliver oxygen. Different-sized adapters are used to deliver a fixed or predicted $FiO_2$. It is ideal for $CO_2$ retainers or hypoxic drive patients.

### Head box

A head box may be used to deliver oxygen to an infant and consists of a transparent plastic box that fits over the head or shoulders. The infant can be observed easily, and high concentrations of oxygen can be administered.

The concentration of oxygen to be delivered to the individual will be specified by the medical officer and depends on the delivery device used and the rate at which the oxygen flows. Oxygen can be delivered from concentrations of 21% to 100%, and the flow rate adjusted by oxygen regulators from 0.25 L/min (low flow) to 3 L/min (high flow). The flow rate is adjusted by turning the valve on the flow meter (Figure 25.32) and observing the ball or dial that indicates the number of litres per minute at which the oxygen is flowing.

Whenever oxygen is to be administered the nurse should refer to the directions that accompany the device, to ensure that the correct concentration of oxygen is delivered to the individual.

## Mechanical ventilation

In specific situations an individual may require oxygen to be administered via a mechanical ventilator. These devices may use either positive or negative pressure.

### Positive pressure

Intermittent positive-pressure ventilation (IPPV) devices push atmospheric or oxygen rich air into the individual's airways to promote adequate lung expansion. Commonly, IPPV is performed via an endotracheal or tracheostomy tube and allows effective control of ventilation and oxygenation. The flow of air to the lungs is set at a predetermined pressure

**Figure 25.32** Oxygen regulators A: An example of an Australian standard regulator B: An example of a New Zealand standard regulator

*(Images of Carnét® Oxygen Pressure Regulators (AS and BS) courtesy of BOC Limited, a member of the Linde group)*

and, as the pressure is attained, the flow is stopped, pressure is released and the person exhales. Types of IPPV devices include:

- Positive end-expiratory pressure (PEEP): maintains a positive pressure in the lungs at the end of the individual's respiratory cycle, by increasing pressure within airways
- Continuous positive airway pressure (CPAP) is a device that maintains a certain amount of pressure to maintain the patency of large and small airways and alveoli. CPAP devices are commonly used in individuals with sleep apnoea. It can be administered with a tight-fitting face mask or over a tracheostomy and is often used to slow or prevent the need for mechanical ventilation.

### Negative pressure

Negative pressure chambers use a negative pressure to maintain inflation of the lung and can be used to administer high volumes of oxygen. Examples include the iron lung and barochamber.

## Measures to promote the comfort and safety of the individual receiving oxygen

There are a number of measures that nurses should consider when caring for an individual receiving oxygen. Such measures include:

- Reducing any anxiety the individual or their significant others experience related to the administration of oxygen. Some people may feel that the administration of oxygen is a sign that the individual's condition is deteriorating, and individuals using face masks may experience anxiety related to having both their nose and their mouth covered. The nurse should explain the purpose of the oxygen and the equipment that is being used. Some people may be educated to use the equipment independently and thus feel they have some control over the situation. Frequent visits to the individual, prompt attention to their needs and efficient handling of the equipment will help to reduce their anxiety
- Constantly monitoring the equipment to ensure that it is functioning correctly. The nurse should check the flow rate and ensure that the prescribed concentration of oxygen is being delivered to the individual. Connections on regulators, concentrators and humidifiers should be checked to ensure their tightness and that they are free of leaks. Measures should be taken to prevent the oxygen tubing becoming twisted, kinked or disconnected, to facilitate a free flow of oxygen to the individual
- Informing the individual of the importance of maintaining the delivery device in the correct position, as changing its position may alter the amount of oxygen being delivered
- Prevention of infection. In the past, oxygen that was delivered by an oxygen mask, nasal cannula or nasal

catheter was humidified to prevent drying of the mucous membranes. Normal practice in most healthcare agencies is to use only sterile methods of humidification and dispose of the equipment according to infection control or manufacturer's guidelines to reduce the potential for nosocomial infections. Oxygen masks and cannulas provide sufficient atmospheric water to humidify the oxygen
- Assisting the individual to meet their hygiene needs. The skin under the tubing, elastic straps or mask should be kept dry to promote comfort and to reduce the risk of skin breakdown caused by humidity or perspiration. Both the individual's face and the face mask should be wiped dry at least every 2 hours, and the skin under the delivery device checked for signs of pressure or irritation. Oral and nasal hygiene needs should be met and a water-based cream or balm may be applied to the lips or nares to prevent dryness and discomfort
- Replacing the mask with a nasal cannula if necessary, while the individual is eating or having their oral hygiene needs met
- Measuring the individual's temperature by the tympanic or axillary route rather than the oral route, as placement of the thermometer in the mouth may cause further ventilatory distress
- Monitoring the individual's condition constantly to assess the effectiveness of the treatment. The individual should be observed for signs of hypoxia or oxygen toxicity. Hypoxia may occur if the oxygen concentration is inadequate or if the equipment is not functioning properly. Oxygen toxicity is more likely to occur if the individual is receiving high concentrations (e.g. over 50%), which can be detrimental to the central nervous system. Manifestations of oxygen toxicity include nausea, muscle twitching, dizziness, restlessness and irritability, convulsive seizures and coma. Prolonged administration of high concentrations of oxygen may also cause damage to the linings of the bronchi and alveoli, resulting in pulmonary congestion or collapse of lung tissue. Any indications of hypoxaemia, hypercapnia ($CO_2$ retention) or toxicity must be reported immediately, as the concentration of oxygen being administered may need to be adjusted. It should also be noted that people with chronic obstructive airways disease, such as emphysema, may have an 'oxygen drive', in which their respiratory rate is controlled by decreasing levels of oxygen, as opposed to the normal regulation of respiratory rate, which is due to an increasing $CO_2$ level. These individuals are never prescribed high-flow oxygen, as it reduces their respiratory drive and rate and increases hypercapnia
- Observing the individual closely after oxygen therapy has been discontinued, as the therapy may need to be resumed if signs of hypoxia become evident
- Handling the oxygen equipment. The equipment used to deliver oxygen to the person should be cared for in the manner specified in the healthcare institution's policy manual. Most of the delivery devices are disposable, which reduces the risk of cross-infection.

## EDUCATION

Planning for an individual's discharge from hospital is of particular importance if their respiratory disorder is chronic or recurrent. The individual must be provided with sufficient information because, by understanding their condition and how to manage the symptoms, they will be better able to cope with chronic respiratory disease. The individual should be encouraged to pursue as normal a lifestyle as possible and should be given information about:
- The importance of avoiding factors that may precipitate or exacerbate their condition, such as extremes of temperature, exposure to allergens or environmental irritants, fatigue or emotional stress
- The importance of avoiding close contact with individuals who have a respiratory tract infection
- The importance of contacting their medical officer at the first sign of a respiratory tract infection
- The nature and correct use of any prescribed medications, nebulisers or aerosol therapy
- Public health education about smoking and its relationship to lung cancer and chronic obstructive pulmonary disease; the means of preventing droplet-spread infection; and the effects of air pollutants on the respiratory tract
- Immunisation against infections such as pertussis, influenza and TB
- How and when to use oxygen, which an individual may need to have immediate access to at all times
- When to contact their medical officer or go to hospital (e.g. if the measures implemented at home fail to sufficiently control their symptoms).

## Summary

The human body requires oxygen and nutrients in order to survive. The circulatory system is the means by which every cell in the body is supplied with oxygen and nutrients, and the means by which the cells' waste products are transported to various organs for excretion. The circulatory system consists of the cardiovascular and the lymphatic systems. The cardiovascular system is composed of the blood, the blood vessels and the heart. The lymphatic system consists of lymph, lymphatic capillaries, vessels, nodes and ducts.

*Continued*

## Summary—cont'd

Blood is a viscous substance composed of a fluid (plasma) in which three types of formed elements are suspended—erythrocytes, leucocytes and platelets—each of which has specific functions. The overall functions of blood are to transport oxygen, nutrients and other substances to the cells, transport wastes away from the cells, protect the body against infection, distribute heat evenly throughout the body and prevent a loss of blood by means of a clotting mechanism. Blood is pumped by the heart into the major arteries, which then form increasingly smaller arteries and eventually arterioles. Arterioles are continuous with a network of minute vessels called capillaries. Blood then enters small veins or venules, which join to form veins. The veins unite to form the major veins, which transport the blood back to the heart. Blood is in constant circulation around the body, in the systemic, pulmonary or portal circulation. The lymphatic vessels pass through one or more nodes, the functions of which are to filter and destroy microorganisms and to produce lymphocytes, antibodies and antitoxins.

The heart is a hollow muscular organ situated in the thoracic cavity. It pumps deoxygenated blood to the lungs, and oxygenated blood to all parts of the body.

The act of breathing allows the passage of oxygen and carbon dioxide to and from the lungs, while the cardiovascular system transports these substances to and from the cells. Ventilation is controlled by centres in the brainstem that are sensitive to $CO_2$ level, while certain factors such as an individual's clinical condition, disease, physical activity or emotions affect the rate, rhythm and depth of breathing. Diffusion is the process by which oxygen and $CO_2$ molecules are transported between the alveoli and the capillary network, and into and out of cells. Diffusion abnormalities can result from cardiac abnormalities such as cardiac failure causing pulmonary oedema, or respiratory disorders that cause a reduction in the amount of functioning lung tissue or fibrosis of the alveolar walls.

Respiratory dysfunction results from inadequate ventilation, from abnormalities of diffusion through the pulmonary membrane or inadequate transport from the lungs to the tissues. In addition to abnormalities of the lungs or respiratory structures, dysfunction of other body systems such as the cardiac system can adversely affect respiratory function, and vice versa. The major manifestations of respiratory system disorders are chest pain, cough, voice change, dyspnoea, altered ventilations, hypoxia and thoracic skeletal abnormalities. Disorders of the respiratory system can be classified as those occurring from multiple causes, from infection, as a result of neoplasms or obstruction or as a result of injury. Specific diagnostic tests used to assess function of the systems include full blood examinations, urea and electrolytes, ultrasound, pulmonary function tests, oximetry, chest x-ray, lung scan, blood gas analysis, cultures, sputum cytology, skin tests, bronchoscopy and thoracentesis.

Care of the individual with a respiratory system disorder includes promoting a clear airway, promoting local hydration, proper positioning, administration of medications, oronasopharyngeal suction, chest physiotherapy and the administration of oxygen. The nurse may be required to obtain a specimen of sputum for laboratory examination, to obtain a nasal or throat swab or to administer inhalation therapy. An individual with a specific disorder of the respiratory system may require the insertion of an artificial airway, and/or mechanical ventilation. The insertion of chest tubes may be necessary to promote the drainage of air or fluid from the pleural space. Care of individuals with cardiac or lymphatic disorders include similar care to that of a respiratory individual but may also include fluid restrictions, weighing and attention to chest or limb pain and skin integrity. Specific disorders of the circulatory system may require surgical intervention.

Some individuals require the administration of oxygen, which can be delivered using one of the various devices available. Whenever oxygen is being administered, the nurse must promote the individual's safety and comfort as part of assisting them to meet their need for oxygen.

## Review Questions

1. Name the various parts of the respiratory tract.
2. Discuss the structure and function of the respiratory system.
3. Discuss the structure and function of the cardiovascular system.
4. What are the common causes of upper respiratory problems?
5. What is the significance of respiration?
6. Explain the process of ventilation.
7. How is oxygen transported?
8. What is oxyhaemoglobin and how is it formed?
9. Identify the four blood groups and the Rh factors.
10. List some of the common clinical features of respiratory disease.
11. List some of the most common manifestations of cardiovascular disease.
12. Describe the differences in cardiac pain for angina and myocardial infarction.

13. What are the main aims of nursing care for an individual with a respiratory or cardiovascular disorder?
14. Describe the nursing care for an individual receiving oxygen therapy.
15. Explain the difference between hypoxia and hypoxaemia.
16. Identify the key areas a person with a chronic or recurrent respiratory condition should be educated on when being discharged from hospital.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing care of an individual: fluid and electrolyte homeostasis

*Kalpana Raghunathan*

CHAPTER 26

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define key terms
- Discuss the fundamental differences in fluid volume content throughout the lifespan
- Describe body fluid compartments and their significance in maintaining mechanisms of homeostasis
- Explain cations, anions and their associated movement
- Explain electrolytes and the common themes associated with their imbalances
- Identify interventions utilised in the correction of electrolyte imbalances in the clinical environment
- Describe the key physiological processes involved in fluid movement
- Explain the concept of tonicity and its relevance to the administration of intravenous fluids
- Describe the key systems essential in regulating body fluid balance and composition
- Discuss common health problems associated with fluid and electrolyte disturbances
- Describe the homeostatic mechanisms involved in maintaining acid–base balance
- Discuss the implications of acid–base imbalance throughout the lifespan
- Describe the components of a comprehensive person-centred nursing assessment for individuals throughout the lifespan
- Apply principles of person-centred care in planning, implementing and evaluating nursing care for individuals throughout the lifespan

## KEY TERMS

acid
acidosis
active transport
albumin
aldosterone
alkaline
alkalosis
anions
antidiuretic hormone
balance
base
body fluid
buffer
cation
dehydration
diffusion
diuretics
electrolytes
extracellular fluid
filtration
fluid
fluid balance
fluid volume deficit
fluid volume excess
homeostasis
hydrostatic pressure
ions
insensible losses
interstitial
intracellular fluid
intravascular
isotonic
oedema
osmolality
osmosis
osmotic pressure
pH
sensible losses
solutes
specific gravity
tonicity
transcellular
urine

## CHAPTER FOCUS

The purpose of this chapter is to outline the theoretical foundations in the science of fluid and electrolyte homeostasis and acid–base balance. Key physiological processes that regulate the delicate fluid, electrolyte and acid–base balance and pathophysiology of altered homeostasis are discussed. This knowledge acquisition informs nursing practice, advancing skills in providing comprehensive person-centred care throughout the lifespan. Specific evidence-based interventions and management of nursing care related to common disturbances of fluid, electrolyte and acid–base balance are explored to assist in developing best nursing practice.

As this chapter provides a brief overview of the subject material, it is recommended that you access the additional reading and resources at the end of the chapter to enhance your knowledge base.

## LIVED EXPERIENCE

As a nursing student, up until now I had been very unaware of just how important it is to meet and maintain fluid and electrolyte needs for the individual person. Only now as I near the end of my course am I beginning to grasp the dramatic impact that even a slight imbalance could potentially have on a person. Although it seems complicated at first it is essential that as nurses we have an understanding not only of the fluids we give, but also why we are giving them and how they will affect the person.

**Kristy, Enrolled Nurse Student**

# HOMEOSTASIS

There is a delicate balance of fluids, electrolytes, acids and bases which play a vital role in the maintenance of a healthy internal environment of the body. **Homeostasis** can be referred to as 'the state of equilibrium in the internal environment of the body, which is naturally maintained by adaptive responses that promote health survival' (Brown et al 2015). Alterations in fluid and electrolyte balances can lead to serious health conditions (McLafferty et al 2014; McMillan & Pitcher 2011; McGloin 2015). In the healthcare environment it is usually the responsibility of the nurse to monitor and maintain fluid balance; therefore, it is critical for nurses to develop a sound understanding of the mechanisms involved in maintaining homeostasis. This knowledge will inform their ability to anticipate fluid, electrolyte and acid–base disturbances and initiate appropriate person-centred nursing assessment and management.

The significance of the nursing role in maintaining and restoring homeostasis can be demonstrated by the multitude of conditions a person presents with that may result in fluid and electrolyte or acid–base disturbances. The person might consume a variety of common medications that can also impact on maintenance of homeostasis. Nursing care includes the early identification of individuals in this group, their assessment and monitoring, and the development of a collaborative plan of care (LeMone et al 2014). Table 26.1 lists the common conditions that can affect fluid and electrolyte homeostasis.

**TABLE 26.1 | Common conditions affecting fluid and electrolyte homeostasis**

| | |
|---|---|
| Skin losses | Excessive sweating, burns, fever |
| GIT losses | Diarrhoea, vomiting, nasogastric suctioning |
| Renal losses | Diuretics |
| Osmotic diuresis | Diabetic ketoacidosis (DKA) |
| Volume loss | Haemorrhage, diabetes insipidus (DI) |
| Third spacing | Burns, sepsis, bowel obstruction, pancreatitis |
| Others | IV fluid administration, chronic heart failure, chronic renal failure, crush injuries |

## Fluid volume content of the body

A large proportion of the human body is made up of **body fluid** or water and its **solutes**, which are small particles of dissolved substances. In a healthy adult total body water accounts for 55% of total body mass in women and 60% in men (McGloin 2015). This value changes quite significantly with age: in a newborn total body fluid can be up to 80% and gradually decrease in a person as they age (McLafferty et al 2014). The proportion of body water is dependent on the amount of lean body mass. As men generally tend to have more lean body mass than women, men naturally have greater body water content than women. Older people also have less lean mass and therefore a lower body water volume, rendering them to be more intolerant to fluid loss. Older people and infants require a particularly astute nursing assessment of their fluid volume status.

Fluids and electrolytes are usually discussed simultaneously because body fluid is the mode of transport for electrolytes and other substances. Figure 26.1 illustrates the percentage of water content in the body.

## Fluid volume distribution

Body water is distributed between two major compartments, approximately two-thirds in the intracellular space and one-third in the extracellular space (Friedman 2010) (see Figures 26.2 and 26.3). **Intracellular fluid** (ICF) is the fluid contained inside the cells which accounts for approximately 40% of total body weight (LeMone et al 2014). Electrolytes contained within the ICF include potassium, phosphorus and magnesium. **Extracellular fluid** (ECF) is located outside the cells and can be further divided into:

- **Intravascular**: contained within the blood vessels (plasma) accounting for 5% of body weight
- **Interstitial**: the fluid that surrounds cells accounting for approximately 15% of body weight
- **Transcellular**: includes fluid in spaces between joints (synovial) and other compartments such as pericardial, pleural, intraocular, cerebrospinal and secretions
- Sodium and chloride are the electrolytes found in the extracellular compartment (LeMone et al 2014).

The ICF and ECF are separated by two specific membranes: a semi-permeable cell membrane and the blood vessel wall including the capillary membrane. Under normal healthy conditions the volume of fluid within each compartment remains relatively unchanged, although fluids and electrolytes move between compartments to maintain their relative compositions (McGloin 2015). The fluids and electrolytes are able to move between compartments via the semi-permeable membrane, meaning only selected substances can cross it. Water and solutes, depending on their size, solubility, electrical properties and concentration, can pass through the cell membrane (Craft & Gordon 2015). This membrane is an example of a homeostatic mechanism (Caon 2008). It plays an integral role in maintaining fluid, electrolytes and other substances at their optimal levels and in the correct spaces for a healthily functioning body. The pathophysiology of diseases affecting the function of the semi-permeable membrane is explored later in this chapter.

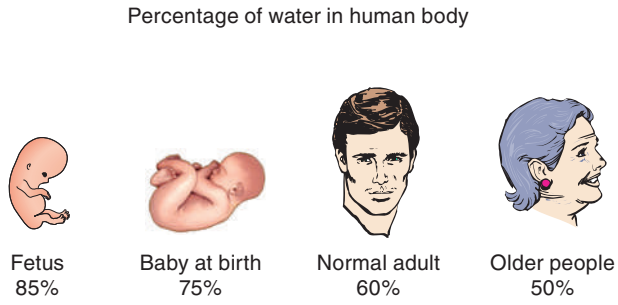

**Figure 26.1** Percentage of water in the human body

## Mechanisms of fluid and electrolyte movement to maintain homeostasis

Fluid and electrolyte movement are critical in maintaining homeostasis of the internal environment. Movement across the semi-permeable membrane is facilitated to maintain the appropriate concentrations of fluids and electrolytes in their respective compartments; this is particularly essential for optimal nerve and muscle function. Generally there are two types of fluid movement: passive transport (no cellular energy is used) and active transport (requires expenditure of cellular energy) (McLafferty et al 2014). The most common methods by which electrolytes and other solutes move are diffusion, osmosis, active transport and filtration.

### Diffusion

**Diffusion** is the movement of a substance, or solute, such as sodium (an electrolyte) or oxygen from an area of greater concentration to an area of lower concentration, resulting in an even distribution of the substance. This could be described as moving from a particularly crowded space to a less crowded space, termed as moving 'down a concentration gradient' (Craft & Gordon 2015). Many substances in the body move

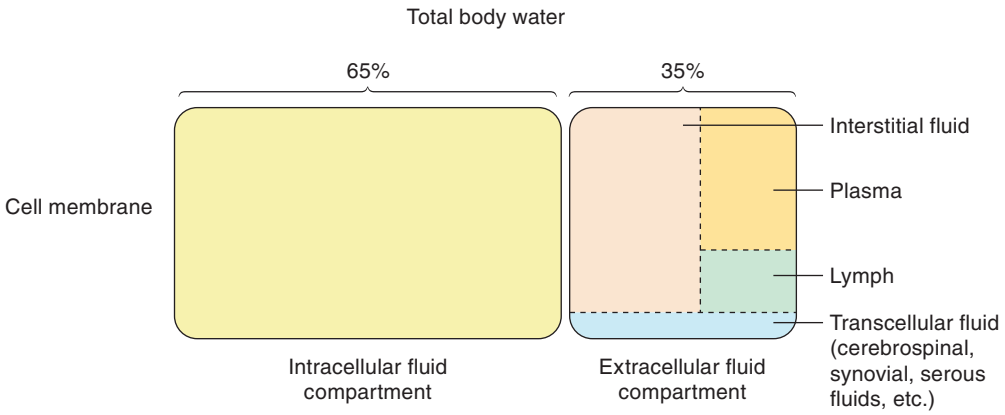

**Figure 26.2** Body water distribution and compartments

*(Saladin 2001)*

**FLUID COMPARTMENTS**

The three major fluid compartments:

- **Intracellular fluid (ICF)** is the fluid within cells, also known as cytosol
- **Extracellular fluid (ECF)** is the fluid found outside of cells.

There are two major kinds of extracellular fluid:

- **Interstitial fluid** is the fluid surrounding the cells
- **Plasma** is the fluid component of blood.

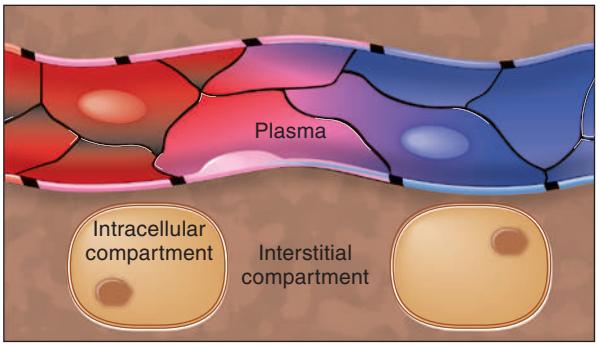

**Figure 26.3** Body fluid compartments

*(Humboldt State University, CC BY SA)*

by diffusion, such as electrolytes, amino acids and glucose. Sometimes diffusion of fluids occurs through a membrane, as in the movement of oxygen from alveoli in the lungs through the capillary membrane into the bloodstream.

Facilitated diffusion occurs when substances need to move but they need a little help to get to their destination. This assistance comes in the form of proteins, which transport substances through specific channels in the cell membrane. As a result of these substances moving down a concentration gradient (to the less crowded area) this process does not require energy (Craft & Gordon 2015). In diffusion through ion channels the membrane proteins allow the movement of specific electrolytes through the cell membrane. The channels are selective and some channels are gated opening only when stimulated to do so, playing an important part in the electrical activity of body cells (McLafferty et al 2014).

## Osmosis

**Osmosis** is the movement of water through a semi-permeable membrane from an area of high water concentration to an area of low water concentration (Caon 2008). This simply means water will move to where there is a stronger concentration of electrolytes—like adding more water to a strong cup of tea or coffee. This ultimately has a dilutional effect on the solution. This movement continues until the concentration reaches equilibrium on either side of the membrane. The rate at which osmosis occurs depends upon several factors, including:

- The concentration of electrolytes
- The temperature of the solution
- The electrical charge of the electrolytes
- The difference between the osmotic pressures exerted by the solutions.

See Table 26.2 for a summary of movement mechanisms for water and substances.

## Active transport

**Active transport** is the movement of substances from an area of lower concentration to an area of higher concentration. Unlike diffusion, this process requires substances to move up the concentration gradient (Craft & Gordon 2015). This process could be described as being similar to swimming against a strong current, therefore requiring more energy. Energy for this process comes in the form of adenosine triphosphate (ATP) (LeMone et al 2014). The sodium–potassium ATP pump is a familiar example of this type of movement. The concentrations of sodium and potassium are maintained within a tight range in the ECF and ICF; this is essential for optimal nerve conduction. As electrolytes have a tendency to want to reach equilibrium on either side of the membrane, they have to be pumped 'against the current' to maintain their concentrations. The sodium–potassium ATP pump is responsible for maintaining their concentrations and the cell 'charge', providing there is enough ATP available for this process (LeMone et al 2014). If ATP is depleted through disease processes, the consequences of homeostasis breakdown would potentially have a significant impact on the health of the person.

## Filtration

**Filtration** is the movement of water and solutes through a permeable membrane as a result of pressure from within the capillaries into the interstitial space (Craft & Gordon 2015). The pressure in the fluid compartments as a result of the movement of fluid and solutes out of the compartment is known as filtration pressure. Hydrostatic and oncotic pressures are involved in this process (McGloin 2015). In the cardiovascular system hydrostatic pressure is the blood pressure generated in the vessels when the heart contracts. In the renal system the proper excretory functioning of the kidneys is dependent on glomeruli filtration and it is particularly relevant to nurses providing care for individuals with compromised renal function. *Creatinine* clearance in the urine is especially important to know before giving some medications which are excreted by kidneys in order to prevent kidney damage (Berman et al 2015). See Clinical Interest Box 26.1 for examples of medications effecting urine production and elimination.

## Osmotic pressure and hydrostatic pressure

**Osmotic pressure** (also called oncotic pressure) refers to the concentration of a solution expressed as a pressure unit, usually mmHg (Caon 2008). Movement of water can be affected by the differences in osmotic pressure on opposite sides of the membrane. Plasma has a higher concentration of proteins compared to interstitial fluid; these proteins (especially albumin) exert osmotic pressure causing water to remain in the intravascular space (LeMone et al 2014).

Additionally, movement of water through a membrane can be affected by differences in **hydrostatic pressure** on either side of the membrane (Caon 2008). The process of water moving from an area of high hydrostatic pressure to low hydrostatic pressure is called filtration (LeMone et al 2014).

**TABLE 26.2 | Summary: mechanisms of movement—fluid and electrolytes**

| Transport mode | Image | Movement of | Movement summary | Is ATP required? |
|---|---|---|---|---|
| Osmosis |  | Water | Movement of water from high to low concentration | No |
| Simple diffusion |  | Substances | Movement of substances from a high to low concentration (crowded to less crowded) | No |
| Facilitated diffusion |  | Substances | Proteins assist in movement from a high to low concentration (crowded to less crowded) | No |
| Active transport |  | Substances | Movement from low to high concentration (to a crowded space) | Yes |

*Adapted from Craft & Gordon 2015; Active transport image © Balint Radu/Fotolia.com*

Hydrostatic and osmotic pressures greatly influence the movement of water between the interstitial and intravascular compartments. For example, hydrostatic pressure at the arterial end of the capillary pushes water into the interstitial space, until the hydrostatic pressure is finally reduced due to the movement of water. The osmotic pressure at the venous end of the capillary is then greater than hydrostatic pressure and so encourages water to move back into the capillary (LeMone et al 2014). Conditions affecting the integrity of the membrane or the amount of protein in the intravascular space will have a profound impact on health. See Figure 26.4 for visual representation of capillary hydrostatic and oncotic pressure.

## Tonicity

Tonicity can be thought of as the 'concentration' or 'osmolality' of a solution (Craft & Gordon 2015). The terms **osmolality** and osmolarity are often used interchangeably. Osmolality refers to the solute concentration in osmoles per litre (per volume of solution), while osmolarity refers to the solute concentration in osmoles per kilogram. According to Caon (2008), the difference between the two terms with relevance to intravenous solutions encountered in nursing practice is so small it is acceptable to use either term.

The **tonicity** or concentration of a solution refers to the concentration of one fluid compared to another (Caon 2008).

It is measured against the normal osmolality fluid within, which is between 275 and 295 mOsm/kg (LeMone et al 2014). An **isotonic** solution has the same tonicity or concentration as body fluid, meaning this solution will not cause water movement into or out of cells if they were placed in this solution. A hypotonic solution is less concentrated than body fluid; therefore it will encourage water to move into the cell, causing it to swell and perhaps burst (haemolyse) if there is a significant influx of water. Hypertonic solution is more concentrated than body fluid and encourages water movement out of the cell, causing the cells to shrink (Caon 2008). The concept of tonicity is particularly relevant to nurses providing care and ongoing management for individuals receiving treatment with intravenous fluids to monitor the effects of them on the person's health. Intravenous fluids will be discussed further at a later point in this chapter. See Figure 26.5 for a visual representation of fluid tonicity.

### CLINICAL INTEREST BOX 26.1 Examples of medications affecting urine production and elimination

- Some antibiotics such as gentamicin can be nephrotoxic
- Abuse of analgesics such as Act-3, Actiprofen, Brufen and Nurofen can be nephrotoxic
- Diuretics cause moderate to severe increase in production and excretion of urine
- Cholinergic medications such as pilocarpine stimulate urine production
- Some analgesics and tranquillisers suppress the CNS system and interfere with urination and neural reflex
- Certain drugs change the colour of the urine (e.g. anticoagulants—red, diuretics—pale yellow, B-complex vitamins—green or blue-green, levodopa—black or brown)

*(Dempsey et al 2014)*

## FLUID BALANCE

**Fluid balance** relates to the correct balance of fluid input and output required in the body and it is crucial to the health of an individual (McMillan & Pitcher 2011). Fluid regulation in the body is managed by the action of the kidneys, and fluid loss and gain are carefully regulated processes in the body (McLafferty et al 2014). In the healthcare environment nurses are involved in the assessment of individuals in their care and play a vital role in monitoring and managing fluid balance. It is therefore important that nurses have a knowledge of the mechanisms involved in fluid regulation and the impact on health. When caring for young children, older people and acutely ill it is particularly important to carefully monitor fluid balance. Children have relatively higher fluid requirements compared with adults because of greater body water content (Coe & Williams 2011). Older people are less likely to respond to the thirst mechanism with age-related changes and are at risk of inadequate fluid balance (Bernoth et al 2014; Shepard 2013). Acute illness is associated with poor appetite and reliance on others for assistance with hydration and nutrition, and physiological effects that may result in fluid loss (McGloin 2015). Some of the causes for reduced or inadequate intake of fluids are:

- Refusal to drink fluid for fear of incontinence
- Cognitive impairment, dementia, Alzheimer's disease
- Reliance on others for assistance with fluid intake
- Physically weak and frail
- Fasting for medical/surgical procedures
- Diuretics and laxatives
- Being ill
- Nausea

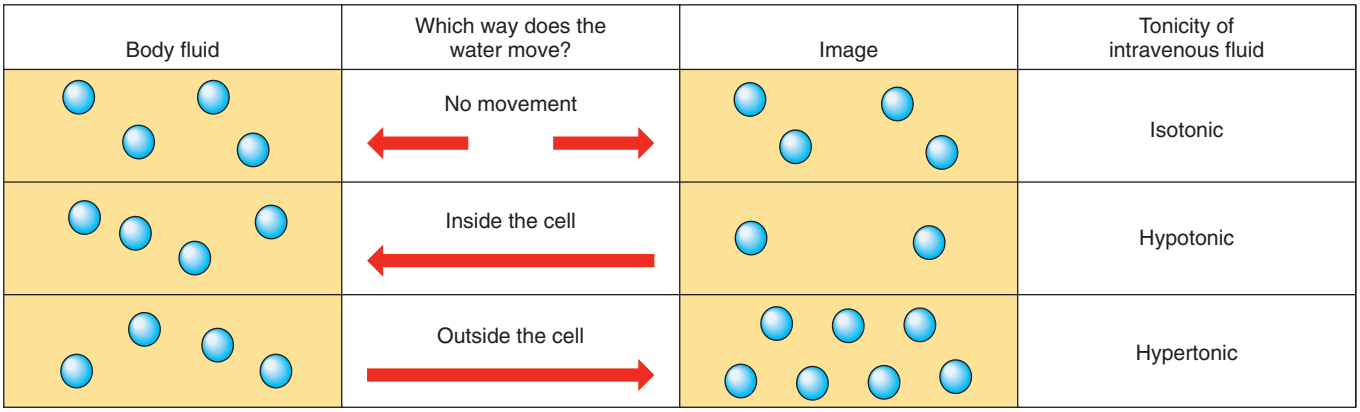

**Figure 26.5** Fluid tonicity

**TABLE 26.3 | Average adult fluid balance as millilitres of water**

| Input | Amount (mL) |
|---|---|
| Drinks | 1500 |
| Food | 800 |
| Metabolism (breakdown of food) | 200 |
| Total | 2500 |
| **Output** | |
| Urine | 1500 |
| Breathing and sweating | 800 |
| Stools | 200 |
| Total | 2500 |

*Adapted from Welch 2010*

- Reduced thirst sensation with ageing
- Fluid restrictions for medical conditions such as heart failure and renal disorders (Shepard 2011).

## Fluid intake

Fluid gain in the body is a homeostatic mechanism triggered by dehydration (McLafferty et al 2014). Fluid intake is mainly regulated by the sensation of thirst and liquid intake, and hydration requirements are highly individual depending on the person's age, gender, body mass, environment and activity levels (Coe & Williams 2011). The normal daily turnover of water in the body is equivalent to approximately 2500 mL (Welch 2010). See Table 26.3 to view the average adult fluid balance.

## Fluid output

Fluid loss from the body and the volume of body water is mainly regulated by the kidneys, determined by the levels of sodium chloride excreted in the urine through hormonal control (McLafferty et al 2014). **Sensible losses** are those which can be measured. These losses are comprised of urine and faeces and amount to approximately 1700 mL daily (Welch 2010). **Insensible fluid losses** occur in the form of invisible vaporisation and are difficult to measure. Insensible losses occur through the skin and lungs, amounting to approximately 800 mL daily.

Increased water loss is associated with an accelerated metabolism. Factors that potentially increase fluid loss in the body can include:

- High temperature
- High altitude
- High-fibre diet
- High sodium intake
- Caffeine and alcohol consumption
- Exercise.

### CRITICAL THINKING EXERCISE 26.1

**Fluid excess**

Joan, 80 years old, was admitted to hospital after seeing her GP. She presented with swollen ankles, pitting oedema and shortness of breath. She has a medical history of renal impairment and hypertension. Recently her medication dosages had been changed to manage her condition. She was confused as to what tablets she was to take and thinks she may have missed some of her regular doses. Her symptoms developed progressively over the past week. Considering Joan's symptoms, based on her medical history what specific medication do you think she may have missed which may have led to her situation?

## The antidiuretic hormone (ADH)

Several mechanisms are integral in the maintenance of fluid balance and homeostasis. They are briefly discussed in Table 26.4. The **antidiuretic hormone** (ADH) is the primary regulator of water balance. ADH is secreted when plasma concentration is elevated or when blood volume or blood pressure is decreased. When plasma concentration is increased, the osmoreceptors in the hypothalamus respond by stimulating the sensation of thirst to encourage fluid intake. The osmoreceptors also signal the posterior pituitary to release ADH, increasing the reabsorption of water by the kidneys (Figure 26.6). This reduces the amount of water lost in the urine and the reabsorbed water reduces plasma concentration (Craft & Gordon 2015). Clinical Interest Box 26.2 lists other factors that may trigger thirst when fluid volume is normal.

## Electrolytes

Electrolytes are also commonly referred to as 'solutes'; the two terms are used interchangeably and carry the same meaning. During this chapter the term electrolytes will be used to avoid any confusion for the reader.

**Electrolytes** are substances that dissociate into electrically charged particles called 'ions'. These can be negatively or positively charged—known as **anions** and **cations** respectively. Electrolytes have an 'osmotic potential'—their ability to pull water into a compartment. Sodium and dextrose are examples of electrolytes with high osmotic potentials. Movement of these electrolytes can result in major fluid shifts between the ICF and ECF (Craft & Gordon 2015). Table 26.5 lists some familiar anions and cations.

Electrolytes vary in number depending on whether they belong inside or outside the cell (in the ICF or ECF). For example, sodium ($Na^+$) is the most abundant cation outside the cells (in the ECF), whereas potassium ($K^+$) is the most predominant cation inside the cell (in the ICF). It is critical for nerve function that electrolytes retain their numbers in their relative compartments to maintain a 'charge'. If this charge is lost, it will ultimately impact on the transmission of electrical impulses across the cell membranes of nerve and

**TABLE 26.4 | A systems approach to fluid balance**

| | |
|---|---|
| Hypothalamus and pituitary | The primary regulator of fluid intake is the thirst mechanism. Thirst can result from fluid loss or an increase in plasma osmolality (an increase in plasma concentration). The thirst centre, located in the hypothalamus, is highly sensitive to changes in the concentration or osmolality of the blood. A change in the blood osmolality or a decrease in blood volume stimulates osmoreceptors in the hypothalamus to trigger the sensation of thirst and the release of the antidiuretic hormone (ADH). ADH is released from the posterior pituitary and acts in the renal tubules, causing water reabsorption. Through these mechanisms, there is an increase in water in the body and a decreased plasma osmolality (Craft & Gordon 2015). |
| Renal control<br>Aldosterone<br>Renin–angiotensin system (RAS) (see Figure 26.6) | In an average adult, total blood volume is filtered through the kidneys numerous times daily (Brown et al 2015). Most of this filtrate (99%) is reabsorbed, resulting in the production of approximately 1500 mL of urine daily. Fluid and electrolytes are selectively reabsorbed in the renal tubules according to the plasma concentration. The renal tubules are where the ADH and aldosterone perform their actions.<br>Aldosterone secretion can be stimulated by decreased renal perfusion: a person presenting with a low blood pressure, for instance. Aldosterone has the ability to retain sodium and excrete potassium. It forms part of the renin–angiotensin system.<br>In response to reduced renal perfusion, renin is released by the kidneys. Angiotensinogen is produced by the liver and is also found in the blood. Renin is an enzyme; it reacts with angiotensinogen to produce angiotensin I which is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II activates the secretion of ADH and aldosterone. Aldosterone works to reabsorb both sodium and water in the renal tubules. The end result is the restoration of plasma volume and concentration. |
| Adrenal cortical control | Glucocorticoids and mineralocorticoids are secreted by the adrenal cortex and both play a role in fluid and electrolyte imbalance. Glucocorticoids have an anti-inflammatory effect and increase glucose levels in the plasma. Cortisol is an example of a glucocorticoid. Mineralocorticoids, such as aldosterone, work by increasing sodium retention and thus water reabsorption, and excretion of potassium. An increase in the secretion of these steroid hormones is associated with physical and psychological stress. |
| Cardiac control | An elevation in blood volume or blood pressure causes atrial natriuretic peptide hormone (ANP) to be released from cells located in the atria of the heart. ANP inhibits activation of the renin–angiotensin system (RAS), promoting excretion of sodium and water. |
| Gastrointestinal control | The gastrointestinal tract secretes approximately 800 mL of fluid a day and in a healthy adult most of this is reabsorbed (Brown et al 2015). A small amount of fluid is eliminated in faeces. From this information, it is easy to imagine the impact diarrhoea and vomiting would have on the secretion and absorption of water. |

muscle cells (Craft & Gordon 2015). The detrimental impact electrolyte imbalances might have on maintaining health can be imagined.

Discussion of all the electrolytes is beyond the scope of this chapter. Electrolyte imbalances commonly encountered in the clinical environment will be discussed and a summary of common themes associated with electrolyte imbalances in general will be presented. See Table 26.6 for the blood values of electrolytes. It is important to note that normal laboratory values for tests may vary and be specific to the health setting.

## Fluid and electrolyte imbalance

Several factors can disturb the body's **fluid** and electrolyte **balance**, resulting in **fluid volume deficit** or **fluid volume excess**. Water volume imbalances are usually accompanied by electrolyte imbalances, particularly sodium. It is important to note that the term 'fluid volume deficit' does not carry the same meaning as 'dehydration' (Brown et al 2015). Dehydration refers to the loss of pure water alone without the associated loss of sodium.

### Dehydration

**Dehydration** can be defined as a sudden loss of 3% or more of the individual's body weight (Welch 2010). Inadequate intake of fluid and an excessive output or combination of the two are the two main issues associated with the problem of dehydration (McMillan & Pitcher 2011). People considered to be at a higher risk for dehydration include: young children, elderly, people with increased insensible fluid loss, confused and immobile individuals, someone with trauma or surgical wounds and individuals being treated with medications that alter electrolyte balance (Rathnayake 2013). Dehydration can lead to hyperkalaemia, cardiac arrhythmia, renal failure and death in some cases. Dehydration is a common clinical presentation among older people and children. People over the age of 85 years are six times more likely to be admitted to

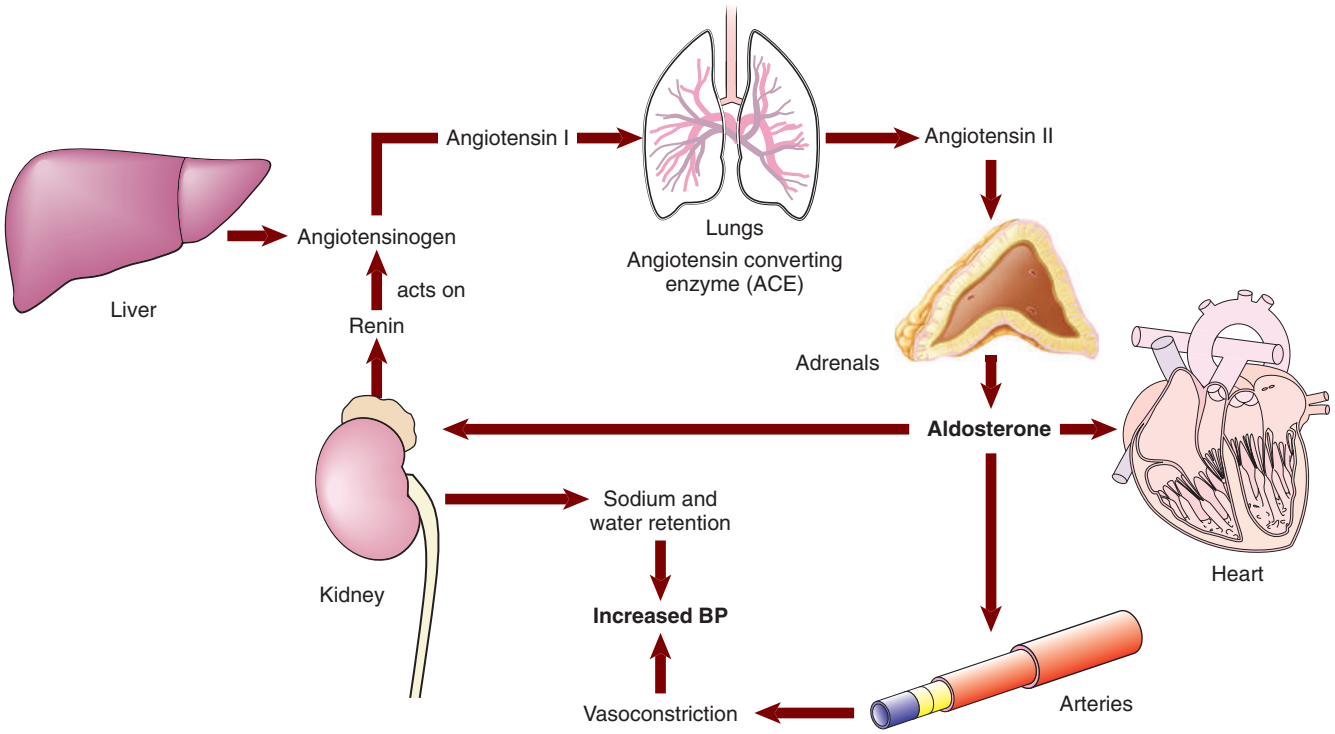

**Figure 26.6** Renin–angiotensin system (RAS)
*(Adapted from Hellman 2016)*

**TABLE 26.5 | Cations and anions**

| Cations | Anions | Major intracellular | Major extracellular |
|---|---|---|---|
| Sodium ($Na^+$) | Bicarbonate ($HCO_3^-$) | $K^+$ | $Na^+$ |
| Magnesium ($Mg^+$) | Chloride ($Cl^-$) | $PO_4^-$ | $Cl^-$ |
| Potassium ($K^+$) | Phosphate ($PO_4^-$) | $Mg^+$ | $Ca^+$<br>$HCO_3^-$ |

## CLINICAL INTEREST BOX 26.2 Other factors that can trigger thirst when fluid volume is normal

Actions such as mouth breathing or eating dry or salty foods can be misinterpreted by the body as thirst. Situations such as these can cause additional fluid intake even though the osmolality of the blood or the blood volume is within normal range.

**TABLE 26.6 | Electrolyte values**

| | |
|---|---|
| $Na^+$ | 135–145 mmol/L |
| $Cl^-$ | 98–110 mmol/L |
| $K^+$ | 3.5–5.0 mmol/L |
| $Ca^+$ | 2.2–2.6 mmol/L |
| $Mg^+$ | 0.7–1.1 mmol/L |
| $PO_4^-$ | 0.7–1.3 mmol/L |
| $HCO_3^-$ | 22–26 mmol/L |

hospital for dehydration, while dehydration in children is a leading cause of morbidity and mortality worldwide (Welch 2010).

Special considerations for older people include:

- Loss of appetite and thirst sensation
- Physical changes resulting in loss of independence
- Biochemical effects of ageing
- Cognitive impairment.

Comorbidities can also have a profound effect on hydration. For example, individuals experiencing incontinence will frequently reduce their fluid intake; this can cause other problems and predispose the person to urinary tract infections (Welch 2010). Dehydration in acutely ill individuals

causes decreased blood circulation volume, seriously affecting cardiovascular and renal functions (McGloin 2015). Some of the effects of dehydration in an acutely ill person include:

- Poor cognition and confusion
- Reduced activity levels
- Headache and fatigue
- Reduced skin turgor
- Sunken and dry eyes
- Dry lips and oral mucosa (McGloin 2015).

The opposite of dehydration is over-hydration. Over-hydration can have a serious effect on people with underlying pathological conditions such as renal failure and heart failure (McMillan & Pitcher 2011). This occurs when the body is unable to deal with the excess water simply by increasing urine output resulting in fluid retention. Excess fluid leaks into the surrounding tissue and is drawn into the cells causing them to swell (oedema). In the lungs fluid leaks through the capillaries, resulting in fluid accumulation and breathing difficulty (dyspnoea) (McMillan & Pitcher 2011).

## Fluid volume deficit

**Fluid volume deficit** is also called hypovolaemia and refers to the abnormal loss of both body fluid and electrolytes in similar proportions from the ECF (Berman et al 2015). Causes for fluid volume deficit can include:

- Decreased fluid intake as a result of unavailability of fluids, or secondary to other conditions (e.g. unconsciousness)
- Increased fluid output secondary to other conditions (e.g. diarrhoea, vomiting, excessive urine output, hyperventilation, excessive perspiration, diabetes insipidus, prolonged fever, haemorrhage or inadequate replacement of aspirated or drained fluids)
- Increased electrolyte load secondary to other conditions; (e.g. hyperglycaemia associated with uncontrolled diabetes mellitus, excessive intravenous infusion of hyperosmotic or concentrated solutions of glucose or sodium bicarbonate).

Fluid volume deficit can also occur when fluid shifts abnormally from the plasma to the interstitial space. This is commonly referred to as 'third-space fluid shifts' in the clinical environment. There is not an absolute loss of fluid: it has simply moved to another compartment. Either disease process causing this shift creates an imbalance in hydrostatic and oncotic pressure and/or there is destruction of the semi-permeable membrane that usually contains fluids within their compartments. Examples of these disease processes include:

- Burns
- Intestinal obstruction
- Ascites
- Sepsis.

The signs and symptoms of fluid deficit include:

- Thirst
- Reduced urine output and increased urine concentration
- Drier mucous membranes and sunken eyes
- Headache and confusion
- Weak and thready pulse, and increased capillary refill time
- Reduced blood pressure and rapid shallow breathing (McMillan & Pitcher 2011).

## Fluid volume excess

**Fluid volume excess**, also referred to as hypervolaemia, is a condition whereby the body retains both water and sodium in similar proportions to the normal ECF (Berman et al 2015). This could be as a result of excess intake or due to disease processes that result in an imbalance in hydrostatic and oncotic pressures causing fluid to shift into the vascular compartment or shift into the interstitial space. The latter exhibits signs such as oedema. Although the overall volume of the ECF does not change, it does affect the volume of fluid in the intravascular space. Examples of these disease processes include:

- Excessive administration of intravenous fluids or hypotonic solutions
- Disturbance of homeostatic mechanisms (e.g. water retention resulting from kidney, cardiac or liver failure)
- Insufficient sodium (e.g. from use of diuretic medications)
- Inappropriate ADH secretion due to cerebral infections, head injury or increased intracranial pressure (Brown et al 2015).

Symptoms of fluid retention vary depending on the severity of fluid overload. In the case of acute fluid overload there may be sudden onset of acute dyspnoea as a result of fluid in the lungs. A person with chronic history of fluid overload may show signs of fatigue, dyspnoea and pitting oedema (Shepard 2011).

### CRITICAL THINKING EXERCISE 26.2

**Fluid balance**

A 78-year-old man was having multiple IV antibiotics throughout the day. Each dose was given with 100 mL normal saline six times a day. Nursing care included 6/24 hourly vital signs observations to be recorded, daily weight, fluid balance chart, total fluid restriction of 1200 mL daily and a low-salt diet. The person has renal impairment. After 24 hours he is exhibiting signs of swollen ankles and shortness of breath. The oral intake column on the fluid balance chart shows 1200 mL and output is 800 mL over 24 hours. What has caused the person's symptoms and fluid retention in this case? What is the critical issue with the fluid balance charting for this person?

## Oedema

**Oedema** (swelling) occurs due to the accumulation of fluid in the interstitial spaces (Craft & Gordon 2015). Causes of oedema include increased capillary hydrostatic pressure, where fluid from the vascular space is forced into the interstitial spaces. This can occur in individuals with heart failure.

A lowered plasma oncotic pressure also causes fluid to shift into the interstitial spaces; this can occur in a person with a low albumin level. Increased capillary permeability affects the ability of the capillary membranes to maintain fluid within the vascular compartment, resulting in fluid shift to the interstitial space. Examples of conditions with increased capillary permeability include burns and systemic inflammatory response syndrome (SIRS). Figure 26.4 shows capillary hydrostatic and oncotic pressure.

## ELECTROLYTE IMBALANCES

Electrolyte imbalance involves either a deficit or an excess of electrolytes such as sodium, potassium, calcium, magnesium or phosphate. Sodium and potassium imbalance are two most common presentations associated with fluid and electrolyte imbalances (McLafferty et al 2014).

### Sodium ($Na^+$)

Normal plasma value: 135–145 mmol/L. Sodium imbalance is one of the most prevalent electrolyte imbalances encountered in the clinical environment. Sodium plays an integral role in the maintenance of irritability and conduction of nerve and muscle tissue. It impacts on volume and concentration of ECF, maintains acid–base balance and influences levels of other electrolytes such as potassium and chloride.

#### Sodium homeostasis

The kidneys are the primary organs responsible for maintaining the plasma concentration (ECF) of sodium within the tightly controlled limits of 135–145 mmol/L. Sodium balance is regulated by the hormone **aldosterone** which is secreted by the adrenal cortex (Craft & Gordon 2015). If plasma sodium levels are decreased, aldosterone is secreted to increase sodium reabsorption in the kidney tubules, and as a result the plasma sodium level will rise.

Sodium imbalances are referred to as being either hyponatraemia or hypernatraemia. Hyponatraemia refers to sodium deficit—a low concentration of sodium in the ECF caused either by the loss of sodium or by gaining more water. Hyponatraemia can be caused by impaired renal function, fluid loss related to burns, impaired ADH secretion, sodium loss associated with diuretics or hyperglycaemia (McLafferty et al 2014). Decreased sodium causes fluid to move by osmosis from the less concentrated ECF compartment to the ICF space, resulting in a fluid shift. This fluid shift can lead to swelling of the cells and cerebral oedema. Severe hyponatraemia can cause seizures and neurological damage (Dempsey et al 2014). Hypernatraemia is the opposite—it refers to an excess of sodium in the ECF as a result of water loss or an overall surplus of sodium. Hypernatraemia can occur as a result of excessive consumption of salt in the diet, prolonged diarrhoea and vomiting or dehydration. Symptoms of hypernatraemia include an intense thirst, hypertension, oedema, agitation and convulsions (McLafferty et al 2014). See Table 26.7 for a list of conditions and signs and symptoms associated with hypernatraemia and hyponatraemia. These will be dependent on whether there is an associated hypervolaemic or hypovolaemic state. Refer to the online resource Nutrient Reference Values from NHMRC for information about specific electrolyte values.

**TABLE 26.7 | Causes, signs and symptoms associated with hypo/hypernatraemia**

| Causes of hyponatraemia | Associated signs and symptoms |
|---|---|
| • Water retention (dilutional): chronic heart failure, renal failure, liver failure<br>• $Na^+$ in excess of water: diuretics, diarrhoea, vomiting, hyperglycaemia, NG suctioning, third space losses | Cramps<br>Muscle weakness<br>Headache<br>Anorexia<br>Nausea<br>Confusion<br>Seizures<br>Ataxia<br>Respiratory depression<br>Coma |
| **Causes of hypernatraemia** | **Associated signs and symptoms** |
| • Dehydration: pure water loss caused by insensible losses: sweat, burns, hyperventilation, GIT losses, diabetes insipidus (DI), hyperglycaemia, excessive $Na^+$ intake, IV fluids | Hypovolaemic signs: tachycardia, thready pulse, hypotension<br>Thirst<br>Dry mucous membranes<br>Cool extremities<br>Muscle weakness<br>Lethargy<br>Confusion<br>Seizures<br>Coma |

**CRITICAL THINKING EXERCISE 26.3**

**Electrolyte imbalance**

Nathan is a participant in a local marathon. He is brought in to ED by ambulance after collapsing at the event. He had been drinking water only during the run. His results show BP 95/55, HR 60, BGL 3 mmol/L, sodium 126 mmol/L, potassium 3.5 mmol/L and he is unable to pass urine. Consider his results. What has happened to Nathan?

### Potassium ($K^+$)

Normal plasma value: 3.5–5.0 mmol/L. Potassium is the chief intracellular cation and has a major role in the concentration of intracellular fluid and neural function. It is particularly essential for the neuronal function of cardiac, musculoskeletal and smooth muscle. Because of this, imbalances in the potassium levels in the intracellular or extracellular environment can be potentially life threatening and

## CLINICAL INTEREST BOX 26.3 Nursing considerations for potassium

- Foods rich in potassium may need to be restricted in individuals with chronic renal failure. Such foods include dates and bananas
- IV $K^+$ administration can be painful
- Consider oral route of administration if appropriate to the clinical situation
- Preparations such as Resonium exchange $K^+$ for calcium ($Ca^+$) in the gut and have a long-lasting effect
- Administration of blood products can cause hyperkalaemia and hypocalcaemia
- $K^+$ levels are usually kept in the high/normal range for individuals with cardiac complaints (i.e. >4.0)
- Digoxin is a medication commonly encountered in the clinical environment. Therapeutic levels of this drug are influenced by serum $K^+$ levels.

often present as a medical emergency (Craft & Gordon 2015). Clinical Interest Box 26.3 outlines the nursing considerations for an individual taking potassium.

### Potassium homeostasis

Potassium is regulated by the kidneys. It is filtered by the nephrons, reabsorbed back into the blood and secreted according to bodily requirements and functioning. An alteration in the flow of urine also influences the secretion of potassium. For a person taking **diuretics** (substances that increase excretion of water) the urine flow will be increased, resulting in increased levels of potassium in the urine. Aldosterone also increases the secretion of potassium when levels are high. Potassium balance is also affected by acid–base disturbances. For example, an increase in hydrogen ions ($H^+$) will cause potassium to shift outside the cell in exchange for $H^+$ ions to maintain a balance of cations on either side of the cell.

Potassium imbalances are referred to as being either hypokalaemia or hyperkalaemia. Hypokalaemia refers to potassium deficit in the ECF. It can be caused by excess fluid loss, dehydration, decreased levels of potassium intake, renal impairment, overuse of laxatives, prolonged diarrhoea and vomiting and some diuretics. Symptoms include thirst, muscle weakness, cramps, increased urine output and confusion. Low potassium can have an effect on cardiac cell activity and cause arrhythmias in severe cases (McLafferty et al 2014). Hyperkalaemia is the excess of potassium in the ECF. It can be caused by high potassium intake, tissue trauma caused by burns or accidents and renal failure inhibiting potassium excretion. Symptoms include skeletal muscle weakness, paralysis, irritability, nausea and vomiting. High potassium levels can have a serious effect on the cardiac muscle function and cause arrhythmias and even cardiac arrest if untreated (McLafferty et al 2014). Table 26.8 outlines conditions and signs and symptoms associated with hyper/hypokalaemia.

**TABLE 26.8 | Causes, signs and symptoms associated with hypo/hyperkalaemia**

| Causes of hyperkalaemia | Associated signs and symptoms |
|---|---|
| • Renal failure<br>• Acidosis<br>• IV $K^+$ administration<br>• Blood products<br>• $K^+$ sparing diuretics<br>• Trauma<br>• Burns | Lethargy<br>Confusion<br>Muscle weakness<br>Calf pain<br>ECG changes<br>Arrhythmias |
| **Causes of hypokalaemia** | **Associated signs and symptoms** |
| • Diuretics<br>• NG suction<br>• Diarrhoea and vomiting<br>• Starvation<br>• Alkalosis | Fatigue<br>Muscle weakness/cramps<br>Nausea/vomiting<br>Arrhythmias<br>Digoxin toxicity |

## NURSING ASSESSMENT OF INDIVIDUALS WITH FLUID AND/OR ELECTROLYTE NEEDS

In the healthcare environment nurses are usually responsible for accurate assessment and adequate fluid management for individuals in their care. Poor fluid management and record keeping can contribute to the worsening of a person's health condition. The nursing process is integral to the provision of person-centred care for individuals in healthcare settings. The process encompasses the following:

- Assessment
- Nursing diagnosis
- Planning
- Implementation
- Evaluation.

The process is not merely a series of steps; a critical thinking approach is adopted by analysing at each stage and updating or changing plans according to the individual's needs (Crisp et al 2013). (Read Chapter 17 for further information on the nursing process.)

The assessment phase refers to the collection, validation, organisation and documentation of data retrieved from the individual (Berman et al 2015). During this phase the nurse will gather information about the person's health status. The use of a model to promote systematic data collection to prevent the omission of important relevant data is recommended. This data will include subjective and objective information, both of which are essential. This will provide the nurse with a holistic overview of the individual's health status to inform the provision of person-centred care. Also see the sample Progress Note Example 26.1 for a person admitted with fluid and electrolyte needs and monitoring.

## PROGRESS NOTE EXAMPLE 26.1

| | |
|---|---|
| 21/03/2015<br>1600 hrs | Nursing: Mrs Kay was admitted for management of congestive heart failure after seeing her GP, complaining of swollen ankles and shortness of breath. Following her admission to hospital the RMO has ordered blood tests FBE and U & E, random blood glucose and a urine test. She is also referred for chest x-ray and ECG. Nursing orders included 2/24 hourly vital signs observations to be recorded, daily weight, fluid balance chart, fluid restriction of 1200 mL daily and a low-salt diet.<br>***M. E. Reynolds*** **(Reynolds) EN** |

With specific reference to fluid and electrolyte needs, obtaining an initial health history would be an appropriate starting point. This could include questioning the person about their present illness/condition/complaint and their past history, including family history where relevant. Subjective data collection should include questioning the person about their lifestyle habits and psychosocial status. For the assessment of fluid and electrolyte needs it is particularly important to gather data on:

- Past medical history: any conditions associated with fluid/electrolyte disturbances
- Medications: any medications associated with fluid/electrolyte disturbances
- Diet: any specific requirements/restrictions, eating habits, supplements, factors limiting access to adequate nutrition/fluid intake
- Exercise: how often, type of exercise and the conditions; whether there are specific nutritional/fluid requirements associated with it
- Other personal habits: alcohol consumption, sports drinks
- Social data: cultural affiliation (some religious practices include fasting during certain periods)
- Psychological: mental health history (e.g. eating disorders; anxiety, stress) (Berman et al 2015).

Table 26.9 outlines assessment findings associated with fluid volume deficit or excess.

Gathering of objective data will include a thorough physical assessment of the person, frequently performed using a systems approach to facilitate comprehensive systematic data collection. These physical findings will be dependent on the associated disease process the person is experiencing. For example, a person with acute pulmonary oedema may be agitated and confused due to hypoxaemia caused by reduced ability of oxygen to diffuse into the pulmonary capillaries.

## Urine

**Urine** volume and concentration is a helpful clinical assessment about a person's fluid, electrolyte and acid balance status (Dempsey et al 2014). It is important to also be aware that when assessing urine there are no absolutes. Urine tests may not be reliable especially in individuals with medical conditions such as renal or heart failure or people taking diuretics. Diuretics are prescribed to manage conditions associated with excessive fluid retention and therefore need to be taken into consideration when assessing urine and urinary output (Kaufman 2014).

Urine **specific gravity** (SG) refers to the density of urine compared with water. Osmolality refers to the concentration of the urine. Urine SG can be measured with a dipstick using a fresh urine sample or through laboratory tests. Normal urine specific gravity is between 1.005 and 1.030 and osmolality between 500 and 1200 mOsm/kg. In states of volume deficit, urine SG can be elevated and the osmolality high, usually accompanied by a decrease in urine output (except in diabetic ketoacidosis). In volume excess, urine tends to be dilute with a low SG and osmolality. See Clinical Interest Boxes 26.4 and 26.5 for more tips on undertaking a physical assessment and additional information to consider when assessing fluid needs of individuals.

## Paediatric assessment

There are some important issues to consider in paediatric assessments. These issues will obviously depend on the age of the child and a detailed account is beyond the scope of this chapter. However, an overview of questions to consider includes:

- Feeding regimen—are there problems with feeding (e.g. lethargy, poor sucking, regurgitation, colic, irritability)?
- What is the typical intake over 24 hours?
- Type of formula?
- Type of fluids?
- Number of wet nappies?
- Bowel movement—any vomiting/diarrhoea?
- Any weight gain/loss?
- Allergies?

Important aspects of physical assessment include:

- Obtaining age-appropriate vital signs
- Assessment of state of alertness—how interactive is the child?
- Sunken eyes, pallor, reduced tears, dry arm creases, dry mucous membranes or depressed fontanelle (age appropriate) may suggest dehydration
- Weight.

If the child's current weight and pre-morbid weight are available, this information can be the most reliable indicator of the fluid volume deficit (refer to the online resource The Royal Children's Hospital Melbourne, *Clinical Practice Guideline: Intravenous Fluids*). In addition there are also physical signs frequently encountered with varying degrees of fluid volume deficit. Volume loss in children is commonly expressed as a percentage of body weight. For example, a 10 kg child who is 5% dehydrated would have a fluid deficit of approximately 500 mL. See Table 26.10 for clinical signs of

## TABLE 26.9 | Assessment findings associated with fluid volume deficit or excess

| Body system | Physical assessment findings—fluid volume excess | Physical assessment findings—fluid volume deficit |
|---|---|---|
| Central nervous system | Agitation<br>Confusion<br>Numbness, tingling, seizures with associated electrolyte losses | Headache<br>Irritability/agitation<br>Confusion/delirium<br>Dizziness<br>Lethargy<br>Numbness, tingling, seizures with associated electrolyte losses |
| Respiratory | Increased work of breathing: use of accessory muscles<br>Dyspnoea<br>Orthopnoea<br>Adventitious breath sounds: crackles, wheezes<br>Hypoxaemia | Non-specific findings<br>Increased work of breathing related to disease process |
| Cardiovascular | Bounding pulse<br>Distended neck veins<br>Third heart sound<br>Oedema<br>Hypertension | Tachycardia<br>Thready pulse<br>Orthostatic blood pressure changes<br>Hypotension<br>Decreased capillary refill<br>Flat neck veins<br>Arrhythmias associated with electrolyte imbalances |
| Renal | Oliguria or anuria | Oliguria or anuria |
| | Diuresis | Increased urine specific gravity |
| Gastrointestinal | Distended abdomen | Abdominal cramps<br>Diarrhoea/vomiting<br>Sunken or distended abdomen<br>Hyperactive bowel sounds |
| Skin | Non-specific | Cracked lips<br>Tongue furrows<br>Dry mucous membranes<br>Decreased skin turgor (not reliable in older adults)<br>Decreased sweat<br>Reduced or increased body temperature<br>Flushed or pale skin |

### CLINICAL INTEREST BOX 26.4 Physical assessment tips for nurses

- Physical examination is a critical element for assessing and treating disorders of fluid balance
- It is often more reliable than data obtained by invasive monitoring
- Weight gain is the most consistent sign of volume excess
- Gravity-dependent oedema is an important finding; not usually apparent until 2–4 kg of fluid have been retained

### CLINICAL INTEREST BOX 26.5 Important nursing considerations when assessing fluid needs

- **F**luid/dietary restrictions
- **L**oss of fluid: what is the source, what is the fluid and electrolyte imbalance associated with this?
- **U**nderlying disease processes
- **I**V fluids: what treatment is the person receiving and why?
- **D**rugs, digoxin, diuretics
- **S**ystems assessment

**TABLE 26.10 | Characteristics of dehydration according to severity for children <12 years**

| | Mild | Moderate | Severe |
|---|---|---|---|
| Infants | 1–5% | 6–9% | >10% |
| Older children | 1–3% | 3–6% | >6% |
| Pulse | Full, normal | Rapid | Rapid, weak |
| Systolic BP | Normal | Normal, low | Very low |
| Urine output | Decreased | Decreased | Oliguria |
| Buccal mucosa | Slightly dry | Dry | Parched |
| Anterior fontanelle | Normal | Sunken | Markedly sunken |
| Eyes | Normal | Sunken | Markedly sunken |
| Skin turgor/ capillary refill time | Normal | Decreased | Markedly decreased |
| Skin | Normal | Cool | Cool, mottling |

dehydration that might be observed in children less than 12 years old, depending on the severity of fluid loss. See Clinical Interest Box 26.6 for further details on estimating volume loss in children.

## Care planning and intervention

The data gathered from the comprehensive person-centred assessment will inform nursing diagnoses, subsequent planning of care and nursing interventions. The formulation of nursing diagnoses requires critical thinking skills to be utilised by the nurse (Crisp et al 2013). Diagnostic statements should be specific, including a 'qualifier' in the statement. These qualifiers include:

- Deficient
- Impaired
- Decreased
- Ineffective
- Compromised.

The statement should also include the causative factors.

Most healthcare organisations utilise pre-printed standardised care plans to some degree. Whether the plan is prewritten or not, an integral component of person-centred care is that the plan must be individually relevant to the particular individual's needs. The majority of plans frequently incorporate the key components of:

- Nursing diagnosis/individual's problem
- Desired outcomes/goals
- Nursing interventions
- Rationales
- Evaluation.

(See Nursing Care Plan 26.1 for a sample of how a plan might be provided for a person with fluid and electrolyte needs.)

Some important general aspects of care to assist an individual who requires encouragement with their usual fluid intake, or requires assistance in meeting a higher than usual intake, include:

- Providing assistance to individuals who experience difficulty in pouring fluid or holding a cup or glass
- Explaining the importance of consuming the normal or increased fluid volume
- Providing the individual's preferred types of fluid if not contraindicated
- Ensuring that all fluids are presented attractively and at the correct temperature
- Encouraging smaller amounts of fluid at more frequent intervals
- Ensuring that about 75% of the total volume of fluid is taken by early evening so that sleep is undisturbed
- Ensuring that toilet facilities are easily accessible
- Documenting input and output to assess and maintain the person's fluid and electrolyte balance.

Some people may have restrictions on their fluid intake for medical reasons: those with renal failure, for example. Basic nursing actions to assist individuals in this group might include:

- Explaining to the person and significant others the importance of consuming only the volume ordered
- Planning to distribute fluid evenly throughout the day, including fluid to swallow medications
- Encouraging small amounts at regular intervals to avoid thirst

### CLINICAL INTEREST BOX 26.6 Assessment of dehydration in children

An evaluation of dehydration is based on clinical signs and the degree of dehydration. The degree of dehydration is based on recent loss of body weight.

- Mild dehydration: less than 3% in older children or less than 5% in infants, generally no clinical signs
- Moderate dehydration: 5% to 10% in infants and 3% to 6% in older children, with some clinical signs
- Severe dehydration: more than 10% in infants and more than 6% in older children, with multiple pronounced clinical signs.

*(Perry et al 2014)*

## NURSING CARE PLAN 26.1

**Assessment**: Fluid balance and hydration
**Issue/s to be addressed**: At risk of dehydration due to impaired swallow mechanism
**Goal/s**: Prevent dehydration through:
Maintaining fluid balance—input and output
Maintain urine output at 30 mL/hr
Maintain urine specific gravity 1.005–1.025
Maintain current weight
Maintain serum Na levels within the normal range
Maintain moist mucous membranes

| Care/Actions | Rationale |
|---|---|
| Monitor fluid intake and output on a fluid balance chart and communicate imbalances with medical staff | To identify fluid volume deficit/excess early and prevent complications |
| Administer and monitor intravenous therapy as prescribed and record on the fluid balance chart | IV therapy is an important adjunct in maintaining hydration in a person unable to tolerate oral fluids |
| Perform urinalysis to assess SG | Urine specific gravity is an indicator of increased or decreased serum osmolality |
| Daily weights | Weight loss or gain is a reliable indicator of fluid loss/gain |
| Monitor serum Na levels | Serum Na levels are strongly associated with fluid loss/gain |
| Observe all mucous membranes and provide necessary care to maintain integrity | Mucous membranes are a reliable indicator of hydration status and they may be at risk of breakdown |
| Document findings and liaise with interdisciplinary team accordingly | Alterations may require prompt medical management |

**Evaluation**: Assessment and monitoring of individual to include:
Fluid intake and output on a fluid balance chart
Status of IV site, IV cannula and dressing
Check IVT flow rate
Mobility and comfort level with IVT
Urinalysis
Daily weight
Serum Na levels
Observation of skin integrity and mucous membranes
Vital signs (Temp, BP, P, R)

- Providing thirst-quenching fluids (e.g. water) and avoiding sweetened drinks that increase thirst
- Notifying ancillary staff (e.g. dietitians and kitchen staff) of changes
- Ensuring that the person's mouth does not become dry by regular attention to oral hygiene
- If not contraindicated, the person may be permitted sweets or sugar-free gum to stimulate production of saliva to keep the mouth moist.

## Weighing and fluid balance charts

Clinical assessment of individuals, reviewing fluid balance charts and blood chemistry are key elements for assessing fluid balance and hydration (Shepard 2011). Fluid balance charts (Table 26.11) are commonly utilised in clinical practice and are considered to be an important aspect of nursing documentation. The fluid balance chart is a record of fluid input and output, documented over a 24-hour period, indicating if the person is in fluid balance, deficit or overload (McGloin 2015). The charts are used concurrently with the person's daily weights to assess hydration status. However, an evidence summary presented by the Joanna Briggs Institute (Le 2014) summarises some of the concerns with the use of fluid balance charts, which include inaccurate cumulative fluid balance, inconsistency with standardised body weight measurements, omission or duplication of information, inappropriate chart design and arithmetical errors. Tang and Lee (2010) also report inconsistency and poor documentation with the use of fluid balance charts. The evidence currently recommends the use of daily weights without the use of fluid balance charts (JBI 2014); however, fluid balance charts continue to be used in many healthcare facilities. If the decision is made to use a fluid balance chart, evidence strongly supports the individual's involvement in completing the chart to achieve more accurate charting (Le 2014).

The person should be weighed daily at the same time, wearing the same type of clothing and using the same set of scales. Weight can be measured with a standing scale or chair or bed scale and the measurement should be recorded on the appropriate form. The measurement can be affected by bowel and urine elimination pattern and this should be taken into account. Table 26.12 outlines the key aspects of care for a person with fluid imbalance. See Clinical Skill 26.1 for the correct steps in completing a fluid a balance chart.

## TABLE 26.11 | Sample fluid balance chart

| FLUID BALANCE CHART | | | | | | | | | | IDENTIFICATION LABEL | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| **Date** | **Input** | | | | | | **Output** | | | | | | |
| | | | | | | | | | | OTHER | | | |
| **Time** | **Oral** | **Enteral** | **IV** | **IV** | **IV** | **Total Input** | **Time** | **Urine** | **Faeces** | **Gas asp** | **Wound** | **Total Output** | |
| 0700 | Water 150 mL | | N/S 0.9% 1 L/10 hours | | | 150 mL | | 400 mL | | | | 400 mL | |
| 0800 | | | 100 mL | | | 250 mL | | | | | | | |
| 0900 | | | | | | | | | | | | | |
| 1000 | Tea 150 mL | | 100 mL | | | 500 mL | | | 150 mL (loose) | | | 550 mL | |
| 1100 | Water 150 mL | | 100 mL | | | 750 mL | | 350 mL | | | | 900 mL | |
| 1200 | | | 100 mL | | | 850 mL | | | | | | | |
| 1300 | Water 150 mL | | 100 mL | | | 1100 mL | | 150 mL | | | | 1050 mL | |
| 1400 | Tea 150 mL | | 100 mL | | | 1350 mL | | | | | | | |
| 1500 | | | 100 mL | | | 1450 mL | | | 100 mL (loose) | | | 1150 mL | |

**TABLE 26.12 | Key aspects of care for individuals with fluid imbalance**

| Fluid volume deficit | Fluid volume overload |
|---|---|
| Administer pharmacological interventions (within scope of practice) as prescribed:<br>• Anti-emetics<br>• Medications for the treatment of diarrhoea<br>• Paracetamol for fever if appropriate<br>• IV fluids<br>• Electrolyte replacement as ordered, monitor for effects and consider a 12-lead ECG and continuous cardiac monitoring<br>• Rehydration via nasogastric or gastrostomy tube (if this is the person's usual method of fluid intake). A nasogastric tube may need to be inserted for rehydration—more commonly used in the paediatric setting as a non-invasive method of fluid administration<br>• Continuous nursing assessment and evaluation of response to management<br>• Monitor vital signs—frequency according to the acuity of the person's condition<br>• Infection control measures for individuals with suspected gastroenteritis<br>• Comfort measures—fans, blankets as appropriate<br>• Monitor serum electrolytes and urine SG<br>• Monitor input/output on a chart<br>• Maintain skin integrity and attend to hygiene needs | Administer pharmacological interventions (within scope of practice) as prescribed:<br>• Treatment of the underlying condition may require management with diuretics<br>• Monitor associated electrolyte imbalances and replace as required/prescribed. Consider a 12-lead ECG and continuous cardiac monitoring<br>• Continuous nursing assessment and evaluation of response to management<br>• Monitor vital signs—frequency according to the acuity of the person's condition<br>• Recording fluid balance<br>• Daily or twice-daily weighing<br>• Care of oedematous limbs: increased risk of skin breakdown. Also, reduced healing capabilities due to reduced blood supply<br>• Elevation where appropriate and comfortable<br>• Adhere to dietary/fluid restrictions |

## INTRAVENOUS THERAPY

Management of individuals receiving intravenous therapy incorporates:

- Monitoring of the IV site
- Maintenance of equipment
- The prevention of complications occurring during and after completion of the intravenous (IV) infusion
- Educating the individual
- Assistance with mobility needs
- Continuous assessment.

Insertion of an intravenous cannula is performed by a registered medical officer or a Registered Nurse (RN) who within their scope of practice is certified to insert IV cannulas. Prior to the insertion of a cannula, the most appropriate site is selected, which depends on several factors, including the condition of the person's veins—avoiding areas that are oedematous, infected or otherwise impaired—and general comfort considerations (Figure 26.7).

Other site determinants include:

- A vein in the non-dominant arm is preferably used
- The initial site should be in the most distal part of the vein to allow more proximal replacement in the same vein in the event of cannula blockage, infiltration or phlebitis. A commonly selected site is one of the superficial veins on the dorsum of the hand
- If the site chosen is near a joint, extension and splinting of the limb may be necessary; for example, by back slab (Figure 26.8).

Healthcare facilities will have individual policies and guidelines pertaining to the management and insertion of IV cannulas. An example of a guideline document in relation to management of IV cannulas in the health setting is the NSW guideline for PIVC insertion and post-insertion care in adult patients (NSW Health 2013). As an overview, IV cannulas should be inserted by competent accredited healthcare professionals. They should be inserted utilising a sterile technique and the insertion site labelled with the corresponding date/time to allow for timely removal (usually replaced every 72 hours). Documentation in the person's chart should be completed. An extremely important aspect of care is monitoring the site for complications such as swelling and oedema. A site that is suspicious for infection should be reported and managed immediately. Infections from IV sites can have potentially lethal complications for individuals, and preventing them is integral to hospital quality and risk programs.

The nurse caring for individuals receiving IV therapy has the responsibility of ensuring that the person's care is within their scope of practice. IV fluid is prescribed depending on the desired treatment outcome for the individual. We have previously discussed fluid tonicity in this chapter; it is an extremely important concept relevant to the administration of IV fluid. For example:

- Isotonic solution has the same tonicity as the internal environment of the body—it has approximately the same amount of $Na^+$ concentration. Therefore the administration of this type of fluid is used to increase the circulating fluid volume or simply used for fluid/hydration maintenance. Normal saline (0.9%) is an example
- Hypotonic solution has a lower tonicity or solute concentration than the internal environment. This type of solution will attract water into the cell—causing cells

## CLINICAL SKILL 26.1 Fluid balance charting

**Review and carry out the standard steps for all nursing procedures/interventions**

An accurate fluid balance chart (FBC) should be completed using the correct equipment listed below.

It should be completed immediately post meals (input) and with intravenous fluid hourly. All insensible losses (vomit, NG aspirates/drainage and drain tubes) should be recorded including accurate measurements of urine and faeces.

Six-hourly totals should be recorded which will enable an individual's accurate fluid status.

Healthcare organisations' policy and procedure regarding recording of FBCs should be adhered to.

**NMBA Decision-Making Framework considerations:**

1. Am I educated?
2. Am I authorised?
2. Am I competent?

If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator.

**Equipment:**

Fluid balance chart
Weigh scale (calibrated)
Calculator
Biro (blue/black)
List of correct amounts of fluid containers (oral)
Bed pan and/or urinal
Measuring jug
Appropriate PPE

| Skill activity | Rationale |
|---|---|
| Explain procedure to the individual | Reduces anxiety/apprehension and gains individual's trust and cooperation<br>Reinforces consent of individual |
| Establish the reason for the commencement of a fluid balance chart (FBC):<br>• Fluid restriction<br>• IV fluid administration<br>• Critically ill/haemodynamically unstable individual<br>• Prevention of fluid overload<br>• Dehydration<br>• Electrolyte replacement<br>• Multiple infusions<br>• Blood product administration<br>• Indwelling catheter (IDC)/urinary retention<br>• IV antibiotic administration<br>Check medical orders and review healthcare organisation's policies and procedures regarding FBCs | Ensures correct use of FBC<br>Abides by legal and healthcare organisation's guidelines |
| Ensure a list of the correct amount of millilitres per container of fluid (intake) is available<br>Ensure all IV fluid administration is via an IV pump | Ensures accuracy of individual's intake |
| Ensure urinal, bedpan or plastic urinal female toilet available for the individual to urinate into, or that an IDC is in situ if haemodynamically unstable<br>Ensure all wound drainage, vomitus, loose bowel actions and gastric fluid also recorded on the individual's output | Ensures accuracy of individual's output |
| Maintain hourly 24-hourly fluid balance totals (depending on the medical officer's orders and/or the healthcare organisation's guidelines)<br>Observe for any signs of under- or over-hydration | Establishes an accurate positive or negative balance to determine the individual's fluid status so that intervention may be prompt<br>Prevents circulatory overload and complications |
| Document in the progress notes and report any changes to the relevant registered nurse and/or medical officer. | |

*(Shepherd 2011; Berman et al 2015)*

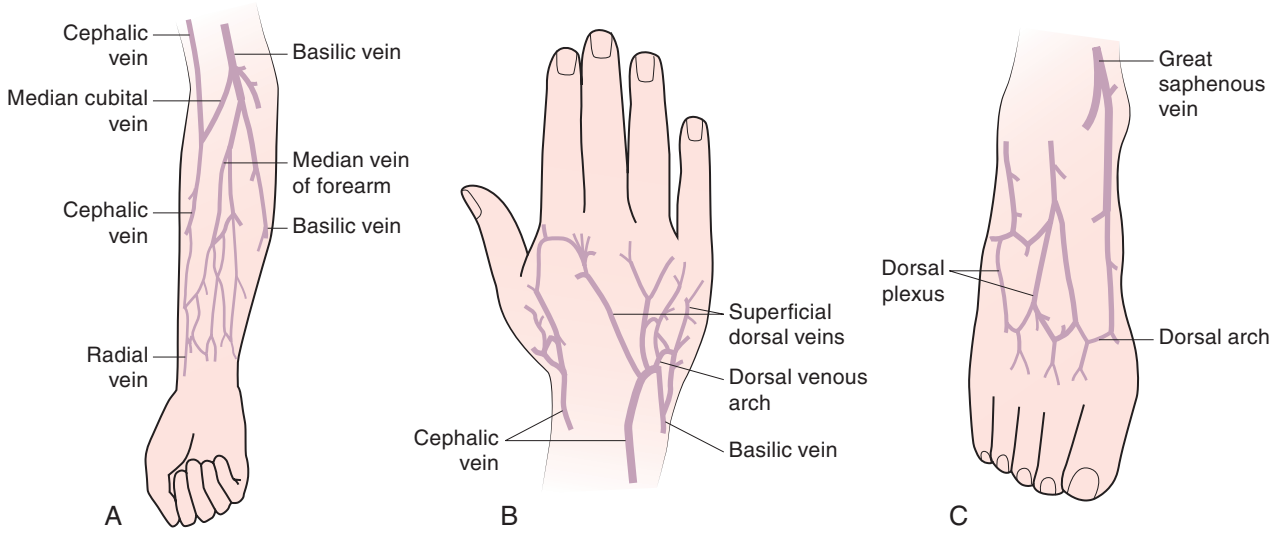

**Figure 26.7** Common IV sites

*(Redrawn from Potter & Perry 2008)*

**Figure 26.8** Back slab

*(Potter & Perry 2008)*

to swell. It is used for individuals who are very dehydrated, individuals with an elevated $Na^+$ (depending on the cause) or increased serum osmolality. 5% dextrose is an example of a hypotonic solution. The dextrose is metabolised (used by the body for energy) so it leaves behind water.

Hypertonic solution has an increased tonicity compared to the internal environment. Therefore it draws water out of the cells and into the vascular space. Twenty per cent albumin is an example. **Albumin** is an important protein in the maintenance of plasma oncotic pressure and so assists with attracting fluid into the vascular compartment.

## Care of individuals with an intravenous infusion

As previously stated within this chapter, nurses have a professional accountability and responsibility to be aware of the scope of their role in relation to the management of IV infusions. The scope of practice and responsibilities for care and management of IV infusions varies in nursing practice in different settings. Enrolled Nurses must ensure that they practise within their scope and educational level in relation to intravenous infusions. See NMBA (2015) Enrolled Nurse and Medicine Administration for specific information about IV administration.

Of prime importance is careful observation of the individual and the IV equipment used during the infusion, and accurate reporting of the person's assessment and vital signs. Complications that may occur when a person has an IV infusion, and which must be recognised and reported immediately, are:

- A flow rate that is too slow or too fast, or cessation of flow
- Infection, pain or infiltration at the insertion site
- Phlebitis of the vein being used for the infusion
- Circulatory overload
- Air embolism.

The nurse also has a responsibility to promote the general comfort of the individual, to ensure that the infusion is administered as prescribed and to observe for and prevent complications. Key aspects related to the care of a person with an IV infusion are described as follows:

- Ensure that the flow rate is set as prescribed and adjusted when necessary to deliver the correct amount of fluid within the prescribed time. Various methods of determining the number of millilitres per minute are used to distribute the total amount of solution equally over the time period prescribed for the infusion
- A calibrated burette (e.g. macrodrip or microdrip volume control set) can be incorporated into the infusion system. Such devices enable very small or precise amounts of fluid to be administered and can also be used when medications are to be given IV. A formula is used to determine the number of drops per minute at which the solution should flow.

To calculate the flow rate, the following formula is used:

$$\frac{\text{Volume (mL)} \times \text{Drop factor (drops/mL)}}{\text{Time (hours) 60 min}} = \text{Drops per minute (dpm)}$$

- When calculating the rate it is essential to know the calibration of the drip rate for each manufacturer's product, as these vary from 10 drops/mL to 60 drops/mL
- The flow rate should be checked every 15 minutes to ensure that the drip rate is stable, then every hour or at the time intervals specified in the institution's policy on IV infusions
- Check the level of solution to determine the volume of fluid remaining in the flask. It is important to ensure that a flask does not empty completely, as this can interfere with the flow rate and permit air to enter the tubing, which could lead to an air embolism. Air emboli can result in sudden decrease in blood pressure, rapid weak pulse, cyanosis and loss of consciousness
- Check the insertion site every 24 hours for signs of infection, inflammation or infiltration. Infection at the insertion site is indicated by redness, warmth, swelling and tenderness. The vein may become injured or irritated and phlebitis may occur. Signs and symptoms that indicate phlebitis are pain, swelling and inflammation along the course of the vein; the vein may also feel hard and warm to touch. Infiltration occurs if the needle becomes displaced, causing IV solution to flow into the surrounding tissues. Signs and symptoms of infiltration are cool skin in the site area, swelling and discomfort at the site, oedema of the limb, sluggish flow rate and absence of blood in the tubing when it is lowered
- Observe the person for signs of over-hydration or circulatory overload, caused by excessive or too rapid fluid administration. Signs and symptoms of circulatory overload include elevated blood pressure, venous dilation (especially of the neck veins), coughing, tachypnoea and shortness of breath
- Check the information on the label of the flask when each new flask is started and at the start of each shift. It is essential that the person receives the prescribed solution; the nurse should therefore follow the nursing protocol regarding checking of IV solutions
- The type, volume and expiry date of the solution is checked. Glass containers are inspected for chips and cracks and the seal over the opening is observed to ascertain if it is intact. Plastic containers should be squeezed gently to detect leaks. The solution is examined for particles, abnormal discolouration and cloudiness. The container is not to be used if any doubt exists, and the intact container is retained for further investigation
- Throughout the course of the infusion, document details of the flow rate, the type and amount of fluid and additives being administered and the person's fluid input from other sources and fluid output. The vital signs (temperature, pulse, respirations and blood pressure) are also measured regularly and documented. See Case Study 26.1.

### CASE STUDY 26.1 ADMINISTERING INTRAVENOUS FLUIDS

Mary, an 84-year-old female, was brought into the emergency department from her nursing home. The staff at the nursing home reported that Mary has become increasingly confused and has developed a fever of 38.2°C. Mary has a background of a previous stroke, affecting her ability to self-care, and Alzheimer's disease. Mary has been commenced on IV fluids and antibiotics and she has been admitted to your ward for ongoing care.

1. What risk factors could have contributed to Mary's dehydration?
2. What risk factors could have contributed to Mary developing a urinary tract infection?
3. What are some possible nursing diagnoses for Mary?
4. How will you manage Mary's infusion of IV fluid? What are some important considerations?
5. What will your ongoing assessment of Mary consist of and what complications will you be monitoring Mary for?

There are also a number of equally important safety and quality initiatives around IV therapy that must be adhered to in order to prevent risk of infections. Prior to using the IV line, it is important that the intravenous access port is cleaned with a single-use alcohol swab before each use. Sterile single-use devices must be used for intermittent medication administration through the IV access ports. Where possible it is also recommended that continuous IV fluids should be administered to promote patency of the line and maintain asepsis. Disconnecting and reconnecting lines for intermittent infusions increases risk of infections. Health facilities will have specific guidelines with details for care of IV lines. As an example refer to *Guideline for Peripheral Intravenous Catheters (PIVC)* (Centre for Healthcare Related Infection Surveillance and Prevention & Tuberculosis Control 2013).

## Electrolyte replacement

Nurses should be especially cautious when administering IV solutions containing electrolytes or fluids that have had electrolytes added to them. Potassium ($K^+$) is a classified high-risk medication in IV replacement and may require the person to be cardiac monitored. It is important for the nurse to be aware of and to monitor serum $K^+$ levels. A common side effect associated with administration of intravenous potassium is significant pain at the IV site and sometimes to the whole limb. This is usually associated with larger doses and shorter administration times. Cold packs can be applied, but it might be necessary to liaise with the medical team for

further problem resolution. For more information about medication safety and alerts for potassium and electrolytes refer to the Australian Commission on Safety and Quality in Health Care (ACSQHC) online resource at the end of this chapter.

### Intravenous fluid administration in paediatrics

Intravenous fluid therapy is less commonly used in children and is indicated only in emergency situations. Wherever possible, the enteral route (usually via a nasogastric tube) should be used in paediatric settings. If the enteral route is not suitable, then intravenous fluid administration can be utilised. Nurses need to exercise caution prior to and during the administration of IV fluids in children and should ensure that it is within their scope of practice. Accurate prescribing of the fluid and careful monitoring is very important for IV fluid administration in children. If a nurse is uncertain of the fluid order for any reason, liaising with the prescribing medical officer is critical and safe practice. Healthcare facilities will have specific guidelines pertaining to managing IV fluid administration in paediatric settings. As an example see the *Intravenous Fluid Management—CHW Practice Guideline* (SCHN 2015) from the Children's Hospital at Westmead, Sydney.

In a child with normal fluid volume status not consuming oral fluids, maintenance fluid will usually be administered. It is termed maintenance because it replaces insensible losses usually expected. A child's maintenance fluid requirement decreases proportionately with increasing age (and weight). The calculations in Table 26.13 approximate the maintenance fluid requirements of well children according to weight in kilograms.

Choice of IV fluid will depend on the clinical situation. A commonly used maintenance fluid is 0.45% NaCl with 5% glucose, although it may not be appropriate in all situations.

If a child presents with dehydration then initial replacement of the loss is essential. The formula for this is 10–20 mL/kg administered as boluses until the desired clinical outcome is achieved. The fluid of choice in this situation is usually 0.9% saline.

**TABLE 26.13 | Fluid requirements in paediatric settings**

| Child's weight | mL/day | mL/hour |
|---|---|---|
| 3–10 kg | 100 × wt | 4 × wt |
| 10–20 kg | 1000 plus 50 × (wt – 10) | 40 plus 2 × (wt – 10) |
| >20 kg | 1500 plus 20 × (wt – 20) | 60 plus 1 × (wt – 20) |

wt = weight in kg
*Adapted from Sydney Children's Hospital Network (SCHN) (2015)*

The Royal Children's Hospital Melbourne outlines the following recommendations in its guidelines (refer to the online resource The Royal Children's Hospital Melbourne, *Clinical Practice Guideline: Intravenous Fluids*).

Monitoring of children receiving treatment with IV fluids should include:

- Obtaining a weight from the child prior to commencement and then 6–8 hourly after fluid has been commenced. Daily weights should then continue
- Electrolytes and glucose should be checked prior to fluid administration and within 24 hours.

Clinical Interest Box 26.7 outlines the treatment of gastroenteritis in children.

## UNDERSTANDING ACID–BASE BALANCE

### Acids and bases

An **acid** is any substance that releases hydrogen **ions** ($H^+$) when dissolved in water. Acids have chemical properties essentially opposite to those of bases. Examples of acids found in the body include hydrochloric, lactic, pyruvic, carbonic, citric, folic and fatty acids. A **base** is any substance that accepts hydrogen ions in chemical reactions. Alkalis are bases that are soluble in water. Examples of bases found in the body include hydrogen bicarbonate and sodium hydroxide (Craft & Gordon 2015).

### The meaning of pH

The **pH** scale is used to express the concentration of hydrogen ions ($H^+$) in acids or bases. The 'p' stands for potential or power, and the 'H' stands for hydrogen. Therefore, pH represents the potential, or power, of hydrogen ions present. The

**CLINICAL INTEREST BOX 26.7**
**Paediatric gastroenteritis**

Treatment of gastroenteritis in the young requires special attention to fluid and electrolyte balance. Fluids such as flat lemonade and mineral water are often used for rehydration. This treatment has potential life-threatening consequences. Lemonade has a high sugar content, and sugar acts as an osmotic agent, drawing water into the gastrointestinal tract (GIT) from the body's fluid compartments. This fluid loss results in increased diarrhoea and dehydration. Sugar is also utilised by bacteria in the gastrointestinal tract as a form of nutrition, resulting in increased gas production by the bacteria, causing gaseous distension and abdominal pain.

Hydration in the young needs to be assessed by a medical officer. The person often requires rehydration with products such as Gastrolyte, by oral or nasogastric administration and, in more severe cases, intravenous therapy may be required.

pH of a solution is determined by measuring the amount of $H^+$ present. The scale is numbered from 0–14; the lower the number on the scale, the more $H^+$ is present, therefore the more acidic the solution is. A pH of 7 indicates a neutral solution, while a pH above 7 is termed basic, or alkaline, and a solution below 7 is acidic. Each integral step in the pH scale (i.e. 14, 13, 12 … to zero pH) represents a tenfold increase in $H^+$ ion concentration; thus, the pH scale is an inverse logarithmic scale of the amount of hydrogen ions present.

## Acid–base balance

In order to maintain optimal cellular function the hydrogen ion ($H^+$) concentration of body fluid is maintained within a close range (LeMone et al 2014). The pH of body fluid is maintained between 7.35 and 7.45; this means it is slightly basic (**alkaline**) as neutral is a pH of 7. A number of buffering systems are required to maintain a normal pH; this is because the normal cellular metabolism of nutrients in the human body continuously produces acids (LeMone et al 2014).

The body's capacity to form, excrete and 'buffer' acids and bases is known as the acid–base balance. Acid–base imbalances are classified as either respiratory or metabolic depending on the underlying cause (Berman et al 2015). The acid–base balance is critical to the survival of the human body. Variations outside the normal arterial range of a pH of 7.35–7.45 indicate serious dysfunction in the body. The normal metabolism of nutrients by cells produces large amounts of hydrogen ions ($H^+$) that form acids. The concentration of hydrogen ions in the cells and tissues must, however, be kept low to prevent cellular damage. To maintain pH within normal limits, the body excretes acids at the same rate that they are produced and buffers any excess hydrogen ion (Craft & Gordon 2015).

## Buffer systems

A **buffer** is a chemical substance that resists changes in the pH of solutions by either removing or releasing hydrogen ions (LeMone et al 2014). When bodily fluid is too acidic buffers bind with hydrogen ions to keep the pH within the homeostatic range. When body fluid is alkaline buffers release hydrogen ions, again returning the pH to normal (LeMone et al 2014).

For example, $CO_2$ is an end product of cellular metabolism and when combined with water, forms carbonic acid ($CO_2 + H_2O = H_2CO_3$), which drains back into the circulation. Excess carbonic acid in the blood is rapidly decomposed into carbon dioxide and water ($H_2CO_3 = CO_2 + H_2O$) and the $CO_2$ is excreted by the lungs to maintain the pH at normal physiological levels. Conversely, if water is lost from the blood, it is replaced by the ionisation of carbonic acid, and a rise in pH is prevented. Thus, carbonic acid acts as a buffer in the blood. An example of the buffering action of bicarbonate ion is its reaction with lactic acid. Lactic acid is produced from glucose during muscle contraction, and the dissociation of lactic acid tends to lower the pH. As lactic acid is a stronger acid than carbonic acid, its conjugate base (lactic ion) is weaker. The stronger base (bicarbonate ion) combines with the hydrogen from lactic acid forming dissociated carbonic acid (Craft & Gordon 2015).

## Acidosis and alkalosis

**Acidosis** is a condition in which the blood becomes acidic (pH <7.35) due to an increase in hydrogen ion concentration as a result of an accumulation of an acid, or the loss of a base. **Alkalosis** is a condition characterised by an increased pH, above 7.45, due to a decrease in hydrogen ion concentration as a result of a loss of acids or the accumulation of a base.

An acid–base imbalance occurs when there is a deficit or excess of carbonic acid or base bicarbonate. In some situations in which a person cannot efficiently excrete enough $CO_2$—for example, in an individual with pneumonia—the buffer system may be unable to keep the pH within the normal range. In this situation the excess $CO_2$ will make the blood more acidic, reducing the pH. If the pH falls below 7.35 the condition is termed acidosis; if the pH rises above 7.45 the condition is termed alkalosis. Normally the body can soak up or neutralise acids as they are formed (buffering). This is done by:

- Blood: initial buffering of acids occurs in tissue, blood cells and the plasma
- Lungs: rapidly alter blood pH by increasing or decreasing the respiratory rate, increasing the removal of carbon dioxide
- Kidneys: excrete additional acids that cannot be excreted by any other method; they also reabsorb bicarbonate back into the bloodstream after acids have been excreted.

A pH above or below the normal pH of arterial blood (7.35–7.45) may result in severe dysfunction and potential death.

### CRITICAL THINKING EXERCISE 26.4

**Acid–base imbalance**

Sara is 17 years old. She has been complaining of excessive thirst and passing a lot of urine. Her breath smells, and she is deep breathing. Her results show BGL 21 mmol/L and pH 7.1. What could be the issue in this case?

## Causes of pH disturbances

### Respiratory causes

Respiratory acidosis occurs with hypoventilation, when the body is unable to ventilate enough $CO_2$ out of the lungs, as may occur in airway obstruction, emphysema, asthma or opiate overdose. (The kidneys compensate, e.g. by retaining bicarbonate.) Respiratory alkalosis occurs with hyperventilation, when rapid respirations blow off too much carbon dioxide, resulting in alkalosis of a respiratory nature, as may occur in panic attacks. (The kidneys compensate, e.g. by excreting more bicarbonate.)

### Metabolic causes

Metabolic acidosis occurs when the body is unable to excrete enough acids because of a problem with malabsorption, such

## CLINICAL INTEREST BOX 26.8 Diabetic ketoacidosis

Individuals with diabetes who have not been administered enough insulin or are unwell, or those with undiagnosed diabetes, are at risk of developing diabetic ketoacidosis. Without adequate insulin the body uses its muscle and fat for metabolism, producing ketone acids. To rid the body of acids, emesis and later hyperemesis occurs, resulting in a loss not only of acid but also of fluid and other electrolytes. The ketone acids can severely affect the pH of the blood, causing a metabolic acidosis. The body tries to compensate by excreting acid by the lungs (compensatory respiratory alkalosis), kidneys and skin.

Hyperglycaemia causes an osmotic-induced polyuria and a subsequent fluid and electrolyte imbalance and may result in severe dehydration. If insulin is not administered and the correct rehydration therapy instigated, in severe cases the condition can result in cerebral oedema, coma and death.

as diarrhoea; metabolism, for example, diabetic ketoacidosis (see Clinical Interest Box 26.8); or organ failure, such as kidney failure. (The lungs compensate, e.g. by increasing ventilation and increasing excretion of acidifying $CO_2$.)

Metabolic alkalosis occurs when too much acid is lost, for example by vomiting, nasogastric drainage or use of some diuretics. (The lungs compensate, e.g. by decreasing ventilation and decreasing excretion of acidifying $CO_2$.)

### Compensation

A change in pH by one system of the body will tend to cause an opposite compensatory change in pH, known as respiratory or metabolic compensation. If respiratory acidosis exists, the body will compensate by producing a metabolic alkalosis. If metabolic alkalosis exists, the body will compensate by producing a respiratory acidosis.

Implementing nursing care for individuals with acid–base imbalances involves monitoring, prevention and correction of the particular imbalance. Treatment and care of individuals in these situations is directed towards reversal or correction of the acid–base disorder and may include modification of dietary and fluid intake, administration of medications, intravenous therapy and the administration of blood, blood products or total parenteral nutrition (TPN) (Dempsey et al 2014).

## Summary

This chapter provides an overview of the key physiological concepts implicated in fluid, electrolyte and acid–base homeostasis. Developing an understanding of these theoretical underpinnings is critical for nurses as this knowledge will inform the basis of evidence-based person-centred care. Knowledge acquisition will particularly assist nurses to utilise their critical thinking skills and strengthen their position as advocates. To consolidate learning, further reading and completion of the review and critical thinking exercises is highly recommended.

Several essential homeostatic processes are integral in the maintenance of fluid, electrolyte and acid–base balance within the body. Water is distributed within both intracellular and extracellular compartments. This fluid provides a transport medium for electrolytes and other substances. Movement of fluids and electrolytes is dynamic and constant and is essential for a healthily functioning body. Osmosis is the mechanism of movement for water; diffusion and active transport are mechanisms facilitating the movement of other substances. The semi-permeable membrane is a critical structure in the regulation of intracellular and extracellular fluid composition and in the maintenance of electrolytes within optimal levels in their respective compartments. Damage to the semi-permeable membrane through disease processes, such as burns and infections/sepsis, can result in fluid and electrolyte shifts detrimental to healthy function.

It is natural for the body to lose water through both sensible and insensible mechanisms. Sensible losses include those that are able to be measured, that is, urine and faeces. Insensible losses are not easily measurable, for example, perspiration. Under certain conditions fluid losses may increase; but in the healthily functioning body homeostatic mechanisms will act to restore body water volume and composition. Key systems for these mechanisms of action are the neural (hypothalamus and pituitary) system, the renal system (RAS—aldosterone) and the GIT. Disease processes resulting in fluid volume excess have also been discussed in this chapter. Bodily mechanisms that compensate for this also include the neural, renal and cardiovascular mechanisms.

Major cations and anions have been discussed with reference to their significance in maintaining nerve and muscle function. Electrolyte imbalance rarely occurs in isolation; there is usually more than one imbalance involved. Sodium is associated with water imbalance and it is important for the clinician to establish whether there has been a loss of sodium, for example, or an increase in water volume. Potassium is an extremely important electrolyte in the maintenance of an optimally functioning cardiac conduction system. It should be monitored closely and administered with caution as it is associated with potentially lethal complications.

The maintenance of the pH of blood within a closely regulated range is critical to survival. Maintenance is achieved through both renal and respiratory buffering capabilities. These buffering mechanisms can be overwhelmed by disease processes.

Person-centred care is aimed at treating the underlying clinical condition and providing supportive therapies

## Summary—cont'd

during this process. An integral element of the nurse's role is the completion of a comprehensive person-centred assessment, which includes considering additional risk factors associated with older adults and the paediatric population. The nurse is required to execute astute physical assessment skills; these accompanied by theoretical underpinnings will form the basis of planning, implementing and evaluating care and of timely reassessment of the individual.

Maintaining a person's safety is paramount. The nurse is required to consider their individual scope of practice prior to the administration of intravenous fluids. Individuals undergoing treatment with IV fluids must be monitored appropriately and continuously reassessed. It is vital for the nurse to understand the clinical reason for the particular IV fluid administration so the effects of the treatment can be evaluated accordingly.

Physiological concepts in fluid, electrolyte and acid–base homeostasis are likely to be frequently encountered in a multitude of clinical settings. The application of this knowledge in clinical practice not only promotes high quality, safe person-centred care but also renders satisfying and rewarding care delivery for the nurse.

### DECISION-MAKING FRAMEWORK EXERCISE 26.1

Sophia is an 83-year-old lady with heart failure. She has a past history of ischaemic heart disease including a myocardial infarction 3 years ago. Sophia is admitted to your ward with swollen ankles and shortness of breath suggesting fluid overload. She is on a small dose of frusemide (20 mg daily), weighs 76 kg and is 155 cm tall. Her urea and electrolyte blood tests come back showing a sodium low of 133 mmol/L and a reduced potassium of 3.1 mmol/L. Blood glucose is elevated (12 mmol/L). Sophia has been ordered IV frusemide and insulin (S/C) by the admitting medical officer.

How should you (as her nurse) respond to this situation in accordance with clinical practice standards and the decision-making framework for nurses?

## Review Questions

1. Draw a table with three columns. Title the first column 'Fluids' and list the following fluids in that column:
   - 0.9% saline
   - 5% dextrose
   - 4% dextrose and 1/5 normal saline
   - Hartmann's/lactated Ringer's solution
   - 0.45% sodium chloride

   Title the second column 'Indications for use' and the third 'Tonicity of the fluid'. Complete the table.
2. An 18-month-old infant is admitted for gastroenteritis and is 7% dehydrated. The infant has been refusing all oral rehydration fluids. What clinical signs would you expect to find in your assessment of the infant and what are the reasons for your findings?
3. John presents with a 5-day history of severe vomiting and diarrhoea on returning from an overseas trip.
   a. What are some electrolyte disturbances you might expect to see in John and why?
   b. What clinical symptoms are associated with these electrolyte disturbances?
   c. What type of IV fluids might be initiated for John and why?
   d. What would you expect John's urine SG and osmolality to be and why?
4. While observing Table 26.1 think about individuals (in the health setting) you may have come into contact with. Reflect on what you would need to know to provide safe person-centred care. Make a note of your answers.
5. Fluid balance will be achieved if there is:
   a. Free access to water
   b. Normal thirst mechanism
   c. Normal ADH mechanism
   d. Normally functioning kidneys

   Consider this list and individuals that may be affected by one or more of these factors. Make a note of your response.
6. What symptoms do you think might be present in a person with dehydration?
7. What are the symptoms associated with chronic history of fluid overload?
8. Refer to the fluid balance chart provided as a sample in this chapter and as a practice exercise complete a fluid balance chart for an 8-hour shift based on the following information:
   - Shift AM. Volume of cup is 100 mL
   - John has had 2 glasses of water since 0700 hrs (0800, 1300)
   - He has also had a cup of tea at 1030 hrs
   - Urine output 0830 hrs is 200 mL, 1100 hrs is 150 mL, 1330 hrs is 150 mL
   - IV therapy normal saline 1 L bag running at a 24-hourly rate. Commenced at 0700 hrs.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER 27

# Promotion of health and wellbeing: rest and sleep

*Heather Redmond*

## KEY TERMS

central sleep apnoea
circadian rhythm
insomnia
non-rapid eye movement (NREM)
obstructive sleep apnoea
parasomnias
polysomnography (PSG)
rapid eye movement (REM)
rest
restorative sleep
sleep
sleep disorder
sleep disturbance
sleep hygiene
sleep–wake cycle
snoring

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the importance of rest and sleep to the wellbeing of the individual
- Explain the functions of sleep
- Outline and describe the phases of the sleep cycle
- State the factors that may interfere with the process of rest and sleep
- Describe the supportive nursing measures that may be implemented to promote the individual's need for rest and sleep
- Demonstrate an awareness to identify a range of sleep disorders and the impact of these disorders on wellbeing

## CHAPTER FOCUS

Rest and sleep are important factors to enable individuals to achieve and maintain a state of wellbeing. Rest is a state of feeling mentally and physically relaxed, calm and free from worry (Rebeiro 2013). Sleep is a basic physiological need and relates to a decreased level of consciousness that occurs on a cyclical basis. The state of sleeping enables a period of rest, which is essential for restoration of physiological and psychological processes of the body (Rebeiro 2013). The amount of sleep an individual requires depends on age, lifestyle, personality, environment and state of health. The need for a required amount of sleep generally becomes less as a person ages.

An important nursing responsibility is implementing measures that will promote physical and emotional comfort, thereby assisting the individual to experience sufficient rest and sleep. Factors affecting rest and sleep can result from a variety of physical or psychosocial reasons. Without adequate rest and sleep, the ability to perform the normal activities of daily living may be affected (Rebeiro 2013). Most people report 'difficulty with sleeping' at some stage in their lives, and for most this is usually a temporary problem. Nurses need to assess the individual's sleep problems and use critical thinking skills to implement measures to promote effective sleep (Rebeiro 2013).

This chapter explores the promotion of optimal rest and sleep and strategies the nurse can provide to enhance the individual's physical and psychological comfort and wellbeing. The ability to achieve adequate rest and sleep is closely associated with comfort; therefore, the nurse should be aware of the measures necessary to ensure that comfort needs are met. Rest and relaxation can occur only when there is freedom from physical discomfort and emotional tension, and individuals are more likely to sleep well if normal sleep hygiene habits are maintained.

## LIVED EXPERIENCE

How are people expected to sleep at all in hospital? I don't know how anyone is supposed to get better. During my recent stay for hip surgery, I was woken frequently for observations, medications and by noise—the person snoring in the next bed, buzzers going off, nurses talking loudly and footsteps down the hall, the pump dinging, lights being turned on and, not only that, I was in pain! Everything was different … I felt like I was out of my normal routine and the bed wasn't all that comfortable, the meals came too early to what I was used to at home, and it was so hot in the room I was in, I felt stifled … I was glad to be finally discharged and go home, so I could get some rest and sleep in my own bed!

**Norman, 68, recent surgical inpatient**

# REST

**Rest** is a state where the individual assumes a comfortable position and is relaxed for a period of time, allowing the individual to feel refreshed and rejuvenated, ready to continue on with daily activities (Rebeiro 2013). Individuals at rest are considered free from any physical or mental exertion (Christensen & Kockrow 2011). Individuals who are confined to bed for physical reasons may not always feel rested, as psychological issues may impact on the ability to completely rest (Rebeiro 2013). Individuals have different methods of achieving adequate rest and this may be disrupted when admitted to a healthcare facility (Christensen & Kockrow 2011).

# PHYSIOLOGY OF SLEEP

**Sleep** can be defined as a period of reduced conscious awareness of the environmental surroundings from which individuals can be easily woken (Lewis et al 2014). Certain stimuli, for example a sudden loud noise, will usually rouse the individual, although not necessarily to full alertness. The **sleep–wake cycle** is a process that promotes sleep and maintains wakefulness (Christensen & Kockrow 2011).

## Sleep regulation

The control and regulation of the sleep–wake cycle depends on the interrelationship between structures in the brainstem, hypothalamus and thalamus (Lewis et al 2014). The sleep–wake cycle is controlled by the brain's higher centres where one mechanism causes wakefulness, while the other causes sleep (Rebeiro 2013). The reticular activating system (RAS) is located in the upper brainstem and is believed to contain special cells that maintain alertness and wakefulness (Rebeiro 2013). The RAS is activated when it receives visual, auditory, pain and tactile sensory stimuli as well as thoughts and emotions. When a person tries to sleep in a darkened room they become relaxed, and stimuli to RAS is decreased (Rebeiro 2013). In addition the hypothalamus releases neurotransmitters and peptides which promote sleep by inhibiting the RAS (Lewis et al 2014). The pineal gland also plays a part in the sleep–wake cycle by releasing melatonin as the environment gets darker, inducing sleep. With light exposure from natural or artificial light melatonin release is suppressed, and the individual awakens (Lewis et al 2014).

## Circadian rhythm

The concept of circadian rhythm (derived from the Latin: *circa*—about, and *dies*—day) refers to the cyclical measures that are part of our everyday life (Rebeiro 2013). **Circadian rhythms** are physical, mental and behavioural changes that follow roughly a 24-hour cycle, responding primarily to light in the environment (Lewis et al 2014). Circadian rhythms are produced by natural factors within the body, but they are

also affected by environmental signals such as a person's daily activities, as well as internal physiological signals such as hormones, temperature, pulse and blood pressure, the individual's mood and their sensory awareness (Bernhofer et al 2013; Rebeiro 2013). It appears that the 24-hour cycle to which the human body synchronises is highly individualised, allowing variation as some people are distinctly described as 'morning people', while others fit well into the 'night-owl' category. Any disruption to a person's circadian rhythm can cause discomfort and manifest in a disturbed sleep pattern (Rebeiro 2013).

An example of the consequences of a disrupted circadian rhythm is the state known as 'jet lag'. This condition occurs when a person's circadian rhythm is disrupted by travel across several time zones in a relatively short time, and is characterised by fatigue, insomnia and sluggish physical and mental function. Individuals who are ill in hospital may also experience sleep disruptions where quantity and quality of sleep are affected (Thomas et al 2012). Some wards may be brightly lit during the night as well as during the day; therefore, the regular pattern of light and dark, together with perhaps increased noise levels, poor control of pain and the activities of others disrupt the normal 24-hour rhythm (Thomas et al 2012). A person who engages in varied shift work may experience symptoms similar to jet lag, as the body attempts to adapt to changes in the 24-hour biological clock. Working on night shift removes sleeping from the normal night-time routine and renders it out of order with the body's normal circadian rhythm (Christensen & Kockrow 2011).

## Stages of sleep

Sleep is a diverse and complex process that includes **non-rapid eye movement (NREM)** or quiet sleep, and **rapid eye movement (REM)** or active sleep (Rebeiro 2013). It is generally recognised that each **sleep cycle** consists of five stages. NREM sleep consists of the first four stages where light sleep occurs in stages 1 and 2 and progresses through to a deeper sleep in stages 3 and 4 (Christensen & Kockrow 2011). The reverse then occurs where the person will progress from stage 4 back to stage 2, ending with the fifth stage of sleep, REM. This process takes about 90 minutes and continues with the person going through 4–6 of these cycles of sleep per night, with the REM stage increasing in length and the NREM stages shortening with each cycle (Rebeiro 2013). If the person wakes fully on occasions during sleep, the sleep cycle needs to restart at stage 1; if this occurs the total time spent in deep sleep may be lessened. Infants spend a greater proportion of time in REM sleep than adults, with about 40% of total sleep time being REM sleep. With adults, about 20% of total sleep time is REM sleep. (See Clinical Interest Box 27.1 for details of the five stages of sleep and Clinical Interest Box 27.2 for physiological changes during NREM and REM sleep.)

## Dreams

Dreams occur during both the NREM and the REM sleep stages. Dreams are more vivid and elaborate in the REM sleep period, which is also believed to contribute to the consolidation of long-term memory (Rebeiro 2013). Through each REM period dreams may progress in content, including current events to emotional dreams from childhood, or events and experiences that have occurred in the past. Dreams often relate to experiences that may have occurred over the day, or incidents that have caused stress such as with relationships and work (Rebeiro 2013). Many dreams are forgotten and not recalled; therefore, people do not believe they have dreamt at all. Remembering a dream requires a person to consciously think about their dream upon waking. Recall of vivid dreams usually occurs if the person has woken just after a period of REM sleep (Rebeiro 2013).

## Quality of sleep

The quality of sleep is a subjective experience where the amount of restfulness, depth of sleep, number of times woken and amount of sleep impact on the individual's perception of quality of sleep. The quality of sleep is equally as important as the quantity of sleep achieved. The amount of sleep a person reports that they need to feel refreshed is both subjective and individualised (McCance et al 2015). It is also reported that quality of sleep decreases with age, although many middle-aged individuals will report a change in sleep quality, and sleep disorders may be diagnosed during this period of the lifespan (Rebeiro 2013). The length of lighter stages of sleep (especially stage 1) is often increased in older people and stages 3 and 4 often decrease. This may explain why many older adults often report the quality of their sleep as poor and feeling less rested even after being observed to have slept soundly.

## Sleep patterns across the lifespan

There are many variations in the optimal amount of sleep each individual requires. The range of 7–9 hours per night is the average required for an adult, meaning that about one-third of the day and, consequently, one-third of an individual's life is spent sleeping (Rebeiro 2013). Sleep patterns change throughout the lifespan and as a person ages, the amount of time spent sleeping at night is usually less than earlier in life. The quantity of sleep diminishes from about 20 hours a day in infancy to about 8–12 hours a day in adolescence, to perhaps as little as 6–8 hours of sleep at night in adulthood. In older adulthood, the amount of sleep achieved at night will often decrease; however, older adults often report 'napping' during the day. Daytime napping may occur due to poor night-time sleep, early wakening and/or changes in the central nervous system (CNS) regulation of sleep and circadian rhythm. In addition many older adults will wake more often during the night and report an inability to return to sleep after rousing (Rebeiro 2013). Clinical Interest Box 27.3 outlines the sleep requirements across the lifespan.

There are several theories about the purpose of sleep, with the most frequently accepted concept being that sleep contributes to physiological and psychological restoration, influencing and regulating body functions, and behavioural

## CLINICAL INTEREST BOX 27.1 Sleep cycle stages

### Stage 1: NREM

Stage 1 sleep is light sleep. It can be considered a transition from awake to sleeping, an experience of drifting in and out of sleep. It lasts only a few minutes (1–7 minutes).

- Easily woken
- Eye movement and body movements slow down
- May experience sudden jerky movement of legs or other muscles
- Easily awoken and, if awoken, may not feel like having been asleep.

### Stage 2: NREM

Stage 2 lasts for approximately 10–25 minutes. Relaxation progresses.

- More difficult to rouse
- Body temperature starts to decrease
- Heart rate begins to slow.

### Stage 3: NREM

Stage 3 is the first stage or transitional phase to deep sleep. Muscles are completely relaxed. It lasts a few minutes.

- Very difficult to wake
- If woken during this stage, may feel groggy and disoriented for several minutes
- Vital signs decrease but remain regular.

### Stage 4: NREM

Stage 4 sleep is the second stage of deep sleep. It lasts 20–40 minutes.

- Very difficult to wake up
- Both stages of deep sleep are important for feeling refreshed in the morning
- If these stages are too short, sleep will not feel satisfying
- Sleepwalking and enuresis may occur.

### Stage 5: REM sleep

Lasts 5–30 minutes, begins about 90 minutes after falling asleep.

- The sleep stage in which dreaming occurs, but will usually not be remembered unless person briefly rouses
- Breathing becomes fast, irregular and shallow
- Brain becomes highly active
- Difficult to rouse
- Distinctive eye movement occurs; voluntary loss of muscle tone and reflexes; men may develop an erection
- The REM period of first sleep cycle is usually shorter than subsequent REM periods
- REM sleep is not fully understood. What is known is that REM sleep is important in the creation of long-term memory.

  The full sleep cycle usually lasts 90–110 minutes.

*(Adapted from Berman et al 2015; Rebeiro 2013; Christensen & Kockrow 2011)*

## CLINICAL INTEREST BOX 27.2 Physiological changes during NREM sleep

- Arterial blood pressure falls
- Pulse rate decreases
- Peripheral blood vessels dilate
- Cardiac output decreases
- Skeletal muscles relax
- Basal metabolic rate decreases
- Growth hormone levels peak
- Intracranial pressure decreases

*(Adapted from Christensen & Kockrow 2011; Rebeiro 2013)*

## CLINICAL INTEREST BOX 27.3 Sleep requirements across the lifespan

Newborns: 16–18 hours/day
Infants: 14–15 hours/day
Toddlers: 12–14 hours/day
Preschoolers: 11–13 hours/day
School-age children: 10–11 hours/day
Adolescents: 9–10 hours/day
Adults: 7–9 hours/day
Older adults: 7–9 hours (with more difficulty)

*(Adapted from Berman et al 2015)*

responses (McCance et al 2015). It appears that the level of circulating hormones, such as human growth hormone and those secreted by the adrenal glands, vary during sleep. The levels of these hormones circulating during sleep is thought to facilitate cell growth and repair (Berman et al 2015). Sleep is also a time that allows for conservation of energy, prevention of fatigue and provision of organ respite, with the relaxation of skeletal muscles and the lowering of basal metabolic rate (McCance et al 2015). Alternatively, cerebral function during periods of sleep is increased, with important cognitive restoration and the filtering and storage of the day's activities (Rebeiro 2013). It is therefore of particular importance that the person who is ill or hospitalised has the opportunity to benefit from the restorative nature of sleep (Thomas et al 2012). A person who suffers from chronic illness or chronic pain syndrome that disturbs effective sleep may not wake feeling rested or restored, no matter how long they spend resting in bed.

### Sleep disturbances

Any interruptions to sleep may have an impact on a person's ability to carry out their usual daily activities. A person who experiences a **sleep disturbance** may exhibit changes in behaviour response and performance, and also may show signs of irritability, lack of energy and fatigue, which can occur within 24 hours (Lewis et al 2014). Sleep-pattern disturbances include difficulty in falling asleep, periods of wakefulness during the night, waking earlier than usual and not feeling rested after sleep (see Clinical Interest Box 27.4 for conditions of proper rest and Clinical Interest Box 27.5 for cultural aspects of sleeping).

Some people experience nightmares or sleepwalking. A nightmare is a dream that arouses feelings of intense fear or extreme anxiety and usually wakes the sleeper. Sleepwalking is a state that culminates in the individual walking about, but will have no recollection of the episode. Other disorders that affect sleeping patterns include insomnia, snoring, sleep apnoea, narcolepsy and parasomnias. A person who develops a sleep disorder may require referral to a sleep disorders centre for investigation.

## SLEEP DISORDERS

Individuals may at some stage in their lives experience a **sleep disorder**. The most severe types of sleep disorders include 'obstructive sleep apnoea (OSA), narcolepsy, restless legs syndrome (RLS), periodic limb movement disorder, insomnia, parasomnias, circadian rhythm disorders including jet lag and shift work, and sudden infant death syndrome' (Deloitte Access Economics 2011:8). Sleep disorders impose a burden on the Australian healthcare system and in 2010 cost approximately $818 million for medical services and pharmaceutical supplies. Much of these costs are attributed to sleep apnoeas, insomnia and restless leg syndrome (Deloitte Access Economics 2011). Sleep disorders decrease quality of life causing increased morbidity and mortality (Lewis et al 2014) and contribute to workplace incidents and motor vehicle accidents (Deloitte Access Economics 2011).

If a sleep disturbance persists despite the implementation of sound sleep hygiene measures and lifestyle changes, medical advice may be sought. A referral then may be made to a sleep physician so that **polysomnography** (PSG) sleep studies can be conducted at sleep clinics or in the individual's home. Night-time PSG involves attaching monitoring leads to multiple areas of the body and, while the person sleeps, data regarding the stages of sleep are recorded, as well as night-time wakefulness, to detect any sleep abnormalities (Rebeiro 2013). This process usually involves an overnight admission in a sleep disorders unit or an in-home PSG, where sleeping patterns are monitored. The annual rates of

### CLINICAL INTEREST BOX 27.4 Conditions for proper rest

- Physical comfort
- Eliminate sources of physical irritation and pain
- Control room temperature and provide adequate ventilation
- Maintain proper alignment and anatomical position
- Remove environmental distractions
- Freedom from worry
- Have knowledge of health problems and their implications
- Make own decisions
- Participate in personal healthcare
- Practise restful and relaxing activities frequently
- Know that environment is safe
- Sufficient sleep
- Know and obtain the hours of sleep that are needed to feel refreshed
- Follow good sleep hygiene habits

*(Christensen & Kockrow 2011; Rebeiro 2013)*

### CLINICAL INTEREST BOX 27.5 Cultural aspects of sleep

- Practices and patterns of sleep and rest differ between cultures
- Many cultures favour daytime rest and shorter night-time sleep periods
- Western cultures reinforce autonomy in children sleeping independently, whereas Asian and African cultures favour infants and children co-sleeping for much of their childhood. Even within these cultures, differences now being seen may be due to industrialisation
- Co-sleeping in which infants sleep with their parents may result in alterations to both parents' and child's sleeping patterns
- Research continues on the value of touch in inducing rest and sleep, especially in neonatal intensive care situations, and parental bonding and attachment

*(Adapted from Rebeiro 2013)*

PSG in Australia have increased from 339 in 2005 to 608 in 2008 per 100 000 people. This is largely attributed to the use of in-home PSG (Woods et al 2014). Prior to the PSG occurring, a specialised nurse or technician obtains a thorough sleep history from the individual, which includes information of both past and current sleep problems. Specific information collected in relation to sleep include the time of settling and waking, the number of times sleep is disturbed, physical illnesses, medications, diet, any aids or techniques that the person is currently using to achieve sleep and an environmental assessment.

## Sleep deprivation

Many individuals experience disturbed sleep and sleep deprivation as a result of hospitalisation (Missildine et al 2010). This results in decreased amount, quality and consistency of sleep due to sleep being interrupted or fragmented. This causes changes in the normal sequence of sleep stages, and the normal cycles cannot be completed (Rebeiro 2013). Gradually a cumulative sleep deprivation occurs (see Clinical Interest Box 27.6). Chronic sleep deprivation is linked to several common health problems, many related to metabolic syndrome, such as cardiovascular diseases, weight gain, type 2 diabetes, poor memory, depression, digestive problems and even links to cancer (Lewis et al 2014). The severity of symptoms is often related to the duration of sleep deprivation. The most effective treatment for sleep deprivation in any environment is eliminating or correcting the factors that lead to disruption of sleep (Rebeiro 2013).

## Insomnia

**Insomnia** is the most common sleep disorder and is characterised by difficulty falling asleep or staying asleep, more than three times a week (Lewis et al 2014). The individual may complain of trouble falling asleep or staying asleep, early awakening and feeling un-refreshed upon awakening (Lewis et al 2014). This results in insufficient quantity and quality of sleep, which may lead to excessive daytime sleepiness (EDS). Acute insomnia is the most common of the insomnias, and is often in relation to one or a number of the factors that are associated with sleep disorders (illness, stress or change in sleeping environment) (Rebeiro 2013). This type of insomnia will usually subside once the acute event or causative factor has passed or been eliminated. In the short term, having less sleep than normal usually causes no harmful effects. Often lifestyle and environmental conditions are able to be easily modified, such as reducing alcohol and caffeine intake before bed, not napping through the day and use of stress-modifying techniques. Teaching individuals about the factors influencing sleep and sleep routine (sleep hygiene) may help in improving sleep quality in the individual suffering insomnia.

Chronic insomnia consists of the same symptoms as acute insomnia; however, it lasts for more than a month or longer (Lewis et al 2014). It may be the result of an underlying medical, behavioural or psychiatric problem. Depression can often cause insomnia. Chronic insomnia usually requires investigation as to its cause, and treatment usually requires more than simple lifestyle and environmental assessment and modifications (Rebeiro 2013). The fear of not being able to sleep can be enough to cause wakefulness, thus potentiating the underlying feelings of sleep deprivation, and daytime sleepiness, fatigue, depression and anxiety (McCance et al 2015).

### CLINICAL INTEREST BOX 27.6 Signs and symptoms of sleep deprivation

**Physiological symptoms**

- Ptosis, blurred vision
- Fine motor clumsiness
- Decreased reflexes
- Slowed response time
- Decreased reasoning and judgment
- Decreased auditory and visual alertness
- Cardiac arrhythmias

**Psychological symptoms**

- Stress and anxiety
- Confusion and disorientation
- Increased sensitivity to pain
- Irritable, withdrawn, apathetic
- Agitation
- Hyperactivity
- Decreased motivation
- Excessive sleepiness

*(Rebeiro 2013; Pilkington & Lorenz 2013)*

## Snoring

**Snoring** is defined as breathing during sleep accompanied by harsh sounds and is caused by any obstruction of the air passages at the back of the mouth and nose. Poor muscle tone, excessive tissue or deformities such as a deviated septum may cause snoring. Obstructed airways due to colds or allergies can also cause snoring. Snoring can also be a symptom of sleep apnoea. The mild snorer should exercise to develop good muscle tone and lose weight if needed (deWit & Williams 2014).

## Sleep apnoea

**Sleep apnoea** is a disorder characterised by the lack of airflow through the nose and mouth for periods of 10 seconds or more. There are three types of sleep apnoea: obstructive sleep apnoea (OSA), central sleep apnoea (CSA) and mixed sleep apnoea, with OSA being the most common (Rebeiro 2013).

### Obstructive sleep apnoea

**Obstructive sleep apnoea** (OSA) is characterised by repetitive upper airway closure during sleep causing a partial or full obstruction, resulting in blood oxygen desaturation and fragmented sleep (Australasian Sleep Association 2015). Structures in the upper airway collapse during sleep, which may involve the tongue and soft palate falling backwards, causing

air entry to cease from anywhere between 15 and 90 seconds (Lewis et al 2014). The individual may be seen to be attempting to breathe with the rise and fall of the chest or abdominal wall, but as the airway is obstructed there is no air entry (McCance et al 2015). The decrease in oxygen to the brain causes the person to rouse slightly, often snorting and gasping, causing the soft palate and tongue to move forwards, allowing the airways to open (Lewis et al 2014). Often the person will not become consciously aware that they are rousing and will continue to sleep, with further apnoeic cycles occurring. The individual fails to maintain the deep sleep period required for a restful sleep (Rebeiro 2013). Nurses monitoring hospitalised individuals during sleep may observe apnoeic episodes and will need to document the findings and report to the medical officer for further assessment. (See Progress Notes Example 27.1.)

A number of studies have shown that approximately 24% of middle-aged males and 9% of middle-aged females suffer with OSA, which may repeat itself many times during the night, leaving the person sleep-deprived and fatigued (Australasian Sleep Association 2015). Given that the major modifiable risk factor for OSA is obesity the prevalence of OSA is increasing (McCance et al 2015). OSA is a serious and potentially life-threatening condition. The episodes of apnoea during sleep may cause various organ systems to function abnormally and possibly contribute to many disorders such as hypertension, heart attack and stroke (Rebeiro 2013). It also commonly leads to EDS, which is the most common presenting complaint of individuals suffering sleep apnoea, leading to poor concentration, and is potentially one of the causes of workplace and road accidents (McCance et al 2015).

Treatment options may begin with lifestyle changes, if these are indicated, such as weight loss and a decrease in alcohol intake (Rebeiro 2013). Referral may be made to an ear, nose and throat (ENT) surgeon to assess whether airway obstruction could be caused by mechanical factors. A dental splint may be utilised in mild cases of OSA to hold the jaw in a forced-forward position, keeping the airway open. Moderate to severe sleep apnoea usually requires the long-term use of a continuous positive airway pressure (CPAP) device—a nasal mask worn while sleeping (Lewis et al 2014). The CPAP device keeps the back of the throat open by creating a backward pressure through the airways, preventing the upper airway structures from collapsing and thereby preventing apnoeic periods (Rebeiro 2013). Individuals require education and support to adapt to the use of a CPAP device, as non-compliance is high, but in the long term, OSA can be managed, and effective restorative sleep achieved (Lewis et al 2014).

### Central sleep apnoea

**Central sleep apnoea** (CSA) is similar to OSA, where breathing periodically ceases. However, there is no obstruction in the upper airways. CSA occurs due to signals failing to reach the respiratory muscles, and therefore no effort is made to breathe (Snore Australia 2015). When breathing slows during sleep the respiratory control centres in the brain do not respond fast enough to the changes in oxygen and carbon dioxide levels in the blood (Sleep Disorders Australia 2015). When the signal eventually does come through, breathing is quietly resumed, without the snorts and jerks associated with obstructive apnoea. This condition is commonly seen in people with congestive heart failure (Snore Australia 2015). Other disorders like stroke or a weakened diaphragm can also contribute to CSA (Sleep Disorders Australia 2015). CSA is managed with CPAP therapy, at low pressure, providing a positive impact on the quality of sleep achieved.

## Narcolepsy

Narcolepsy is a chronic sleep disorder characterised by an abnormality in the sleep–wake area of the brain resulting in persistent and excessive daytime sleepiness (Lewis et al 2014). An overwhelming urge to sleep overcomes the individual during hours of wakefulness and brief periods of sleep occur, lasting from seconds to several minutes (Lewis et al 2014). Individuals with narcolepsy may experience symptoms of EDS, loss of muscle tone, hallucinations, disrupted sleep at night and be unaware of their actions (Giacomini et al 2012). The individual will often fall straight into the REM period

### PROGRESS NOTES EXAMPLE 27.1

| | |
|---|---|
| 15/02/15<br>06:30 hrs | Nursing: Mr Adams was admitted to the medical ward at 22:30 hrs for overnight observation and review by the cardiac physician in the morning. He was brought in by the ambulance to the emergency department with chest pain 9/10 at 14:00 hrs. His chest pain was relieved with 600 mcg of Anginine × 3 and 2.5 mg of IV morphine given by the ambulance officers. He has a past history of angina and a stent to his left main coronary artery. On arrival to the ward he was pain free, and admission ECG and vital signs were within normal parameters. Refer to medication chart for medications commenced. At 02:00 hrs it was observed that Mr Adams appeared to be having an apnoeic period. He struggled for breath, awoke slightly snorting and then resumed a normal breathing pattern. Vitals signs were performed and no alterations from previous observations were noted. The oxygen saturation probe was left in situ. The oxygen saturation machine alarmed approximately every 15–30 min with varied desaturations down to $SpO_2$ of 75%. Mr Adams was reviewed overnight by the night resident medical officer as per the medical emergency team (MET) call criteria. Appointment to be made upon discharge for the sleep study clinic.<br>***J. McArdle* (McArdle) EN** |

of sleep (Lewis et al 2014). Narcolepsy often occurs in individuals in their teens or early 20s and research suggests the prevalence is increased if family members have narcolepsy (Giacomini et al 2012). There is no cure, but narcolepsy may be managed with medication (i.e. amphetamines), changes in lifestyle, counselling and support (Rebeiro 2013). Narcolepsy is usually diagnosed by conducting a daytime sleep study measuring the individual's tendency to fall asleep.

### Parasomnias

**Parasomnias** are sleep disorders that include a range of physical and behavioural occurrences such as sleep walking, nightmares, enuresis (bed wetting) and bruxism (tooth grinding), which occur more commonly in children than in adults (Rebeiro 2013). These can occur during REM or NREM periods of sleep. Sudden infant death syndrome (SIDS) is also considered a parasomnia and is thought to be an autonomic nervous system abnormality causing apnoea, hypoxia and cardiac arrhythmias during sleep (McCance et al 2015). It is recommended that infants be placed in the supine position during sleep. There are specific treatments recommended for parasomnia disorders which vary according to the sleep disturbance. Safety is paramount when providing education and treatment to support the individual with their disorder (Rebeiro 2013).

## FACTORS AFFECTING SLEEP

Frequently a number of factors affect the quantity and quality of sleep, rather than one individual factor (Rebeiro 2013). Clinical Interest Box 27.7 outlines the factors that affect sleep. Some of these factors are often transient; however, the individual may seek advice about a sleeping problem. Many stressors associated with daily living, and particularly with illness, may have a detrimental effect on a person's ability to rest and sleep, and this will further impact on their general wellbeing. It is vital that the nurse is aware of the factors that affect a person's ability to sleep in order to assist in alleviating or minimising these factors.

### Shift work

Shift work is a necessary and inherent part of the nursing profession. Nurses rotate through day, afternoon and night shifts, all of which may occur over a working week. Shift work causes disruption to the body's circadian rhythm, affecting physical and psychological wellbeing, which can lead to an increased risk of workplace and personal accidents (Gkrizioti et al 2010). Shift work can affect a nurse's normal sleeping pattern and quality of sleep. Fatigue and the ability to catch up on sleep when not rostered on are the main complaints from nurses who work night shift (Powell 2013). Just as nurses care for individuals' rest and sleep needs, nurses need

### CLINICAL INTEREST BOX 27.7 Factors affecting sleep

**Physical illness**: pain and discomfort may interfere with falling asleep, or disrupt the sleep pattern. The impact of a plaster cast, traction, a brace or splint will physically limit movement and position when sleeping.

**Pain**: chronic pain can increase feelings of fatigue, and intensity may be increased at night.

**Nocturia**: getting up at night to urinate will disrupt sleep pattern, and difficulty in falling back to sleep may be experienced.

**Dyspnoea**: the position that must be assumed to sleep and to ease difficulty breathing may be different or difficult for the individual to adjust to without disruption to sleep cycle. Fear of increasing difficulty in breathing is often experienced at night, particularly in cardiac disease when individuals may awaken with dyspnoea.

**Hypertension**: individuals may experience increased fatigue and early morning awakening.

**Drugs and substances**: see Clinical Interest Box 27.9.

**Lifestyle**: work shifts (especially rotating shifts) disrupt sleep patterns. It may take several weeks for the body to adjust to shifts such as night duty with the change in exposure to light and activity levels (see 'circadian rhythm').

**Exercise and fatigue**: physical activity that results in individuals feeling tired may actually increase quality of sleep. Fatigue, however, and feelings of exhaustion often result in difficulty falling asleep.

**Nutrition**: changes in body weight can influence sleep patterns, with weight gain causing longer sleep periods, and weight loss sometimes causing a reduction in sleep continuity. The timing and type of meals (e.g. a heavy or spicy meal close to the time of sleeping) may interfere with falling asleep and the ability to achieve restorative sleep, as the digestive system will be engaged in activity during sleep periods.

**Stress and emotional state**: worry over personal problems, health or work issues can disrupt sleep. Emotional problems cause tension, both physically and psychologically, and can interfere with the relaxation and calm required to fall asleep. Individuals may become frustrated at not being able to fall asleep, may wake frequently because of their emotional state or may oversleep as a result of sleep pattern disturbances.

**Grief**: also a realistic cause of sleep disturbance, not just in relation to death of a loved one, but also in relation to loss of position in society (such as retirement) or in relocation such as moving homes.

**Environment**: simple factors such as heating/cooling, lighting, comfort and familiarity of bed and bedding, noise (such as that experienced in hospitals or residential care facilities) may all impact on the ability to fall asleep and/or remain asleep.

*(Christensen & Kockrow 2011; Rebeiro 2013)*

to be aware of their level of fatigue and care should be taken to ensure adequate rest and sleep is obtained between shifts and on non-rostered shifts. It is also important to consider a good diet and exercise regimen as they can have a positive impact on circadian rhythms, leading to improved sleeping patterns (Pakieser-Reed 2013).

### CRITICAL THINKING EXERCISE 27.1
### Care of the nurse and night duty

You work on the medical ward and are rostered to work on two night shifts after working a late/early. You already feel tired from working the late and then an early, after only 5 hours' sleep in between. On the early shift at the morning handover the night shift RN reported that it had been quite busy on the night shift. There are a few palliative individuals requiring specialised care to manage their pain and comfort levels. There are also several individuals who have had dense CVAs (cerebrovascular accidents) who are long term, requiring extra care. What strategies could you put in place to ensure that you are not too fatigued to commence and work the two night shifts as rostered? What strategies can you put in place to care for self, working shift work?

## ASSESSING REST AND SLEEP PATTERNS

Assessment of rest and sleep patterns plays an important role in assisting individuals and their caregivers to identify habits and factors that contribute to poor sleep (Lewis et al 2014). The information gathered can allow the nurse to identify strategies and incorporate them into the nursing care provided (Rebeiro 2013).

### Sleep pattern

When assessing an individual's status in relation to comfort, rest and sleep, the nurse should obtain information of the individual's usual periods of rest and sleep behaviour, such as periods of rest during the day and the time normally gone to sleep, the quality of sleep and the time of waking (Rebeiro 2013) (see Clinical Interest Box 27.8). It is helpful to know the individual's sleep hygiene routine; for example, if they normally have a hot drink before bedtime, or if they require medication to help them sleep (Clinical Interest Box 27.9).

### CLINICAL INTEREST BOX 27.8
### Questions to assess sleep patterns

- What time do you usually go to sleep?
- How quickly do you fall asleep?
- What is the average number of hours you sleep during the night?
- How many times do you wake at night
- Do you know what wakes you at night?
- When do you usually wake in the morning?
- Do you rise once you wake or do you stay in bed?
- How do you feel physically after awakening in the morning?

*(Christensen & Kockrow 2011; Rebeiro 2013)*

### Physiological factors

The nurse should also assess whether there is any discomfort that may disturb rest and sleep, such as nausea, difficulty

### CLINICAL INTEREST BOX 27.9
### Effects of medications on sleep

**Hypnotics**
- Interfere with reaching deeper sleep stages
- Provide only temporary (1 week) increase in quantity of sleep
- Eventually cause 'hangover' during day; excess drowsiness, confusion, decreased energy
- Sometimes worsens sleep apnoea in older adults

**Antidepressants and stimulants**
- Suppress REM sleep
- Decrease total sleep time

**Alcohol**
- Speeds onset of sleep
- Reduces REM sleep
- Awakens person during night and causes difficulty returning to sleep

**Caffeine**
- Prevents person from falling asleep
- Causes person to awaken during night
- Interferes with REM sleep

**Diuretics**
- Night-time awakenings caused by nocturia

**Beta-adrenergic blockers**
- Cause nightmares
- Cause insomnia
- Cause awakening from sleep

**Benzodiazepines**
- Alter REM sleep
- Increase sleep time
- Increase daytime sleepiness

**Narcotics**
- Suppress REM sleep
- Cause increased daytime drowsiness

**Anticonvulsants**
- Decrease REM sleep time
- Cause daytime drowsiness

*(Christensen & Kockrow 2011; Rebeiro 2013)*

breathing or any acute or chronic pain related to the illness. Pain is associated with chronic poor sleep (Dzierzewski et al 2015). Pain causes the person to have fragmented sleep as it stimulates the cortical areas of the brain, leading to arousal, and lack of sleep intensifies the experience of pain (Fillary et al 2015).

Nursing assessment of individuals with chronic illnesses is important so that the sleeping environment can be modified or referral for further assessment can be initiated to assist in achieving adequate rest and sleep. Individuals with chronic lung disease or congestive heart failure are often short of breath when lying flat and will require two or more pillows to sleep on. They may be woken during the night due to congestion or shortness of breath (Rebeiro 2013). Nocturnal chest pain is common in the early hours of the morning in people with coronary artery disease related to the REM period of sleep where dreams occur (McCance et al 2015). Hypertension also causes early morning waking and fatigue (Rebeiro 2013).

Nocturia disturbs sleep due to the frequent waking to void or when incontinence occurs. Nocturia may be caused by diabetes where high blood sugars cause polyuria; loss of bladder tone causing incontinence or frequent urination; congestive heart failure where elevating legs in bed results in increased venous return and the filtering of increased blood volume creates more urine; or prostatic enlargement resulting in frequent urination overnight (Rebeiro 2013).

Musculoskeletal issues affecting sleep include inability to reposition self when uncomfortable or in pain; restless leg syndrome where deep muscles become itchy and the only relief is by moving them; muscle cramps due to poor circulation in the legs causing pain and waking a person suddenly (Rebeiro 2013).

## Emotional factors

It is important also to assess for psychological and emotional factors (that may not be visible) that may be impacting on the individual's ability to relax and achieve a state of calm to facilitate rest and sleep. Worry or stress about an illness state or the impact of the illness on an individual's lifestyle can result in poor sleep habits (Rebeiro 2013).

## Environmental factors

Hospitalised individuals' sleep pattern may be affected by illness or the hospital environment and routines (Rebeiro 2013). The normal pattern and quality of sleep deteriorates greatly when a person is in a hospital environment (Thomas et al 2012). There is a correlation between disruptions to sleep and noise levels. Electronic sounds are more likely to wake individuals than other noises at the same volume (Fillary et al 2015). Assessment of environmental factors affecting a person's ability to maintain sleep is important in being able to modify the environment to promote sleep and rest. This may be as simple as turning down the volume of the volumetric pump or dimming lights. Review Case Study 27.1 in relation to changes in sleep patterns due to hospitalisation.

### CASE STUDY 27.1

Mrs Walsh is a 75-year-old woman diagnosed with bowel cancer, who has been admitted to the surgical ward preoperatively for an anterior bowel resection with the possibility of the formation of a colostomy. She has been admitted for preop bowel preparation. On admission, Mrs Walsh tells you that she dreads coming into hospital because she finds it very difficult to sleep, and when she gets home it takes her ages to catch up on all the sleep she has lost.

1. What steps will you undertake to develop a sleep plan to assist Mrs Walsh to improve her expected sleep pattern in hospital? What strategies might she use to regain her previous sleep quality once home?
2. Identify factors that may impact on Mrs Walsh's ability to sleep post surgery. Develop a brief care plan to meet postop rest and sleep needs.
3. What do you believe individuals should expect to achieve in terms of quality sleep while in hospital and how would you implement nursing strategies that could improve quality of sleep?

## Medication factors

Assessment of the individual's medication regimen is important to determine if the side effects of particular prescribed medications are contributing to daytime sleepiness or drowsiness (Rebeiro 2013) or night-time wakefulness (e.g. prednisolone taken at night causes insomnia and nightmares, which is why it is prescribed as a dose). If so, the ability to achieve an adequate night's sleep may be affected. An individual may need the assistance of medications to fall asleep and maintain sleep but these are indicated for short-term management only (Bryant & Knights 2014).

The information obtained, together with observation of the individual, provides the nurse with a foundation on which to plan and implement nursing actions to promote comfort, rest and sleep. When possible the person's usual sleep hygiene routine should be maintained, and the immediate environment arranged so that it is conducive to comfort, rest and sleep.

## Hospitalisation/residential care

Sleep and rest disruption is prevalent in hospitalised individuals. Thomas et al (2012) highlighted that inadequate pain control, frequent disturbances from staff and presence of other persons in the room are major disturbances to sleep reported by hospitalised individuals. Sleep problems in individuals in residential aged care facilities include difficulty getting to sleep, night-time waking, night-time wandering and over- or under-sleeping (Swann 2013). Both short- or long-stay hospitalisation can cause sleep deprivation, leading to negative health outcomes (Pilkington & Lorenz 2013). Adequate rest and **restorative sleep** is crucial for optimal

recovery from illness (Ye & Keane 2013). The need to promote adequate rest is an important aspect of nursing care as without it individuals may experience fatigue and irritability as well as having a decreased ability to deal with stressors (Christensen & Kockrow 2011). Nursing interventions should therefore be aimed at improving the quality of rest and sleep to promote health (Rebeiro 2013).

Many of the causes of sleep deprivation in hospitalised individuals are environmental, and the nurse needs to focus on reducing these effects by modifying the environment (Pilkington & Lorenz 2013). An individual may find it difficult to rest in a hospital environment because of constant activity levels and attention by nursing staff, or disturbing sights and smells that may occur. In addition an individual may be subjected to sensory stimulation not normally experienced in the home environment (see Clinical Interest Box 27.10). During the night, nurses continue to observe individuals and perform certain procedures or treatments as required. Nurses can control the ward environment to optimise sleep by avoiding waking individuals for non-essential activities, and timing them so they are completed when the individuals are awake (Rebeiro 2013). However, as part of the nurse's responsibility and accountability in delivering care it is at times unavoidable to disturb individuals from their sleep to perform nursing observations and activities required to ensure an individual's safety and wellbeing. For example, an individual on hourly neurological observations may appear to be having a restful sleep but has deteriorated neurologically. A critical error can be made if the individual is not woken up for the hourly assessment and the changes in neurological status are not detected.

## CLINICAL INTEREST BOX 27.10 Controlling noise in the hospital setting

- Close doors to individual's room when possible
- Keep doors to work areas of unit closed when in use
- Reduce volume of nearby telephone and paging equipment
- Wear rubber-soled shoes. Avoid clogs
- Turn off bedside oxygen and other equipment that is not in use
- Turn down alarms and beeps on bedside monitoring equipment
- Turn off room TV and radio unless individual prefers soft music
- Avoid abrupt loud noise such as flushing a toilet or moving a bed
- Keep necessary conversations at low levels, particularly at night
- Conduct conversations and reports in a private area away from individuals' rooms

*(Rebeiro 2013)*

It is optimal to achieve at least 90 minutes of continuous sleep as this gives the individual at least one full REM cycle, which can have a positive influence on the effectiveness of sleep (Missildine et al 2010). If woken, and the individual experiences difficulty resettling, measures such as a change of position, adjustment to the bedding or a warm drink may help with resuming sleep. It should be noted if an individual does not resettle after these supportive measures have been implemented, the nurse on night duty must ensure that the individual's comfort and safety are promoted.

## CRITICAL THINKING EXERCISE 27.2

Mrs Pratt is a young mother of three children, aged 2, 4 and 6 years. She has just been discharged from hospital after a 3-day admission for the treatment of exacerbation of asthma. She has been prescribed an anti-inflammatory prednisolone 25 mg on a reducing dose, as well as her preventer and reliever. Identify factors that may affect her ability to sleep, and briefly describe nursing interventions that may assist her to rest to facilitate her recovery.

Continuity of care is essential, and as there are usually fewer staff working at night, the nurse's observational skills are vital in detecting any change in an individual's condition or comfort levels. The nurse is also in a position to observe any specific physiological problems related to sleep including pain, discomfort, excessive restlessness, snoring or airway obstruction. Referrals may also need to be made to a sleep study centre, pain management team, social worker, counsellor or psychologist to address the sleep disturbance issue.

Stressors or psychological issues associated with illness or hospitalisation may cause difficulty in maintaining the usual sleep pattern (Rebeiro 2013). Being in hospital involves a variety of potential stressors; the nurse should therefore implement measures to provide as stress free an environment as possible. Anxiety related to illness, and its consequences, may prevent relaxation and interrupt sleep. Emotional tension may be reduced by providing individuals with adequate information before any treatment or procedure starts. See Nursing Care Plan 27.1 on sleep alteration. To provide opportunities for questions to be asked and answered, the nurse should promote a climate that is conducive to communication by spending time with the individual and their significant others.

Some healthcare facilities have regulations and specified visiting hours, which are designed to provide rest periods and avoid overtiring hospitalised individuals. Throughout the rest periods, visitors to, and activities in, the ward are kept to a minimum to provide a quiet relaxed environment where individuals should be encouraged to try to sleep or to engage in some relaxing non-stressful activity. To facilitate rest and relaxation, an individual's physical comfort should be promoted, as it is difficult to rest in the presence of discomfort such as pain, a full bladder or an uncomfortable position. (See Clinical Interest Box 27.11.)

### CRITICAL THINKING EXERCISE 27.3

Ms Barbara White, a 49-year-old woman on the surgical ward, has recently undergone knee reconstruction surgery. You are on night shift, and find her awake at 0100 hrs. She tells you that she has been having trouble sleeping since her surgery 4 days ago. What strategies could you implement to assist Ms White to have optimal sleep?

## SLEEP-PROMOTION MEASURES

Sleep is influenced by a variety of factors that may be described as physical, psychological or environmental. Effective sleep may be facilitated by a range of natural/non-pharmacological measures, which include:

- Sleep in a room that is quiet, darkened and at a comfortable temperature (coolness or warmth), which has sufficient fresh air or ventilation
- Engage in physical exercise/activity during the day to promote rest at night, and go to bed when feeling tired

### CLINICAL INTEREST BOX 27.11 Promoting rest and sleep in hospitalised adults

- Follow regular sleep hygiene routines
- Encourage individuals to wear loose-fitting nightwear
- Remove any irritants against the individual's skin, such as moist or wrinkled sheets or drainage tubing
- Position and support body parts to protect pressure areas and aid muscle relaxation
- Administer necessary personal hygiene measures
- Keep linen clean and dry
- Encourage the individual to void before going to sleep
- Administer any analgesics or sedatives about 30 minutes before bedtime
- Provide a quiet environment

*(Rebeiro 2013)*

### NURSING CARE PLAN 27.1 SLEEP ALTERATION

**Assessment:** Mr Brown is an 85-year-old farmer who has recently entered a nursing home after a failed rehabilitation, post repair to a compound fracture to his right neck of femur. Prior to this Mr Brown was living independently at home with his wife. Mr Brown was an inpatient in an orthopaedic ward for 20 days and then in a rehabilitation unit for 3 weeks. Mr Brown has not been able to regain the ability to walk and requires assistance to mobilise in on-bed and off-bed tasks. As a result he requires repositioning several times overnight due to pain in his right leg. Mr Brown has mentioned prior to coming into hospital that he normally slept soundly until morning. He is feeling stressed about the pain and not getting enough quality sleep due to the noises in the night within the nursing home. He also feels depressed at having to be cared for in a nursing home, and wishes to be home with his wife as he worries about her being alone on the farm.
**Issue/s to be addressed:** Disturbed sleep pattern related to pain in right hip and stress
**Goal/s:** Mr Brown will be able to have improved quality of sleep within 2 weeks
Mr Brown will achieve a normal sleep pattern within 2 weeks

| Care/Actions | Rationale |
|---|---|
| Assess pain levels prior to sleep | To prevent pain waking Mr Brown |
| Refer Mr Brown to pain management team | To provide adequate treatment to optimise pain relief measures allowing optimal sleep |
| Adjust the environment to minimise the noise levels; close door, darken room or soft music | A quiet, darkened environment promotes sleep and soft music masks environmental noises that may keep a person awake |
| Encourage Mr Brown to verbalise concerns to decrease stress prior to sleep | Excess worry or stress prior to sleep may stimulate wakefulness |
| Refer family situation to a social worker to enable Mr Brown to discuss concerns about the farm and his wife | To decrease worry and concern, which may relax Mr Brown, enabling him to sleep |
| Promote relaxation techniques to promote sleep | Relaxation techniques may promote sleep by decreasing thought processes and reducing stress |
| Provide aids to promote comfort; air mattress to cushion body against pressure. Correct body alignment supported with pillows to promote comfort | Falling asleep only occurs if a person feels relaxed and comfortable |

**Evaluation**

Ask Mr Brown regarding his perception of quality of sleep.
Ask Mr Brown if pain is waking him in the night.
Observe amount of night-time wakefulness and daytime sleepiness.

- Spend some time relaxing and unwinding before going to bed. Sleep may also be more easily achieved if the person is calm and has been able to resolve any problems prior to going to bed
- Resist stimulants such as tea, coffee or cocoa immediately before going to bed. Individuals may find it easier to sleep if they avoid going to bed feeling hungry or overfull
- Adopt a sleep hygiene routine (e.g. similar time each night, warm bath or shower, warm drink and some peaceful music or relaxing reading). For children, this may include quiet time and perhaps story reading, as well as settling with a familiar object, such as a doll or soft toy. Clinical Interest Box 27.12 outlines how to promote safe sleeping for infants.

The need for comfort is closely related to the need for sufficient rest and sleep. Rest depends on relaxation and to be relaxed a person must be physically comfortable and free from emotional tension. Rest and relaxation do not necessarily mean inactivity; for example, a person who has a sedentary occupation may find the physical exercise of a brisk walk relaxing. People confined to bed may find it more relaxing if they are reading or watching television rather than lying in bed unoccupied (Christensen & Kockrow 2011).

### CRITICAL THINKING EXERCISE 27.4

Mr Herron is a middle-aged factory worker who works permanent evening shift, finishing work each weeknight at 2300 hrs. After work he eats his main meal of the day and drinks at least six cans of beer. He normally goes to bed at 0200 hrs and sleeps in short periods, for about 5 hours. He gets up at least once to urinate. He relaxes by watching television in bed. You perform a sleep assessment on Mr Herron's sleep habits and history. How could you assist Mr Herron to develop effective sleep hygiene habits that will improve his sleep patterns?

### CLINICAL INTEREST BOX 27.12 Promoting safe sleeping for infants

The SIDS and Kids Safe Sleeping program teaches parents how to create a safe sleeping environment for babies and young children:

1. Sleep baby on the back from birth, not on the tummy or side
2. Sleep baby with head and face uncovered
3. Keep baby smoke free before birth and after
4. Provide a safe sleeping environment night and day
5. Sleep baby in their own safe sleeping place in the same room as an adult caregiver for the first 6 to 12 months
6. Breastfeed baby.

*(SIDS and Kids 2014)*

## Meeting sleep needs/sleep hygiene

Good sleep hygiene promotes sleep and minimises factors that impact on individuals' ability to achieve adequate sleep (Hellstrom et al 2011). Hospitalised individuals should be encouraged to maintain their usual pre-sleep routine (Rebeiro 2013). (See Clinical Interest Box 27.13.) **Sleep hygiene** is the routines and habits an individual performs prior to sleep to maximise the effectiveness of sleep. In hospital, the nurse should assist a person in preparation for sleep by ensuring that the following key physiological and psychological needs are met.

### Hygiene needs

When required the individual should be assisted to meet all hygiene needs, such as washing face and hands and cleaning teeth. An ambulant individual may like to have a warm shower or bath before settling to sleep. A non-ambulant individual may require repositioning and turning.

### Nutritional and fluid needs

Large spicy meals, caffeine and alcohol must be reduced or avoided prior to retiring to bed as they can disturb sleep (Rebeiro 2013). A warm drink and snack could be offered to the individual, unless this is contraindicated. An individual may prefer a non-stimulating milk-based drink rather than tea or coffee, which can have a stimulating effect. In addition oral fluids that can be consumed during the night if desired should also be provided.

### Elimination needs

Individuals should be provided with toilet facilities before settling for sleep. The nurse may need to provide assistance with the appropriate toileting aids and facilities. Urinary drainage equipment should be checked, and the collection bag emptied if necessary.

### Comfort needs

Preparing the individual's room includes ensuring that there is adequate ventilation and warmth and that lighting is reduced to a minimum (Rebeiro 2013). The individual's nurse call bell and any other items that may be required

### CLINICAL INTEREST BOX 27.13 Sleep hygiene

- Bedtime routines and sleeping environment
- Use of sleep and other prescription medications, and over-the-counter drugs
- Pattern of dietary intake and amount of substances that influence sleep
- Symptoms experienced during waking hours
- Physical illness
- Recent life events
- Current emotional and mental status

*(Adapted from Rebeiro 2013)*

during the night need to be placed within easy reach. Nursing measures include ensuring that the individual is positioned comfortably and that the bedclothes and pillows are arranged to meet the individual's needs. The bottom sheets should be free of wrinkles or creases, and supplementary items such as a sheepskin or bed cradle may be used to enhance comfort and to prevent the risk of pressure on skin and bony prominences. Whenever possible, treatments and procedures are completed before individuals settle for sleep. For example, any splints or dressings should be checked and, if necessary, adjusted or changed (Rebeiro 2013). (See Chapter 23.)

## Protection and safety needs

The National Safety and Quality Health Service (NSQHS) standards (ACSQHC 2012) on preventing and managing pressure injuries, and preventing falls and harm from falls, need to be considered in the protection and safety needs of hospitalised individuals (see Chapter 19). Extended bed rest from illness and immobility can lead to pressure injuries and can occur in individuals with risk factors including poor nutrition, skin integrity and pressure points, or be age related (ACSQHC 2012). The intention of the NSQHS standard regarding pressure injuries is to prevent the occurrence of pressure injuries. The nurse needs to perform a risk assessment on admission to provide the appropriate interventions when assisting the individual with rest and sleep needs.

The NSQHS standard regarding falls prevention aims to prevent falls or minimise the harm from falls. Measures need to be taken to promote the individual's safety during sleep. If a person is restless (but not confused or disoriented), the use of bed rails (one or both) may be indicated, but a comprehensive falls risk assessment must be completed with appropriate consent and documentation undertaken. Then an individualised falls prevention plan must be implemented (ACSQHC 2012). For a confused individual, it is usually more appropriate to adjust the height of the bed to its lowest level. As an alternative safety measure, 'hi-lo' beds, which can be situated at floor level, may be appropriate for an individual who is disoriented and inclined to get out of bed and wander. The risks to a confused or disoriented individual are greatly increased in raising bed rails as the feeling of being enclosed or limited in activity may result in them climbing over the rails, thus causing an unnecessary injury. Confused or disoriented individuals need frequent monitoring and measures that limit the risk of injury. Adequate lighting should be provided, perhaps via a night light, particularly if the individual needs to mobilise during the night.

Other safety measures include regular monitoring throughout the night to assess an individual's health status and ensure that any equipment such as intravenous infusion apparatus, monitoring leads, indwelling catheters, drain tubes or any assistive devices are in place and functioning appropriately.

## Physiological needs

It is the role of the nurse to assess an individual for any physiological disturbances that may impact on adequate sleep and to promote comfort conducive for rest and sleep (Rebeiro 2013). This includes interventions such as alleviating pain, attending to hygiene or any distressing symptoms, such as difficulty breathing, which may affect adequate rest and sleep (Rebeiro 2013). In collaboration with a Registered Nurse, measures (either non-pharmacological or pharmacological) should be undertaken to alleviate these factors (as much as possible).

## Psychological needs

Anxiety and an active mind can interfere with effective sleep (White et al 2011). If an individual is anxious or worried, the nurse should try to ascertain the reason and provide appropriate support. For example, a person may be concerned about some aspect of treatment, such as forthcoming surgery, and providing them with more information (as appropriate within scope of practice) may help to alleviate some of their anxiety (Rebeiro 2013). Reassurance that a nurse will be available to respond to needs may also be helpful.

## Pharmacological measures

In the short term, and particularly while hospitalised, an individual may be prescribed medication by a medical officer to promote sleep; for example, a sedative. Long-term use of sedatives can be detrimental to sleep routines. Therefore, alternative measures to assist a person to improve sleep patterns are important (Rebeiro 2013). Natural sleep hygiene measures to promote settling should be undertaken first but, if difficulty getting to sleep persists, mild sedation may be considered by the medical team to be appropriate (White et al 2011). After a sedative medication has been administered, the individual should be encouraged to relax and allow it to take effect. In most cases, light sedatives assist individuals to fall asleep, but do not have an impact on keeping the individual asleep; therefore, once the individual has settled, activity, noise and light should be reduced to a minimum. The response to, and effects of, such medication must be noted and recorded (Rebeiro 2013).

## Stress reduction

A range of techniques are available for reducing stress and promoting relaxation, all of which aim to help the individual control reactions to stress. A calm relaxed person is likely to fall asleep quickly and sleep soundly through the night (White et al 2011). Relaxation techniques should initially be learned in a quiet restful environment and, with practice, may then be used in most situations to reduce stress. Physical and psychological relaxation is the aim of relaxation techniques, reducing the body's physical tension as well as interrupting constant thoughts that prevent sleep. Some individuals benefit from utilising relaxation techniques and do sleep longer; however, not all people respond to relaxation techniques (White et al 2011). Individuals should be encouraged to pursue activities that reduce stress.

## Management of weight

Individuals who are overweight tend to sleep longer and have fewer interruptions than an individual who is underweight,

who will have more interruptions and wake earlier (Christensen & Kockrow 2011). Discussion with a dietitian should be made to assist in formulating a dietary plan to manage weight issues to promote health and wellbeing and reduce the risk of diet-related conditions and chronic diseases (Australian Dietary Guidelines 2015).

## Complementary and alternative therapies

Individuals are increasingly turning to complementary therapies to use alongside traditional medical treatments to enhance health and wellbeing (Christensen & Kockrow 2011). A range of complementary therapies can assist with promoting rest and sleep. Some of these may include meditation techniques, relaxation, exercise, creative therapies, religious activities, acupuncture, biofeedback, massage, reflexology, aromatherapy and herbal treatments (Christensen & Kockrow 2011). They are known as alternative therapies when the complementary therapy becomes the main form of treatment, replacing medical treatment.

***Yoga, mindfulness, meditation and tai chi*** Yoga, meditation and tai chi are forms of relaxation and exercise that are helpful to many people and, while they have degrees of difficulty, can be practised by many age groups and people of varying degrees of wellness. Mindfulness is a form of self-awareness meditation which is used as an adjunct to both medical and psychological therapies. It is a process that allows an individual to become aware of physical and psychological events affecting sleep and to develop strategies to manage the reactions to sleep disturbances (Ong & Sholtes 2010). It is important that techniques for alternative therapies are taught by people with expertise in these methods (Halpern et al 2014).

***Relaxation breathing*** This technique consists of controlled breathing, performed while the individual assumes a comfortable position. The person is encouraged to concentrate on their breathing, and may find it helpful to visualise each breath as providing muscles with energy-giving oxygen. The person is encouraged to take a deep breath, hold it briefly and then exhale slowly. With each exhalation the person is encouraged to say 'relax' and, as the technique is repeated, should feel progressively more relaxed (Beyond Blue 2015).

***Progressive muscular relaxation*** The theory behind this technique is that a relaxed body leads to a relaxed mind. The technique consists of consciously tensing and relaxing the major muscles of the body in sequence. The individual is encouraged to tense one or a group of muscles for approximately 10 seconds, feel the tension and then slowly ease the tension by relaxing the muscles (Beyond Blue 2015). As the technique is repeated there should be an awareness of the sensation of relaxation in the muscles.

***Massage*** Massage is a method of communication without words, and can induce a feeling of physical and mental relaxation and calm. Massage therapy releases chemical neurotransmitters (endorphins) that contribute to a feeling of wellbeing, and decreases the levels of stress hormones, adrenaline, cortisol and noradrenaline (Hellstrom et al 2011). Muscles contract and become tense in stressful situations, and massage can be an effective method of promoting muscle relaxation (Salvo 2016). There are many types of massage and, while most are relatively easy to learn, instructors with experience can teach caregivers simple relaxation massage techniques to assist others to relax.

Although a massage can be beneficial, some people may not feel comfortable about being massaged. Also, an individual's physical condition may contraindicate the use of massage. In older individuals, with age-related skin changes, extreme care must be taken to ensure that massage is gentle and light to avoid disruption of the epidermal–dermal junction, which becomes weaker with age (Salvo 2016). In older individuals, the risk of skin tears is greatly increased because of this junction weakness, and massage should be limited to small areas of the hands, feet or shoulders as tolerated. In the right situation, however, massage, particularly of the neck and back, can be very relaxing and promote rest (Salvo 2016).

## Exercise

Exercise can be useful in sleep promotion; however, it is recommended that it be performed at least 2 hours prior to bedtime to allow the body to relax (Rebeiro 2013). In relation to older adults who may have age-related changes or chronic ill health, or those who are experiencing episodes of illness or changes to health status (such as surgery or treatment), the degree of physical activity that may be undertaken may be limited, but simple activity such as sitting out of bed or gentle ambulation several times a day may meet the same activity level for an individual with health limitations that regular exercise has for a person in a state of wellbeing (Christensen & Kockrow 2011). Exercise is not always practical, especially if the person is unwell; therefore, relaxation techniques may be used instead (Christensen & Kockrow 2011).

Clinical Interest Box 27.14 outlines some ways in which sleep and rest can be promoted at home.

### DECISION-MAKING FRAMEWORK EXERCISE 27.1

You are looking after Mr Adams on night shift. You go to do his vital signs at 02:00 hrs and notice that he does not appear to be breathing normally. When you touch his arm and speak to him he rouses and starts to snort. You ask him if he has had any sleep issue at home. He tells you that he is not aware of any, although his wife reports he stops breathing sometimes. You apply the $SpO_2$ saturation probe to his finger and leave it in situ. Not long after that Mr Adams falls back to sleep and the $SpO_2$ machine alarms. You enter the room and his $SpO_2$ is at 79%.

1. What is your responsibility in regards to the nursing care for Mr Adams?
2. Using the decision-making framework, what is your role in the need for a MET call?

## CLINICAL INTEREST BOX 27.14 Promoting rest and sleep at home

### Sleep pattern

- Establish a regular bedtime and waking time for all days of the week. Eliminate lengthy naps during the day. Limit naps to only 30 minutes a day
- Exercise adequately during the day. Avoid physical exertion 2 hours before bedtime
- Avoid dealing with work or family problems before bedtime
- Establish a regular sleep hygiene routine before sleep (e.g. reading, listening to music)
- When unable to sleep, pursue a relaxing activity until you feel drowsy
- If having trouble falling asleep, get up until you feel sleepy
- Use the bed mainly for sleep; avoid activities like watching TV

### Environment

- Ensure appropriate lighting, temperature and environment
- Keep noise to a minimum

### Diet

- Avoid heavy meals in the 3 hours before bedtime
- Avoid alcohol- and caffeine-containing foods and beverages at least 4 hours before bedtime
- Decrease fluid intake 2–4 hours before sleep
- If a bedtime snack is necessary consume only a light snack or a warm milk drink

### Medications

- Use sleeping medications only as a last resort
- Take analgesics 30 minutes before bedtime to relieve aches and pains
- Consult with a healthcare provider about adjusting other medications that may cause insomnia

*(Adapted from Berman et al 2015)*

## Summary

Comfort is necessary for relaxation, rest and sleep. A person's ability to achieve comfort and relax, and therefore to receive sufficient rest and sleep, may be disrupted during illness or hospitalisation. Measures that can be implemented to promote rest may include certain techniques that facilitate relaxation. Sleep can also be promoted by allowing the hospitalised individual to maintain their normal pre-sleep routine, and by ensuring that the person's safety and comfort are promoted during the night, as at any other time. Sleep behaviours and patterns can be assessed by the nurse, and simple measures to promote effective sleep may be taught and implemented. Assisting individuals and self to meet comfort, rest and sleep needs is essential in the promotion of individual physical and psychological wellbeing.

## Review Questions

1. Describe the importance of rest and sleep to a person's wellbeing.
2. Briefly describe the five stages of the sleep cycle.
3. List the factors that may interfere with the process of rest and sleep.
4. What is the circadian rhythm?
5. Describe the supportive nursing measures that may be implemented to promote the individual's need for rest and sleep.
6. Briefly describe why individuals have difficulty achieving restful sleep while hospitalised.
7. Identify factors across the lifespan that may impact on an individual's perception of their quality of sleep.
8. What measures can be implemented by nurses to assist an older individual to re-establish their sleep pattern when they have changed their living environment (such as moving to a new home or residential facility)?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

pursed-lip breathing
range of movement (ROM)

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe and implement the principles of good posture and body mechanics
- Describe the role of the musculoskeletal system in the regulation of movement
- Describe how joints are involved in movement
- State differences between isotonic, isometric and isokinetic exercise
- Describe and define range of movement (ROM)
- Identify and demonstrate joint movements involved in ROM exercises
- Define obesity and describe how variables such as family values and diet influence adult obesity
- Describe how older adults may benefit from exercise
- Identify and describe the complications associated with immobility and implement appropriate preventative measures
- State the influences and effects associated with disorders of the musculoskeletal system
- Identify the major musculoskeletal system disorders that impact movement and exercise
- Describe the major manifestations of musculoskeletal system disorders
- Briefly describe the specific disorders of the musculoskeletal system outlined in this chapter
- Define the diagnostic tests that may be used to assess musculoskeletal function
- Assess individuals for impaired mobility and activity intolerance
- Assist in planning and implementing nursing care plans for individuals with a musculoskeletal disorder
- According to specified role and function, perform the nursing activities described in this chapter safely and accurately in the clinical environment

## CHAPTER FOCUS

Movement and exercise are essential components for restoring, maintaining and enhancing physical and psychosocial health. As society becomes increasingly sedentary in both work and home environments, government and health agencies are researching and evaluating the effects of inactivity on health, disease processes, ageing and morbidity. Research suggests that despite the rising trend in health conditions related to obesity and immobility, the commencement of an exercise program can retard and even reverse the progression of conditions such as osteoporosis, heart disease, diabetes mellitus and the effects of ageing.

The human body is ideally suited to movement. Regular exercise promotes health, feelings of wellbeing and prevents illness throughout the lifespan. Exercise is made possible by the muscular, skeletal and nervous systems. These interconnected systems work together to make movement possible and for most human movement they must function effectively for optimal physical performance. Disease processes that disable one or more of these systems may inhibit or restrict mobility. To ensure mobility and exercise are maximised and maintained, allied health teams should devise care plans to meet individual needs and abilities based on the specific strengths and disabilities of each individual in their care.

Healthcare workers are in a unique position to educate and support people to make lifestyle changes for improvement in health and prevention of disease. Effective and timely health promotion can significantly contribute to the long-term health of a person and potentially reduce disease progression and hospital re-admission. For those with recurring mobility issues, nurses and allied health professionals can support the transition to mobility aids and promote independence and quality of life on discharge to home or an assisted facility. Nurses who promote and encourage mobility and movement play a significant role in the individual's healthcare experience. This important contribution can have a lasting impact on a person's recovery and rehabilitation and benefit society with its positive outcomes.

## LIVED EXPERIENCE

When I turned 50 I began to worry more about my bone and muscle health. I regularly attend Pilates and yoga and now that I am 60 I am noticing how much more agile and active I am in comparison to some of my friends who stayed more sedentary. I have also started swimming and cycling which keeps my joints moving. I feel better now than when I was 30.

**Vanessa, 65 years**

# THE PHYSIOLOGY OF MOVEMENT

## The skeletal system

The skeletal system is the internal framework that supports, shapes, protects and moves the human body. The bones that form the skeleton serve many functions. These functions include support of body shape, protection of organs, movement, storage of fat and minerals and **haematopoiesis** or blood cell formation in bone marrow. To understand the importance of the skeletal system, imagine performing a task such as running or throwing. If the bones required in this movement are disabled due to damage or pain, this activity becomes more challenging, if not impossible, to perform (Patton & Thibodeau 2010).

## The muscular system

The muscular system enables body movement, joint stabilisation and maintenance of posture. The function of muscle is to contract or shorten (see Clinical Interest Box 28.1). Skeletal muscle attaches to bone and can rapidly contract to exert great power or fine movement under voluntary control. Muscles are supported by a network of connective tissue and tendons that anchor muscle to bone for strength and support. Skeletal muscle is classified by the kind of movement it makes; for example, flexors allow joints to bend or flex, while abductors allow shortening so that joints are straightened or abducted (moved away from the body). When muscle contracts it pulls on a bone or bones and produces movement at a joint, where two bones meet. As joints are weak points in the skeleton, synovial fluid, cartilage, ligaments and tendons add protection and support (Patton & Thibodeau 2010).

### CLINICAL INTEREST BOX 28.1 Muscle coordination

The muscular system plays a vital role in maintaining correct body posture by means of good muscle tone and coordinated activity. Most skeletal muscles work in pairs or groups, with one pair or group antagonising the action of another pair or group to achieve controlled movement. For example, during elbow flexion, the triceps muscle relaxes to allow the forearm to be pulled up when the biceps muscle contracts. Extension of the arm is made possible by the relaxation of the biceps, as the triceps contracts and pulls on the arm. The erect position of the trunk is maintained as a result of coordination of groups of muscles (Marieb 2013; Patton & Thibodeau 2010).

## The nervous system

Muscle movements occur as a result of stimulation by a motor or efferent nerve. These nerves activate muscles to respond to voluntary signals, such as grasping an object or towel drying hair. Muscle can respond to voluntary control, those movements controlled by human thought, or to involuntary control through the autonomic nervous system (Marieb 2013). Transmission of the impulse from the nervous system to the musculoskeletal system requires a chemical transmitter to cross the myoneural junction. Acetylcholine transfers the electric impulse from the nerve to the muscle to stimulate muscle and initiate movement (Crisp & Taylor 2012). An imbalance in this chemical neurotransmitter can result in impeded nerve transfer which delays the potential for coordinated or rapid musculoskeletal response.

The co-dependent relationship between the skeletal, muscle and nervous system in body movement can be demonstrated in a person with a spinal cord injury. A lesion in the spinal cord inhibits nerve transmission beyond the point of injury. With no nerve impulse to contract or react, muscle lays dormant. While still providing shape and connection with the underlying bones, the posture cannot be supported and the bones are unable to mobilise due to absence of muscle contraction and voluntary stimulation (Marieb 2013).

# BODY MECHANICS

Fatigue, muscle strain and injury can result from improper use or positioning of the body during activity or rest. Good posture is achieved when all parts of the body are in correct alignment when sitting, lying, standing or moving. Normal spinal curves should be maintained and the joints should be supported in their normal positions. Good posture and alignment reduces strain on all muscles and enables internal organs to function without interference (Figure 28.1). **Body mechanics** is the term used to describe the physical coordination of all parts of the body to promote correct posture and balanced effective movement. The practice of correct body mechanics results in less fatigue and reduces the risk of muscle and joint injury (Marieb 2013).

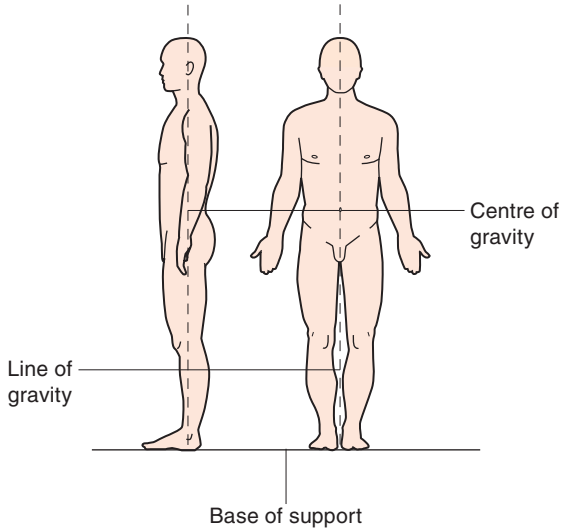

**Figure 28.1** Body mechanics: correct standing posture

Protection of the musculoskeletal system is essential to ensure continuing ability to undertake activities of daily living (ADLs). Everyday activities including walking, showering, cooking and employment are dependent on a functioning and healthy body support system. Nurses in their own activities and during instruction of an individual must familiarise themselves with the mechanics of movement to protect themselves and assist the individual in movement and recovery.

A national health survey of Australians (ABS 2009) revealed that 14% of adult respondents reported long-term medical conditions of back pain and disc disorders. Backache may be a symptom of various health conditions, yet up to 80% of cases result from weak muscles in the abdominal, back and hip regions. These muscles reinforce spinal posture and weakened or damaged muscles through inactivity or poor lifting techniques can result in pain, discomfort and even disability. To maintain a healthy back for optimal posture and mobility, weight control, daily exercise and correct alignment should be practised (Marieb 2013). (See Clinical Interest Box 28.2.)

# DISEASE PROCESSES THAT INFLUENCE BODY MECHANICS

## Diseases of the bones and skeletal system

### Osteoporosis

**Osteoporosis** is a condition in which the amount of bone tissue is reduced because the rate of bone deposition lags

### CLINICAL INTEREST BOX 28.2 Protecting the back through correct body alignment

- Pull abdominal muscles inwards to support your back and counterbalance weight
- Avoid high-heeled shoes as they change spinal alignment and increase stress on abdominal and back muscles
- Stand straight with head and back aligned
- Practise safe lifting techniques—wide stance with bent knees
- Face the direction of movement, avoid twisting
- Use other methods to move things such as rolling, turning or pivoting
- Include periods of rest into activities
- Avoid sitting for long periods of time
- Stretch for 10 minutes a day to strengthen abdominal muscles and stretch and loosen skeletal muscles.

*(Adapted from Marieb 2013)*

behind the rate of resorption. It may be progressive, temporary or permanent. Cancellous bone is usually affected before compact bone. Osteoporosis may be localised or occur throughout the skeleton. Bones become brittle and are susceptible to fractures. The factors that contribute to excessive bone loss include diminished oestrogen levels, immobility and lack of exercise, nutritional deficiencies and certain endocrine disorders. Manifestations include low back pain, kyphosis (rounded back) and spontaneous or pathological fractures from minor injuries (Christensen & Kockrow 2010).

### Osteomalacia

Osteomalacia (also known as Paget's disease) is a metabolic disease of inadequate or delayed bone mineralisation. This results in bones becoming soft, bowed and prone to fractures. Paget's disease is found in people over 40 years of age. The disease is of unknown origin and characterised by hyperactivity of **osteoblasts** and **osteoclasts** with rapid turnover of bone tissue. Bones are soft, thick and enlarged and may 'bow'. Usually the pelvis, long bones, lumbar vertebrae and skull are affected.

### Tumours

Tumours of the bone may be benign, primary malignant or metastatic. **Benign tumours** may be single or multiple, or of several types. The most common benign form is giant-cell tumour, which is composed of multinucleate giant cells or osteoclasts. Individuals complain of pain and tenderness, with localised swelling. **Osteogenic sarcoma** is the most common primary malignant bone tumour. The areas most often affected are the ends of long bones, especially the distal femur or proximal tibia, and metastases may occur most commonly in the lungs. Bone tumours are characterised by the gradual onset of pain in a limb, or the sudden onset of pain after a minor injury to the limb, with a localised mass, swelling and limp in weight-bearing limbs. Fatigue is a common symptom. **Metastatic bone tumours** occur when cells of a malignant primary tumour in another part of the body enter the blood or lymph and are spread to the bone (Christensen & Kockrow 2010).

### Osteomyelitis

**Osteomyelitis** is an acute or chronic infection involving bone, bone marrow and surrounding soft tissues. Acute osteomyelitis is characterised by rapid onset of severe pain in the involved bone, with local heat, swelling and inflammation as well as pyrexia, tachycardia, nausea and malaise. Chronic osteomyelitis is characterised by slight pyrexia, pain and persistent drainage of purulent material from a sinus tract injury (Christensen & Kockrow 2010; Marieb 2013).

## Disorders of the joints and tendons

### Rheumatoid arthritis

Rheumatoid arthritis is a systemic disease characterised by chronic inflammation of the synovial joint linings, with periods of remission and exacerbation. Joints most commonly affected are those of the wrists, hands and feet. Rheumatoid arthritis results in muscle atrophy and osteoporosis. Signs and symptoms include swelling and stiffness of the joints, followed by marked deformities resulting from soft tissue weakness and joint destruction (Farrell & Dempsey 2011).

### Osteoarthritis

Osteoarthritis is a degenerative non-infectious disease that causes pain and restricted movement of affected joints (Figure 28.2). Cartilage in the joints becomes thinner and eventually the two bones come into contact and begin to degenerate, followed by inflammation and effusion. Thought to be caused by excessive use, it usually develops in late middle age and affects large weight-bearing joints (hips, knees and cervical and lower lumbar spine) (Farrell & Dempsey 2011).

### Gout

Gout is a condition characterised by joint inflammation due to deposits of sodium urate crystals in joints and tendons. Causes include a metabolic defect responsible for increased serum uric acid production and impaired excretion of uric acid by kidneys. Use of alcohol and diuretics may precipitate attacks. The large toe is commonly affected and becomes tender, inflamed and very painful. It occurs in males more often than females (Farrell & Dempsey 2011).

## Diseases of the muscles

### Myasthenia gravis

Myasthenia gravis is an autoimmune disease of unknown origin. Defective muscle stimulation is caused by the development of antibodies that damage receptors in the neuromuscular junction, blocking impulses to muscle fibres. Progressive and extensive muscle weakness occurs, with the eyelids affected first, followed by the neck and limb muscles. Remissions and relapses are precipitated by exercise, infections, emotional disturbances and pregnancy (Crisp & Taylor 2012; Farrell & Dempsey 2011).

### Muscular dystrophies

Progressive muscular dystrophies are an inherited group of diseases in which there is progressive degeneration of groups of muscles. The major differences between these types of conditions are age of onset, rate of progression and groups of muscles involved. For example, the Duchenne type is gender-linked and presents at about 5 years of age, while myotonic dystrophy usually begins in adulthood. Both progress without remission, and death occurs from respiratory failure or cardiac disease (Crisp & Taylor 2012; Farrell & Dempsey 2011).

### Diseases of the nervous system

Multiple sclerosis, Parkinson's disease and Huntington's disease are progressive neurological disorders that affect neurotransmission along motor pathways. With varying aetiology and signs and symptoms, these diseases affect voluntary and involuntary muscle groups and have long-term effects on gait, mobility and ability to independently undertake and complete activities of daily living (Christensen & Kockrow 2010; Crisp & Taylor 2012; Marieb 2013).

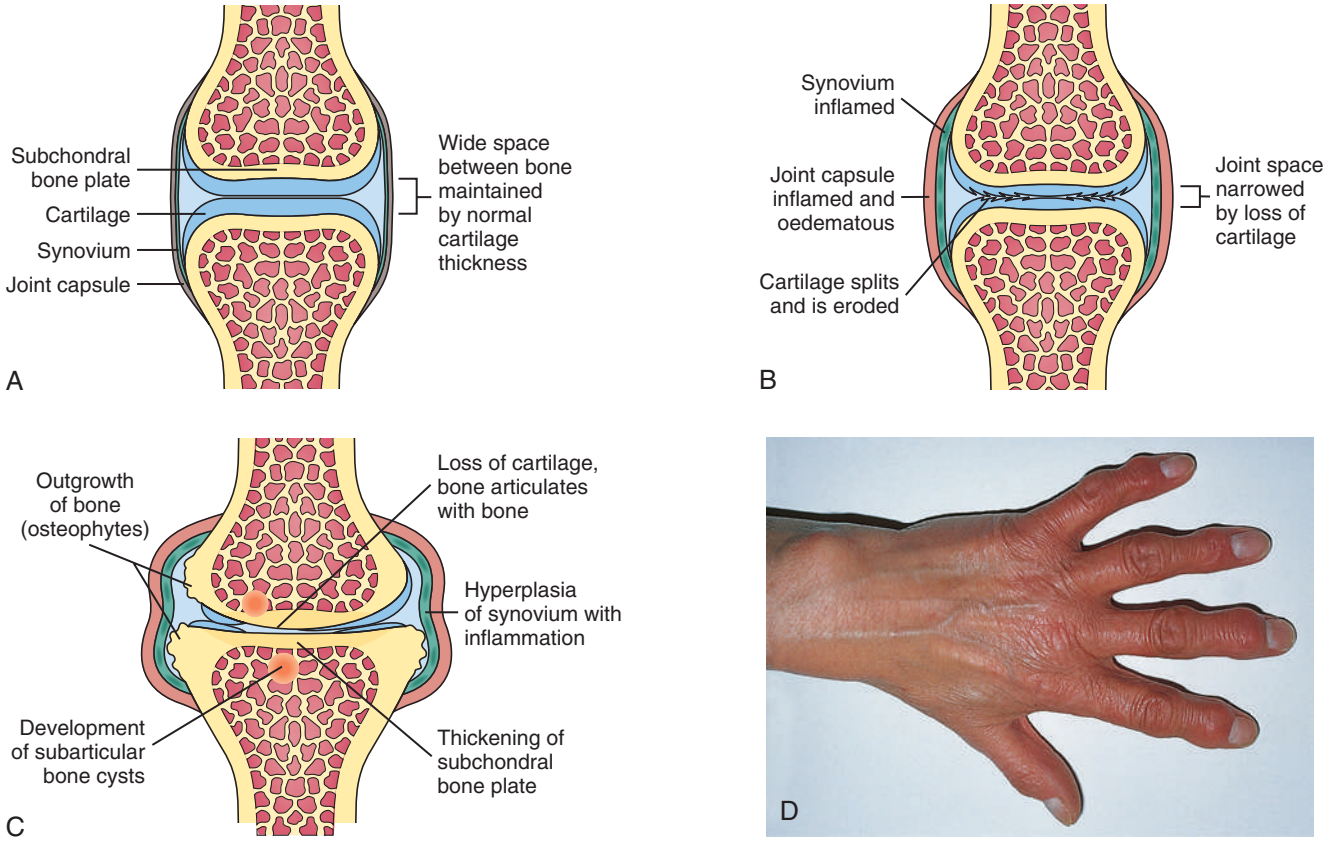

**Figure 28.2** Pathological changes in osteoarthritis

A: Normal synovial joint B: An early change in osteoarthritis is destruction of articular cartilage and narrowing of the joint space. There is inflammation and thickening of the joint capsule and synovium. C: With time, there is thickening of subarticular bone caused by constant friction of the two bone surfaces. Osteophytes form around the periphery of the joint by irregular overgrowths of bone D: In osteoarthritis of the hands, osteophytes on the distal interphalangeal joints of the fingers are termed Heberden's nodes and appear as small nodules

*(Stevens et al 2008)*

## DEVELOPMENT OF MOVEMENT AND EXERCISE THROUGH THE LIFESPAN

The provision of holistic care must consider individuals within the context of their life and development. A well-structured nursing care plan will incorporate growth and developmental changes, family and social support and cultural, spiritual and ethnic influences that give a person life, meaning and purpose (Crisp & Taylor 2012). To achieve this goal, nurses gather subjective and objective data. Care is planned and implemented based on identified nursing diagnoses and development of goals that can be measured, achievable and relevant to human stages of development.

The body changes throughout the lifespan (see Table 28.1). Nurses encounter people in all stages and are in a perfect position to promote **health and wellbeing** to assist optimal performance, regardless of an individual's age, ability or co-existing medical conditions. The role of exercise in health and wellbeing has been found to have benefits for both people and society and should be practised by all. Yet resistance to movement and physical exertion is a well-documented phenomenon and has been proven to contribute to the

**TABLE 28.1 | Stages of development**

| | |
|---|---|
| Infant | Flexible musculoskeletal system that matures to allow for movement from rolling to crawling and standing when lumbar spine matures |
| Toddler | Swayback and protruding abdomen gives awkward appearance as legs and feet are splayed apart for balance when walking |
| Preschool to adolescent | Greater coordination, skeletal growth and improved balance continue to adolescence when periods of rapid growth, sexual organ maturation and muscle development predominate |
| Adult | Period of greatest strength, coordination and muscle/posture changes related to pregnancy |
| Older adult | Bone density reduction related to inactivity, hormonal changes and bone tissue absorption result in weakening skeletal system with risk of fracture, injury and falls |

development of diseases such as hypertension, diabetes and osteoporosis.

A child's behaviour is modelled on that of their caregiver. Children learn the value of regular exercise if they are raised in an environment in which exercise is seen as a positive experience for the family to enjoy. Children with two active parents are themselves more active than those with one or no active parents. Parents can promote physical activity at home by encouraging the child to play outside and providing active play spaces and equipment (Ostbye et al 2013) (Figure 28.3).

The role of schools in keeping children active is important as indoor activities at home lead to increased rates of childhood inactivity and obesity. Families, schools and communities can work together to promote healthy eating and physical activity by providing water to drink, healthy breakfasts and school foods, active transport to and from school, participation in organised sport in and around school time and positive body image (Millar et al 2011) (Figure 28.4).

### CRITICAL THINKING EXERCISE 28.1

A friend of yours is a primary school teacher. He is worried about the number of overweight children in his Year 4 class. He seeks your advice on how to promote healthy diet and exercise with his students. As an Enrolled Nurse what strategies might you recommend?

The challenge to keep children active into adulthood may be lost post secondary school as a downward trend towards inactivity occurs (Crisp & Taylor 2012). While community and government initiatives support increased activity, the stresses of work, family, money and time constraints can sometimes make participation a challenge. The World Health Organization (WHO 2011) suggests that between 60% and 85% of adults lead partial or complete sedentary lifestyles and this inactivity can be attributed to death in 10% of the global population.

The findings of the National Health Survey published by the ABS (2009) indicated that as age progressed, exercise level regressed. Sedentary or low levels of exercise were more common in women and were above 70% for age groups of 15 years and above. The highest was in the 75 years and over who reported 83% were sedentary or had low levels of exercise. These findings demonstrate Australians need to increase their activity and movement levels. Not only because of the immediate benefits, but because of the associated health issues that sedentary behaviour intensifies. Healthy eating is more common in those who exercise. Half of those with low exercise levels ate less than the recommended fruit and vegetable intake per day. More were found to smoke and drink alcohol than their exercising counterparts. Inactivity is estimated to increase death rate and the chance of weight-related diseases including breast cancer, colon cancer, diabetes and heart disease (ABS 2009).

## OVERWEIGHT AND OBESITY IN AUSTRALIA

The National Health Survey (NHS) released disturbing statistics on Australia's expanding waistline. Up to 61% of Australian residents are either overweight or obese, posing a challenging problem about how to tackle this rising statistic.

**Figure 28.3** Toddler development and activity
*(© Christine Ingram)*

**Figure 28.4** Child playing team sport

**Overweight** and **obesity** are defined as abnormal or excessive fat accumulation that may impair health (WHO 2011). Comparison with data from the 1995 National Nutrition Survey (ABS 1997) shows that the percentage of persons 18 years and over who are classified as overweight or obese has increased. The male population increased from 64% in 1995 to 68% in 2008. The increase for women was from 49% to 55%. The highest rate of obesity was in the 65–74-year-old age group. Of this category, 75% of those surveyed were classed as overweight or obese (ABS 2009).

Childhood obesity is of particular concern because the evidence shows that one in three obese children will become obese adults, increasing their vulnerability to weight-related diseases. Overweight and obesity in children and adolescents is generally caused by lack of physical activity, unhealthy eating patterns, or a combination of the two, with genetics and lifestyle both important determinants of a child's weight. Nurses need to be aware that inactivity is a health risk and that obesity is a serious health risk, not just a cosmetic issue (Kozier et al 2010). Clinical Interest Box 28.3 provides an outline of some self-care behaviours and exercises.

### Fit versus fat

Obesity and fitness may be considered polar opposites, but can an individual be fit and 'fat'? Studies by Joshua Bell (University College London) show that people with a BMI greater than 30 (obese) may have normal cholesterol, blood pressure and blood sugar levels. However, over a period of 20 years, at least half of the studies' participants had progressed to unhealthy metabolic levels, even without any changes in weight. The studies sum up that being overweight and 'fit' is only a short-term phase (Brenza 2015).

## THE BENEFITS OF PHYSICAL ACTIVITY

Participation in regular exercise can enhance the life of individuals, families, community groups and society (Figure 28.5). At least 30 minutes of moderate exercise (or 150–300

### CLINICAL INTEREST BOX 28.3 Self-care behaviours and exercise

- Make the most of opportunities for exercise—use stairs, park a kilometre away from work or walk to work once or twice a week, walk faster and use lunchtimes for exercise
- Choose an enjoyable physical activity
- Plan 3–4 exercise activities per week
- Before starting exercise sessions, ensure medical clearance if in a high-risk group
- Alternate different types of exercise to keep interest up; for example, Pilates followed by weight-training sessions then walking or bike riding
- Invite a friend to walk or join a health club or gym
- Build up exercise sessions to avoid over-exertion
- Keep it simple—gradually increase your exercise time and activity.

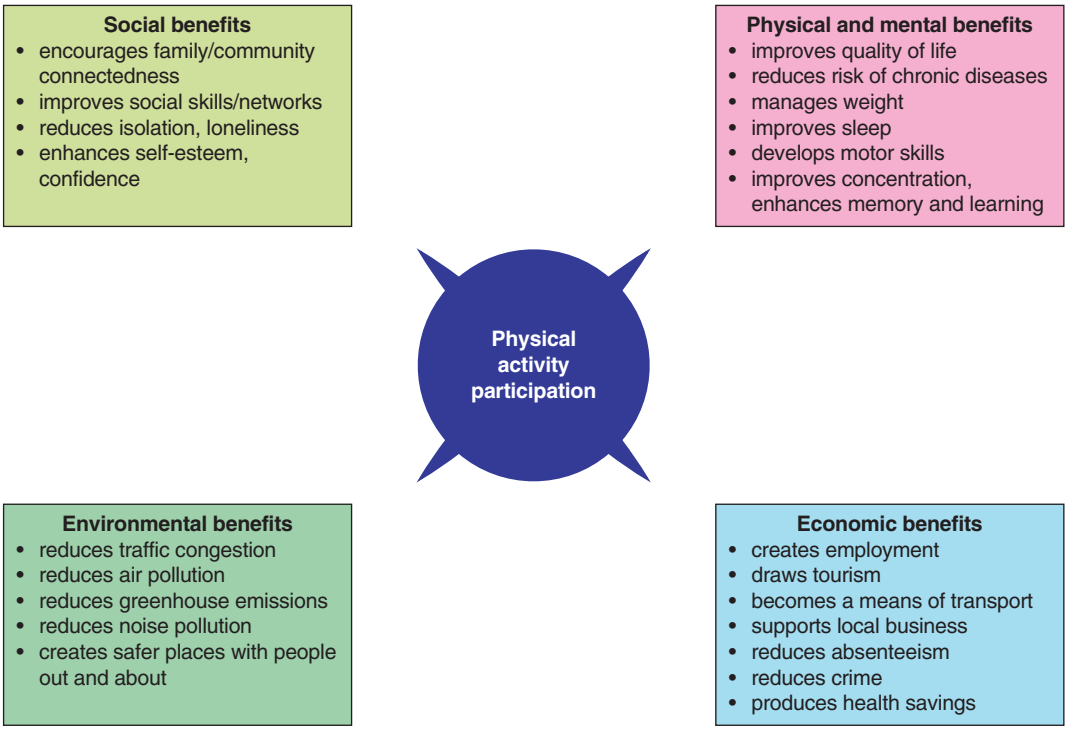

**Figure 28.5** Benefits of physical activity

*(© The State of Queensland (Queensland Health) 1996–2016)*

minutes per week) is recommended and provides considerable health benefits. Exercise has been shown to reduce blood pressure and risk of stroke and cardiovascular disease, prevent **deep vein thrombosis** and enhance joint mobility. Other studies have shown that exercise reduces the risk of developing some cancers, especially colon and breast cancer, and has psychosocial benefits including protection against depression (Brown et al 2012).

Exercise can boost concentration, alertness, mood and optimism through promoting better sleep, coping abilities, self-esteem and a sense of control (Johnson 2014).

## Exercise and the older adult

As humans age, body systems deteriorate. Research suggests that up to half of the functional decline associated with ageing is the result of disuse and can be reversed with exercise. Exercise improves cardiopulmonary fitness, strength, coordination, mental health, motor control and cognitive function. Improved flexibility, balance and muscle tone can help prevent falls.

The benefits of physical activity can be enjoyed even if regular practice starts late in life (Figure 28.6). Physical activity improves self-confidence and self-sufficiency to enhance psychological wellbeing. Active lifestyles provide occasions to establish new friendships, maintain social networks and interact with people of all ages. Walking, swimming, stretching, dancing, gardening, hiking and cycling are excellent activities for older persons. With the number of people over 60 years of age projected to double in the next 20 years, reducing and postponing age-related disability is an essential public health measure that must be initiated now (WHO 2011).

**Figure 28.6** Regular activity creates a sense of health and wellbeing

*(© Dorothy Lanyon)*

A study by Allen and Morelli (2011) demonstrated that in older adults regular exercise reduced the occurrence of health changes associated with ageing and helped prevent diseases associated with a sedentary lifestyle. The exercise recommended included a combination of aerobic exercise, strength training (i.e. using resistance bands), flexibility (stretching) and balance (use of exercise ball). Health changes documented included improvement in blood pressure, diabetes, lipid profile, OA, osteoporosis, mood, neurocognitive function and overall morbidity and mortality.

### Falls risk

The older adult is more prone to falls related to reduced exercise tolerance, reduced joint mobility and comorbidities such as neurological conditions (Parkinson's disease), depression, acute infections and lower limb arthritis. Other factors such as a cluttered environment, inappropriate footwear, medications, incontinence, leg muscle weakness and postural hypotension also contribute to the likelihood of a fall. A person-centred approach is needed to screen for falls risk, and then assess comprehensively the likelihood of falls in an individual.

Individuals should be assessed for falls risk upon admission to a healthcare facility, daily as part of a care plan and after a fall or change in health status. Healthcare professionals then must implement strategies to minimise this falls risk (The Victorian Quality Council 2004).

## Exercise attitudes within Indigenous communities

Identified health issues within the Indigenous communities of Australia include hypertension, stroke, diabetes, smoking, obesity and alcohol abuse. In an ABS report, high levels of sedentary behaviour were reported in the 15 years and above age group, which accounts for 75% of the Indigenous population in non-remote areas of Australia (ABS 2010). Of those who exercised, the prevalence of arthritis, diabetes, heart and vascular diseases was significantly reduced. Similarly, those who regularly exercised at moderate levels reported good self-assessment of their general health and smoked less than their sedentary counterparts (ABS 2010).

## Finding exercise to suit the individual

Like any activity that humans undertake, exercise must be enjoyable or rewarding if commitment is to be assured. While some are motivated by weight loss or muscle definition, others may be encouraged by improvement in mood, freedom of movement or cardiovascular fitness.

New Australian physical activity guidelines recommend that doing any physical activity is better than doing none. Guidelines recommend 150–300 minutes per week of moderate physical activity (e.g. brisk walking or swimming) or 75–150 minutes per week of vigorous physical activity (e.g. jogging or aerobics), or an equivalent combination of both. Guidelines also suggest an individual be active most days, do muscle strengthening activities at least 2 days per week and minimise prolonged sitting time (Brown et al 2012).

Movement and exercise should form part of any treatment program for individuals with neurological disorders. While the exact mechanism of effectiveness is unclear, the benefits can be demonstrated in those suffering symptoms of stroke or Parkinson's disease. New studies are showing that when individuals move and exercise, dopamine is released within the brain, reducing the motor symptoms of Parkinson's disease. Benefits of exercise such as dance therapy include improved balance and gait function (Nogrady 2013). Barriers to exercise in the older person include medical conditions and frailty, depression, lack of confidence and fears associated with injury (Well for Life 2012). Many Australian aged-care facilities offer in-house exercise programs based on the Easy Moves for Active Ageing program. This chair-based program aims to maintain function and prevent physical decline in older adults by working through a low-impact series of ROM movements (see Case Study 28.1). While the benefits of exercise have been discussed, the Well for Life study revealed factors that can cause resistance in older adults. Many residents find these sessions enjoyable, social and empowering; others may experience barriers that inhibit their participation (see Clinical Interest Box 28.4).

### CRITICAL THINKING EXERCISE 28.2

You are working in a low-level aged care facility. The resident you are caring for is complaining of joint stiffness. An exercise class is being run that morning and you believe they would benefit from the chair-based movements. The resident is resistant to attending the session. What steps could you take to encourage them to attend?

### CASE STUDY 28.1

Clara Black is a 92-year-old resident of an aged care facility. Up until a year ago, Clara was ambulant and quite active. As Clara's nurse, you would like her to start participating in the facility's exercise program.

1. In educating Clara, outline five (5) benefits of exercise in the older individual.
2. Outline how you would plan for Clara to attend the exercise classes, including overcoming obstacles to participating in exercise.
3. Describe exercise appropriate for a 92-year-old woman with limited mobility.

## PRINCIPLES OF MUSCLE MOVEMENT IN EXERCISE

### Isotonic exercise

**Isotonic exercise** involves muscle shortening and active contraction and relaxation of muscles. Isotonic activity occurs with movement, such as carrying out activities of daily living, independent **range-of-movement (ROM)** flexing exercises, swimming, walking, running, cycling or jogging.

### Isometric exercise

**Isometric exercise** involves muscle contraction without shortening of the muscle length. These exercises build muscle bulk and are a popular muscle activity for body builders; for example, lifting weights.

### Isokinetic exercise

**Isokinetic exercise** causes muscle contraction, shortening and relaxation at an even speed. Isokinetic movement occurs during swimming as arms move evenly through water resistance (Marieb 2013).

### CRITICAL THINKING EXERCISE 28.3

Vivienne is 67 and is learning how important an active lifestyle is to slow the ageing process. Vivienne has asked you to design a simple exercise plan to help maintain her health and wellbeing. Using the above principles of exercise, create a simple program for Vivienne to follow.

### Encouraging maintenance and restoration of muscle strength

As communities become increasingly sedentary, the cost is reflected in the calibre of individuals in the healthcare system.

### CLINICAL INTEREST BOX 28.4
### To facilitate chair-based exercises

- Ensure person goes to the toilet before the exercise session
- Administer analgesia prior to or after an exercise session
- Plan exercise into daily activities
- Educate the person about the benefits of the exercise and what is to be expected
- Dress the individual appropriately for exercise
- Ensure the individual is positioned safely to exercise and that there is no risk of falling
- Use a variety of techniques to teach the exercise such as repetition, demonstration and one-on-one assistance
- Ensure the individual can see and/or hear the exercise instructor.

With increasing numbers of cases of osteoporosis and arthritis requiring in-hospital care, nurses may frequently find themselves caring for immobilised or physically disabled people. To aid return to mobility after the acute care phase, provision of movement activities is essential to prevent long-term complications sustained during immobility. Until this stage, nurses should undertake muscle and joint movement. Using the principles of muscle movement, a range of exercises can be incorporated into everyday situations to enhance the individual's health and recovery (Crisp & Taylor 2012):

- Isotonic bed exercises: pushing or pulling against a stationary object, using a trapeze to lift the body off the bed, lifting the buttocks off the bed by pushing with the hands against the mattress and pushing the body to a sitting position (Crisp & Taylor 2012)
- Isometric bed exercises: Benefits of isotonic and isometric exercise include increase in muscle tone, mass and strength, improved joint mobility, increased circulation and osteoblastic activity. Examples may include lifting of hand weights and gripping of tennis ball to aid arm strength and mobility. Quadriceps extension: push knee into mattress while attempting to lift heel off bed to strengthen thigh muscles (Crisp & Taylor 2012)
- Isokinetic bed exercises: for example, rehabilitative exercises for knee and elbow injuries. In this case, isokinetic devices are used to take muscles and joints through a complete ROM without stopping, with resistance at each point. Mechanical devices are available for specific joints, which place these joints through continuous passive ROM (Crisp & Taylor 2012).

## Encouraging maintenance of joint mobility

Joints are capable of a wide range of movement or motion (Figure 28.7). ROM or motion exercises are either **active**, when the individual is able to move the joints themselves, or **passive**, when the nurse moves the individual's joints within the normal ROM, noting joint flexibility and/or limitations of movement. Joints that are not moved regularly can develop contractures (shortening of a muscle and eventually ligaments and tendons and eventual loss of function). It must be remembered that when a nurse performs passive ROM exercises in which a person's muscles do not exert effort, some of the potential benefits are reduced in favour of improved joint mobility and circulation (Christensen & Kockrow 2010; Farrell & Dempsey 2011).

The frequency with which ROM exercises are performed depends on the individual's condition and medical and nursing management, but they are commonly performed at least

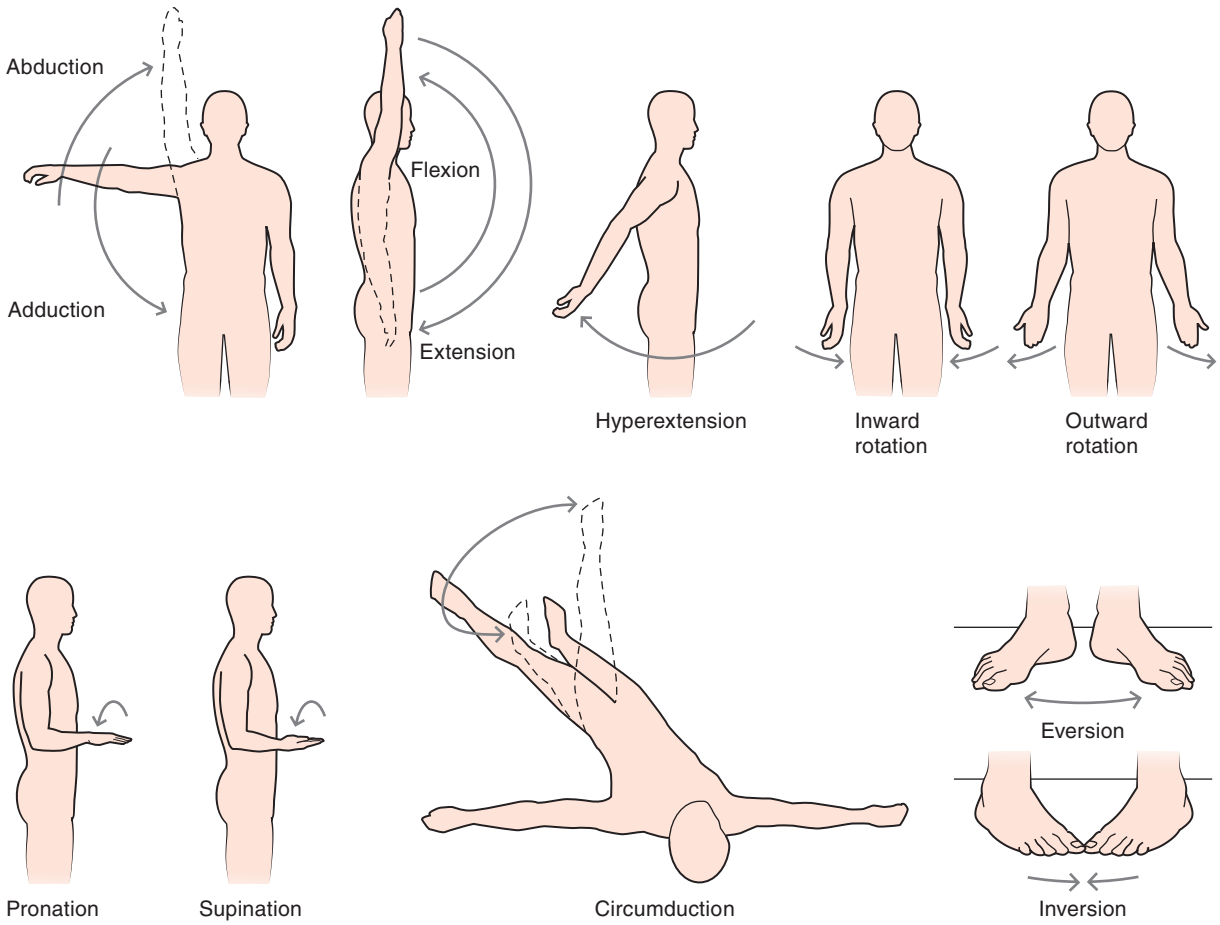

**Figure 28.7** Range-of-movement joint movements

twice daily. However, it is important not to overtire the person partaking in the exercises. ROM exercises may be performed independently or with assistance. Using appropriate movements, all joints are exercised in a logical sequence. Exercise routines are normally individually designed and the intensity and frequency depend upon a person's general condition, level of fitness and capabilities (Crisp & Taylor 2012).

## ASSESSMENT OF MOVEMENT, MOBILITY AND THE MUSCULOSKELETAL SYSTEM

Undertaking a systematic assessment of an individual will identify issues of movement and mobility. After prioritising care by applying first aid and pain management measures prior to examination, the nurse should obtain a musculoskeletal medical history that includes:

- Activity and exercise level prior to hospital presentation
- Past history of muscle and joint pain or injury
- Current treatment for existing muscle and joint pain or injury, including medications, physiotherapy, osteopathy, chiropractic or other complementary therapies
- Presenting problem including details of injury, cause of injury, symptoms, duration and treatment received (if hospital presentation is due to a musculoskeletal condition)
- Recent changes in mobility or movement unrelated to current hospital presentation
- Use of aids for mobility.

On completion of verbal data collection, a physical examination should be undertaken to provide a baseline for ongoing assessment and completion of a management or care plan. Identifying current and potential movement and mobility issues will tailor treatment needs and identify potential discharge issues. A physical assessment will incorporate observation of gait and posture, pain and nerve changes, limb deformities, neurovascular assessment and spinal conditions including congenital and acquired pain or abnormalities (Crisp & Taylor 2012).

See Clinical Skill 28.1 for information and guidelines on assisting with transfer.

### Gait

Gait describes the manner of walking and, while varying from one person to another, there is normally a certain rhythm to a person's walk. Gait abnormalities may occur when there is a disorder of the musculoskeletal or nervous system; for example, unilateral hip dislocation produces a distinct 'waddle' with each step. A staggering, or ataxic, gait may be caused by a lesion in the brain or spinal cord, and a 'scissors' gait is one in which the legs cross each other in progression. An abnormal gait may also result from pain or discomfort due to a lesion on the foot, such as a corn, or from ill-fitting and uncomfortable shoes (Crisp & Taylor 2012).

### Pain and nerve (sensory) changes

Pain is a common symptom of musculoskeletal disorders, as a result of trauma, inflammation or degeneration. People may describe the pain as mild, aching, severe or throbbing, and it may be localised or generalised, depending on the specific disorder. Pain may increase with movement, be exacerbated by changes in external temperature and relieved by rest. It may be worse at certain times; for example, joint discomfort from degenerative disease is often worse in the evenings. Numbness, tingling and lack of sensation are other sensory changes. Swelling from injury or tumours may cause pressure on nerves, resulting in loss of sensation (Farrell & Dempsey 2011).

### Swelling, deformity and impaired mobility

Swelling of an affected area may be the result of the formation of inflammatory exudate in response to injury from physical trauma, chemicals or infection. Swelling will also occur when blood is lost from the circulation into surrounding tissues (haematoma); for example, after a fracture. A joint may become swollen if there is an increase in the amount of synovial fluid or if blood or purulent discharge is present in the joint capsule. Deformity may be the result of growths, fractures, dislocations, abnormal curvature of the spine or contractures. The effects of a deformity include changes in range of joint motion, posture and gait. Mobility may be impaired to such an extent that the individual is unable to move without pain or unable to carry out activities of daily living, or it may only restrict mobility at certain times, such as after activity or be related to certain positions (Figure 28.8).

## CLINICAL SKILL 28.1 Assisting with transfer

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Transfer belt<br>Sling<br>Lap board<br>Slide sheet<br>Mechanical/hydraulic lift |

| **Skill activity** | **Rationale** |
|---|---|
| Assess the individual for:<br>• Joint mobility<br>• Presence of paralysis or paresis<br>• Activity tolerance<br>• Orthostatic blood pressure<br>• Level of consciousness<br>• Pain level<br>• Ability to follow instructions | Provides information regarding individual's ability to transfer and the number of people required to assist |
| Adjust height of the bed and ensure the brakes are locked in place | Safety of the individual and nurse<br>Prevents strain on nurse's back |
| **Assisting individual into sitting position on side of bed** | |
| With the individual in a supine position, raise the head of bed to 30 degrees | Decreases amount of work required by the individual and nurse to raise person to a sitting position |
| Where possible, the individual should be encouraged to move into the position themselves | Decreases amount of work needed by individual and nurse to raise person to a sitting position |
| Turn the individual to side, facing nurse on side of bed on which the individual will be sitting | Prepares the individual to move to side of bed and protects the individual from falling |
| Stand opposite to the individual's hips and turn diagonally to face the individual and the far corner of foot of bed | Places nurse's centre of gravity near to individual<br>Reduces twisting |
| Place feet apart with foot closer to head of bed in front of other foot | Increases balance and allows nurse to transfer weight as individual is brought to sitting position on side of bed |
| Place arm nearer head of bed under individual's shoulder, supporting head and neck | Maintains alignment of head and neck as nurse brings individual to sitting position |
| Place other arm over individual's thighs | Supports hip and prevents individual from falling backwards during procedure |
| Move individual's lower legs and feet over side of bed. Pivot towards rear leg, allowing the individual's upper legs to swing downwards | Decreases friction and resistance. Weight of individual's legs when off bed provides gravity to lower legs, and weight of leg helps pull upper body into a sitting position |
| At same time, shift weight to rear leg and elevate individual | Allows nurse to transfer weight in direction of motion |
| Remain in front of the individual until they regain balance | Reduces risk of falling |
| **Transfer individual from bed to chair** | |
| Adjust the bed so that it is slightly higher than the chair. Assist the individual to a sitting position on side of the bed. Have chair in position at 45-degree angle to the bed and ensure the brakes are on | Positions chair within easy access for transfer |
| Apply transfer belt or other transfer aids if required | Reduces risk of falling |

*Continued*

| CLINICAL SKILL 28.1 Assisting with transfer—cont'd | |
|---|---|
| Ensure individual has stable, non-skid shoes. Weight-bearing or stronger leg is placed forwards with weaker foot back | Decrease risk of slipping. Bare feet increases risk of falls |
| Spread feet apart | Ensures balance with wide base of support |
| Flex hips and knees, aligning feet and knees with individual's feet | Flexion of knees and hips lowers nurse's centre of gravity to object to be raised; aligning knees with individual allows for stabilisation of knees when individual stands |
| Grasp transfer belt from underneath, if used, or reach through individual's axillae and place hands on individual's scapulae | Transferring individual with hands on scapulae reduces pressure on axillae and maintains the individual's stability. Transfer belt is grasped at each side to provide movement of individual at centre of gravity |
| Rock individual up to standing position on count of three while straightening hips and legs and keeping knees slightly flexed. Individual is instructed to use hands to push up if possible | Rocking motion gives individual body momentum and requires less muscular effort to transfer individual |
| Maintain stability of individual's weak or paralysed leg with knee | Ability to stand can often be maintained in paralysed or weak limb with support of knee to stabilise |
| Pivot on foot further from chair | Maintains support of individual while allowing adequate space for individual to move |
| Instruct the individual to use armrests on chair for support and ease themselves into chair | Increases individual's stability |
| Flex hips and knees while lowering individual into chair | Prevents injury to nurse from poor body mechanics |
| Assess the individual for proper alignment for sitting position. Provide support for paralysed extremities. Lap board or sling will support flaccid arm. Stabilise leg with bath blanket or pillow | Prevents injury to individual from poor body alignment |
| Praise individual's progress, effort and performance | Continued support and encouragement provides incentive for individuals |
| **Use mechanical/hydraulic lift to transfer individual from bed to chair (two nurses)** | |
| Bring lift to bedside. Before using lift, be familiar with its operation | Prepares environment for safe use of lift and subsequent transfer |
| Position chair near bed and allow adequate space to manoeuvre hoist | Prepares environment for safe use of lift and subsequent transfer |
| Raise bed to safe working height with mattress flat. Lower side rails | Allows nurse to use proper body mechanics |
| Roll the individual towards one nurse | Positions individual for use of lift sling |
| Place sling evenly under individual's back (follow manufacturer's guidelines) and roll individual to opposite side to position sling | Places sling under individual's centre of gravity and greatest portion of body weight |
| Roll individual supine on sling and position hoist over individual. Lower boom and attach sling to frame with the head end attached first. Raise individual's knees and feed the leg sections of the sling under the thighs and attach to frame | Sling should extend from shoulders to knees to support individual's body weight equally |

| CLINICAL SKILL 28.1 Assisting with transfer—cont'd | |
|---|---|
| Elevate head of bed | Positions individual in sitting position |
| Ask or assist the individual to fold arms over the chest | To prevent injury during transfer |
| Pump hydraulic handle using long, slow, even strokes, or activate electronic hoist until individual is raised off bed ensuring the head is supported | |
| Using steering handle to move lift from bed and manoeuvre to the chair | Moves individual from bed to chair |
| Slowly lower the individual onto chair | |
| Detach sling from frame and remove hoist. Pull leg straps to the side, tilt the individual forwards to slide out the sling | Safely guides individual into back of chair as seat descends |
| Reposition the individual to a comfortable and safe position | |
| Perform hand hygiene | Prevents cross-infection |
| Report and document the procedure, including level of assistance required and individual's responses and tolerance. Report and record any sign of pressure injury | Enables appropriate care to be implemented |
| *(Tollefson 2010; Rebeiro et al 2013; Varnam 2011)* | |

## Sprains

A sprain is an injury to a ligament, caused when a joint is forced beyond its normal ROM. A ligament may be stretched or torn and local bleeding and bruising present with restricted movement. Sprains commonly occur in the wrist and ankle. Treatment is aimed at resting and supporting the area and reducing pain and inflammation with anti-inflammatory medications (Farrell & Dempsey 2011).

## Strains

A strain is an injury to a muscle and/or a tendon, resulting from excessive physical effort. Both sprains and strains cause pain and swelling, but strains may cause muscle spasm as well. Nurses can suffer strain injuries from incorrect manual handling techniques (Crisp & Taylor 2012; Christensen & Kockrow 2010).

## Fractures

A fracture is a broken bone, often with nearby soft tissue, blood vessel and nerve damage. A stress fracture occurs when a bone is subjected to repeated or prolonged stress such as jogging. A pathological fracture may occur in weakened bone as a result of osteoporosis. Fractures are classified as open or closed, simple or complicated. Open (or compound) fractures are those in which the bone breaks through the skin, while closed fractures are those where the skin is intact. In a simple fracture only the bone is involved, while in complicated fractures nearby blood vessels, nerves or organs are affected. Table 28.2 and Figure 28.9 demonstrate and describe the various types of fractures. Signs and symptoms vary but usually encompass pain, swelling, muscle spasm, bruising, deformity, abnormal mobility and loss of function. Crepitus (grating caused by bone fragments rubbing together) may be heard on examination or experienced and described by the person. Shock may occur as a result of haemorrhage or extensive damage (Farrell & Dempsey 2011; Patton & Thibodeau 2010).

## Neurovascular assessment

A neurovascular assessment is performed on people who have experienced a fracture, have been fitted with a cast, have undertaken vascular surgery or have had spinal surgery. Neurovascular protocols vary depending on the individual's diagnosis and treatment undertaken. Nurses should familiarise themselves with neurovascular guidelines within their place of work and employment facility. For example, a person with a fracture should have neurovascular observations undertaken every hour for 24 hours, then every 4–8 hours if fitted with a cast (Berman et al 2015; Farrell & Dempsey 2011).

Assessment must be undertaken by the primary care nurse at the commencement and throughout the shift to identify early changes that can indicate a pathological deterioration. Inability to recognise significant changes in a timely manner may influence an individual's potential for recovery

**TABLE 28.2 | Types of fractures**

| Type | Description |
|---|---|
| Greenstick | The fracture is incomplete and does not extend through the bone. The bone bends, and splits or cracks on one side |
| Transverse | The fracture line is straight across the bone |
| Oblique | The fracture line is at an angle across the bone |
| Spiral | The fracture line coils around the bone. This type of fracture generally results from twisting of the limb |
| Impacted | The fragments of broken bone are pushed (telescoped) into each other |
| Comminuted | The bone is broken into a number of fragments |
| Depressed | The broken edges are pushed below the level of the rest of the bone. This type of injury may occur when the skull is fractured |
| Avulsion | A fragment of bone, connected to a ligament, breaks off from the rest of the bone |
| Intracapsular | The fracture is within the joint capsule |
| Extracapsular | The fracture is close to a joint, but is outside the joint capsule |

*Adapted from Crisp & Taylor 2009; Marieb 2009; Patton & Thibodeau 2010*

and rehabilitation. A neurovascular assessment might include inspection of:

- *Skin:* inspect area distal to the injury; inspect for skin discolouration and palpate skin temperature with the back of the hand and compare with the opposite extremity or site
- *Movement:* have the person move the area distal to the injury, or move it passively; there should be no discomfort
- *Sensation:* enquire about feelings of numbness or tingling; check sensation with a paper clip and compare bilaterally—sensation should be the same
- *Pulses:* palpate pulses distal to the injury; compare bilaterally
- *Capillary refill*: check this in the nail beds distal to the injury. Capillary refill should occur within 3 seconds and within 5 seconds in the older adult
- *Pain:* enquire about the degree, location, nature and frequency of pain, noting any increase in intensity or change in the type of pain (deWit & Williams 2013).

## Dislocation

Dislocation is complete displacement and subluxation is partial displacement of a joint's articulating surfaces; both processes damage surrounding soft tissue structures. Joint effusion is the accumulation of synovial fluid in a joint and occurs if blood vessels in the synovium are damaged. Joint effusions may result from severe sprains, dislocations or fractures. Signs and symptoms of dislocation and effusion include severe pain, limited movement, joint deformity and swelling. Dislocations may affect fingers, elbows, shoulders, hips, knees and ankles and are often caused by sporting injuries or pressure on the affected area after a fall (Marieb 2013).

## Lower back pain

Lower back pain is a common symptom that has a variety of causes, including poor posture, injury, inflammatory conditions, obesity, metabolic bone disorders, degenerative processes and intervertebral disc disease. Discomfort or pain may be mild, severe, continuous or intermittent and be aggravated by certain movements or posture; it may radiate into the buttocks or down the back of the legs. People with lower back pain should not sit for more than 30 minutes at any one time, and frequent stretching (thrusting the hips forwards while the upper body leans back) is recommended. Most lower back pain can be safely and effectively treated after an examination by an orthopaedic surgeon and a prescribed period of activity modification and medication to relieve the pain and diminish the inflammation. Although a brief period of rest may be helpful, most studies show that light activity speeds healing and recovery. It may not be necessary to discontinue all activities, including work. Instead, people may adjust their activity under the guidance of medical officers or physiotherapists (Marieb 2013).

When the initial pain has eased, a rehabilitation program may be suggested to increase muscle strength in the lower back and abdominal muscles, as well as stretching exercises to increase flexibility. If overweight, weight loss is recommended, as this may decrease the chance of recurrence of lower back pain. The best long-term treatment is an active program of maintaining optimal physical condition. This can be achieved by regular exercise and using the principles of body mechanics including practising correct lifting techniques, and assuming good posture (Crisp & Taylor 2012; Radomski & Latham 2013).

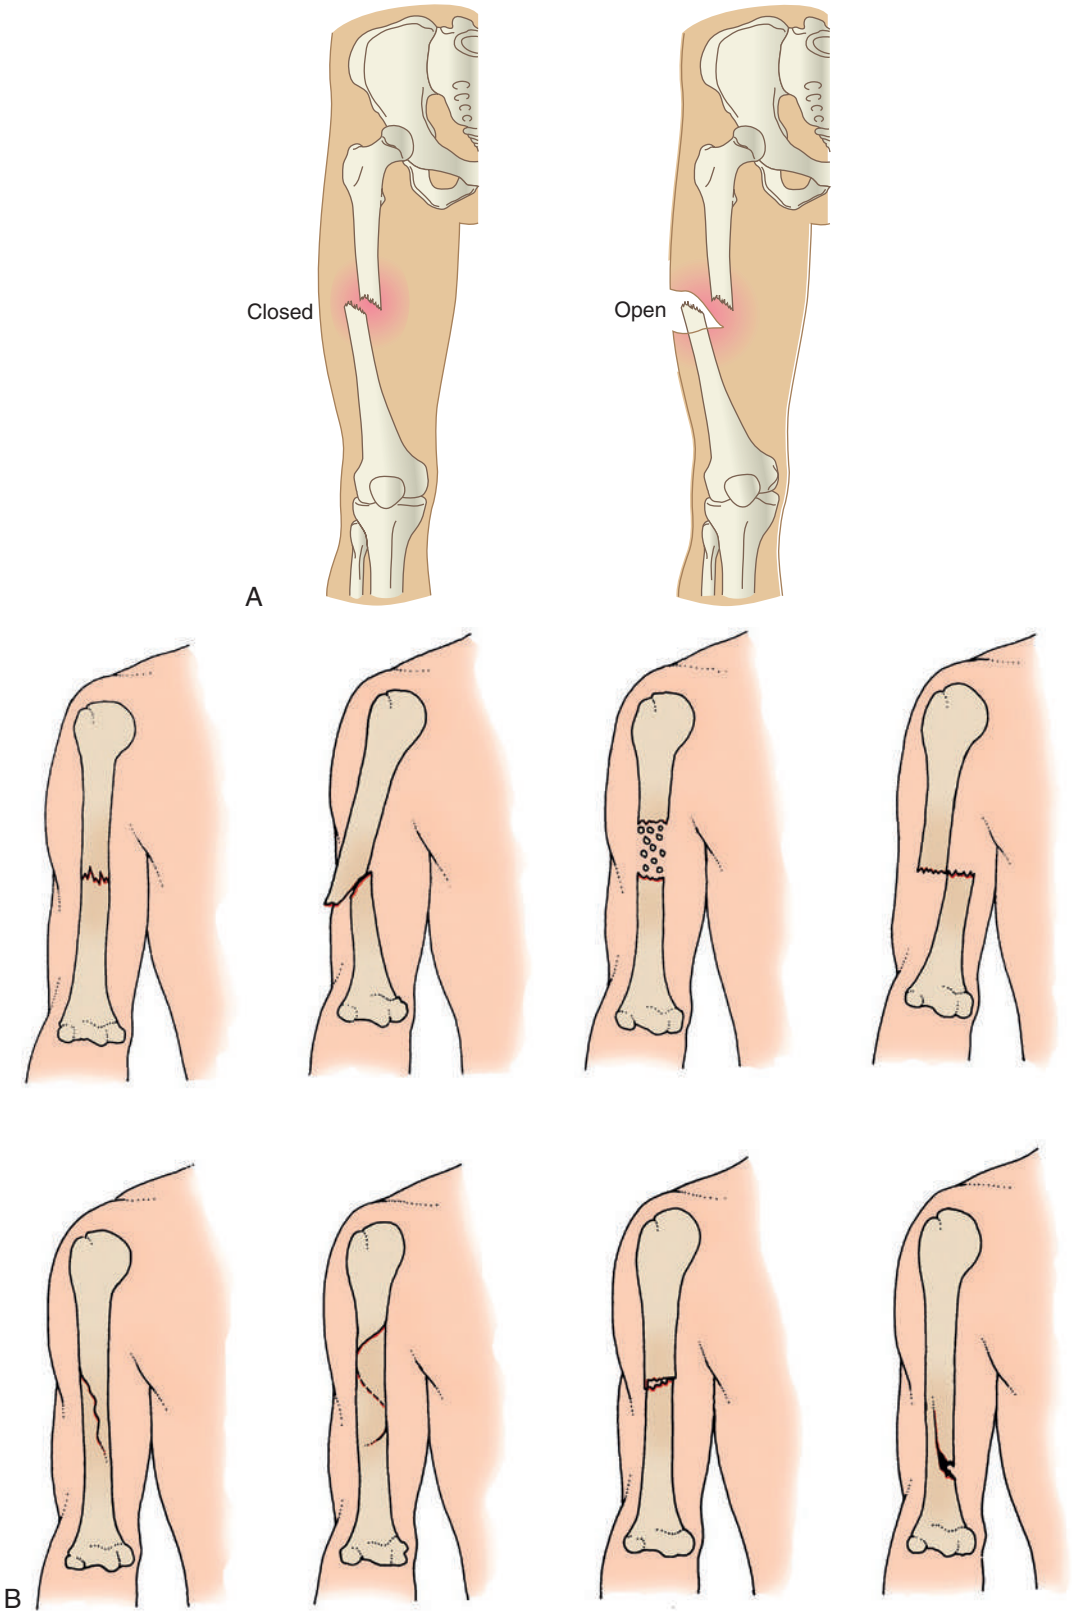

**Figure 28.9** A: Closed and open fracture B: Common types of fractures
*(A Figure 4.22 from Christensen & Kockrow 2010; B Figure 4.23 from Christensen & Kockrow 2010)*

## DIAGNOSIS OF A MUSCULOSKELETAL DISORDER

Diagnosis of musculoskeletal disorder will be confirmed by:

- Presenting history of injury, disorder or change in range of movement
- Physical examination including observation, palpation and assessment of joint movement
- Radiological examinations including plain x-ray, arthrogram, **arthrography**, bone scan, arthroscopy, biopsy, ultrasound, MRI and CT scan (Marieb 2013) (see Figure 28.10 and Table 28.3).

## NURSING CARE OF THE INDIVIDUAL WITH A MUSCULOSKELETAL DISORDER

While medical management and nursing care will depend on the specific disorder, the general aims of care of an individual with a musculoskeletal disorder are to:

- Promote rest and relieve pain
- Prevent complications of inactivity and promote movement when possible
- Maintain skin integrity
- Maintain or improve nutritional status
- Prevent and recognise potential psychosocial problems
- Promote rehabilitation (Berman et al 2015; Crisp & Taylor 2012).

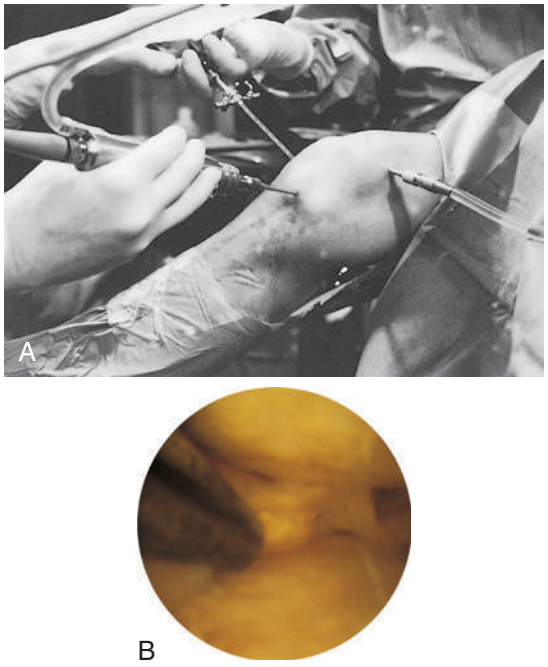

**Figure 28.10** Arthroscopy of knee

A: Insertion of a fibreoptic light source into joint B: Internal view of joint

*(Courtesy of Lanny L. Johnson, MD, East Lansing, MI. Used with permission)*

**TABLE 28.3 | Musculoskeletal diagnostic tests**

| Type | Description |
|---|---|
| Plain x-ray | Standard x-ray of bones and joints that detects abnormalities in shape and alignment |
| Arthrogram | Outlines soft tissue (e.g. meniscus) which is not usually visualised on x-ray |
| Arthroscopy | Visual examination of a joint with a fibreoptic endoscope. Commonly performed on the knee to remove loose fragments, view suspected damage or obtain a biopsy |
| Biopsy | May be performed on bone, muscle or synovial membrane. Takes blood and tissue samples to test for tumours, enzymes, antibodies and antigens, erythrocyte sedimentation rate (ESR) and calcium, phosphorus and uric acid levels |
| Arthrocentesis | Aspiration of synovial fluid for analysis of infection and inflammation |
| Bone scan | Provide imaging of the skeleton after intravenous injection of a radioactive isotope that collects in bone tissue at sites where there is increased activity (i.e. at the site of a tumour) and lesions can be detected earlier. |
| Ultrasound | 2D examination of soft tissue for signs of bleeding, haematoma and fluid collection |
| Magnetic resonance imaging (MRI) | Magnetism and radiowaves form cross-sections and images to detect pathological abnormalities in soft tissue and blood vessels |
| Computerised axial tomography (CT or cat scan) | 3D cross-sections that provide detail about injuries to ligaments, tendons, tumours and fractures difficult to determine on plain x-ray. May use iodine contrast medium for greater clarity of affected area to be examined |

*(Adapted from Crisp & Taylor 2012; Marieb 2013; Patton & Thibodeau 2010)*

## Individuals with a bone injury

Bone fractures can take weeks or months to heal, and healing occurs in stages:

- Stage 1: The formation of a haematoma between the two ends of the bones
- Stage 2: Inflammation and accumulation of white cells to break down (phagocytose) the haematoma (this takes approximately 5 days)
- Stage 3: The development of granulation tissue and new blood vessels is followed by the development of a callus (calcified osteoblasts) and shaping of new bone by osteoclasts, which remove excess callus (Figure 28.11).

Bone healing is individualised. For most, healing takes place within a standardised time frame; however, some healing is delayed and can be influenced by the following factors:

- Infection
- Fat emboli (from the medullary canal) that lodge in the lungs
- Splinters of dead bone not removed by phagocytosis
- Ischaemia (the neck of the femur is vulnerable, as it has a poor blood supply)
- Continued mobility and the person's age
- The individual's nutritional status (Farrell & Dempsey 2011; Marieb 2013).

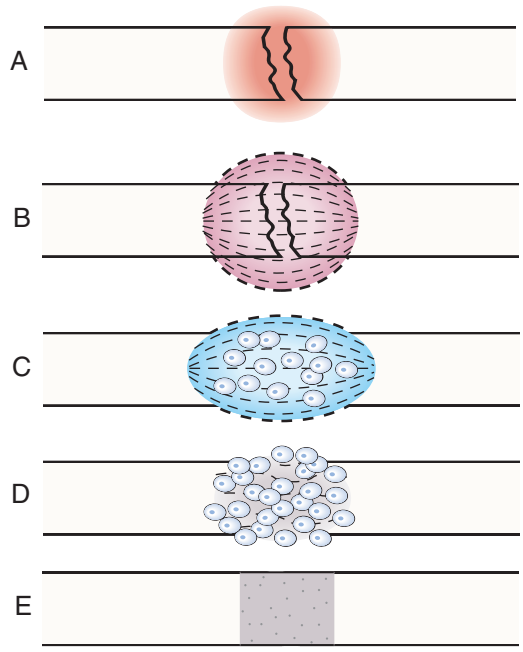

**Figure 28.11** Stages in bone healing

A: Bleeding at fractured ends of the bone with subsequent haematoma formation B: Organisation of haematoma into fibrous network C: Invasion of osteoblasts, lengthening of collagen strands and deposition of calcium D: Callus formation: new bone is built up as osteoclasts destroy dead bone E: Remodelling is accomplished as excess callus is reabsorbed and trabecular bone is laid down

*(Fig 62-9 from Brown & Edwards 2012)*

# TREATMENT OF BONE INJURIES AND MUSCULOSKELETAL DISORDERS

## Surgical repair

For some bone and joint disorders, surgical repair of the affected area is essential to restore alignment, control pain and enhance rehabilitation for full joint mobility. Simple fractures require return of bone fragments to their original position and may be achieved by surgical review and realignment with an internal or external fixture. Compound fractures require surgical debridement to remove dirt, foreign material and necrotic bone fragments (Christensen & Kockrow 2010; Patton & Thibodeau 2010).

A closed fracture may be reduced using closed reduction manipulation, where bony fragments are repositioned into normal alignment by applying pressure and traction distal to the fracture.

Skeletal fixation devices such as casts, metal pins, braces, skeletal and skin traction are used to hold bone and bone fragments in a normal position. Internal fixation is a surgical procedure in which pins, screws, plates and rods fix bony fragments into normal alignment. This procedure is called an open reduction with internal fixation (ORIF) (Christensen & Kockrow 2010).

External devices such as wires or pins which are inserted into the bone allow easy access to wounds, adjustment of the device throughout the course of healing and more functional use of the limb. External fixation is commonly used to treat complex limb deformities and fractures, and the surgery is considered less invasive than internal fixation surgery (Timms et al 2011).

Skeletal traction may be applied to the bone via the skeletal fixation device. Traction aids reduction and immobilisation of fractures, as well as being used to treat muscle spasms, correct or prevent deformities and relieve pressure on a nerve. A steady pull in opposite directions keeps the bone in place. Weights, ropes and pulleys are used to create the pull required to stabilise the limb. Traction can be applied to the neck, arms, legs or pelvis. Skin traction is applied directly to adhesive materials attached to the skin below the site of the fracture. Weights are attached to the pulley system and to a boot, splint or elastic bandage (Christensen & Kockrow 2010) (Figure 28.12).

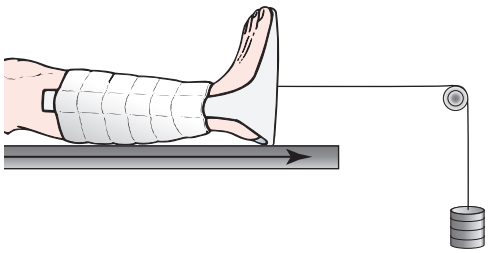

**Figure 28.12** Common type of traction

*(Fig 63-10 from Lewis et al 2011)*

### Casts

Casts are immobilisation devices made of plaster or fibreglass. They are applied after bone alignment by internal or external fixation. Applying the cast can be painful during manipulation for alignment and the person should be advised of the warmth they will experience as the plaster undertakes its setting process. Casts may be complete (encase the affected limb) or partial; that is, backslabs only. Backslabs are applied longitudinally to the affected limb and bandaged into place while still soft. Once firm, the cast provides support with less risk of limb constriction. Indications for backslabs include:

- Minor injuries of the wrist
- Elbow fractures
- Temporary support for foot or hand injuries
- Tibial fractures with significant swelling or oedema
- Crush injuries
- Open fractures
- Support for injuries prior to surgical intervention (Royal Children's Hospital 2015).

A person with a fracture should have neurovascular observations undertaken every hour for 24 hours, then every 4–8 hours if fitted with a cast (or per hospital protocol) (Berman et al 2015; Farrell & Dempsey 2011). As stated previously, the neurovascular assessment should include:

- *Skin:* inspect area distal to the injury; inspect for skin discolouration and palpate skin temperature with the back of the hand and compare with the opposite extremity or site
- *Movement:* have the person move the area distal to the injury, or move it passively; there should be no discomfort
- *Sensation:* enquire about feelings of numbness or tingling; check sensation with a paper clip and compare bilaterally—sensation should be the same
- *Pulses:* palpate pulses distal to the injury; compare bilaterally
- *Capillary refill*: check this in the nail beds distal to the injury. Capillary refill should occur within 3 seconds and within 5 seconds in the older adult
- *Pain:* enquire about the degree, location, nature and frequency of pain, noting any increase in intensity or change in the type of pain (deWit & Williams 2013).

People discharged home wearing a cast should have their cast inspected for rough edges and signs of bleeding or drainage, and be educated to seek medical advice if they notice their cast is cracked, moist or emitting an offensive odour. Other education re cast care includes resting for the first couple of days post application, to let the cast set and keeping the cast dry (plastic bag to cover if bathing or if raining). No foreign objects should be put down the inside of the cast as there is potential for skin damage, and the cast should not be cut or altered by the person wearing it (Better Health 2015).

The limb should be kept elevated to reduce swelling and advice sought if the limb becomes cool, swollen, increasingly painful or changes colour. Casts may remain in place for several weeks to some months, depending on the bone or joint requiring immobilisation (Berman et al 2015; deWit & Williams 2013; Farrell & Dempsey 2011).

Compartment syndrome is a condition of progressive arterial vessel compression and decreased blood supply to an extremity. Factors predisposing to development of compartment syndrome are fractures of the tibia or forearm resulting in muscle oedema, and too-tight casts or dressings (Christensen & Kockrow 2010). If a developing compartment syndrome is suspected, the affected limb should be placed at heart level (not elevated). Elevation of the affected limb decreases arterial blood flow and narrows the arterial/venous pressure gradient (Rasul 2015).

## GENERAL TREATMENT OF MUSCULOSKELETAL DISORDERS

### Promoting rest

Rest helps minimise pain and swelling, promotes healing of injured tissues, relieves muscle spasms and prevents further tissue destruction in inflammatory conditions. Rest may be classified as general, when the individual is confined to bed (e.g. if several joints are inflamed), or local, when a specific body part is immobilised, such as a limb in a splint or cast. General care during the rest phase involves:

- Providing a suitable bed with a firm mattress, pillows and sheepskins to promote comfort
- Meeting basic needs; that is, helping those who are immobilised with activities of daily living
- Preventing complications associated with immobility
- Maintaining correct posture and body alignment (deWit & Williams 2013; Farrell & Dempsey 2011).

### Maintaining joint movement

Some joints require movement, not immobilisation post repair. The continuous passive movement (CPM) device provides gentle forward and backward joint movement after total knee replacement surgery (arthroplasty). Used on people who are resting in bed, the joint is strapped into the device and moved continuously while the person is immobilised. This movement ensures the joint remains mobile, resulting in reduced pain, swelling and eventual immobility (Crisp & Taylor 2012). Because the patella is not disrupted in partial knee replacement surgery, the individual usually may resume walking 3–4 hours after surgery.

Mobilisation of the affected joint after hip replacement surgery (arthroplasty) is dependent on the prostheses used and treating medical officer. Physiotherapists may start mobilisation (weight bearing or non-weight bearing) day 1 post surgery per the medical officer's orders. Exercises may be passive or active involving straight leg raising, flexion and extension to all joints, including the replaced joint (Christensen & Kockrow 2010).

## Maintaining skin integrity

Individuals who are immobilised for prolonged periods are at high risk of developing pressure injuries. Skin must be maintained in good condition and protected from irritation, friction and prolonged pressure (Crisp & Taylor 2012). General care of the skin and prevention of pressure injuries are described in Chapter 29.

## Positioning techniques

People with musculoskeletal disorders who are immobilised require help from nurses to ensure proper body alignment and comfort. Aids to comfort in bed, such as pillows, foot boards, trochanter rolls, trapeze bars, sandbags and slippery-type sheets for ease of movement in bed, are all useful to ensure that an immobilised person is comfortable (Crisp & Taylor 2012). See Clinical Skill 28.2 for more information and guidelines on positioning individuals in bed.

Various positions and proper positioning are discussed in Chapter 23.

## Maintaining or improving nutritional status

Nutrition for individuals with a musculoskeletal disorder includes a well-balanced diet and maintenance of recommended body weight. The diet should contain adequate amounts of protein, calcium and vitamin D to promote healing and maintenance of the musculoskeletal system. Adequate fibre and fluids aid elimination. If a person is overweight, a weight-reduction diet is recommended to prevent stress on inflamed or diseased joints (Berman et al 2015; Crisp & Taylor 2012).

### CRITICAL THINKING EXERCISE 28.4

Why might children from developing countries be more prone to developing bone deformities and delayed healing than children from developed countries? How can nutrition in these communities be enhanced to ensure strong bones and non-delayed healing?

## Relieving pain

While the general approaches to pain management described in Chapter 33 are relevant to people with musculoskeletal disorders, specific measures may also be indicated. A person may experience acute or chronic pain, depending on the specific disorder, and general measures to promote comfort and minimise pain should be implemented; that is, changing position, massage, handling a painful limb gently and rest. If not contraindicated, elevating the limb may relieve discomfort and pain. Specific measures include checking to ensure that splints, casts or dressings are not too tight or rubbing against the skin. Hot or cold packs or treatments may be used to provide relief and increase ROM. Heat is sometimes used in chronic joint disorders, as it relaxes muscles, relieves stiffness and provides analgesia, and is often applied before exercise and massage. Applying a cold pack to a limb or area is useful for acute pain or acutely inflamed joints. When these treatments are used, caution is necessary to prevent tissue damage. Analgesia may be prescribed and administered in accordance with nursing regulations and the institution's policy (Crisp & Taylor 2012).

## Prevention of psychological problems

Management of a musculoskeletal disorder may require a person to be confined to bed, and possibly hospital, for an extended time, and often leads to boredom, frustration or depression. To prevent such problems, the individual should be encouraged to express their feelings and be allowed to participate in making decisions about their care. Active involvement in all aspects of care and self-care techniques are taught, as this allows the individual to take responsibility for some of their care and can help to reduce problems associated with dependence and immobilisation. Regular programs of activity developed with the individual and other allied health professionals need to be incorporated into the nursing care plan. Participation in group physiotherapy or rehabilitation sessions promotes social interaction with others in similar situations (Crisp & Taylor 2012; Farrell & Dempsey 2011).

## Promoting remobilisation and rehabilitation

As the musculoskeletal system is crucial to activity, a routine of exercise and rehabilitation is developed and implemented. A planned exercise program is generally developed by the physiotherapist, but the nurse is required to encourage and supervise regular exercise. The goals of musculoskeletal rehabilitation and exercise are to relieve symptoms, improve musculoskeletal function, control inflammation, restore range of movement, restore and improve muscular strength and power and train to return to daily and recreational activities (Lennard et al 2011).

The overall aim of rehabilitation is to limit the effects of a disability and increase independence in activities of living. This requires a multidisciplinary team approach consisting of nurses, medical officers, physiotherapists, occupational therapists and even members of the individual's own family. Depending on specific needs, a social worker and splint-maker may be involved. Preparation for discharge includes informing the individual of the need to continue any exercise program, on the use of splints or braces, about limits of physical activity and the importance of attending any future appointments or ongoing rehabilitation programs. Information on rehabilitation is provided in Chapter 40.

## Nursing care of a person requiring prolonged bed rest

Older people are more prone to problems associated with prolonged bed rest. These individuals need careful planning and enactment of care to minimise these potential problems (see Nursing Care Plan 28.1 and Case Study 28.2).

## CLINICAL SKILL 28.2 Positioning individuals in bed

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Slide sheet/slip sheet<br>Pillows<br>Lifting device if required |

| **Skill activity** | **Rationale** |
|---|---|
| Assess the individual's body alignment and correct positioning<br>Assess the individual's comfort level | Baseline data<br>Maintains and helps restore body functioning and helps to prevent the complications with bed rest and immobility |
| Assess the individual's physical ability to help with moving and positioning | Ensures individual's independence is maintained<br>Determines needs for additional assistance<br>Ensures safety |
| Explain the procedure to the individual | Ensures consent and cooperation<br>Assists to decrease anxiety and increase cooperation |
| Adjust the height of the bed to between mid-thigh and hip height | Raises level of work towards the nurse's centre of gravity |
| Place the individual in supine position with head of the bed flat and remove the pillows, place pillow at the head of the bed | Enables nurse to assess body alignment<br>Reduces gravity's pull on individual's upper body<br>Prevents striking the individual's head against head of the bed |
| Assess the need for extra help | Ensures the individual's and nurse's safety |
| Determine the most appropriate position for the individual | Various conditions and diseases preclude moving individuals into some positions |
| Perform hand hygiene | Reduces risk of transmission of infection |
| Utilise principles of efficient body mechanics | To protect the nurse's back |
| Perform pressure area care<br>Wash and dry area<br>Apply moisturiser if appropriate<br>Change linen | Prevents skin breakdown<br>Maintains skin integrity |

## NURSING CARE PLAN 28.1

**Assessment:** Immobile, urine and faecally incontinent, mature-aged person.
**Issue/s to be addressed:** Potential for sacral pressure area injury related to immobility and prolonged bed rest.
**Goal/s:** The person's sacral area will remain intact and healthy, with no signs of redness, excoriation or pain, during the period of immobility.

| Care/Actions | Rationale |
|---|---|
| Reposition the individual every 2 hours while sitting or resting in bed | Repositioning relieves pressure on dependent tissues and enables the nurse to visualise and assess sacral areas for changes in skin condition |
| Clean, dry and moisturise sacral skin 3 times a day or as indicated by incontinence | To reduce friction caused by moisture of body fluids and to enable the nurse to visualise and assess the sacral area |
| Use slide sheets and lifting devices to change the person's position | To reduce friction and shearing caused by dragging the person across surfaces |
| Apply pressure-relieving devices such as an air mattress, pressure-reducing foam mattress or pressure-reducing mattress overlay under the individual | To reduce pressure points on dependent tissues and promote rest and sleep |

**Evaluation**

During the period of immobilisation, the individual's sacral area remained intact with no signs or symptoms of redness, excoriation or pain.

*(Adapted from Crisp & Taylor 2012; Gulanick & Myers 2010)*

### CASE STUDY 28.2

Judy Blackwater is 78 and admitted to a surgical ward postoperatively a L knee replacement. She is required to be immobilised for 4 days. Judy has a past history of atrial fibrillation and currently has a BMI of 30 (obese).

1. Identify and give reasons for the potential problems of immobility that Judy may experience.
2. Because of Judy's history of AF and obesity, outline some strategies to prevent formation of an embolus/DVT.
3. List the assessments you would perform on an individual with a musculoskeletal disorder.

## General treatment for exercise-related injuries

Exercise can be the cause of injuries that are mostly orthopaedic in nature and caused by irritation of bones, tendons and ligaments and/or muscle tissue. Injury may be as a result of weight-bearing stress or collision. Nurses can teach individuals the acronym **PRICE: prevention, rest, ice, compression** and **elevation**, and advise of the need for a medical officer to diagnose the injury. Generally, further injury can be avoided by resting the affected limb (Christensen & Kockrow 2010; Stroppler 2014).

## Meeting movement and exercise needs

To determine what the individual can and cannot do without assistance, the clinician must assess the individual in how cognitive and physical deficits cause disabilities. The nurse assists the health professional team by providing subjective and objective data about the individual, and facilitating rehabilitation activities and exercises (Daroff et al 2012).

It is important to identify potential problems that may affect a person's ability to exercise. Impaired mobility may result from:

- A decrease in the individual's strength
- Presence of pain or discomfort
- Impaired cognition or perception, such as dementia, severe anxiety or depression
- Impaired neuromuscular or skeletal function
- Imposed restrictions such as bed rest.

Being in hospital is likely to alter a person's normal movement and exercise routine and, although there is often a degree of restriction in activities and ability to ambulate, they should be encouraged to do so, while those who are immobilised may require assistance to move. Nurses promote safety and comfort while encouraging, when possible, a return to independent function (Crisp & Taylor 2012; Farrell & Dempsey 2011).

When planning care to meet an individual's need for movement and exercise the nurse must consider factors such as:

- Maintaining and promoting normal mobility
- Assisting those with restricted mobility
- Providing and assisting with use of equipment to aid mobility
- Preventing and alleviating discomfort associated with reduced mobility.

A sample nursing care plan is shown in Nursing Care Plan 28.2.

### CRITICAL THINKING EXERCISE 28.5

Individuals with spinal injuries have varying degrees of mobility. Select one form of paralysis resulting from a spinal cord injury. Using the internet, devise a set of exercises (active or passive depending on the severity of injury) for the person you have chosen.

## NURSING CARE PLAN 28.2

**Assessment:** Individual with newly applied leg cast following surgery, non-weight bearing, resting in bed only, with pain score of 5/10 at rest.
**Issue/s to be addressed:** Discomfort related to prolonged bed rest, newly applied leg cast and surgical wound.
**Goal/s:** To reduce and maintain pain score to less than 2/10 (0–10 pain scale) by the end of the shift.

| Care/Actions | Rationale |
|---|---|
| Assess pain characteristics (quality, severity, location, onset, duration, causing and relieving factors) every 4 hours | To map and evaluate the pain in the individual |
| Administer analgesics as prescribed, at regular intervals when pain present and/or prior to pain-inducing activities (i.e. exercise) | To maintain therapeutic analgesic serum levels within the person |
| Apply non-pharmacological therapies to reduce pain, such as heat/cold packs, relaxation exercises, position change, massage | To provide adjunct therapy to reduce pain experience and promote rest and sleep |
| Eliminate other stressors that may cause discomfort (i.e. noise, thirst, hunger) | Rest and relaxation promote better pain management and recovery |

**Evaluation**

By the end of the shift, the individual reports a pain score of 3/10 on movement.

## PROGRESS NOTE EXAMPLE 28.1

| | |
|---|---|
| 18/02/2015<br>1100 hrs | Nursing: CNS: Individual alert and orientated, complaining of aching pain in left leg, 6/10 pain score. Paracetamol 1 g PO given with pain score decreasing to 2/10 after 30 minutes. Equal movement and strength all limbs.<br>CVS: Peripherally perfused but cool to touch. Pedal pulses present. BP dropped from 130/80 lying to 90/60 standing when getting out of bed. Individual stated 'I feel dizzy'. Reported to doctor. To continue lying and standing blood pressures QID.<br>Respiratory: Equal air entry to right and left lungs auscultated. Occasional dry cough. Short of breath on exertion.<br>GIT: Tolerated LWD. Bowels not open for 4 days, and abdomen firm when palpated. Faint bowel sounds heard. Aperient administered as ordered and fluids encouraged.<br>Renal: Incontinent of urine. Urinalysis = leucocytes ++ and S.G 1.030. Reported to doctor.<br>Musculoskeletal: Ambulant with supervision.<br>Integument: Skin intact—reddened areas observed to both heels. Air mattress applied to bed and individual encouraged to change position every hour when awake.<br>***K. Adams*** **(Adams) RN** |

# AMBULATION AFTER PROLONGED IMMOBILISATION

## 'Dangling' before ambulating

Ambulating, or walking, is encouraged and facilitated to prevent the complications associated with even short-term but especially with long periods of immobility. Certain individuals may need to relearn how to walk; for example, after a cerebrovascular accident or leg surgery, an individual may need the assistance of aids such as a walking stick, crutches or walking frame. After an extended period of immobility, nurses need to instruct the individual to mobilise progressively. A bedridden person who is able to raise each leg 4–6 cm straight up from the bed usually possesses enough strength to walk, provided that they are mentally alert.

Nurses begin re-educating muscle groups by first allowing the person to sit on the edge of the bed for 1–2 minutes with their feet on the floor, a technique called **dangling**. The person then progresses to standing, then walks a few steps, gradually increasing the distance. Blood pressure can drop dramatically and the person could faint if they were to stand up suddenly. Application of anti-embolic stockings (to facilitate venous return), dangling and assisting the individual to move slowly and in stages, allow the blood pressure to adjust, and reduce the risk of falls (Radomski & Latham 2013) (see Progress Note Example 28.1).

When the nurse assists an individual who has a one-sided weakness, or hemiplegia, it is important to decide which walking aid or technique has been recommended. Although the method used to assist is individualised, most people require assistance and support on the affected side. When

assisting a person to walk it is helpful if they remain close to a railed wall and are able to rest on a chair before beginning the return walk. If an ambulant person has an intravenous infusion or urinary or wound-drainage bag, the nurse ensures that therapy or drainage is not affected, by checking tubing or drainage bags in case they have become dislodged after exercise.

Well-fitting, supportive, non-slip footwear should always be worn, the floor should be clean and dry and the environment cleared of obstacles. The individual should not be allowed to walk barefoot or with just socks or slippery footwear (e.g. women with nylon hose) on the feet. Each individual is encouraged to walk at their own pace and resting points established along the way should the individual become tired, dizzy or unsteady. If the individual begins to fall, the nurse should assume a wide stance and guide the person to the floor, protecting their head as they do (Crisp & Taylor 2012).

## WALKING AIDS

Walking aids broaden the base of support and increase stability. The type of aid used depends on the person's condition, disability and amount of support required. An individual is commonly instructed in the use of walking aids by a physiotherapist; however, it is important for nurses to know the principles involved in the use of walking aids. Walking aids that may be required on a temporary or permanent basis include crutches, walking sticks and walking frames. Callipers, leg braces or splints may be used to provide extra support for a weak leg, to prevent or correct deformities or prevent joint movement.

### Crutches

Crutches enable a person to ambulate by taking the weight of the body off one or both legs. Successful use of crutches requires balance and upper body strength. Selection of crutches and particular type of gait depends on individual needs, but must be appropriate to be safe and effective. The two types commonly used are the underarm and forearm crutches.

Underarm crutches are often used by people with a sprain or leg cast, while forearm crutches are more commonly used by those with a through gait (which is a type of swinging gait), as in paraplegia (Walk Easy Inc 2015). Underarm crutches must be measured so that the person's weight is carried on their wrists and palms and not on the axillae. The axilla bar should be 4–5 cm below the axilla, and the hand bar positioned to permit 15–30-degree flexion of the elbow at rest. Forearm crutches must also allow 15–30-degree flexion of the elbow at rest. Before crutches are used they should be assessed for safety, ensuring that all screws and bolts are tightened and rubber tips are in good repair. It is important to ascertain the amount of weight bearing allowed on the affected leg(s); that is, partial or none (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011) (Figures 28.13 to 28.15).

**Figure 28.13** Using the goniometer to verify correct degree of elbow flexion for crutch use
*(Potter & Perry 2013)*

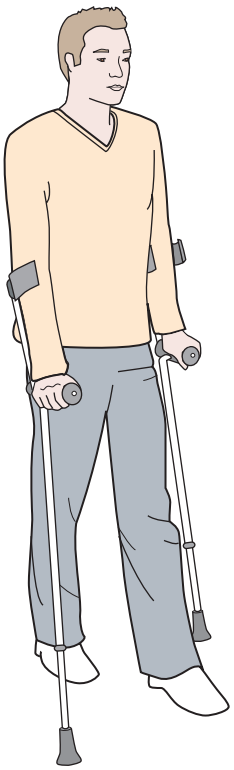

**Figure 28.14** Double adjustable forearm crutch
*(Potter & Perry 2013)*

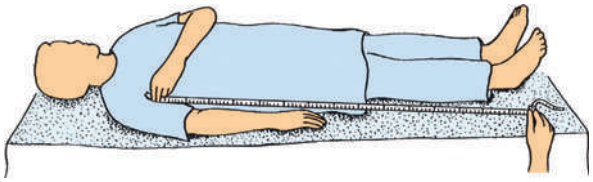

**Figure 28.15** Measuring crutch length
*(Potter & Perry 2013)*

## Crutch-walking gaits

Individuals are instructed in one of several **crutch-walking gaits**, according to need. The most common is the three-point gait, in which weight is borne on the unaffected leg, and the crutches moved forwards first, followed by the unaffected leg, then the affected leg follows in a swinging movement because it is raised from the ground. This gait is used when a person is unable to bear weight on one leg. The two-point and four-point gaits are used when both feet can bear some weight; that is, partial weight bearing. The two-point gait requires the individual to advance one crutch and the opposite leg together, followed by the other crutch and leg. The four-point gait requires greater coordination but provides more stability, as there are always three points on the floor as each leg is moved alternately with the opposite crutch.

The swing-through gait is used when a person has no use of the lower body (i.e. in paraplegia), and both crutches are advanced simultaneously. The person swings both legs either parallel with or beyond the crutches, the pelvis moving first, followed by the shoulders and head in order to maintain balance.

When rising from a chair the individual is taught to hold both crutches in one hand, tips resting firmly on the floor, and to push up with their free hand, using the crutches for support. To sit down, the process is reversed, the person supports themselves with the crutches in one hand, holds the arm of the chair with a free hand and lowers into the chair. To use stairs, the three-point gait is easiest, so that when going up stairs a person leads with the unaffected leg, follows with both crutches then the affected leg. When going down stairs a person leads with the crutches and affected leg, followed by the unaffected leg (Mercy Health Services 2014).

## Walking sticks

A walking stick may be used for people with one-sided weakness or injury, occasional loss of balance or to reduce weight bearing on a hip or knee, as well as to provide balance and support for walking, reducing fatigue and strain on weight-bearing joints. Walking sticks should extend from the individual's greater trochanter to the floor, and be fitted with a rubber tip to prevent slippage. Sticks are available as single-tipped, tripod or four-point, and should permit 15–30-degree flexion of the elbow. Three and four point sticks provide a broad base and greater stability and may be used by a person with poor balance or one-sided weakness.

To use a stick the individual holds it close to the body on the unaffected side; taking the weight off the affected leg, the person then moves the stick and the affected leg simultaneously, followed by the unaffected leg. Sometimes the three or four-pronged stick is held on the affected side. Individuals are encouraged to keep the stride of each leg, and the timing of each step, equal. While a person is learning to use the stick, the nurse stands behind them to support them if they become unsteady. When going up stairs the stick should be held in one hand and the person encouraged to hold the stair rail, leading with the unaffected leg; when going down stairs the affected leg leads (Farrell & Dempsey 2011).

**Figure 28.16** Walking frame
*(© Norman Lanyon)*

## Walking frames

Walking frames consist of a metal frame with hand grips, four legs and one open side (Figure 28.16). A frame may be used by an older adult, as it provides greater support and sense of security than a stick and is useful for those with an unsteady gait, or when partial weight bearing is recommended. The height is selected to allow 15–30-degree flexion of the elbows when the hand grips are held. Attachments such as baskets and trays are available to meet specific needs and to promote greater independence. To safely rise from a chair, the frame is placed in front of the person, who then inches forwards in the seat of the chair and, with both feet firmly on the ground and both hands on the arms of the chair, pushes with their arms to stand and, when standing, grasps the frame. Commonly, the individual picks the frame up and moves it 15–20 cm forward, then moves one foot, followed by the other, up to the frame. If an individual has a one-sided weakness, the affected leg is moved first (Crisp & Taylor 2012; Mercy Health Services 2014; Walk Easy Inc 2015).

When an individual is learning to use a frame, the nurse stands behind them to support the hips and encourages the person to stand upright and look straight ahead. To sit down, the person stands with the back of their knees against the front of the chair, then reaches behind to securely grip the armrests, bending their arms to lower themselves into the chair. When a walking aid is used, the person is assisted until they are confident in the use of the aid and when unassisted use is decided by their medical officer, physiotherapist or nurse, in consultation with other health professionals (Mercy Health Services 2014).

## COMPLICATIONS ASSOCIATED WITH REDUCED MOBILITY

The body works more efficiently when people are active, so when a person is confined to bed or immobilised, each system is affected in a negative way. Depending on age, health status and length and degree of immobility, inactivity can cause both short- and long-term complications. Disuse of muscles leads to degeneration and subsequent loss of function and it is important that individuals receive some form of exercise to prevent **muscle atrophy**. Atrophy begins almost as soon as muscles are immobilised. Individuals also experience a limitation in their endurance, which makes activities of daily living difficult. Restoring muscle strength and tone in people who have been immobilised for any length of time is a slow process.

Systemic effects of immobility include:

- Pressure injuries
- Contractures
- Cardiovascular and pulmonary stasis
- Urinary stasis
- Constipation
- Depression, anxiety or boredom.

### Pressure injuries

Pressure injuries result from localised damage to the skin and underlying tissue caused by pressure, shear or friction (for a bedridden person, shear or amount of friction increases as their head is elevated). Pressure, especially on bony prominences, results in poor circulation, so that the area is deprived of essential nutrients and oxygen, and cellular death may occur. Any person with a mobility or activity deficit should undergo a pressure-sore risk assessment. Pressure injuries remain a significant problem in hospitals and residential care settings despite being largely preventable (Crisp & Taylor 2012; Farrell & Dempsey 2011). See Chapter 29 for factors that affect skin integrity.

### Effects of immobility upon the musculoskeletal system

Effects of immobility are evident after even short periods of inactivity. People who attempt to walk after several days of bed rest are surprised at how weak their leg muscles have become. Immobilisation and the resultant disuse of muscles lead to decreased joint mobility, bone demineralisation and atrophy of muscles with decreased size, strength and tone.

#### Contractures and ankylosis

Contractures are abnormal conditions of a joint. **Contractures** are characterised by flexion and fixation and caused by atrophy and shortening of muscle fibres. **Ankylosis** is joint consolidation and immobilisation. Contractures may result from improper support or positioning of a joint, or as a result of inadequate joint movement. For example, if a joint is allowed to remain in one position for an extended length of time, the muscle fibres that normally provide movement shorten to accommodate that position, and lose the ability to contract and relax. Weight-bearing activity stimulates bone formation and balance; however, during immobilisation, bone formation slows, while breakdown of bone increases. With the subsequent loss of bone calcium, phosphorus and matrix, disuse osteoporosis results, and the brittle demineralised bones fracture easily.

For prevention, encourage physical activity and isometric or isotonic active ROM exercises while the person is in correct body alignment. An immobilised person may need direction as well as assistance when they perform ROM exercises. Pressure-relieving devices, such as a bed cradle, may prevent the bedclothes pressing down and forcing joints into abnormal positions. Supportive devices such as splints, slings and wheelchair attachments help prevent or realign joints (Berman et al 2015; Crisp & Taylor 2012; Wagner & Clevenger 2010).

#### Footdrop

**Footdrop** is another term for **plantar flexion**, which is caused by damage to the nerve supply of the muscle responsible for dorsiflexion of the foot (Figure 28.17). If an individual's feet are allowed to assume plantar flexion for long periods they become fixed in that position so that, when that individual attempts to stand or walk, they will be unable to place their heels on the floor and walk normally.

Prevention includes using a foot board or firm pillow in the bed to maintain the feet in proper alignment, or dorsiflexion, as if in a standing position (if not contraindicated); that is, at a 90-degree angle. Devices and techniques to keep pressure off the feet should be used, such as a bed cradle or foot pleat in the upper bedclothes. The person's feet should be exercised through their ROM, either actively or passively. If footdrop occurs, management includes use of an orthopaedic brace, intensive physiotherapy or surgical intervention (Crisp & Taylor 2012).

### Effects on the cardiovascular and pulmonary systems

The primary negative effects of immobility on the cardiovascular system are increased cardiac workload, postural hypotension and venous thrombosis. An increase in the workload on the heart may be due to less resistance by blood vessels and changes in blood distribution. Heart rate increases and cardiac output falls after prolonged rest. A significant drop in

blood pressure on standing (25 mmHg systolic and 10 mmHg diastolic) is termed **orthostatic or postural hypotension**, and is due to a decrease in neurovascular reflexes and muscle tone. In addition, stasis of blood may precipitate clot formation. A lack of muscular activity that would normally help move blood towards the heart results in calcium exiting the bones to enter the systemic circulation. This action influences clot formation. If a clot or thrombus detaches from the vessel wall and is transported in the bloodstream, it is called an embolus. Emboli that lodge in the pulmonary artery tree are referred to as pulmonary emboli. Depending on the size of the embolus, consequences may be serious (Berman et al 2015; Marieb 2013).

## Prevention of venous thromboembolism

Prevention of venous thromboembolism (VTE) includes exercises to stimulate venous blood circulation in the legs.

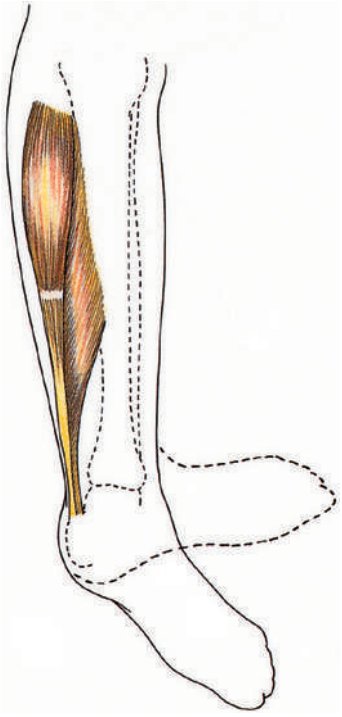

**Figure 28.17** Footdrop
*(Potter & Perry 2013)*

Active or passive 2-hourly exercises should be performed and consist of rotating the ankles, dorsiflexion and plantar flexion of the feet, flexing and extending the knees and raising and lowering each leg. Individuals are advised not to cross their legs while lying in bed or sitting. Prolonged pressure on the backs of the legs should be avoided by careful positioning and repositioning. Upper bedclothes should remain loose to allow movement of the legs.

Anti-embolic elastic stockings may be prescribed to facilitate venous return from the lower extremities, prevent venous stasis and venous thrombosis and reduce peripheral oedema. The stockings expose the toes but cover the foot and extend up the leg to the knee or groin. They give firm support to superficial veins in the leg, maintaining adequate venous pressure and reducing the incidence of thrombi. The individual's leg(s) are measured to ensure correct fit, then the stockings applied by rolling them slowly from the foot up the leg. Firm, even pressure is essential, and the toes are exposed to check that they remain warm and pink and blood supply is not impeded by the stockings.

An alternative or adjunct therapy to prevent VTE is sequential compression device therapy (SCD). SCDs are considered first choice for VTE prevention. These devices sequentially inflate and deflate air-filled sleeves applied to the lower limbs. This inflation/deflation mimics the muscle activity of ambulation, pushing blood up towards the heart. SCD may be used in conjunction with anti-embolic elastic stockings. SCD is contraindicated in individuals with deep vein thrombosis, compartment syndrome, extremity deformities and open wounds of the extremities (Moore et al 2013).

For people requiring surgery, additional preventative measures may include antithrombotic agents pre- and postoperatively (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011).

See Clinical Skill 28.3 for more information and guidelines on the application of anti-embolic stockings.

## Prevention of postural hypotension

Prevention involves the gradual reintroduction of ambulation and allowing time to adjust to changes such as moving from a lying to a sitting or standing position (see 'dangling technique' earlier in this chapter).

### CLINICAL SKILL 28.3 Application of anti-embolic stockings

**Review and carry out the standard steps for all clinical skills/interventions**

**NMBA Decision-making Framework considerations:**

1. Am I educated?
2. Am I authorised?
3. Am I competent?

If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator.

**Equipment:**

Tape measure
Correct size of anti-embolic elastic stockings
Talcum powder

## CLINICAL SKILL 28.3 Application of anti-embolic stockings—cont'd

| Skill activity | Rationale |
|---|---|
| Observe for signs and symptoms and conditions that might contraindicate the use of anti-embolic elastic stockings:<br>• Skin grafts<br>• Size of thighs | Anti-embolic elastic stockings may aggravate skin conditions<br>Continuous pressure is necessary to keep graft adherent to recipient bed, but pressure should not be firm as to cause death of the graft<br>Anti-embolic elastic stockings that do not fit correctly due to larger thighs may cause excessive pressure and constriction around the thighs, which could then lead to reduce venous return |
| Obtain medical prescription | May be required for legalities or associated costs |
| Ensure understanding by individual and/or carer<br>Explain procedure to individual | Ensures informed consent<br>Identifies possible education needs<br>Reduces anxiety |
| Assess individual's skin, colouration and circulation of legs | Identifies a baseline |
| Use tape measure to measure individual's legs to determine correct stocking size | Stockings must be measured as per the instructions on the packaging. The length of the stockings will be determined by the medical orders and the individual's condition<br>If stockings are too large, they will not support the extremities adequately<br>If stockings are too small, stocking may impede circulation |
| Position individual in supine position | Ensures good body mechanics for the nurse and enables ease of application<br>Stockings should be applied before standing to prevent stagnation of blood in lower extremities |
| Ensure the individual's legs are clean and dry and apply a small amount of talcum powder | Allows for easier application and reduces friction |
| Stockings are applied by rolling them slowly from the foot up the leg<br>Ensure the foot fits into toe and heel position of the stocking<br>Ensure the stocking is completely extended up the leg<br>Ensure it is smooth and no creases are present<br>Ensure toes are able to be exposed to check they remain warm and pink and blood supply is not impeded by the stockings | Creases in stockings can impede circulation to lower region of extremities |
| Inspect stockings to make sure there are no creases or binding at the top | Can lead to increased pressure and alter circulation |
| Ensure individual is aware not to adjust stockings or roll them down<br>Note individual's reaction to stockings | Rolling down of stockings can have a constricting effect and impede venous return<br>Ensure the individual is adapting to stockings and is not experiencing discomfort |
| Remove stocking once per shift | Ensure they remain in the correct position<br>Ensures skin intact<br>Ensures adequate circulation<br>Identifies any complications |
| Document size and length of stockings that were applied<br>Record skin condition and circulatory assessment | Informs healthcare professionals and assists with planning and implementing care |

*(NSW Health Prevention of Venous Thromboembolism Policy Directive 2014; Rebeiro et al 2013)*

### Development and management of pulmonary embolus

Management of emboli in the pulmonary system includes administration of oxygen, analgesia and anticoagulant therapy. When immobilised, a person's pulmonary system declines in function and effects are related to a decrease in the rate and depth of breathing and effort, as well as an increase in bronchial secretions. Lung expansion decreases and breathing deeply is inhibited. In addition, secretions pool in the bronchial tract, which predisposes a person to respiratory tract congestion and infection. **Hypostatic pneumonia** may result and the risk increases when a person is dehydrated or is given medication that causes respiratory depression, such as morphine.

Atelectasis, or collapse of the lung, may occur and inhibits gaseous exchange at the alveoli. This results in hypoxaemia. Signs and symptoms of lung congestion include a cough and production of sputum, rattling, distressed or painful breathing and increased body temperature (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011).

### Prevention of pulmonary stasis

Preventing pulmonary stasis includes nursing an individual sitting up when possible and encouraging coughing and deep breathing. Deep breathing exercises are performed with the person in a sitting position. The nurse places one hand on the chest and the other on the abdomen just below the ribs. The person is instructed to inhale slowly and deeply, pushing the abdomen out to promote optimal distribution of air to the alveoli, then breathe out through pursed lips while contracting their abdomen, which forces air out of the lungs. **Pursed-lip breathing** improves oxygen diffusion, encourages a slow deep-breathing pattern and puts positive back-pressure on the airways so that they stay open longer and expel greater amounts of stale air. Abdominal contraction pushes the diaphragm upwards, exerts pressure on the lungs and helps to empty them. Deep breathing and coughing (DB&C) involves incorporating deep breathing exercises with voluntary coughing. Deep breathing before coughing stimulates the cough reflex. The nurse instructs the individual to take a deep slow breath and exhale slowly (repeated several times). The individual then takes a short breath and coughs from deep inside the lungs. Analgesia may need to be administered prior to DB&C to facilitate effective results (Smeltzer et al 2010).

Additional chest physiotherapy such as postural drainage and chest percussion and vibration may be added. Fluids should be increased (provided there are no contraindications) to help liquefy secretions and facilitate coughing up secretions or phlegm. Oxygen therapy may be necessary, and medications such as antibiotics may be prescribed if infection is present. Analgesia is offered before chest physiotherapy begins. Nebulisation using normal saline can loosen secretions for ease of expectoration (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011).

## Urinary stasis

Immobility can lead to retention of urine, urinary tract infection or renal calculi. Difficulty in using the pan or bottle in bed can result in incomplete bladder emptying and stasis of urine. Immobility reduces the amount of circulating lactic acid, which leads to alkaline urine (i.e. high urinary pH values) and, together with excess blood calcium (which is excreted by the kidneys), may result in kidney stones.

### Prevention and management of urinary stasis

To prevent stasis of urine, nurses promote an adequate intake of fluids (unless contraindicated), and ensure that the person understands the importance of not postponing urination and of the need to empty the bladder completely. Management depends on the cause and includes increasing fluids and treating any infection (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011). Information on elimination of urine and disorders affecting the urinary system is provided in Chapter 31.

## Constipation

Constipation may occur as a result of decreased intestinal peristalsis due to reduced mobility or as a result of difficulty in using the bedpan in bed. Preventing and managing constipation includes promoting adequate fluids, exercise and fibre, as well as the appropriate aperient or suppository when required. Individuals are encouraged to maintain as normal a routine as possible to promote normal bowel function. Information on bowel elimination is provided in Chapter 32.

## Psychological effects of reduced mobility

Psychological stress, anxiety, depression or boredom can occur when a person is immobilised. Loss of independence occurs when people have to rely on other people or aids to carry out activities of daily living. It interferes with all aspects of living, and people become bored by the lack of stimulation or variety. A change in the level of independence and physical impairment or isolation from family and friends result in feelings of depression, and people may also be anxious and feel worthless, irritable, apathetic and restless. Nurses need to try to improve the person's self-esteem.

Individuals are encouraged to participate in decisions regarding care, which allows some control over their life. Changes of environment may be beneficial; for example, some time spent in the day room or outside, reading, exploring the internet, using the radio, TV or telephones may prevent boredom. Encourage the individual to pursue hobbies or studies, or the occupational therapy department may be able to provide alternative activities. A social worker may assist with any problems about finance or the home situation. Flexible visiting hours are important, as well as communication with the person showing concern, respect and empathy, active listening and providing information about care and treatment. It is important that people are allowed to express their emotions (Berman et al 2015; Crisp & Taylor 2012; Farrell & Dempsey 2011).

### DECISION-MAKING FRAMEWORK EXERCISE 28.1

You are a newly registered Enrolled Nurse on a busy surgical orthopaedic ward. One of your tasks is to shower a person on a commode chair as he is faecally incontinent. The only safe way to move this person is by electric hoist; however, you have never used one before. The person waiting to be showered is becoming extremely uncomfortable and extremely impatient.

Using the decision-making framework:

1. What strategies could you use in this situation?
2. Is it appropriate to attempt to shift this individual by yourself? Give reasons for your answer.
3. What strategies could you use to plan care for this individual in the future?

## Summary

Movement and exercise are necessary to maintain cardiopulmonary efficiency, muscle strength and tone and joint mobility. Some form of movement and exercise is advisable for health and wellbeing, as it stimulates the mind, enhances awareness and improves the psychological state. The practice of good body posture and body mechanics reduces muscle fatigue and prevents injury and is important whether lying, sitting, standing or moving. During exercise the joints should move through their full ROM.

An individual's ability to exercise should be assessed in order to plan and implement nursing measures to meet their needs. Some people will be able to move and ambulate independently, while others will require assistance. Any technique or aid used to assist a person to move should be one that promotes safety and comfort. Immobility presents challenges for nurses, who can often prevent serious complications by implementing simple measures for movement and exercise. Nurses have a duty of care to identify individuals at risk of developing complications while immobilised, and to promote movement and exercise in those who are capable, encouraging independence.

Knowledge of the musculoskeletal system gives the nurse insight into how the body functions during exercise and movement and the way in which exercise can improve health and wellbeing. Pathological changes in the musculoskeletal system can result from inflammation, infection, degeneration, nutritional influences, neoplasms or trauma. Major manifestations include pain, sensory changes, swelling, deformity and impaired mobility. Disorders of the musculoskeletal system may be classified as congenital, degenerative, infectious or inflammatory, immunological, metabolic, neoplastic, traumatic or from multiple causes.

Care of individuals with musculoskeletal disorders includes promoting rest, preventing complications of immobility, maintaining skin integrity and nutritional status, relieving pain, preventing psychosocial problems, remobilisation, regaining independence and rehabilitation. Nurses need to be aware of correct positioning of person who is immobilised, as comfort and correct body alignment are important aspects of care. The general objectives of fracture management are reduction, immobilisation and restoration of function. Exercise has many physical and psychological benefits that greatly enhance wellbeing. Healthy attitudes towards regular exercise can mean a population that ages well and values exercise to prevent disease and illness.

## Review Questions

1. What are the principles of good posture and body mechanics?
2. Describe the effects of exercise on the human body.
3. What is the difference between isotonic, isometric and isokinetic exercise?
4. Describe the range of movement exercises used to maintain joint mobility in the immobilised person.
5. Describe the benefits of exercise on health, fitness and the older person.
6. What are the complications associated with bed rest and immobility?
7. Discuss the importance of initiating an exercise program in an aged care facility with a centre manager who is resistant to change.
8. Outline the components of a neurovascular assessment.
9. List factors that may contribute to delayed healing of a person with a neuromuscular disorder.
10. Outline the subjective and objective data that should be collected from the individual with a neuromuscular disorder.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER
29

# Maintaining and promoting skin integrity and wound care

*Kerrie Coleman*

## KEY TERMS

burn injuries
delayed primary intention
first intention
leg ulcers
pressure injuries
primary intention
risk factors
secondary intention
skin disorders
skin tears
third intention
wound assessment

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the structure of the skin
- Describe the functions of the skin
- Identify the risk factors for loss of skin integrity
- Discuss the wound healing process
- Describe the different wound healing intentions
- Describe the classifications of wound types
- Identify the principles of wound management
- Identify nutritional needs to promote wound healing
- Describe the differences between acute and chronic wounds
- Describe the procedures related to care of surgical wounds
- Describe the care required to prevent and manage pressure injuries
- Discuss the differences between arterial and venous leg ulcers
- Describe the care required to prevent and manage skin tears
- Describe the management of loss of skin integrity related to burns
- Describe the major manifestations of skin disorders
- Complete an assessment for an individual with impaired skin integrity
- Assist in planning and implementing nursing care for the individual with a loss of skin integrity
- Identify the purpose of commonly used wound dressings
- List appropriate nursing interventions for the individual with impaired skin integrity

## CHAPTER FOCUS

The skin has several functions, which are largely concerned with protection of the body against infection, physical trauma and ultraviolet radiation. Any disorder that disrupts normal skin function will affect the efficiency with which it carries out its functions, and may place the physiological integrity of the individual at risk. The effects that disorders of the skin have on the individual range from minor and temporary to major and life threatening. Some serious skin disorders such as burns affect the individual to the extent that self-concept and body image are severely impaired. Wound management is a major role of the nurse. It is important that all nurses understand normal wound healing and the variances that can occur with ageing and disease processes. There is an abundance of literature on wound management and a vast array of wound-care products. The aim of this chapter is to assist the nurse to increase their knowledge in this rapidly changing area.

## LIVED EXPERIENCE

I had a leg ulcer that would not heal. I had it for over a year. A new nurse came one day to do my dressing at home and she suggested a new type of dressing. I started using the new dressing and the ulcer started to look much better. After a few months it was almost healed. I am so thankful to the nurse for being able to help my ulcer heal.

**Dulcie, 65**

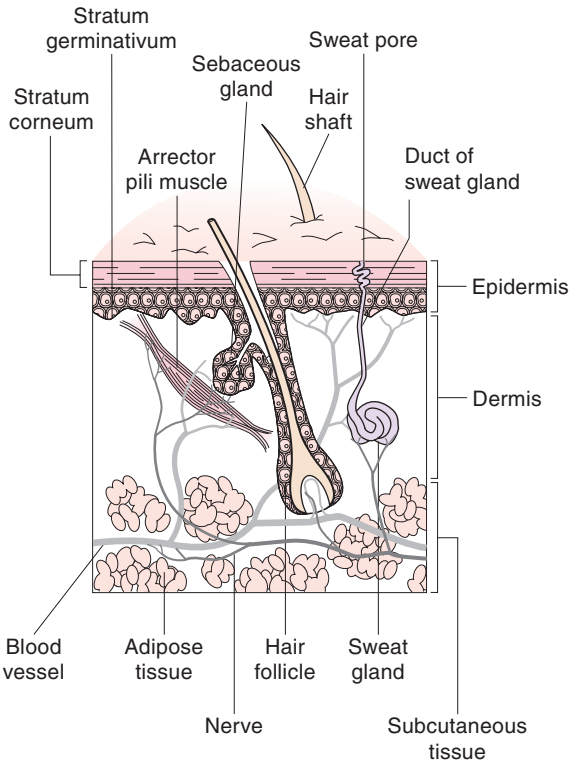

**Figure 29.1** Structure of the skin

# THE INTEGUMENTARY SYSTEM

The integumentary system consists of the skin and its appendages; the hair, nails, sweat and sebaceous glands. The skin (or integument) is the largest organ of the body, covering about 7500 $cm^2$ of surface area in an average adult (Figure 29.1). It is a protective barrier to the outside world, plays a vital role in homeostasis and also provides a major means of communication through touch and sensation. The appendages of the skin, hair, nails and glands, arise from the epidermis but are present in the dermis.

## Structure of the skin

The skin is comprised of two basic layers: the epidermis and dermis. Under the dermis is a layer of adipose tissue called subcutaneous tissue. While this layer is not considered to be part of the skin, subcutaneous tissue does protect and insulate the deeper tissues and is composed primarily of fat and loose connective tissue.

### The epidermis

The epidermis is the thin outermost layer and is composed of epithelial cells arranged in layers of stratified epithelium. The number of layers varies according to the amount of wear and tear experienced; for example, there are many more layers on the soles of the feet and the palms of the hands than there are between the toes and the fingers.

The epidermis is divided into two layers. The horny layer (stratum corneum) is the uppermost layer, and consists of about 30 layers of dead, flattened keratinised cells. These keratinocytes contain a waterproof hard protein substance called keratin. Keratin's waterproofing properties protect the body and prevent escape of fluid from the deeper tissues. Keratin is also responsible for the formation of hair and nails. The germinative layer (stratum germinativum) is the deeper layer of the epidermis. It is here that new cells are constantly being formed and pushed upwards to replace cells that die and are rubbed off. Millions of new cells are produced daily and are pushed up away from the source of nutrition, to become part of the outermost layer.

Melanocytes are present in the germinative layer. Their function is to produce a brown pigment called melanin. Melanin gives colour to the skin and protects the body against the damaging effects of ultraviolet rays in sunlight. Brown-toned skin results when large amounts of melanin are

produced, whereas light-toned skin results when the body produces less melanin.

The epidermis does not contain any blood vessels, but receives its essential substances from fluid that comes from the blood supply to the dermis. As cells are pushed towards the surface, away from the source of nutrition, they die and are eventually rubbed off. Thousands of dead epithelial cells are flaked off every day, which means that they are deposited on clothing and on every surface touched. They become part of the dust in a room, serve as food for mites and harbour microorganisms. A person sheds about 0.5 kg of dead cells per year, much of which goes down the bathroom drain.

The patterns of lines and ridges in the epidermis are due to projections in the dermis called papillae. On the fingertips these patterns are the fingerprints, which are different in every individual. For this reason, fingerprints are useful for purposes of identification. Nails are formed from the stratum corneum and are composed of modified epithelium.

## The dermis

The dermis consists of white fibrous tissue containing many elastic fibres. Elasticity of the skin is essential to allow for changes in the size of a part of the body without tearing, such as the abdominal area during pregnancy. In old age the fibres become less elastic, causing wrinkles and folds to appear in the skin. The following structures are contained in the dermis.

## Network of blood vessels

The blood vessels transport blood containing oxygen and nutrients to the dermis and transport blood containing wastes such as carbon dioxide away from the dermis. The blood vessels also play a role in regulating body temperature. If the body temperature is elevated the dermal capillaries become engorged with blood, which allows loss of body heat from the skin surface through radiation. If the environmental temperature is low, blood vessels in the skin constrict, conserving body heat by reducing radiation from the body.

## Nerve endings

The dermis has a rich nerve supply consisting of several types of nerve endings. Each type of nerve ending reacts to a different stimulus, such as pain, touch, pressure and temperature. Impulses are transmitted from the nerve endings to the brain for interpretation.

## Hair follicles and hairs

Hairs grow from hair follicles, which are deep pouch-like cavities in the skin. Although hair follicles are present in most areas of the skin, they are not found on the palms of the hands, lips or the soles of the feet. Hair is composed of modified epithelium and grows from roots deep in the follicles. The part of a hair projecting above the epidermis is called the shaft. Hair colour reflects the amount of pigment, generally melanin, in the epidermis. Hair is a protection from the elements and from trauma; for example, the scalp hair and eyebrows are barriers against sunlight, and the nasal hairs filter inhaled air.

Hair growth is influenced by the sex hormones oestrogen and testosterone. An excessive growth of hair is called hirsutism. Like other cells that compose the skin, the hair cells also become keratinised. The hair that we brush, blow dry and curl is a collection of dead keratinised cells. Hair colour is genetically controlled and is determined by the type and amount of melanin. The absence of melanin produces white hair. Grey hair is due to a mixture of pigmented and non-pigmented hairs. Red hair is due to a modified type of melanin that contains iron. Hair is important cosmetically. Hair loss can be very distressing for some people. The most common type of hair loss is male-pattern baldness. It is a hereditary condition characterised by a gradual loss of hair with ageing.

## Arrector pili muscles

The arrector pili muscles are minute involuntary muscles, with one end attached to a hair follicle and the other end to the dermis. When these muscles contract (e.g. during fear or exposure to cold) the follicles and hairs become erect. Contraction of the muscles also causes some elevation of the skin around the hairs, giving rise to the 'goose pimple' appearance. The contraction of the arrector pili muscles increases heat production. This response is called shivering.

## Skin glands

Two major types of glands are associated with the skin: sebaceous glands and sweat glands.

***Sebaceous glands*** Sebaceous glands are small glands, most of which open into hair follicles. The glands produce sebum, which is an oily substance and a lubricant that keeps the skin soft and moist and prevents the hair from becoming brittle. Combined with sweat, sebum forms a moist, oily acidic film that is mildly antibacterial. During periods of increased hormonal activity, such as adolescence, sebaceous glands become very active and the skin becomes oilier. Sebaceous glands are present on all areas of the skin except for the palms of hands and soles of feet, and are most abundant on the face, scalp and upper chest and back.

***Sweat glands*** Sweat glands, which are widely distributed, are either eccrine or apocrine. Eccrine glands are present all over the body and produce a clear perspiration. Apocrine glands are found mainly in the axillary and genital areas, and secrete sweat that has a strong characteristic odour. Sweat glands are coiled in appearance, with a straight duct that releases sweat onto the surface of the skin through an opening called a pore.

Sweat glands play a part in regulating body temperature. They excrete large amounts of sweat when the external, or body, temperature is high. When sweat evaporates off the skin's surface it carries large amounts of body heat with it. Sweat consists of water that contains sodium chloride, phosphates, urea, ammonia and other waste products. Under normal circumstances, the amount of sweat secreted by an individual is about 700 mL/day. Under some conditions, such as strenuous physical exertion or pyrexia, the amount can be increased to as much as 1500 mL/day. Much of the water lost through the skin evaporates immediately, so it is not noticeable and is called insensible perspiration. Sweat that makes the skin damp and is noticeable is called sensible perspiration.

## Functions of the skin

The major functions in which the skin and its appendages play a role are protection, thermoregulation, metabolism and sensory perception.

### Protection

The skin is the first line of defence against the external environment. It provides a barrier to a variety of harmful agents, such as microorganisms, radiant energy and chemical substances. The skin acts as a barrier to harmful agents only as long as it remains intact. The waterproof quality of the outer layer prevents excess water absorption and abnormal loss of body fluids. The skin contains nerve endings that are sensitive to painful stimuli. The nerve endings transmit impulses to the brain that alert the individual that damage is occurring.

### Thermoregulation

The skin plays a major role in the maintenance of constant body temperature. Blood conducts heat from internal structures to the skin for dissipation. The skin dissipates excess body heat by radiation, conduction, convection and evaporative cooling. Body temperature is controlled by the hypothalamus, which is the heat-regulating centre in the brain. This centre is sensitive to the temperature of the blood passing through it and also receives sensory stimuli from nerve endings in the skin that react to heat and cold (thermoreceptors). The hypothalamus in turn relays impulses requiring vasodilation and activation of the sweat glands (for cooling), or vasoconstriction and inhibition of sweat glands (for heat retention). Thus, the hypothalamus acts like a thermostat that initiates heat-losing activities when the body temperature begins to rise and heat-retaining activities when the body temperature starts to fall.

### Metabolism

The skin assists in the regulation of fluid and electrolyte balance by eliminating water and small amounts of sodium chloride through the sweat glands. Sweat consists of 99.4% water, 0.2% salts and 0.4% urea and other wastes. In the presence of sunlight or ultraviolet radiation, the skin begins the process of forming vitamin D (calciferol), a substance required for absorbing calcium and phosphates from food.

### Sensory perception

Through perception of a painful stimulus, the skin causes an avoidance reaction, while other receptors perceive sensations of pressure and touch. The skin is therefore an agent of communication between the outside environment and the body, as the activity of sensory nerve endings informs the individual of what is happening outside the body.

## Factors that affect skin integrity

Many **risk factors** can affect the integrity of the skin, including:

- Immobility and inactivity
- Restlessness
- Sedation
- Neurological factors, such as paraplegia, quadriplegia and multiple sclerosis
- Poor nutrition and hydration status
- Systemic and local circulation and oxygenation
- Presence or absence of excessive moisture
- Vascular conditions such as peripheral vascular disease
- Age-related factors
- Obesity
- Exposure to pressure, friction, shearing forces or burns
- Exposure to chemicals
- Diseases such as diabetes mellitus
- Immunological suppression as a result of systemic conditions or medications
- Trauma from falls, accidents or burns
- Surgical intervention
- Inappropriate or ill-fitting prostheses and footwear
- Infection
- **Skin disorders** (e.g. genetic factors, idiopathic causes, hypersensitivity rashes).

# WOUND HEALING

Wound healing is a dynamic and complex process. Tissue replacement involves two main mechanisms: repair and regeneration. In humans, the mechanism of repair for any wound is determined by the tissue layers involved and their capacity for regeneration (Doughty & Sparks-DeFriese 2012). See Table 29.1 for definitions of repair and regeneration.

The wound healing process consists of four stages: haemostasis, the inflammation stage, the reconstruction phase and the maturation phase. The process of wound healing begins at the moment of injury and can continue for some years.

**TABLE 29.1 | Definition of repair and regeneration**

| Healing properties | Definition | Tissue types |
|---|---|---|
| Repair | Repair is the process of producing connective tissue to fill the defect or knit tissues back together | Deep dermal structures (e.g. hair follicles, sebaceous glands, sweat glands), subcutaneous tissue, muscle, tendons, ligaments and bone lack the capacity to regenerate |
| Regeneration | Regeneration is when damaged cells and tissue are replaced by proliferation of similar cells | Wounds that are confined to the epidermal and superficial dermal layers heal by regeneration because epithelial, endothelial and connective tissue can be reproduced |

*(Doughty & Sparks-DeFriese 2012)*

## Haemostasis

The first stage of wound healing is haemostasis, which has three components: vasoconstriction, platelet response and the biochemical response. Vasoconstriction occurs when the bleeding in the wound is arrested by spasm in the arteries, arterioles and capillaries.

The platelet response is commonly described as the formation of the platelet plug. When platelets come into contact with parts of a damaged blood vessel, such as collagen or endothelium, their characteristics change. They become larger and irregular in shape and stick to the collagen fibres in the wall of the vessels and to each other. The platelets release various chemicals: serotonin, prostaglandins, phospholipids and adenosine diphosphate (ADP) that attract more platelets, which stick to the original platelets and form the plug. This platelet plug is very effective in preventing blood loss in a small vessel.

The biochemical component is the formation of a blood clot through the processes of the intrinsic and extrinsic clotting pathways, clot retraction and fibrinolysis. This is a complex process involving different clotting factors that are released from the damaged tissue. A clot is developed and retraction of the wound takes place.

The next stage of the healing process is termed tissue repair. This stage also has three phases: inflammation, reconstruction and maturation, which overlap each other and have varying time intervals.

## The inflammation phase

This phase begins the moment that injury is incurred. The capillaries contract and thrombose to facilitate haemostasis. Vasodilation of the surrounding tissues occurs in response to the release of histamine and other vasoactive chemicals. This process causes increased blood flow to the surrounding tissue, which produces erythema, swelling, heat and discomfort, such as throbbing. A variety of white blood cells called polymorphonuclear leucocytes arrives at the site of the wound as a defence response and is involved in the immune response to fight infection. Polymorphs, macrophages and their associated growth factors produce various local and systemic effects. This phase continues for about 3 days.

## The reconstruction phase

This is a time of cleaning and temporary replacement of tissue. The polymorphs kill bacteria, and the phagocytic macrophages digest the dead bacteria and debris to clean up the wound. Dermal repair is necessary if the wound is one of full thickness. New blood capillaries are developed (angiogenesis) and granulation tissue, which consists largely of collagen, is laid down. Epithelial cells migrate over the granulation tissue from the surrounding wound edges, hair follicles, sweat or sebaceous glands in the wound. These cells are very fragile. When the wound is covered the epithelium begins to thicken to 4–5 layers, forming the epidermis. Wound contraction then occurs, reducing the overall size of the wound. This phase can continue for 2–24 days.

## The maturation phase

This is commonly known as the remodelling phase. The matrix of collagen cells is reorganised and strengthened. This phase can continue for about 24 days to 1 year. The wound is still at risk during this phase and should be protected.

## Factors that affect wound healing

Factors that affect wound healing include:

- Wound infection
- Allowing the wound to dry out and form a scab (wound hydration)
- Allowing maceration of the wound to occur (exudate management)
- Inappropriate dressings
- Temperature variances
- Not treating the underlying cause
- Keloid formation
- Foreign bodies
- Friction, shearing forces and pressure
- Age
- Underlying disease e.g. diabetes
- Vascularity
- Obesity
- Disorders of sensation and movement
- Drugs
- Psychological state
- Nutritional status
- Radiation therapy.

### Wound healing and nutrition

The role of nutrition in wound healing is vital. Whereas good nutrition facilitates healing, malnutrition delays, inhibits and complicates the process. Carbohydrate, protein and fat provide the energy source for the body (Schols 2014). Adequate energy supports collagen and nitrogen synthesis and promotes anabolism by sparing body protein from being used as an energy source (Schols 2014). It is vital that nutrition is a part of the wound assessment process. Nutritional screening should include assessing body mass index (BMI) and time over which nutrient intake has been unintentionally reduced, and/or the likelihood of future impaired nutrition (Stechmiller 2010). In Australia the common tool used for nutritional screening is the Malnutrition Screening Tool (MST) tool which has a sensitivity and specificity of 70% (Neelemaat et al 2011).

Nutrition for chronic wounds needs to be assessed on an individual basis; some types of wound such as pressure injuries or multiple wounds place high demand for nutrients on the body. See Table 29.2 for a detailed review of nutrition and wound healing.

The use of arginine-enriched oral nutritional supplements may have a positive effect on the healing of chronic wounds; however, at the present time there is limited research to support the use of these products (Schols 2014). Nutrition is a key element in the prevention and treatment of chronic wounds and has to be incorporated into the wound management plan (Schols 2014).

**TABLE 29.2 | Nutrition**

| Nutrient | Function | Key facts | Dietary sources |
|---|---|---|---|
| Fat | Energy source, component of cell membranes, involved in formation of inflammatory mediators and clotting components | Dietary energy should be provided in the form of carbohydrate and fat | Butter, margarine, other spreading fats, oils, cream, full-fat milk, cheese |
| Carbohydrate | Major source of calories for use by the body; its availability is essential to prevent other nutrients (i.e. protein) from being converted into energy | Increased intake provides energy; this is essential for optimal healing | Wholegrain cereals, breads, potatoes, rice, pasta |
| Protein | Necessary for tissue synthesis and repair. Deficiency can inhibit wound remodelling and may increase oedema. This will further impair delivery of oxygen and nutrients to the wound | Excess protein can tax liver and kidney function and cause dehydration | Meat, eggs, cheese, milk, yoghurt, fish, poultry, pulses, nuts |
| Vitamin A | Increases the inflammatory response in wounds, stimulating collagen synthesis. Low levels can result in delayed wound healing and susceptibility to infection | It has been shown that vitamin A can restore wound healing impaired by long-term steroid therapy. Supplementation with vitamin A requires caution as there is a risk of toxicity | Milk, cheese, eggs, fish, dark green vegetables, oranges, red fruits and vegetables |
| Vitamin C | Involved in collagen synthesis and subsequent cross-linking, as well as the formation of new blood vessels. Adequate levels help strengthen the healing wound. Has important antioxidant properties that help the immune system; increases absorption of iron | Deficiency impairs wound healing and is associated with an increased risk of wound infection | Found mostly in fruit and vegetables, especially oranges, grapefruit, tomatoes and leafy vegetables |
| Vitamin B | Helps with production of energy from glucose, amino acids and fats. Vitamin B6 is important for maintaining cellular immunity and forming red blood cells. Thiamine and riboflavin are needed for adequate cross-linking and collagenation | Includes thiamine, riboflavin, niacin, folate, vitamin B12, vitamin B6 | Wholegrains, breakfast cereals, milk and milk products, meat, fish, liver |
| Vitamin E | Can reduce injury to the wound by controlling excessive free radicals | There is limited evidence for the benefits of vitamin E in decreasing scar formation. There is some evidence that suggests oral supplementation of vitamin E over 400 mg/day has an increased health risk | Vitamin E supplementation or topical application is rarely needed for wound healing Vegetable oil, egg yolk, nuts, seeds |
| Vitamin K | Blood clotting | Deficiency very rare | Liver, green vegetables |
| Selenium | Antioxidant | Deficiency relatively common | Brazil nuts, meat, vegetables, fish, cereals |
| Copper | Responsible for collagen cross-linking and erythropoiesis | Deficiency rare | Meat, vegetables, cereals, tea, coffee |
| Manganese | Component of enzymes needed for tissue regeneration | Deficiency rate | Tea, widely distributed in various foods |

*Continued*

**TABLE 29.2 | Nutrition—cont'd**

| Nutrient | Function | Key facts | Dietary sources |
|---|---|---|---|
| Zinc | Plays a role in protein and collagen synthesis and in tissue growth and healing | Zinc deficiency has been associated with delayed wound healing, reduced skin cell production and reduced wound strength | Best sources include red meat, fish and shellfish, milk products, poultry and eggs |
| Iron | Provides oxygen to the site of the wound | Iron deficiency can impair healing, collagen production and strength of wound | Iron absorption from non-meat sources can be enhanced with vitamin C. Best sources are red meat, offal, fish, eggs, wholemeal bread, dark green leafy vegetables, dried fruits, nuts and yeast extracts |

*(Johnston 2007; Schols 2014)*

## CLINICAL INTEREST BOX 29.1 Skin flaps

A flap is a surgical relocation of tissue from one part of the body to another part to reconstruct a primary defect. This creates a secondary defect that will require skin grafting or primary closure.

### Types of flaps

Skin, or cutaneous, flaps are grafts of tissue consisting of skin and superficial fascia. Composite tissue flaps are described according to the type of tissue they are composed of (e.g. fasciocutaneous flap).

Flaps can be classified as free and pedicle. A free flap is the relocation of skin and subcutaneous tissue as a complete segment, with an anastomosis of the segment's blood supply to vessels at the affected site. A pedicle flap is the surgical transfer of skin and subcutaneous tissue to another body site. Blood supply to the flap is maintained via a vascular pedicle attached to the body donor site.

*(Sussman & Bates-Jensen 2011)*

**Figure 29.2** Venous leg ulcer

# TYPES OF WOUND

## Acute and chronic wounds

### Acute wounds

An acute wound is any surgical wound that heals by primary intention, or any traumatic or surgical wound that heals by secondary intention, and which proceeds through an orderly and timely reparative process that results in sustained restoration of anatomical integrity (Carville 2012). Examples of acute wounds are those made by surgical incision or traumatic injury. An example of a surgical wound is a skin flap (see Clinical Interest Box 29.1).

### Chronic wounds

A chronic wound occurs when the reparative process does not proceed through an orderly and timely process as anticipated and healing is complicated and delayed by intrinsic and extrinsic factors that impact on the person, their wound or their environment (Carville 2012). An example of a chronic wound is a venous leg ulcer (see Figure 29.2).

# TYPES OF HEALING

When the wound has minimal tissue loss the edges can be brought together by sutures or clips; as in a surgical wound. The wound is said to heal by **primary intention**, or **first**

## CLINICAL INTEREST BOX 29.2
## Skin grafts

Skin grafts speed up the healing process and reduce the risk of infection. Grafts may be partial or full thickness. Skin grafts are classified as:

- Autograft: a surgical relocation of skin to the wound from another site of the body. A second wound results and is known as the donor site
- Allograft: a donor graft of skin between allogenic individuals, such as from one person to another
- Xenograft: a donor graft of tissue transplanted between different species, such as tissue of porcine origin transplanted to a human being
- Cultured: the cultivation of epidermis from a small amount of epithelial cells taken from the donor or recipient's body and cultivated under laboratory conditions to form epidermis, before being transplanted back to the individual.

*(http://www.wounds-uk.com)*

**intention**. Granulation tissue is not obvious. Healing by **secondary intention** occurs when wound edges cannot be brought together, as with a gaping wound. Granulation tissue fills in the wound until re-epithelialisation takes place and a large scar results. **Third intention**, or **delayed primary intention**, healing occurs when wound closure is delayed for a few days so that an infected or contaminated wound can be debrided (dirt, foreign objects, damaged tissue and cellular debris are removed from a wound or burn to prevent infection and promote wound healing). Closure of contaminated wounds is usually delayed until all layers of wound tissue show no signs of infection, usually within 4–10 days. At other times some wounds need surgical intervention such as the application of skin grafts or flaps to speed the healing process and reduce the risk of infection. Clinical Interest Box 29.2 provides details on skin grafts.

# WOUND MANAGEMENT

Wound management employs the principles of moist wound healing; that is, keeping the wound bed moist enough to facilitate the movement of new epithelials across the granulation tissue.

The benefits of moist wound healing are:

- Thermoregulation
- Less pain
- Less injury and damage to cells on removal of the dressing
- More efficient autolytic debridement of necrotic tissue
- Less risk of transmission of microorganisms
- Fewer dressing changes and therefore less disturbance of the wound, resulting in reduced costs in dressing consumables and reduced workload for care staff
- The individual's lifestyle is interrupted less and, with most dressings, the individual can continue to shower as usual.

## CLINICAL INTEREST BOX 29.3
## Principles of wound management

- Assess and define aetiology
- Control factors affecting healing (e.g. smoking, nutrition)
- Select an appropriate wound dressing
- Plan for maintenance of wound healing
- Evaluate and review

*(http://www.amwa.com.au)*

## Wound assessment

An initial holistic assessment of the individual includes a comprehensive health history, demographics, nutritional status, psychosocial status, medication, mobility and activity, vascularity and current health status. **Assessment of the wound** identifies the wound characteristics, cause of the wound (e.g. traumatic, surgical), appearance of the wound bed, exudate (amount, type), peri-wound skin condition, type of wound (skin tear, pressure injury), location, size of the wound and its chronicity. A wound management history should be obtained to determine previously effective or non-effective treatments. Presence of infection is assessed. Pain management is a vital aspect of care and impacts on the quality of life for the individual with a wound. Clinical Interest Box 29.3 outlines the principles of wound management.

Assessment tools capture essential components of the individual and wound and include medical/surgical history of the individual, clinical history of the wound, relevant investigations to assist diagnosis of aetiology and local wound characteristics. Consistency in the information collected can be obtained in tools such as the mnemonic tool HEIDI: History (H), Examination (E), Investigation (I), Diagnosis (D) and Indicators (I) (Harding et al 2007). Specialised assessment tools are available for pressure injuries: National Pressure Ulcer Advisory Panel (NPUAP)/Agency for Health Care Policy and Research (AHCPR) staging system (see Pressure Injuries) (NPUAP et al 2014); PSST: Pressure Sore Status Tool, automated version known as the Wound Intelligence System (Bates-Jensen 1997); and PUSH: the NPUAP Pressure Ulcer Scale for Healing (NPUAP 2015). Other general tools are the WHS: Wound Healing Scale (Krasner 1997) and the SWHT: Sussman Wound Healing Tool (Sussman & Bates-Jensen 1998).

## Description of wounds

### Colour

Wounds may be described by the colour of the wound bed:

- Black: necrotic tissue can be dry or moist
- Yellow: usually indicates slough, a fibrous material in the wound; can be moist or dry
- Red: healthy granulating wound
- Pink: epithelialising wound usually has a translucent appearance.

### Degree of injury

- Superficial: wounds affecting the epidermis
- Partial thickness: wounds affecting the epidermis and the dermis
- Full thickness: wounds that have affected the epidermis, dermis and the subcutaneous tissue. The muscle, tendon and bone may also be involved.

### Wound location

Anatomical description; for example, lower left leg, upper right arm. This allows consistency in assessment.

### Wound size measurement

- Area
- Depth, at deepest area
- Length, at longest measure in head to toe direction
- Width at widest measure from side to side direction
- Examples of measurement methods available include simple disposable paper rulers and probes, tracing grids and photography.

### Exudate

- Type
  - Serous—clear
  - Haemoserous—slight blood-stained fluid
  - Sanguinous—frank or heavily blood stained
  - Purulent—pus
- Amount
  - Scant, moderate, large, copious
- Colour
  - Clinical indicator for stage of healing or complication; for example, infection or fistulae formation
- Consistency
  - Dependent on type of exudate: fluid, thick, liquid
- Odour
  - Indicates infection or contamination
- Sign of non-viable tissue breakdown
- Drainage of body fluids such as faeces from a fistula.

### Peri-wound skin

- Cellulitis, oedema, maceration, foreign bodies, contact dermatitis
- Colour, warmth, capillary return
- Pulses
- Wound edge for sign of healing.

### Pain

- Identify and manage underlying cause of pain
- Implement appropriate pain management strategies.

### Wound infection

- Monitor for signs and symptoms of infection
- Report and manage
- Infection delays healing.

### Psychosocial

- Individual person-focused outcomes are the foundations of care
- Quality of life/wellbeing

## Wound bed preparation

Schultz and colleagues (2003) defined wound bed preparation as 'the management of the wound to accelerate endogenous healing or to facilitate the effectiveness of other therapeutic measures'. Wound bed preparation uses an algorithm called the TIME principle. These principles identify four key areas of the chronic non-healing wound, though the principles can also be applied to acute wounds (Schultz 2007). All chronic wounds start as acute wounds but fail to progress and get trapped in the inflammatory phase of healing with bacterial and biochemical imbalance. **TIME** provides a systematic approach to wound care. The four elements are **T** (tissue non-viable or deficient), **I** (infection or inflammation), **M** (moisture imbalance) and **E** (edge of wound non-advancing or undermining epidermal margin) (Leaper et al 2012). The wound bed preparation concept has gained international recognition as a framework that provides a structured approach to wound care.

### Tissue non-viable

Non-viable tissue is black (necrotic) dead tissue or thick yellow slough that impairs the growth of new tissue, obscures the true depth of a wound and is a haven for bacterial growth preventing wound healing. Non-viable tissue also increases the risk of wound infection. Serial debridement is required to remove the tissue to, for example, produce a healthy wound bed.

### Infection/inflammation

All wounds contain bacteria at some level often without harmful effects. Wound infection results from an imbalance of the host's (the individual) immune system and its ability to combat bacteria (host resistance), and the virulence of the microorganism: some bacteria have greater disease-producing ability than others. Table 29.3 provides the differences between inflammatory response and infection.

**TABLE 29.3 | Recognising the differences between inflammatory response and infection**

| Inflammation | Infection |
|---|---|
| Localised redness | Erythema (spreading redness) |
| Pain | Increasing local wound pain |
| Heat | Change in the appearance of the wound tissue |
| Swelling | Increase in the amount of wound exudate |
| | Purulent or very foul smelling exudate |
| | Induration (hardness of the surrounding tissue) |

*(Swanson et al 2014)*

## CLINICAL INTEREST BOX 29.4 Identifying wound infection

- Increased discharge
- Delayed healing
- Wound breakdown
- Pocketing at base of wound
- Epithelial bridging
- Unexpected pain or tenderness
- Friable granulation tissue
- Discolouration of wound bed
- Abscess formation
- Malodour

*(WUWHS 2008)*

Failure to control bioburden can lead to infection especially in the immune-compromised individual. Chronic wounds are likely to be colonised with bacterial or fungal microorganisms due to the nature of the open wound and tend to be polymicrobial. The presence of slough and necrotic tissue provides an environment for bacterial growth. It is when these bacteria interfere with wound healing that intervention is required.

Infection in acute or surgical wounds is relatively easy to recognise—spreading redness, local pain and swelling, peri-wound area warm to the touch. Infection in the chronic wound might be less obvious. Delayed healing can be an indicator of infection common to most wounds (Schultz et al 2003). Other signs can be an increase or change in wound exudate, or discolouration of the granulation tissue depending on the cause of the wound (Cutting et al 2005; Swanson et al 2014) (see Clinical Interest Box 29.4). It is recognised with increasing evidence that different wound types exhibit specific characteristics of infection (Swanson et al 2014; WUWHS 2008).

Bacteria can also cause prolonged inflammation by stimulating a continuing influx of neutrophils that release cytotoxic enzymes, free oxygen radicals and inflammatory mediators inducing a cycle of continuing tissue damage (Han et al 2011). Biofilms are also increasingly thought to play a role in prolonging inflammation and delaying healing (Wolcott et al 2010). See below for further information on biofilms.

The risk of infection increases when 'any factor that debilitates the individual, impairs immune resistance or reduces tissue perfusion' (Swanson et al 2014; WUWHS 2008). Comorbidities such as diabetes mellitus, arterial, cardiovascular or respiratory disease, renal impairment, malignancy, malnutrition, obesity, rheumatoid arthritis or an immune-compromised state contribute to an increased risk of infection. Certain medications also affect wound healing and increase the risk of infection, such as corticosteroids, cytotoxic drugs and immuno-suppressants (Swanson et al 2014; WUWHS 2008). In elective surgery the amount of blood loss, the type and length of the procedure and a lack of pre-operative warming can influence the development of postoperative wound infection.

## CLINICAL INTEREST BOX 29.5 Definition of antimicrobial agents: disinfectants, antibiotics and antiseptics

**Disinfectants**

Non-selective agents that kill or remove microorganisms from inert surfaces such as work surfaces, medical instruments. They are not intended for use on the body or human tissue.

**Antibiotics**

Act selectively to inhibit or kill microorganisms. They can be administered either topically (not usually recommended) or systemically (orally or intravenously). Increasing resistance is an international concern among healthcare practitioners.

**Antiseptics**

Non-selective substances that inhibit multiplication of organisms (bacteriostatic) or kill (bactericidal). They can be used on intact skin and some open wounds and do not rely on the bloodstream for access to the wound so are useful for ischaemic wounds. They may have toxic effects on human cells. Low levels of bacterial resistance due to action at multiple sites within the microbial cell.

*(Adapted from WUWHS 2008)*

## Biofilms in wounds

It is theorised that biofilms play a role in the delayed healing of chronic wounds. A biofilm is a community of multiple bacteria that attach to surfaces or each other to form highly complex communities embedded in a matrix that can be difficult to remove as the matrix offers protection from antimicrobials and the host immune system. There is an increasing awareness that microorganisms colonising a wound may be present as a biofilm (Percival & Bowler 2004). Acute bacterial infections are considered to result from growth of planktonic cells (single free floating bacteria) while many chronic bacterial infections involve biofilms. James et al (2008) found 60% of chronic wounds had characteristics of a biofilm compared to only 6% in acute wounds and evidence that biofilms exist in chronic wounds such as pressure injuries, diabetic foot ulcers and venous leg ulcers. Wound swabbing for microscopy and culturing will fail to detect biofilms in wounds and special molecular techniques are necessary.

Difficulties in treating biofilm-related conditions suggest that prevention is a more feasible option and the speed at which biofilms form necessitates rapid therapeutic action. Wolcott et al (2010) demonstrated that sharp debridement followed by the application of topical antimicrobials (e.g. a dressing that contains iodine, polyhexamethylene biguanide (PHMB) or silver) provides a time-dependent window of sensitivity which is effective at targeting bacteria and suppressing their regrowth (Wounds UK 2011). See Table 29.4 and Clinical Interest Box 29.5 for further description of antimicrobial agents.

**TABLE 29.4 | Examples of topical antimicrobial dressings***

| Dressing name (manufacturer) | Content |
|---|---|
| Acticoat™ (Smith & Nephew) | Silver coated rayon and gauze dressing containing nanocrystalline silver |
| Aquacel™ Ag (Convatec) | Silver impregnated dressing with hydrofibre composed of hydrocolloid and 1.2% ionic silver |
| Atrauman Ag (Paul Hartmann) | Polyamide mesh wound contact layer impregnated with neutral triglycerides and coated with metallic silver |
| Biatain™ Ag (Coloplast) | Adhesive polyurethane foam impregnated with silver |
| Contreet™ (Coloplast) | Hydrocolloid foam dressing impregnated with ionic silver |
| Flamazine™ (Smith & Nephew) | Cream containing silver sulfadiazine 1.0% w/w S4 requires doctor's prescription |
| Mepilex™ Ag (Mölnlycke) | Foam dressing containing ionic silver |
| PolyMem™ Silver (Ferris) | Contains nanocrystalline silver particles (nominally 124 micrograms of silver/cm$^2$) distributed throughout a foam pad does not release silver into the wound bed |
| Kerlix™ AMD (Covidien, Kendall) | Gauze dressing impregnated with 0.2% polyhexamethylene biguanide (PHMB) |
| Iodosorb™ (Smith & Nephew) | Cadexomer iodine: slow release polysaccharide lattice formed into spherical microbeads that contain iodine 0.9%. Tissue iodine supply is at a 0.1% concentration |
| Inadine™ (Systagenix Wound Management) | Non-adherent dressing impregnated with 10% povidone–iodine |
| Medihoney™ (Medihoney) | Medical-grade honey incorporated into a variety of presentations |
| Sorbact™ | Non-medicated dressing that has a unique bacterial binding action using the principle of hydrophobicity to remove bacteria and fungi from a wound. |
| Prontosan™ | Contains polyhexamethylene biguanide (PHMB) antimicrobial agent and betaine (surfactant). Comes in a solution and a gel. Used for cleansing, rehydrating and decontaminating acute and chronic wounds. |

*(Adapted from Cowan 2011; Carville 2012; Bradbury & Fletcher 2011; Probst et al 2012)*
*List is not exhaustive. Refer to manufacturer for product information. All trademarks acknowledged.

### Moisture imbalance

Exudate production is a normal part of wound healing. Excessive wound exudate can lead to maceration of the peri-wound skin. Absorbent dressings assist with removal of excessive exudate to re-establish moisture balance. Too little moisture in a wound desiccates the cells and in this situation additional moisture (e.g. a hydrogel dressing) can help maintain a moist wound bed. Chronic wound fluid differs from acute wound fluid. Chronic wound fluid contains high levels of tissue enzymes known as matrix metalloproteinases (MMPs) that are destructive to new tissue growth (Trengove et al 1999).

### Edge of wound non-advancing or undermined

Failure to address the above three elements of TIME will result in the non-migrating keratinocytes and a non-responsive wound.

## Pain

Pain is a significant factor affecting the quality of life for a person with wounds and in one study of people living with a chronic leg ulcer was found to be the most common feature strongly expressed (Douglas 2001).

Causes of pain vary and include procedural, operative, incident and background pain (Briggs et al 2004). Assessment of pain occurs with an initial history taking and is performed before, during and after wound care and documented in the person's medical records. The goal is to minimise pain. Pain scoring can indicate how the wound is progressing; for example, worsening pain can be a sign of infection. Visual or numerical scales can be used to assist in the assessment of pain. Providing adequate and effective analgesia is vital in controlling pain especially at dressing changes and can include oral and topical analgesia.

Dressing selection can affect wound pain. Dressings that provide a moist wound environment and can stay in place for several days, and therefore require less frequent dressing changes, reduce the risk of trauma to the wound and surrounding skin. Soft silicone dressings facilitate non-traumatic removal and can be considered to reduce pain at dressing changes. Avoiding unnecessary handling of the wound at dressing changes can also lessen the pain experienced by the

person. Asking and documenting the types of interventions that worsen or lessen wound pain contribute to the continuing assessment of an individual's pain history.

## Wound debridement

Wound debridement is intended to remove necrotic tissue or fibrous slough from a wound to clean and prepare the wound bed for healing. A variety of debridement modalities are available in clinical practice. Each one listed below will have their own clinical indications, benefits, limitations, precautions, contraindications and requirements for equipment, knowledge and skill. Healthcare professionals are bound by both professional and ethical codes of conduct and regulated by the boundaries of their individual scope of practice. It is imperative that the healthcare professional ensure that they have reviewed local policy regarding debridement, gained appropriate education and training to perform debridement and undertaken risk assessment as part of their clinical decision-making process. As part of the risk assessment important considerations must include the person, their wound, the healthcare practitioner, the health setting and available resources (White & Asimus 2014).

### Autolytic debridement

This method occurs spontaneously in most wounds as macrophages and proteolytic enzymes liquefy and separate non-viable tissue and slough, promoting granulation tissue. Dressings that create or maintain a moist wound environment will assist autolysis. Hydrogels will donate water to necrotic tissue or dry fibrin slough. Hydrocolloids gel on contact with wound exudate and create a moist environment. Film dressings are permeable to water vapour but impermeable to water, bacteria and microorganisms and help to create and maintain a moist wound environment.

### Enzymatic debridement

Enzymatic debridement is a less common method of debridement. Enzymatic agents are applied topically to the wound and work with endogenous enzymes to remove non-viable tissue. They need to be replaced frequently to maintain effectiveness. Several enzyme agents are available but not in all countries. The only enzymatic dressing available in Australia is a hydrogel Flaminal™.

### Mechanical debridement

***Wet-to-dry*** Wet-to-dry dressings are one of the oldest methods of mechanical wound debridement. Wet gauze dressings are applied to the wound and when dry, stripped from the wound, indiscriminately removing necrotic tissue or fibrin slough. They can also remove healthy tissue, causing bleeding. They are not generally recommended as they can cause pain to the individual and can inhibit wound healing (see Clinical Interest Box 29.6).

***Hydro-surgical debridement*** Hydro-surgical debridement is a form of mechanical debridement though under more controlled conditions. Hydro-surgical debridement uses a high-pressure water jet pushed through a suitable hose to the tip of a procedure-specific hand piece. This method is fast and precise in the hands of a skilled operator such as a surgeon for excising unwanted tissue. Its use in practice is mostly in burn injuries and vascular leg ulcers.

***Low-frequency ultrasound debridement*** Low-frequency ultrasound debridement (LFUD) uses lower frequencies than are used in imaging or other forms of therapy. Sound waves produce energy which is transferred to the wound via a hand piece using continuous movement and fluid (normal saline). This causes cavitation and acoustic streaming, which in turn break down devitalised tissue promoting wound debridement. This type of debridement promotes efficient wound bed preparation and offers an alternative to surgical/sharp debridement. Specialised equipment, training and skills are required to undertake LFUD, along with adequate local anaesthetic and pre-emptive analgesia to prevent and minimise discomfort during and post procedure.

### Biological (larval therapy) debridement

In the biological debridement method, sterile maggots are applied to a wound, covered with a sterile semi-permeable dressing and allowed to sit for 1 to 3 days before being removed. The maggots will only 'eat' non-viable tissue and fibrin slough. The procedure is painless though not socially agreeable to all individuals and nurses.

### Surgical and conservative sharp wound debridement

Surgical sharp debridement is the fastest and most effective method of debridement and is performed by a surgeon in an operating theatre under general or local anaesthesia. It is considered when the presence of non-viable tissue is extensive (Joanna Briggs 2014a). With this method all non-viable tissue and slough is removed until a clean, healthy wound bed is exposed. Conservative sharp wound debridement (CSWD) is the removal of loose avascular tissue without (or with very minimal) pain or bleeding. It is appropriate when there is a moderate amount of non-viable tissue (Joanna Briggs 2014a). Sharp scissors, scalpels, forceps and curettes can be used to remove dead tissue. Some pain may be experienced with this method; the use of a topical anaesthetic cream can be applied prior to debridement to help allay the person's concerns. CSWD can be performed by a competent healthcare professional who has undergone relevant education and training and is subject to workplace policies and procedures (Joanna Briggs 2014a).

## CLINICAL INTEREST BOX 29.6
## Clinical note: surgical debridement

It is important to note that in cases where peripheral vasculature is poor, or has not been assessed and investigated, aggressive debridement and moist wound dressings are not indicated as new tissue growth cannot be supported.

*(Adapted from WUWHS 2008; Wounds UK 2011)*

## Managing wound infection

The deleterious effect of infection in wounds is well recognised. Effectively managing wound infection requires optimising the host (person) response, minimising risk factors where possible, reducing bacterial load and managing signs and symptoms such as fever and pain. Regular re-evaluation of the individual and the wound and adjustment in treatment is necessary to assess and optimise the effectiveness of treatment. A systemic antibiotic should be considered for locally infected wounds and spreading infection in a wound.

Managing bioburden (removal of non-viable tissue, preventing and controlling infection and maintaining moisture balance) is essential for wounds to progress to healing. This should be directed by the clinical response of the tissue and individual to the treatment and not dictated by strict times; for example, 2 weeks of antibiotic therapy or the length of time an antimicrobial dressing is used. This means adjusting therapy to the clinical signs and symptoms of infection with the use of topical antimicrobial agents. For example, if the wound is progressing after a week of topical antimicrobial therapy then the therapy may be stopped. See Table 29.4 and Clinical Interest Box 29.5 for definition of antimicrobial agents. If the wound is unchanged after the introduction of therapy, then reassessment and alternative topical therapies need to be used (Swanson et al 2014; WUWHS 2008). Gaining early control requires detection of subtle changes, especially in the chronic wound, such as a reduction in wound odour and reduction in pain. Wound infection requires prompt management to prevent the spread of infection systemically.

Diagnosing wound infection is a combination of clinical signs and symptoms (see Clinical Interest Box 29.4), full systems evaluation, assessment of medications and comorbidities. Microbiological analysis can be used to assist diagnosis. This can be achieved by wound swabbing, wound biopsy or needle aspiration. Wound swabbing might help to detect the causative microorganisms but can also be misleading as it will detect only surface microorganisms, not those in the deeper tissue and there is little supporting evidence of the role of wound swabs in identifying infection (Swanson et al 2014; WUWHS 2008). Results from a wound swab should not be used in isolation to diagnose a wound infection. When a wound swab is to be taken to assist in diagnosing the causative microorganism, clean the wound first with tap water or normal saline and where appropriate debride non-viable tissue. There is no agreed best technique (e.g. Z-technique, Levine, cleansing or no cleansing before swabbing) for wound swabbing. It has been reported that the Levine technique is perhaps the more accurate method for identifying infection (Angel et al 2011; Gardner et al 2006). This technique uses a swab that is rotated over a 1-$cm^2$ area of the wound surface with enough pressure to squeeze fluid from within the wound tissue. See Clinical Skill 29.1 for guidelines on performing a wound swab.

To prevent further wound contamination or cross contamination, infection control procedures should be used to protect the individual and the wound. This includes thorough hand hygiene and the use of suitable protective clothing and gloves at dressing changes. The wound should be cleansed at each dressing change with an appropriate wound cleanser; this can be sterile normal saline or water. Absorbent dressings are used to manage excess exudate. Topical negative pressure therapy can be used for wounds with high volumes of exudate. Serial debridement of non-viable tissue will reduce the medium for bacterial growth and remove biofilms.

### Topical antimicrobial dressings/agents

Topical antimicrobial dressings contain agents that are capable of killing bacteria (bacteriocidal) commonly found in wounds. These agents are impregnated into various wound dressing materials and include silver, iodine, honey, chlorhexidine, polyhexamethylene biguanide (PHMB) and glucose oxidase enzyme systems. Topical antimicrobial dressings can assist in treating local infection in wounds and reduce the risk of infection in immune-compromised people at risk of infection, such as those with diabetes. Systemic antibiotic use should be considered in spreading infection in a wound. Topical antibiotics should be avoided for use on infected wounds to minimise the risk of allergy and the emergence of bacterial resistance (Swanson et al 2014; WUWHS 2008).

Examples of these dressings are listed in Table 29.4 and Clinical Interest Box 29.5 outlines the difference between disinfectants, antibiotics and antiseptics.

## Wound dressings

There are many different types of wound dressings available from numerous manufacturers; therefore, the clinician involved in wound care requires a sound clinical knowledge of how the main groups of dressings perform. Dressings do not heal wounds, but appropriately selected dressings can enhance the body's ability to heal. Maintaining a moist wound bed provides the optimum environment to promote healing (Winter 1962) and forms the foundation for contemporary wound care practice.

The ideal dressing will have many of the attributes listed below:

- Maintains a moist wound environment
- Allows for gaseous exchange
- Provides an effective bacterial barrier
- Protects wound and surrounding tissues
- Promotes comfort and reduces pain
- Maintains an optimal wound temperature and pH
- Controls and prevents odour
- Manages exudate
- Assists to prevent or manage clinical infection
- Covers wound from view of individual and/or significant others
- Does not shed damaging substances into the wound
- Is easy to apply and wear
- Produces minimal pain on application and removal.

Dressings are generally categorised by mode of action or material. Holistic assessment and individual focused outcomes identify the characteristics that determine the specific

## CLINICAL SKILL 29.1 Wound swab

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Gloves<br>Wound swab kit<br>Wound dressing<br>Biohazard specimen bag<br>Laboratory request form<br>Apron<br>Adhesive tape<br>Waste receptacle |

| **Skill activity** | **Rationale** |
|---|---|
| Wound swabs are often taken at the time of wound dressing changes. These are taken when the wound is suspected of containing microorganisms. Identification of the microorganism will enable correct treatment regimens to be implemented. | |
| Assess the individual's record to determine previous appearance of wound and any previous dressings<br>Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for pain<br>Assess for any allergies<br>Visually assess the wound for signs and symptoms of infection | Determines requirements for equipment and dressing requirements<br>Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Pain may be caused during the procedure<br>Determines any adverse reactions to wound irrigation solution, dressing or tape (if required) |
| Assist the individual to assume an appropriate position of comfort, ensuring that only the wound area is exposed<br>Obtain additional assistance if required | Promotes comfort and facilitates performance of the procedure<br>Assistance is available when required |
| Perform hand hygiene | Prevents the spread of infection |
| Place the equipment in a convenient location near the bedside. Open procedure pack using corners. Assemble the required equipment, using aseptic technique. Drop sterile equipment into sterile field | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the dressing is being performed<br>Prevents contamination of sterile items<br>Additional items are available for use |
| Perform hand hygiene and loosen wound dressing | Prevents spread of microorganisms and allows ease of removal of wound dressing |
| Put on apron. Perform hand hygiene, apply gloves if required. If other PPE required put on before gloves | Prevents spread of microorganisms |
| Position dressing towel around the wound, remove old dressing and place in waste bag/container | Protects the wound from environmental contamination |
| Dispose of gloves and perform hand hygiene<br>Put on clean non-sterile gloves | Removes microorganisms and prevents cross-contamination |
| Cleanse the wound with normal saline. Open the swab container, move the swab in a zig-zag motion across the wound surface, rotating during swabbing, and cover at least a 1 cm square area using gentle pressure. Replace swab back into culture medium. Repeat with another swab if required | Removes excessive debris and any dressing residue. Don't swab pus or exudate as these surface organisms may contain contaminants that are different from those causing the wound infection<br>Prevents swab from becoming contaminated. If the wound is fairly dry the swab may be moistened with sterile normal saline; if the wound is moist the swab can be used dry |

| CLINICAL SKILL 29.1 Wound swab—cont'd | |
|---|---|
| Label specimen according to facility/organisation policy. Place in specimen bag. After the wound care is completed, dispatch specimen to the laboratory with the request form. Only store specimen in refrigerator if a delay of more than 24 hours between collection and transport to the laboratory is expected | Decomposition and cell growth occur if specimen is left standing, and may provide a false result<br>On the specimen, ensure the following are clearly labelled: individual's name, DOB and UR number; type of specimen; date and time of specimen |
| Remove gloves and perform hand hygiene | Prevents spread of microorganisms |
| Put on clean gloves. Apply wound dressing as required using aseptic technique | Covers wound and prevents spread of microorganisms |
| Remove and attend to the equipment appropriately. Perform hand hygiene | Prevents spread of microorganisms |
| Assist the individual to reassume a comfortable position | Promotes comfort of individual |
| Report and document all relevant information including type and date of specimen correctly in the healthcare record. Communicate abnormal findings to Registered Nurse/medical officer and any complications | Medico-legal requirement. Allows for the planning and implementation of care |
| *(ACSQHC 2012; 2015; AWMA 2010; Berman et al 2015; Crisp et al 2013; LeMone et al 2014; Lynn & LeBon 2012; NHMRC 2010; NMBA 2013; 2016; Rebeiro et al 2013; Rowley & Clare 2011; Smith et al 2011)* | |

ideal dressing. The criteria listed above will be available in a dressing product which can be selected to meet the needs of the wound—to promote healing and achieve the desired individual-focused outcomes. Table 29.5 gives some examples of dressings and their actions.

Wound dressings can be classified into three main types:

1. Wound hydration products
2. Moisture-retentive dressings
3. Exudate-management products.

See Clinical Skill 29.2 for information and guidelines on dressing a wound.

## Wound hydration products

Wound hydration products provide additional moisture to dry wounds or wounds with dead (necrotic) or sloughy tissue and are usually in the form of a gel. These products are composed of mostly water, bound together by cross-linked polymers. They can be used as cavity fillers in smaller wounds with minimal exudate. These dressings require a secondary dressing to hold the gel in the wound and require daily to third-day changing depending on how quickly the gel is utilised by the wound. These dressings are not suitable for wounds with high amounts of exudate.

## Moisture-retentive dressings

Moisture-retentive dressings keep the wound bed moist, assisting keratinocytes to migrate across the surface of the wound, for example hydrocolloids. These dressings are used on light-to-moderately exuding wounds. They generally have a waterproof outer layer and are composed of hydrophilic particles (cellulose) and come in various thicknesses, shapes and sizes. These dressings aid the process of natural autolysis and stimulate granulation and re-epithelialisation. They retain moisture and are the ideal secondary dressing to support wound hydration. They can be left in position for several days, do not adhere to the wound, allow the passage of oxygen to the wound and are impermeable to microorganisms and water. Some of the dressings allow visual inspection of the wound. These dressings are comfortable for the individual and alleviate pain because they protect exposed cutaneous nerve endings.

## Exudate management dressings

Exudate management products absorb exudate from the wound surface and hold it within the dressing as well as transpiring fluid. These dressings are calcium alginates, which are composed of polysaccharides derived from seaweed; polyurethane or silicone foam dressings; hydrofibre dressings, which are made from sodium carboxymethylcellulose; and the combination dressings, which marry the technologies of hydrocolloids and the absorption capacity of baby nappy technology.

## Negative pressure wound therapy

Negative pressure wound therapy (NPWT) is the application of sub-atmospheric pressure to a wound. This type of therapy has increased in use over the past 10 years and is now a regular aspect of wound care, with several versions available (Henderson et al 2010). It is used to absorb and control large volumes of exudate that are difficult to manage with absorbent dressings. It can be used on a variety of wound types: abdominal dehiscence, diabetic foot ulcers, burns, venous leg ulcers, surgical infections, skin grafts, orthopaedic trauma and soft tissue trauma. It is considered when the wound is

## TABLE 29.5 | Examples and action of wound dressings*

| Dressing | Action |
|---|---|
| Island dressings | Low amounts of exudate<br>Use as primary dressing<br>Waterproof<br>Non-adherent wound contact layer |
| Semi-permeable film dressings | Nil to low amounts of exudate<br>Semi-permeable<br>Use as a primary or secondary dressing |
| Foam dressings | Adherent or non-adherent variants<br>Sheets or cavity-filling shapes<br>Some incorporate a semi-permeable, waterproof, adhesive layer as an outer layer of the dressing<br>Moderate to high absorbency<br>Provides protection and conforms<br>Facilitates a moist wound environment, but may not be sufficient to promote autolysis of sloughy tissue<br>Use as a primary or secondary dressing |
| Silicone dressings | Minimise wound trauma on removal<br>Conform to different anatomical shapes<br>Extended wear time<br>May require a secondary dressing |
| Calcium alginates | Natural polysaccharide from seaweed<br>Reduce pain by protecting nerve endings (moisture)<br>Low allergenic<br>Biodegradable<br>Adaptable to pack sinuses and cavities<br>Absorbent—small amounts<br>Promote haemostasis in bleeding wounds |
| Hydrocolloids<br>Sheets, paste and powder | Absorb small amounts<br>Clean and debride (assist autolysis)<br>The paste and powder variants reduce dead space in cavity wounds and can be easily irrigated out of a wound |
| Hydrogels available in amorphous gels, sheets or hydrogel impregnated dressings | Provide additional moisture to dry wounds<br>Act as debriding agent by softening dead tissue (assist autolysis)<br>Use as primary dressing<br>May need a secondary dressing<br>Gel sheets allow inspection of the wound through the dressing and can remain in situ for several days |
| Gelling fibre (Hydrofibre is a trademark term) | Promotes a moist wound environment<br>Vertical and lateral wicking of exudate<br>Atraumatic removal<br>Use as primary dressing<br>May need a secondary dressing |
| Odour absorbing | Incorporates activated charcoal<br>Absorb bacteria<br>Eliminate odour<br>Absorb exudate<br>May be used as a primary dressing<br>May need a secondary dressing |
| Acrylic dressings | Transparent adhesive allows for wound monitoring without removing dressing<br>Absorbent<br>Waterproof, semi-permeable |

*Continued*

**TABLE 29.5 | Examples and action of wound dressings—cont'd**

| Dressing | Action |
|---|---|
| Hypertonic saline impregnated | Creates an osmotic action to cleanse the wound by wicking away necrotic tissue and purulent debris<br>Inhibits bacterial growth by changing the pH of the wound<br>Reduces odour<br>Maintains a moist wound environment<br>Reduce wound oedema<br>May be effective in reducing hypergranulation tissue<br>Will require a secondary dressing |
| Cadexomer iodine | Iodine is progressively released into the wound<br>Absorbs exudate 6–7 times its weight<br>Converts to a gel and promotes moist wound healing<br>Provides a broad spectrum antimicrobial effect<br>Reduces the pH of the wound enhancing the antimicrobial effect<br>Reduces odour<br>Will require a secondary dressing<br>Contraindicated for people with allergies to iodine, thyroid disease, pregnancy or lactating mothers, or children |
| Silver dressings | Silver is a broad-spectrum antimicrobial agent<br>Silver comes in a range of dressings: foams, calcium alginate, hydrofibre and synthetic fabric<br>Not all dressings release silver into the wound bed |
| Polyhexamethylene biguanide (PHMB) | Has broad-spectrum antibacterial properties<br>Non-cytotoxic or non-irritant<br>May require a secondary dressing |
| Wound honey | Promotes moist wound healing<br>Promotes autolytic and osmotic debridement<br>Has an antimicrobial activity due to a slow release of low levels of hydrogen peroxide<br>Controls malodour<br>May cause some stinging sensations<br>Requires a secondary dressing |
| Negative pressure wound therapy | Provides a moist wound environment<br>Reduces bacterial colonisation<br>Promotes localised blood flow<br>Reduces localised oedema<br>Foam or gauze is used to reduce dead space in wound<br>Promotes granulation and epithelialisation<br>Facilitates collection of wound exudate<br>Reduces the need for frequent dressing change |

*(Adapted from Cowan 2011; Carville 2012; Wounds UK 2011)*

not healing in the expected time frame, the wound is in an awkward location or difficult size to dress or a reduction in wound size is required before surgical closure (Henderson et al 2010).

NPWT is a closed suction and drainage system and consists of a wound filler, an adhesive wound sealer with a drainage tube connected to a vacuum pump that has an attached fluid collection canister. These devices are portable, allowing the individual to mobilise and to be managed in the community. Pressure settings vary from −80 mmHg to −125 mmHg and depend on the wound type. For example, a thin skin graft will require less pressure than an abdominal wound dehiscence. Negative pressure can be applied continuously or intermittently, though continuous suction is more common, especially for wounds with large volumes of exudate.

Two types of wound interface are used: gauze and foam. Both have been shown to be effective (Campbell et al 2008). Foam tends to produce a thicker granulation tissue with gauze producing a less thick but denser granulation tissue (Borgquist et al 2010). A wound contact layer is often placed

## CLINICAL SKILL 29.2 Dressing a wound

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile dressing pack and dressing materials<br>Additional light source (if required)<br>Gloves<br>Disposable apron<br>Normal saline<br>Additional cotton balls or gauze balls<br>Waste receptacle<br>Dressing trolley<br>Mask and eye protection as required |

| **Skill activity** | **Rationale** |
|---|---|
| Wound dressings are undertaken to provide a moist cover for the wound to prevent the introduction of microorganisms and to promote healing. They also absorb exudate. | |
| Assess the individual's record to determine previous appearance of wound and any previous dressings<br>Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for pain<br>Assess for any allergies<br>Visually assess the wound for signs and symptoms of infection and dressings used | Determines requirements for equipment and dressing requirements<br>Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Pain may be caused during the procedure<br>Determines any adverse reactions to wound irrigation solution, dressing or tape (if required) |
| Assist the individual to assume an appropriate position of comfort, ensuring that only the wound area is exposed<br>Obtain additional assistance if required | Promotes comfort and facilitates performance of the procedure<br>Assistance is available when required |
| Place the equipment in a convenient location near the bedside. Open procedure pack using corners. Assemble the required equipment, using aseptic technique. Drop sterile equipment into sterile field | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the dressing is being performed<br>Prevents contamination of sterile items<br>Additional items are available for use |
| Perform hand hygiene and loosen wound dressing | Prevents spread of microorganisms and allows ease of removal of wound dressing |
| Put on apron. Perform hand hygiene, apply gloves if required. If other PPE required put on before gloves | Prevents spread of microorganisms |
| Position dressing towel around the wound, remove old dressing and place in waste bag/container | Protects the wound from environmental contamination |
| Dispose of gloves and perform hand hygiene<br>Put on clean non-sterile gloves | Removes microorganisms and prevents cross-contamination |
| Observe the wound for size, union, signs of infection, exudate, odour, inflammation and healing. Assess for pain | Evaluates condition of the wound and stage of healing |
| Cleanse the wound with sterile normal saline in accordance with the practices of the facility/organisation, medical officer's orders or as directed by the nurse in charge. Clean from top to bottom and from a clean area towards a less clean area, usually an outward direction. | Wound cleansing removes debris from the wound. Avoids transferring wound exudate and normal flora from the surrounding skin into the wound, and thus prevents wound contamination |

*Continued*

| CLINICAL SKILL 29.2 Dressing a wound—cont'd | |
|---|---|
| Apply dressing using a non-touch technique and secure it in position. If ordered, wound may be left exposed to the air | Provides a moist wound environment. Facilitates healing, absorbs exudate, protects the wound from infection and irritation (e.g. from clothing) |
| Remove personal protective equipment and discard with used equipment in an appropriate waste receptacle. Perform hand hygiene | Prevents spread of microorganisms |
| Assist the individual to reassume a comfortable position | Promotes comfort of the individual |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team. Include date and time, appearance of wound and any exudate, cleansing solution, type of primary and any secondary dressing used, and the individual's response to the dressing. Medico-legal requirement. Allows for the planning and implementation of care |
| *(ACSQHC 2012; 2015; AWMA 2010; Berman et al 2015; Crisp et al 2013; LeMone et al 2014; Lynn & LeBon 2012; NHMRC 2010; NMBA 2013; 2016; Rebeiro et al 2013; Rowley & Clare 2011; Smith et al 2011)* | |

under the foam interface when there is concern there may be complications, or there is exposure of vulnerable structures (Dunbar et al 2005). Tissue growth into the foam interface has been reported in the published literature (Borgquist et al 2009), which is why a wound contact layer is placed under the foam. The function of the wound filler is to deliver negative pressure to the wound. Use of either depends on various factors. For example, foam may be used in areas of large tissue loss where contraction of tissue is required before closure. Gauze may be more beneficial when the wound surface is irregular and cosmetic outcome is important.

A newer smaller device is also available that does not rely on a fluid canister for exudate collection, making it extremely portable. This device (PICO™, Smith & Nephew Australia Pty Ltd) has a specialised dressing that absorbs and transpires exudate. The dressing has a tube connection to a small pump that delivers a fixed negative pressure (–80 mmHg).

NPWT offers several benefits:

- Stimulates new tissue growth (granulation)
- Reduces tissue oedema and manages wound exudate
- Increases the rate of wound healing reducing the wound area
- Helps control bacterial burden (removes exudate which contains bacteria)
- Maintains a moist wound environment
- Causes a reduction in pain
- Removes slough
- Reduces the number of dressing changes required.

Certain factors need to be considered before applying NPWT:

- Effective management of the individual's symptoms
- Dimensions of the wound and ease of application
- Placement of tubing
- Care setting (e.g. home, hospital) and who will care for therapy
- Effective debridement of wound bed
- Ability of the individual to give consent to treatment (adapted from Henderson et al 2010).

There are also several contraindications for NPWT:

- Untreated osteomyelitis
- Necrotic tissue in the wound
- Exposed organs or blood vessels
- Malignancy in the wound bed (except in palliative care cases)
- Unexplored fistulas.

Therapy should be stopped when there is uniform granulation tissue in the wound and the wound's depth has decreased.

See Table 29.6 and Clinical Interest Boxes 29.7 and 29.8 for discussion on the right dressings for the right wound, an outline of the basic factors to consider when selecting a dressing and the myth about wound cleansing, respectively.

**CRITICAL THINKING EXERCISE 29.1**

What factors do you take into account in terms of selecting an appropriate dressing product for a given wound type?

# PATHOPHYSIOLOGICAL EFFECTS AND MAJOR MANIFESTATIONS OF SKIN DISORDERS

## Pathophysiological influences and effects

The major factors that affect normal structure and functions of the skin can generally be classified into six categories:

1. Genetic factors
2. Idiopathic causes
3. Hypersensitivity

## TABLE 29.6 | The right dressing for the right wound

Modern wound dressings improve healing time, reduce pain, reduce the time required to dress the wound and require less frequent changes. It is important to use the most appropriate dressing for the wound at the appropriate stage of healing. One dressing will not suit the entire wound healing process. Match the action of the dressing to the aim of the treatment.

| Condition of wound bed | Aim of treatment | Examples of dressings |
|---|---|---|
| Non-viable tissue (black, hard, dehydrated, necrotic) | Rehydrate, debride, promote granulation tissue | Hydrogels |
| Slough (soft, yellow, creamy or fibrous) | Debride slough, promote granulation, absorb excess exudate | Hydrogels (low exudate only), alginates, hydrofibres, hydroactive dressings, cadexomer iodine, hydrocolloids (small to moderate exudate only) |
| Granulating (red, moist) | Retain moisture, promote and protect granulation tissue and epithelialisation, absorb excess exudate | Foams, alginates, hydrofibre, hydroactive dressings, hydrocolloids, hydrogels |
| Epithelialising (pink wound, evidence of epithelial growth on surface) | Retain moisture, promote and protect epithelialisation | Foams, hydrocolloids (thin), non-adherent dressings, polyurethane films |
| Infected (local or spreading) | Treat infection with systemic antibiotics (spreading infection), topical antimicrobial dressings, absorb excess exudate, debride slough | Silver-impregnated dressings, antimicrobial dressings (i.e cadexomer iodine), medical honey, PHMB-impregnated dressings, Prontosan gel, hydrophobic antimicrobial dressing (i.e. Sorbact) |

*(WUWHS 2008)*

## CLINICAL INTEREST BOX 29.7 Factors to consider when selecting a dressing

- Wound type: superficial, full thickness, cavity
- Wound description: granulating, epithelialising, necrotic, sloughy, infected
- Wound characteristics: dry, moist, heavily exuding, malodorous, excessively painful, difficult to dress, bleeds easily
- Bacterial profile: sterile, colonised, infected, infected and potential source of cross-infection

*(http://www.amwa.com.au)*

## CLINICAL INTEREST BOX 29.8 A myth in wound cleansing

**Myth**: Individuals with wounds should not let the wound come into contact with shower water.

**Fact**: Showering an individual with a postoperative wound does not increase the risk of infection or slow the healing process. It does promote a sense of wellbeing and health associated with cleanliness. Showering of chronic wounds and ulcers may be undertaken with caution. Tap water should not be used if declared unsuitable for drinking. Tap should be run for 15 seconds prior to use.

*(Joanna Briggs Institute 2014b)*

4. Trauma
5. Neoplasia
6. Infections and infestations.

### Genetic factors

Genetic factors determine skin colour and the amount and distribution of hair. Congenital skin disorders include birthmarks, hypopigmentation (albinism) and a condition called ichthyosis, which involves excessive scaling or thickening of the outermost skin layer. Heredity also plays a role in predisposition to the development of acne and atopic dermatitis.

### Idiopathic causes

Many skin disorders have no one known cause, for example, vitiligo and psoriasis. Other skin disorders may be associated with emotional or physical stress but there does not seem to be any one identifiable cause.

### Hypersensitivity

Some individuals have a tendency to react adversely to contact with various substances; for example, when a substance is inhaled, ingested or comes in contact with the skin. Some allergic reactions are manifested in alterations in the skin; for

example, reddening and itching of the skin may be side effects of certain medications.

### Trauma

Damage to the skin can result from exposure to extremes of temperature, from prolonged pressure on the skin or from physical injuries resulting in lacerations, punctures or abrasions.

### Neoplasia

Any abnormal growth of new tissue, whether benign or malignant, is called a neoplasm. Examples include calluses, which can develop on the toes from friction and chronic pressure, or keloid scarring, which can result after injury to the skin. Benign or malignant neoplasms may develop from any type of cell in the skin, but the melanocytes and keratinocytes are the cells most frequently involved. A mole (naevus) is a common type of benign skin tumour. Some benign epithelial cell lesions may develop into malignant neoplasms.

### Infections and infestations

If the skin is broken and pathogenic microorganisms gain entry, infection may result.

Primary skin infections are commonly caused by bacteria, fungi and viruses. Secondary skin infections may occur in conditions such as stasis dermatitis, in which impaired circulation damages skin cells of the lower limbs.

Systemic infections, such as measles, chickenpox and some sexually transmitted infections, also result in manifestations on the skin. Skin infestations occur when parasites such as lice or mites invade and subsist on the skin.

## Major manifestations of skin disorders

Various structural and functional changes accompany skin disorders.

### Pruritus

Pruritus (itching) is one of the more common and distressing symptoms of a skin disorder. Pruritus is thought to result from a disruption in the skin nerve endings. Scratching to relieve pruritus can result in tissue damage and infection, thereby causing further discomfort.

### Lesions

Depending on the type of skin disorder, one or a variety of lesions may be present. Observation of the individual includes assessing any lesions to determine their shape, size and distribution. Table 29.7 lists and describes the various types of skin lesions. Some types of lesions may discharge fluid, which is referred to as exudate.

### Alterations in sensation

In addition to pruritus, the individual may experience other abnormal skin sensations such as numbness, tingling, burning or pain.

### Alterations in skin colour

Disorders of the skin may be accompanied by darkened areas of skin (hyperpigmentation), patches of pale skin (hypopigmentation) or inflammation. Burned skin may be reddened, blanched or charred, depending on the extent of the burn. Cold injuries can result in red areas, as in chilblains, or in extreme pallor, as in frostbite.

### Alterations in skin temperature

In certain skin disorders such as bacterial infection the skin may feel hot to touch, whereas in other conditions such as frostbite the skin is cool to touch.

### Alterations in texture

Abnormalities of texture, for example, roughness or hardness, may result from the presence of certain types of lesions such as scabs or papules. Scaling may occur, or the skin may be thick, wrinkled or atrophied. Some skin disorders may result in areas of oedema; for example, injuries from heat or cold.

### Presence of an odour

Certain skin disorders, particularly those that are accompanied by oozing lesions, may give rise to an offensive odour.

### Systemic manifestations

Certain skin disorders, such as acute contact dermatitis or carbuncles, may be accompanied by systemic effects such as fatigue, nausea, headaches and an elevated body temperature.

# SPECIFIC DISORDERS OF THE SKIN

## Genetic disorders

Genetic disorders are those that are present at birth, become evident soon after birth or those that may be passed on to the next generation.

*Acne vulgaris* is a chronic inflammatory condition involving the sebaceous glands and the pilosebaceous follicles, particularly of the face. A blackhead forms and blocks the opening of a sebaceous gland, which becomes infected. Later, a pustule forms. This condition is most often present in adolescents and young adults. Familial tendencies are thought to contribute to the cause or exacerbation of acne. Other causative factors include endocrine imbalances, use of oral contraceptives, hormone therapy, emotional stress and lack of personal hygiene.

*Ichthyosis* is any one of several inherited conditions in which the skin is dry, hyperkeratotic and fissured, resembling fish scales. It usually appears at, or shortly after, birth. Ichthyosis vulgaris is the most common type and the least severe.

## Idiopathic disorders

Idiopathic disorders are those in which no definite cause can be identified.

*Psoriasis* is a chronic skin disorder characterised by red patches covered by thick, dry, silvery scales. The lesions may be present on any part of the body but are more common on the extensor surfaces of the elbows and knees and on the scalp. Psoriasis can be exacerbated by trauma, infection, stress and the use of specific systemic medications.

**TABLE 29.7 | Skin lesions**

| Term | Description | Examples |
|---|---|---|
| Bulla | Elevated, filled with clear fluid. Similar to a vesicle, but larger | Pemphigus vulgaris, drug eruptions, partial thickness burns |
| Comedo | A plug of secretion contained in a follicle | Acne |
| Crust | A superficial mass caused by dried exudate | Impetigo, eczema |
| Cyst | Encapsulated mass in the dermis or subcutaneous layer. May be raised or flat, and contain fluid or solid material | Sebaceous cyst |
| Erosion | Moist, red, depressed break in the epidermis. Follows rupture of a vesicle or bulla | Chickenpox |
| Excoriation | Superficial break in the skin | Scratches, abrasions |
| Fissure | Deep, linear, red crack or break exposing the dermis | Tinea pedis |
| Macule | Small circumscribed discolouration (e.g. red, white, tan or brown) | Freckle, rubella, scarlet fever |
| Nodule | Circumscribed, elevated area—usually 1–2 cm in diameter | Ganglion, acne |
| Papule | Circumscribed, elevated, firm palpable area | Mole, wart, pimple |
| Plaque | Elevated, rough flat-topped areas | Psoriasis, seborrhoeic warts |
| Pustule | A vesicle or bulla containing pus | Acne, furuncle, folliculitis, impetigo |
| Scale | Mass of exfoliated epidermis | Dandruff, psoriasis |
| Scar (cicatrix) | Ranges from a thin line to thick, irregular fibrous tissue. May be white, pink or red | Healed surgical incision or wound |
| Tumour | Elevated, solid formation | Lipoma, melanoma, fibroma |
| Ulcer | Depressed circumscribed area involving loss of the epidermis, exposing the dermis, and may involve subcutaneous tissue | Decubitus ulcer, stasis ulcer |
| Vesicle | Circumscribed, elevated superficial area filled with clear fluid | Blister, herpes simplex infection, contact dermatitis |
| Weal | Transitory, elevated irregularly-shaped swelling of the epidermis | Urticaria, insect bites |

*Pityriasis rosea* is thought to be caused by a virus, and is characterised by a scaling, pink macular rash that spreads over the trunk and other parts of the body. The condition is self-limiting and usually disappears within 4–6 weeks.

*Vitiligo* is a benign disorder consisting of irregular patches of skin totally lacking in pigment.

*Seborrhoeic dermatitis* is a chronic inflammatory condition characterised by dry or moist, red scaly eruptions. Common sites are the scalp, eyelids, face and trunk. The scales have a greasy feel and yellow crusts. Cradle cap is one form of seborrhoeic dermatitis.

## Hypersensitivity disorders

These disorders result from an immediate or delayed reaction after exposure to a certain substance.

*Contact dermatitis* is caused by an irritant substance that comes into direct contact with the skin, such as detergents, hair dye, metals, preservatives, perfumes or specific fabrics. The resultant inflammation and skin rash may be mild or severe, depending on the individual's response. Chronic exposure to an irritant may result in the skin becoming reddened, scaly or cracked.

*Atopic dermatitis* usually occurs when there is a history of asthma and/or hay fever. The condition is characterised by pruritus, redness of the skin, papules and thickening of the skin. Common sites are the face and neck, behind the knees and in the cubital fossae and on the back of the hands.

*Urticaria* is a pruritic skin eruption characterised by transient weals with well-defined red margins and pale centres. Urticaria (hives) is most frequently caused by foods, insect

bites and inhalants. Specific types of urticaria are associated with systemic diseases. Pruritus associated with urticaria is frequently intense and is commonly accompanied by stinging, numbness or prickling sensations. Urticaria may also be a manifestation of an adverse reaction to a drug, and the skin lesions may appear almost immediately or several days after the drug has been absorbed. Drugs responsible for such adverse reaction include acetylsalicylic acid, penicillin and codeine.

*Pemphigus vulgaris* is an uncommon disorder of the skin and mucous membranes, characterised by the formation of large bullae containing clear fluid. The disorder is thought to result from an autoimmune response, and may be fatal if untreated. The bullae erupt, ooze and bleed readily, and death is often due to a secondary bacterial infection or loss of blood protein.

## Trauma

A traumatic injury, which involves damage to the skin, may be due to direct force, penetration or extremes of temperature.

*Erythrocyanosis* (chilblains) is redness and swelling of the skin as a result of excessive exposure to cold. Burning, itching, blistering and ulceration may occur; the areas most commonly affected are the toes, fingers, nose and ears.

*Frostbite* is the traumatic effect of extreme cold on the skin and subcutaneous tissues, characterised by pallor of the exposed areas, such as the nose, ears, fingers and toes. Vasoconstriction and damage to blood vessels impair local circulation, resulting in oedema, anoxia and necrosis.

*Immersion (trench) foot* is a condition of the skin on the feet that develops from continued exposure to wetness and coldness, such as prolonged immersion in cold water. The feet appear pale, cold and swollen, and the individual experiences tingling followed by loss of sensation.

*Burns* are injuries to the body tissues caused by heat, electricity or chemicals. Thermal burns include injuries caused by flame, steam or hot liquids. Electrical burns result from contact with an electrical current, and chemical burns most often result from contact with caustic substances. A burn may be minor or major, and the degree of local effects and systemic consequences depend on many factors, including the severity of the burn and the age of the individual. (More information on burns and the care of individuals with burns is provided later in this chapter.)

## Neoplasia

A *keloid* is a benign overgrowth of fibrous tissue at the site of a wound to the skin. The new tissue is elevated, thickened and reddened. Most keloids flatten and become less noticeable over a period of years. Keloids are more likely to develop if a wound has been infected or if the edges of a wound have been poorly aligned during healing.

*Sebaceous cysts* are one type of epithelial cyst and consist of a capsule containing a soft yellow–white material. These benign cysts are elevated and firm and range in size from about 0.2–5.0 cm.

A *lipoma* is a common benign tumour composed of adipose tissue, which is generally encapsulated in the subcutaneous layer of the skin. Lipomas vary in size and most frequently occur on the neck, back, thighs or forearms.

*Neurofibromatosis* is a congenital condition characterised by:

- Numerous neurofibromas of the skin and nerves
- Café-au-lait spots on the skin
- In some cases by abnormalities of the muscles, bones and internal organs.

Many large, pedunculated soft-tissue tumours may develop.

*Basal cell carcinoma* is a malignant lesion characterised by a shallow ulcer surrounded by a raised well-defined edge. Basal cell carcinomas may also be referred to as rodent ulcers. The most common site is the face, particularly the nose, eyelids and cheeks. Basal cell carcinomas usually occur in people aged over 40 and, as metastasis is rare, the prognosis is favourable.

*Squamous cell carcinoma* is a malignant lesion characterised by a firm, elevated painless nodule. The most common sites are areas of the body most often exposed to ultraviolet rays. Squamous cell carcinoma is most frequently seen in men over age 55 and, as metastasis is probable, this neoplasm has a higher mortality rate than basal cell carcinoma.

A *melanoma* is a malignant tumour that arises from melanocytes. The incidence of melanoma seems to be related to prolonged exposure to the sun, particularly by fair-skinned people. Because metastatic dissemination is relatively common, the mortality rate is high. In its pre-malignant stage, a melanoma appears as a flat, irregularly pigmented macule. Colour changes appear as the melanoma becomes malignant and invasive, with the colour ranging from red, brown and blue to black. Melanoma can occur on any part of the body but most frequently occurs in areas of the skin exposed to sunlight. There are many types of melanoma and, because of its invasive nature, the nodular type is the most serious. Australians have the highest rate of malignant melanoma in the world, and the incidence is particularly high in Queensland and other tropical regions.

## Infections and infestations

Because the surface of the body is constantly exposed to large numbers of pathogenic microorganisms, the skin is a potential area for infection. In addition, dermatological problems are often the result of infestation by parasites. Many factors increase a person's vulnerability to a skin infection, including ill-health, poor standard of hygiene or a break in the continuity of the skin. Bacterial skin infections include carbuncles, erysipelas, folliculitis, furuncles (boils), impetigo and paronychia.

A *carbuncle* is a cluster of staphylococcal abscesses or boils containing purulent matter. Eventually pus discharges to the skin surface through numerous openings.

*Erysipelas* is an acute streptococcal inflammatory infection involving subcutaneous tissue. The skin of the affected

area is bright red and oedematous, with a sharply defined border. The area may develop vesicles and the individual commonly experiences pain and an elevated body temperature.

*Folliculitis* is a common infection of the hair follicles, caused by staphylococci. Superficial or deep pustules are evident, and the most common site is the face.

A *furuncle (boil)* is an infection caused by either staphylococci or streptococci. A furuncle starts as a painful, hard, deep follicular abscess, and the overlying skin is hot to touch. The area becomes soft and opens to discharge a core of tissue and pus.

*Impetigo* is an acute contagious disorder of the superficial layers of the skin, caused by either staphylococci or streptococci. The condition begins as local erythema and progresses to pruritic vesicles which ooze, with the exudate from the lesion forming a yellow-coloured crust. Lesions usually form on the face and spread locally.

*Paronychia* is a painful inflammatory infection of the tissue around the nails.

*Viral skin infections* include herpes simplex and herpes zoster infections, and verrucae.

Herpes simplex virus (HSV) has an affinity for the skin and usually produces small irritating or painful fluid-filled blisters on the skin and mucous membranes. HSV-1 infections tend to occur in the facial area, particularly around the mouth and nose, whereas HSV-2 infections are usually limited to the genital region. The blisters erupt and thin yellow crusts form as the lesions begin to heal.

Acute infection with herpes zoster, or varicella-zoster virus (V-ZV), is characterised by the development of very painful vesicular skin eruptions that follow the underlying route of cranial or spinal nerves inflamed by the virus. After about 1 week the vesicles develop crusts, and the condition may last several weeks. The pain may last for much longer.

A *verruca (wart)* is caused by the human papilloma virus, and presents as a firm skin lesion with a rough surface. Different types of verrucae include those that commonly affect the hands, fingers or knees; and those that affect the genito-anal region.

*Fungal skin infections* include candidiasis and tinea. Candidiasis is any infection caused by a species of *Candida*, usually *Candida albicans*, characterised by pruritus, a white exudate, peeling and easy bleeding. Oral or vaginal thrush are common topical manifestations of candidiasis, as are red eroded patches in the genito-anal region.

Tinea (ringworm) is a group of fungal skin diseases caused by dermatophytes of several kinds. It is characterised by itching, scaling and painful lesions. Types of tinea include tinea capitis, affecting the scalp, tinea pedis, affecting the feet, and tinea corporis, affecting non-hairy smooth skin on the body.

Infestations of the skin by parasites include scabies and pediculosis. *Scabies* is a condition caused by a mite, *Sarcoptes scabiei*, and characterised by a papular rash, intense pruritus and excoriation of the skin from scratching. The sites most commonly affected are the thin-skinned areas between the fingers, flexor surfaces of the wrists and the inner aspect of the thigh. The mite burrows into the outer layers of the skin, where the female lays eggs. Small, thread-like red streaks appear where the mite has burrowed into the skin.

*Pediculosis* is infestation by blood-sucking lice, which causes intense pruritus, often resulting in excoriation from scratching. Different varieties of pediculi affect the hair on the scalp, the body or the pubic area. The lice can be seen with the naked eye, and their eggs (nits) can be seen as small pear-shaped bodies attached to the hairs.

### Diagnostic tests

To diagnose specific disorders of the skin a variety of tests may be performed.

#### Direct examination

A lesion may be examined using a magnifying lens, or a Wood's lamp may be used to determine the presence of fungal infections. Fungal infections such as ringworm show a characteristic fluorescence under black light.

#### Skin biopsy

The medical officer obtains a sample of skin or part of a lesion for pathological examination. Certain lesions may be surgically excised to provide sufficient tissue for histological diagnosis.

#### Microscopic examination

Specimens for microscopic examination may be obtained by gently scraping the scales or crusts of lesions. Exudate from oozing lesions may also be obtained for microscopic examination.

#### Skin testing

Skin testing may be performed to determine which substance or substances cause a hypersensitive reaction. Patch testing provides a means for assessing contact sensitivity. One or more suspected allergens are placed on a hairless part of the body. The test site is later examined for a visible reaction.

## CARE OF THE INDIVIDUAL WITH A SKIN DISORDER

Although nursing care is planned to meet the individual's needs, according to their specific **skin disorder**, the nursing care of a person with any dermatosis generally involves the following aspects.

### Relief of pruritus

Itching, which can be a source of considerable distress, is a feature of many skin disorders. The natural response to pruritus is to scratch, and scratching can cause further discomfort and may lead to tissue damage and infection. While medical therapy is aimed at resolving the problem responsible for the pruritus, certain nursing measures can be employed to provide some relief:

- As heat tends to aggravate itching, the room should be maintained at a moderate and comfortable temperature.

The bedclothes and personal clothing should be light, loose and cool
- Soothing tepid baths may be helpful in alleviating the itching
- Diversions that are of interest to the individual, such as reading or watching television, may be helpful.

### Topical applications

The application of local soothing preparations or topical medications may be prescribed. The most common mediums used to apply medications to the skin are creams, lotions, ointments and pastes, or powders. Medications that are mixed with the appropriate medium for topical application include: anti-inflammatory drugs such as corticosteroids, antipruritic agents such as tar or corticosteroids, antiseptics such as phenol and antibiotics such as neomycin. Specific substances to be added to the bath water may also be prescribed. For example, oatmeal, bath oils or coal-tar preparations may be prescribed when large areas of the body surface are affected. The nurse must ensure that the bath water is at a comfortable temperature and should be aware that many skin disorders result in changes in sensory perception, so it is essential that the water is not too hot.

Whenever topical applications have been prescribed, the nurse must know the level of responsibilities and the regulations regarding administration of medications in the healthcare facility and geographical area in which they work. Each type of topical medication requires proper application, and the nurse must know the amount to use, whether gloves are required during application and the signs of any adverse effects of the medication. The correct administration of medication is required as with any medication; please refer to Chapter 24 for further detail.

In addition to topical applications, systemic medications may be prescribed, such as analgesics to relieve pain, antibiotics to combat infection or mild sedatives to promote adequate rest.

Dressings may be prescribed as part of the local treatment of skin disorders. Moist dressings may be used in the management of acute inflammatory skin disorders. Any solution that is used to soak the dressing should be warmed to body temperature. Occlusive dressings may be applied over a topical medication to promote penetration of the drug into the epidermis.

### Maintenance of fluid and nutritional balance

Fluid and electrolyte balance may be disrupted because of loss of fluid in exudate from skin lesions. It is important to ensure that adequate fluid replacement is provided to compensate for any abnormal fluid loss.

A diet that is rich in protein may be prescribed to replenish losses and to promote healing. It is important to ascertain whether the individual is allergic to any specific foods, as skin disorders can be caused or aggravated by food allergies. Any known allergens must be eliminated from the diet.

### Preventing infection

Any disruption to the integrity of the skin increases the risk of infection, so measures such as the following should be implemented to protect the skin:
- After bathing or showering, the skin should be gently patted dry. Brisk rubbing could cause damage to already tender skin
- The nails should be kept short and clean to prevent damage from scratching, and the person should be encouraged to resist scratching. It is important to explain that scratching increases the risk of skin trauma and infection. For some people, such as a young child or a disoriented person, mittens may be placed over the hands to reduce skin damage by scratching
- All dressings and applications of topical substances must be performed aseptically
- If the skin disorder is contagious, isolation precautions may be implemented to prevent the spread of infection to others.

### Providing psychological support

A severe skin disorder may cause distress and embarrassment to the person who has it. They may be self-conscious about their appearance, and their body image may be severely impaired. If the person feels that other people will avoid contact because of their unsightly appearance, they may experience anxiety or depression, both of which may be exacerbated if the disorder is likely to result in permanent disfigurement. To assist the individual with a skin disorder, the nurse should be careful not to demonstrate any distaste or repugnance. It is important that the individual and their significant others are kept well informed about the disorder and its likely outcome. The individual should be given the opportunity to express their emotions and fears, such as the fear of disfigurement or alienation from their loved ones.

## PRESSURE INJURIES

**Pressure injuries** are defined as 'a localised injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, shear and/or friction, or a combination of these factors' (Australian Wound Management Association (AWMA) 2012). Pressure injuries have previously been referred to as pressure ulcers/areas, decubitus ulcers, trophic ulcers and bedsores. In 2012 AWMA had adopted the term 'pressure injuries' but in the recent 2014 international update Europe and the US have retained the use of pressure ulcer rather than injury. The prevalence of pressure injuries remains high even with the implementation of guidelines and interventions to reduce their occurrence. Australian prevalence rates have been reported at between 9% and 29.4% with rates declining by 9–16% over a 3-year period (Asimus et al 2011; Mulligan et al 2009; Quality and Safety Branch, Department of Human Services Victoria 2006). In Australia, hospital-acquired pressure injuries are reported at rates between 6% and 68% (Mulligan et al 2009; Quality and Safety Branch,

Department of Human Services Victoria 2006) and have been estimated to independently increase hospital length of stay by over 4 days (Graves et al 2005), deflecting the use of these bed days from other conditions and placing a significant economic and clinical burden on the Australian healthcare system. In the US healthcare system pressure injuries are considered a 'never event', being largely preventable, and have been reported as the most expensive preventable adverse event/medical error, consuming over US$3.8 million annually (Shreve et al 2010). This cost exceeds postoperative infection (US$3.7 million) and mechanical complication of device, implant or graft (US$1.1 million) (Shreve et al 2010). From 2008 the US medical system ceased reimbursement to facilities for hospital-acquired stage III and IV pressure injuries, an indication of the seriousness the system is taking to control the occurrence of pressure injuries (Centre for Medicare and Medicaid Services 2012). In Australia, Queensland Health has imposed financial penalties for both stage 3 and 4 hospital-acquired pressure injuries—$30,000 for stage III and $50,000 for stage IV (Queensland Health 2012).

## Pressure injury aetiology

Pressure injuries result from ischaemic hypoxia of the tissues owing to prolonged pressure on the area when it is over a hard surface such as a mattress or chair. Impaired mobility or activity and impaired sensory perception of the individual affects the ability of the individual to recognise when there is pain and to change position. Clinical Interest Box 29.9 lists conditions in which individuals may be at increased risk to pressure injury.

Pressure impairs blood circulation and the area is deprived of essential nutrients and oxygen, causing cellular death. The major factors contributing to loss of local capillary blood supply are pressure and shearing forces; however, these can be exacerbated by predisposing factors classed as either intrinsic or extrinsic. A combination, of these factors increases the risk of pressure injury.

The greater the pressure on the skin, the more the tissue is compressed. Pressure on the skin over bony prominences can distort the blood vessels to such an extent that the blood flow is interrupted. Pressure can also occlude lymphatic vessels, and the consequent accumulation of toxic substances can contribute to cell damage. Recent research in the laboratory on rats suggests pressure injuries may result from sustained deformation of the tissue, causing an ischaemia-reperfusion injury where there is a cycle of ischaemia and reperfusion of the tissue during prolonged pressure, which contributes to tissue damage (Loerakker et al 2011).

Pressure injuries form in a few hours but may take many months to heal; preventing them is therefore of prime importance. Ensuring adequate blood supply to pressure areas is critical as altered blood supply is the primary cause of pressure injuries. Blood supply to promote tissue healing is dependent on adequate circulation that brings antibodies and leucocytes to combat infection, as well as nutrients and oxygen for regeneration of tissues.

Pressure injuries can develop on body areas when they are subjected to prolonged or excessive pressure (Figure 29.3). The two most frequently reported locations are the sacrum and heels (Quality and Safety Branch, Department of Human Services Victoria 2006).

### CLINICAL INTEREST BOX 29.9 Individuals with increased exposure to pressure

- Spinal cord injury
- Stroke
- Multiple sclerosis
- Trauma (e.g. fracture)
- Obesity
- Diabetes (neuropathy)
- Cognitive impairment
- Medication use (e.g. sedatives, hypnotics, analgesics)
- Surgery

*(Adapted from AWMA & NZWCS 2011)*

## Classification of pressure injuries

Pressure injuries are categorised into four main stages with two sub-categories (NPUAP et al 2014). See Figure 29.4 for images and full descriptions of all the stages.

Stages I and II are generally considered partial thickness wounds (though the skin remains intact in a stage I pressure injury) and stages III and IV are considered full thickness injuries. Tissue destruction can continue through the layers of tissue unless measures are taken early to relieve pressure and increase local tissue perfusion (see Case Study 29.1).

Stage I: non-blanchable erythema. Intact skin with non-blanchable redness of a localised area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its colour may differ from the surrounding area.

Stage II: partial thickness skin loss. Partial thickness loss of dermis presenting as a shallow, open ulcer with a red-pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister.

Stage III pressure injury: full thickness skin loss. Pressure injury presenting as full thickness tissue loss in which subcutaneous fat may be visible but bone, tendon or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss.

Stage IV pressure injury: full thickness tissue loss. Pressure injury presenting as full thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present on some parts of the wound bed. Often includes undermining and tunnelling.

### Subcategories

Unstageable: depth unknown: full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green or brown) and/or eschar (tan, brown or black) in

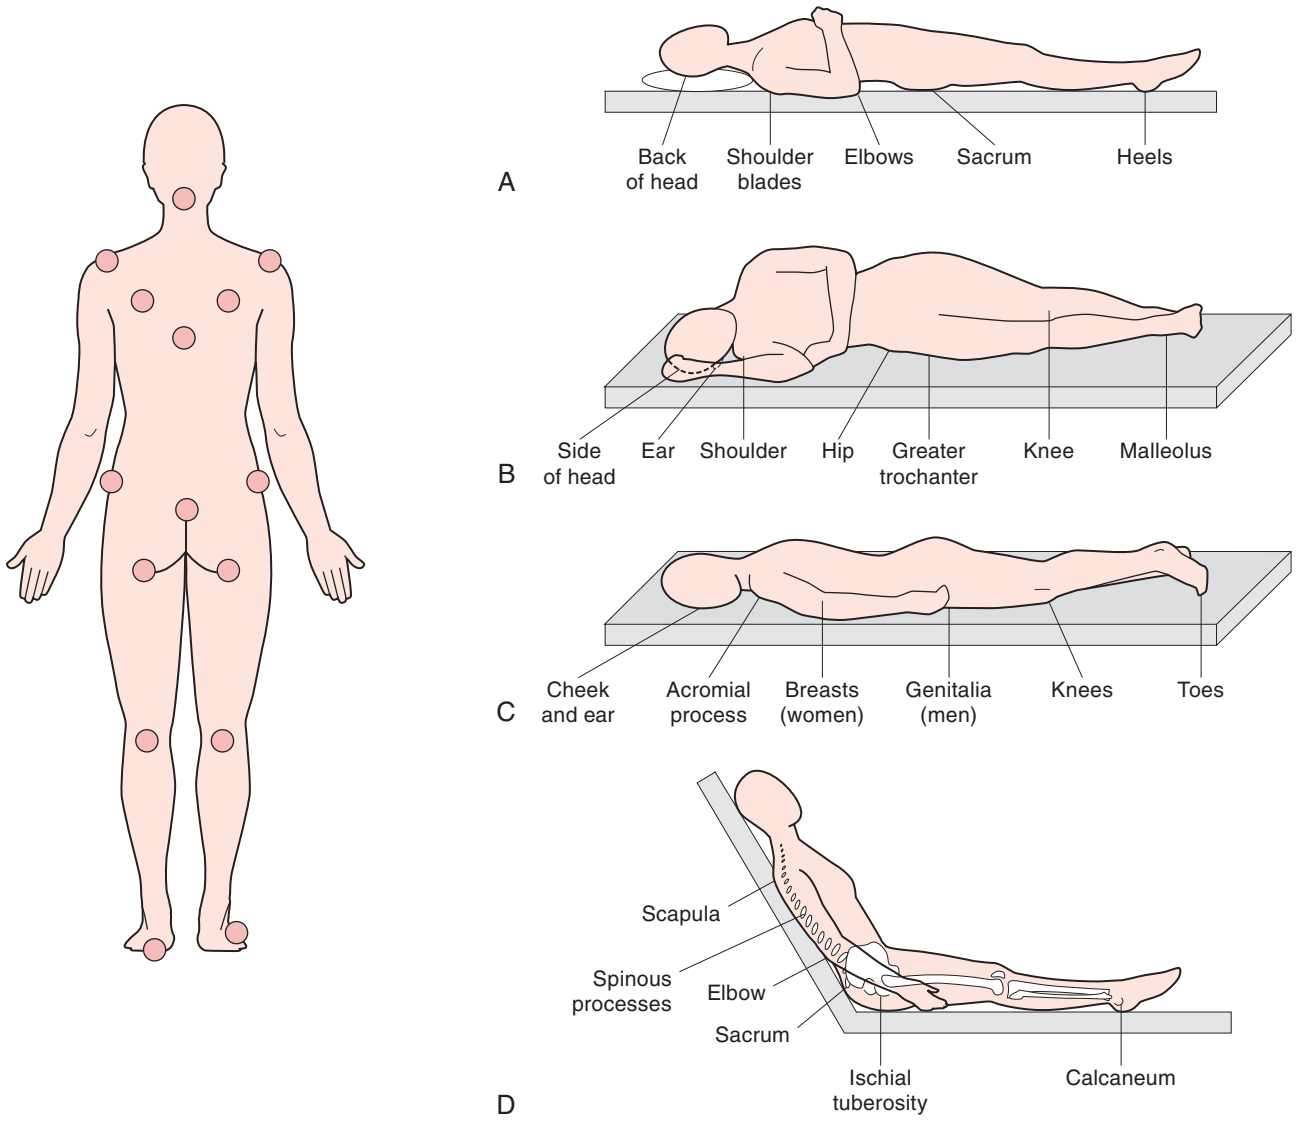

**Figure 29.3** Pressure injury sites

## CASE STUDY 29.1

**Pressure Injury**

Mr Darcy, an 88-year-old man, was discharged from hospital following admission for a urinary tract infection. As he has no family, Mr Darcy was taken home by hospital transport and was escorted into his home where he lives alone, and placed in a lounge chair. Two days later, a nurse from hospital did a follow-up visit on Mr Darcy. On arrival the nurse found Mr Darcy still sitting in the lounge chair; he had not moved from the chair since his arrival at home, 2 days prior. He had been incontinent of both urine and faeces. Mr Darcy made minimal eye contact and was not able to give coherent answers to questions.

While assisting Mr Darcy, the nurse noted a large lesion on his sacrum. Mr Darcy was transferred to an acute care facility where surgical debridement took place, identifying a stage IV pressure injury on his sacrum.

See Nursing Care Plan 29.1 for the recommended nursing care for Mr Darcy.

1. What other allied health professionals would you include in your care of Mr Darcy?
2. What specialised wound dressing regimen will Mr Darcy require?

wound bed. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined.

Suspected deep tissue injury: depth unknown: purple or maroon localised area or discoloured, intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue.

Review Case Study 29.1 that explores pressure injuries.

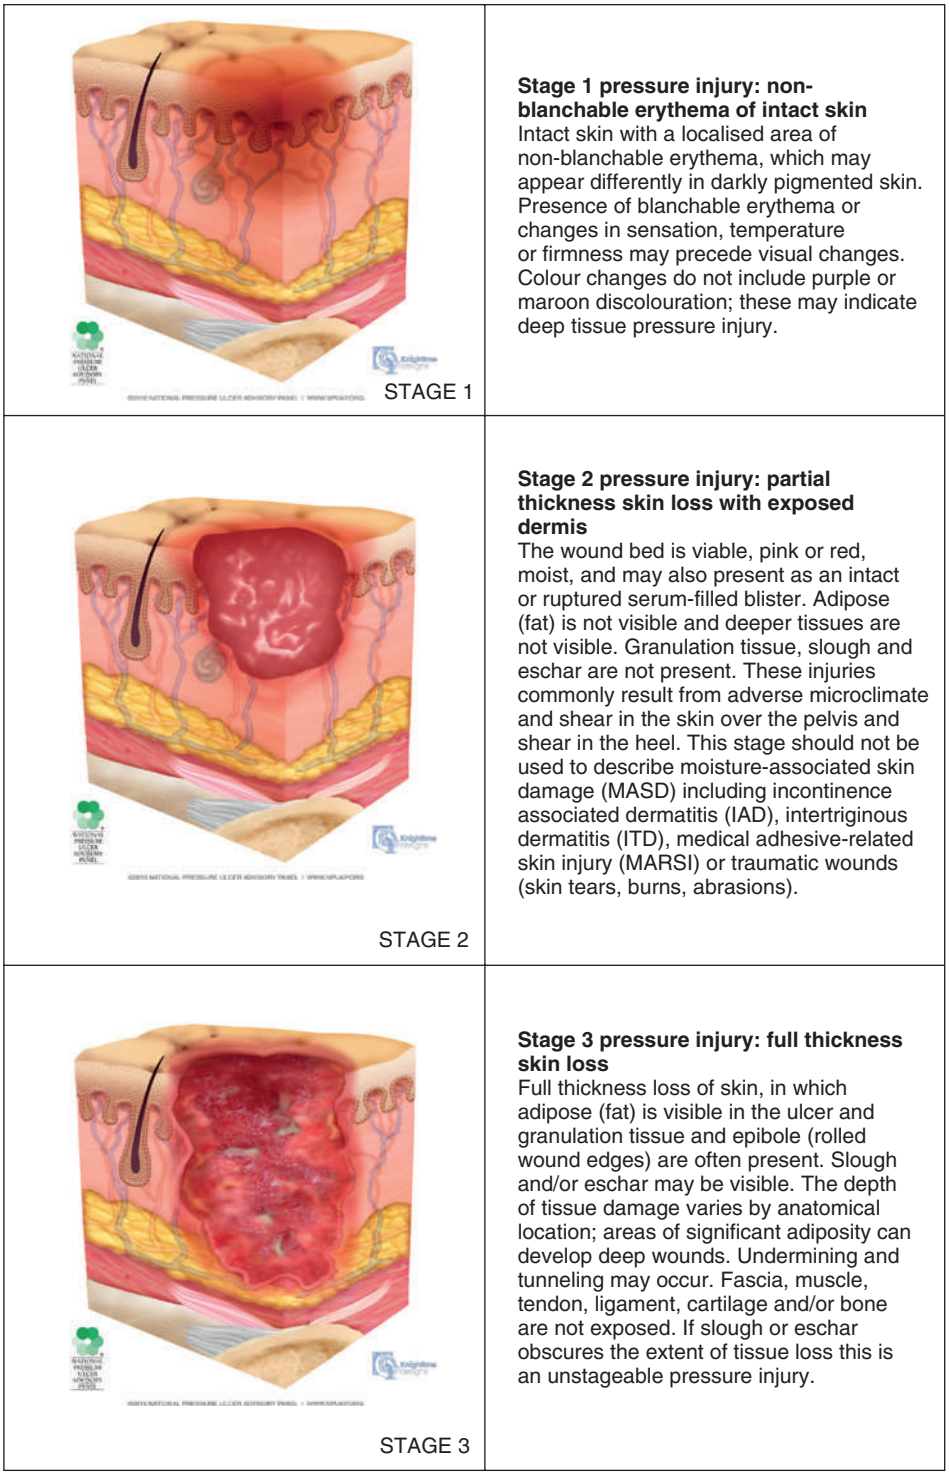

**Figure 29.4** Pressure injury classification system
*(NPUAP et al 2014)*

*Continued*

| | |
|---|---|
|  STAGE 4 | **Stage 4 Pressure injury: full thickness skin and tissue loss**<br>Full thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss this is an unstageable pressure injury. |
|  UNSTAGEABLE | **Unstageable pressure injury: obscured full thickness skin and tissue loss**<br>Full thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar (i.e. dry, adherent, intact without erythema or fluctuance) on an ischaemic limb or the heel(s) should not be removed. |
|  SUSPECTED DEEP TISSUE INJURY | **Deep tissue pressure injury: persistent non-blanchable deep red, maroon or purple discolouration**<br>Intact or non-intact skin with localised area of persistent non-blanchable deep red, maroon, purple discolouration or epidermal separation revealing a dark wound bed or blood-filled blister. Pain and temperature change often precede skin colour changes. Discolouration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone–muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle or other underlying structures are visible, this indicates a full thickness pressure injury (unstageable, Stage 3 or Stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic or dermatological conditions. |

**Figure 29.4, cont'd**

## Intrinsic factors

Intrinsic factors are characteristics specific to an individual. These factors reduce the skin's tolerance to pressure by affecting the vasculature, lymphatic system and supporting structures. Factors include age, mobility, circulation, nutrition, comorbidities and mobility. Chronic illnesses, particularly those affecting tissue perfusion and oxygen delivery (e.g. peripheral vascular disease) and sensation, also contribute to an increased risk of pressure injury development.

### Age

People aged over 65 years are at greatest risk of pressure injuries with the risk increasing over 75 years of age (AWMA 2012).

### Nutritional status

Inadequate nutrition prevents efficient cellular growth and repair, and renders the tissues more vulnerable to damage. A poorly nourished person will usually have less protection over the bony prominences and be more vulnerable to the effects of prolonged pressure.

### Body type

As the sites of maximum skin compression are located over bony prominences, a thin person is more at risk. Conversely, an obese person may be at risk due to shearing forces and added pressure caused by body weight pressing on the skin.

### Mobility

Altered mobility and activity restricts an individual's ability to redistribute pressure on weight-bearing areas.

### Neurological factors

Reduced sensitivity to pressure or pain may occur in certain disease states, such as spinal cord injury, paralysis, multiple sclerosis or diabetes mellitus. Transmission of impulses from receptors in the skin or to the muscles may be impaired, so that the person does not receive the 'message' to change position regularly, a normal body defence mechanism. Other factors can also impact the nervous system such as the use of epidural analgesia, which reduces this protection mechanism (Angel et al 2004).

### Vascular factors

Reduced peripheral tissue perfusion may result from certain disease states, such as atherosclerosis, cardiac failure or diabetes mellitus. As reduced local tissue oxygenation and nutrition are the primary cause of pressure injuries, people with vascular perfusion abnormalities are at increased risk.

## Extrinsic factors

Extrinsic factors are those derived from the individual's environment. The main identified factors are pressure (discussed above), shear, friction and moisture; all of these impact on the ability of the skin to tolerate pressure.

### Shearing forces and friction

When pressure is applied to the skin at an angle, movement of the layers of the skin over one another may cause distortion of the tissue. The mechanical shearing forces involved distort and occlude the dermal capillaries, resulting in thrombosis and capillary occlusion, and tissue necrosis. Friction is also a mechanical force between the skin and another surface, such as bed linen, which creates resistance between the two surfaces. Friction immobilises the epidermis while the deeper layers move, and is an important factor in an individual whose skin is fragile and at risk.

### Moisture

Moisture on the skin can be from incontinence (urinary and faecal), wound exudate, perspiration, mucus or saliva. Prolonged exposure to moisture causes maceration, which weakens the connective fibres of the skin and alters the resilience of the epidermis to external forces (AWMA 2012). Abrasions are more likely to form from friction between the skin and the surface under the individual, making shearing forces more severe. Actions such as excessive washing with soap, unsafe manual handling or rubbing can also damage the skin's integrity. Incontinence of urine or liquid faeces can result in incontinence-associated dermatitis, which can be inaccurately described as a stage I or stage II pressure injury (Black et al 2011) and it is important to be able to clinically distinguish between pressure damage and incontinence-associated skin damage. Incontinence-associated skin damage creates an added risk of exposure to bacterial and faecal enzymes that alter the normal acidic pH of the skin and may lead to an increased risk of skin infection.

## Pressure injury risk assessment

Assessing the potential of an individual for pressure injury development is a combination of the use of a recognised risk assessment tool, skin and nutritional assessment and clinical judgment. Although the use of a risk assessment tool can assist management and provide a structured approach to an individual's care plan it should not be used in isolation. A head-to-toe assessment is made on admission to a facility, including those entering an emergency department, and at regular intervals throughout their stay. Any change in the individual's medical and mental condition also requires reassessment.

### Risk assessment

It is important to identify individuals at risk of pressure injuries and various assessment tools have been designed to assist healthcare professionals. Implementation of a valid and reliable risk assessment tool is considered best practice and is used as a guide to identify an individual at risk of pressure injury development. The tools are intended as a preventative measure to facilitate the implementation of a rational preventative regimen. Several risk assessment tools have been developed with the common ones cited in the published literature being the Braden Scale for Predicting Pressure Sore

**TABLE 29.8 | The Braden Scale for predicting pressure sore risk**

**Patient's name** _____ **Evaluator's name** _____

**Date of assessment** _____

| | | | | |
|---|---|---|---|---|
| Sensory perception<br>Ability to respond meaningfully to pressure-related discomfort | 1. *Completely limited*<br>Unresponsive (does not moan, flinch or grasp) to painful stimuli caused by diminished level of consciousness or sedation<br>OR<br>Limited ability to feel pain over most of body surface | 2. *Very limited*<br>Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness<br>OR<br>Has sensory impairment that limits the ability to feel pain or discomfort over half of body | 3. *Slightly limited*<br>Responds to verbal commands but cannot always communicate discomfort or need to be turned<br>OR<br>Has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities | 4. *No impairment*<br>Responds to verbal commands.<br>Has no sensory deficit that would limit ability to feel or voice pain or discomfort |
| Moisture<br>Degree to which skin is exposed to moisture | 1. *Constantly moist*<br>Skin kept moist almost constantly by perspiration, urine etc. Dampness detected every time patient is moved or turned | 2. *Moist*<br>Skin often, but not always, moist. Necessary to change linen at least once a shift | 3. *Occasionally moist*<br>Skin occasionally moist, requiring an extra linen change approximately once a day | 4. *Rarely moist*<br>Skin usually dry. Require linen changing only at routine intervals |
| Activity<br>Degree of physical activity | 1. *Bedfast*<br>Confined to bed | 2. *Chairfast*<br>Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair | 3. *Walks occasionally*<br>Walks occasionally during day but for very short distances, with or without assistance. Spends majority of each shift in bed or chair | 4. *Walks frequently*<br>Walks outside room at least twice a day and inside room at least once every 2 hours during waking hours |
| Mobility<br>Ability to change and control body position | 1. *Completely immobile*<br>Does not make even slight changes in body or extremity position without assistance | 2. *Very limited*<br>Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently | 3. *Slightly limited*<br>Makes frequent, although slight, changes in body or extremity position independently | 4. *No limitations*<br>Makes major and frequent changes in position without assistance |

Risk© (Braden Scale) (Table 29.8), the Norton Scale and the Waterlow Score. Most encompass a scale or scoring system and include clinical risk factors such as mobility, nutrition, mental condition, activity, incontinence, sensory perception, friction and shear. A cumulative score is reached which is used to determine the type of intervention measures to be utilised for ongoing care. A randomised controlled trial involving 1231 people looked at the effectiveness of risk assessment tools and found no evidence to show that pressure ulcer risk assessment tools are superior to clinical judgment in

**TABLE 29.8 | The Braden Scale for predicting pressure sore risk—cont'd**

| | | | | |
|---|---|---|---|---|
| Nutrition<br>Usual food intake pattern | 1. *Very poor*<br>Never eats a complete meal; rarely eats more than a third of any food offered; eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly; does not take a liquid dietary supplement<br>OR<br>Is NPO and/or maintained on clear liquids or IVs for more than 5 days | 2. *Probably inadequate*<br>Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only 3 servings of meat or dairy products per day; occasionally takes a dietary supplement<br>OR<br>Receives less than optimum amount of liquid diet or tube feeding | 3. *Adequate*<br>Eats over half of most meals; eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally refuses a meal, but usually takes a supplement if offered<br>OR<br>Is on a tube feeding or total parenteral nutrition regimen that probably meets most of nutritional needs | 4. *Excellent*<br>Eats most of every meal; never refuses a meal; usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation |
| Friction and shear | 1. *Problem*<br>Requires moderate-to-maximum assistance in moving; complete lifting without sliding against sheets impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures or agitation leads to almost constant friction | 2. *Potential problem*<br>Moves feebly or requires minimum assistance; during a move skin probably slides to some extent against sheets, chair, restraints or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down | 3. *No apparent problem*<br>Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times | |
| | | | | TOTAL SCORE |

preventing pressure injury (Webster et al 2011). It is important for all healthcare workers when assessing individuals utilising any risk assessment tools to use their clinical judgment to ensure that the risk prevention plan is appropriate for the individual person and not based solely on a number.

## Nutritional assessment

Nutritional screening identifies malnutrition, dehydration and comorbidities and allows for appropriate interventions. In the elderly who may already have a poor diet, comorbidities (e.g. diabetes), malabsorption and infection can affect wound healing and nutritional screening can help to identify dietary deficits to guide management. The Mini Nutritional Assessment Short Form (MNA-SF) is an example of a validated nutritional assessment tool that can be used in the elderly population with pressure injuries (AWMA & NZWCS 2011). Assessment includes: weight, height and BMI, food intake, dental and oral health, drugs that can interfere with appetite, swallowing difficulties and biochemical investigations to detect anaemia, haemoglobin and serum albumin levels. Individuals found to be at risk of nutritional deficit must be referred to a dietitian for assessment and other specialist healthcare practitioners (e.g. speech and occupational therapists) where appropriate (EPUAP & NPUAP 2009).

## Skin assessment

Skin and tissue assessment is important in pressure injury prevention, classification, diagnosis and treatment (NPUAP et al 2014). The condition of skin and underlying tissue can serve as an indicator of early signs of pressure damage, therefore routine skin and tissue assessments provide an opportunity for early identification and treatment of skin damage (NPUAP et al 2014). Standard 8.6 of the National Safety & Quality Health Standards (ACSQHC 2012) outlines the

importance of carrying out comprehensive skin inspections of individuals on admission. The current international guidelines state that a comprehensive skin assessment should be undertaken within 8 hours of admission or on the first visit in the community setting (NPUAP et al 2014). Skin is assessed for erythema, blanching response, moisture damage, infection (e.g. fungal infection), oedema, induration (hardness), localised heat and any sign of loss of integrity (e.g. dry skin). It is important to include observation for pressure damage from medical devices such as oxygen tubing and drain tubes.

See Clinical Skill 29.3 for information and guidelines on shortening a drain tube.

## Psychosocial assessment

As part of a risk assessment tool mental or cognitive status is assessed as an impaired status can affect the individual's ability to comply with treatment (e.g. identify when to change position, unplanned removal of devices due to confusion). Also assessed is their social history, previous disease experience, social support, individual preferences for the type of care to be received, culture and ethnicity, financial support, quality of life and goals of care (AWMA 2012).

## Wound assessment

Pressure injuries should be assessed by their size, depth, location and degree of tissue (and bony) necrosis. They are classified on the degree of tissue loss (see Figure 29.4). The classifications are useful for documentation of the degree of injury and when considering treatment options, especially for debridement. Undermining and tunnelling are included as part of the assessment for stages III and IV pressure injuries when there is extension of the wound under the skin such

| CLINICAL SKILL 29.3 Shortening a drain tube—cont'd | |
|---|---|
| Place the equipment in a convenient location near the bedside. Open procedure pack using corners. Assemble the required equipment, using aseptic technique. Drop sterile equipment into sterile field | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the dressing is being performed<br>Prevents contamination of sterile items<br>Additional items are available for use |
| Perform hand hygiene and loosen wound dressing | Prevents spread of microorganisms and allows ease of removal of wound dressing |
| Put on apron. Perform hand hygiene, apply gloves if required. If other PPE required put on before gloves | Prevents spread of microorganisms |
| Position waterproof sheet and dressing towel around the wound, remove old dressing and place in waste bag/container | Absorbs moisture and prevents bed from becoming wet<br>Protects the wound from environmental contamination |
| Dispose of gloves and perform hand hygiene<br>Put on clean non-sterile gloves/sterile gloves | Removes microorganisms and prevents cross-contamination |
| Observe the wound for size, union, signs of infection, exudate, odour, inflammation and healing. Assess for pain | Evaluates condition of the wound and stage of healing |
| Cleanse the wound with sterile normal saline in accordance with the practices of the healthcare facility, medical officer's orders or as directed by the nurse in charge. Clean from a clean area towards a less clean area, usually an outward direction | Wound cleansing removes debris from the wound. Avoids transferring wound exudate and normal flora from the surrounding skin into the wound, and thus prevents wound contamination |
| Using the stitch cutter, remove any suture securing the tube in the wound | Enables the tube to be rotated, if necessary, and shortened |
| If the tube is round, gently rotate it | Rotation of the tube frees any adherent granulation tissue |
| Withdraw the tube the prescribed length (e.g. 1.25 cm) | Tube must only be shortened the prescribed length, to allow the wound to heal from within |
| Secure tube with sterile safety pin below level of planned cut | Prevents tube from slipping into the wound |
| Cut off excess tube | Prevents it pressing on the wound |
| A split gauze dressing is generally placed between the pin and the skin, and another dressing or pouch placed over the tube | Protects the skin from irritation and from wound drainage |
| Remove personal protective equipment and discard with used equipment in an appropriate waste receptacle | Prevents spread of microorganisms |
| Assist the individual to reassume a comfortable position | Promotes comfort |
| Remove and attend to the equipment appropriately. Perform hand hygiene | Prevents spread of microorganisms |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team. Include date and time, appearance of wound and any exudate, cleansing solution, type of primary and any secondary dressing used, and the individual's response to the dressing. Medico-legal requirement. Allows for the planning and implementation of care |

## PROGRESS NOTE EXAMPLE 29.1

| | |
|---|---|
| 05.06.2015<br>1025 hrs | Nursing: Daily skin assessment performed and all bony prominences checked. Left heel has intact serous fluid filled blister 2 × 2 × 1 cm—stage II pressure injury. Skin is intact but dry and flaky. All other pressure points are intact. Patient is unable to reposition independently or to weight bear on left heel. Patient is incontinent of urine & faeces. Perineum area has 1 cm × 0.5 cm of broken skin in the right groin, no bleeding or exudate, surrounding perineum & groin skin red and excoriated. Pain 4/10. Plan: Heel wedge applied. Patient educated regarding need to keep leg on wedge. Placed on pressure relieving mattress and 1/24 repositioning commenced, on right side at 1000. Heel wedge applied. Cavilon barrier spray applied to broken skin in R groin and 3M wipes used. Incontinence pad in situ and regular toileting offered. Moisturiser cream applied to dry skin of arms, legs and feet. Poor nutritional intake. Referred to dietitian for review as Malnutrition Score Tool 2. PRIME completed (145987) and MO notified (or PI communication sticker may be used).<br>***J. Smith* (Smith) EN** |

## PROGRESS NOTE EXAMPLE 29.2

| | |
|---|---|
| 07.06.2015<br>1930 hrs | Nursing: Tolerating 2/24 repositioning. Heel wedge remains in situ. Patient mobilised with rollator to shower and toilet this shift. Incontinent × 1. Incontinence pad in situ. Sat out of bed for 1 hour with cushion applied to chair. L heel blister remains intact with serous fluid present. Size unchanged. Moisturiser cream continually applied to dry surrounding skin which is improving. Groin/perineum excoriation improving, continuing to use skin barrier wipes. R groin broken skin now 0.5 × 0.5 cm continuing to use skin barrier spray. All other areas and pressure points remain intact. Patient is tolerating diet and nutritional supplements.<br>***K. Jones* (Jones) RN** |

that the wound cavity is larger than the skin opening. Documentation of the assessment findings and stage of pressure injury in the individual's medical records is necessary to provide a comparative review with future assessments and to guide treatment interventions to assess progress of wound healing. A hypothetical case of a pressure injury with additional complications, as well as ongoing documentation following the case, have been outlined in Progress Note Examples 29.1 and 29.2 respectively.

## Prevention and management of pressure injuries

Consideration of psychosocial issues, pain, altered body image and effects on activities of daily living are necessary to provide individual care.

### Skin protection

Protection from pressure, friction and shear forces is identified as the most important measure to reduce the risk of pressure injuries. Appropriate positioning, use of pressure redistribution surfaces, skin hygiene and adequate nutrition all play a role. Local measures include appropriate manual handling techniques when transferring and changing the position of an individual (e.g. using transfer devices) that can lift the individual off the bed to avoid friction and shearing. It is not advisable and cannot be recommended to massage or vigorously rub the individual's skin as part of a pressure injury protocol and is contraindicated where there is 'acute inflammation and where there is the possibility of damaged blood vessels or fragile skin' (EPUAP & NPUAP 2009). Water-based and pH neutral skin cleansers and creams are suggested to maintain skin hydration. Barrier creams help to maintain hydration and prevent maceration.

### Nutrition

Wound healing increases the energy demands on the body. The nutritional requirements of a stage I pressure injury will differ to those of an individual with a stage IV injury and will be affected by the volume of exudate leaking from the wound. As the wound heals nutritional requirements will also change. Australian and New Zealand dietary guidelines suggest increased protein intake (or the inclusion of protein building blocks such as arginine supplements in the diet) and inclusion of vitamin and mineral supplements to the individual's usual diet (TTDWCG 2011). These guidelines also offer recommendations based on the probable risk of healing due to nutritional issues. If a person is unable to tolerate oral food or fluids, an alternative method of meeting nutritional needs, such as gastric tube or total parenteral nutrition (IV) feeding, may be necessary. The 2014 International Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline identifies the importance of nutrition screening using a valid and reliable screening tool, on admission, at each significant change in clinical condition and when the pressure injury is failing to heal (NPUAP et al 2014). A registered dietitian, in consultation with the interprofessional team, should develop an individualised nutrition plan that ensures adequate energy intake. The addition of fortified foods and high-protein oral nutritional supplements between meals can be used to meet increased dietary intake needs.

## Support surfaces

Specialised support surfaces aim to reduce the interface pressure between the skin and the surface on which the individual is placed, such as the mattress on a bed, trolley, operating table or chair. Support surfaces work by increasing the amount of the body's surface area in contact with the surface or alternating the contact with the surface. Using support surfaces does not remove the need for regular skin inspection and care and regular repositioning of the individual. Selection is based on mobility of the individual in the bed, comfort, the microclimate and the care setting. Various types of pressure redistribution devices are available and they fall into two main categories: reactive support surface and active support surfaces. Reactive devices can be powered (e.g. low air loss mattress/beds) or non-powered (e.g. foam/gel/air/combination mattresses). An active support surface is a powered device that produces alternating pressure through mechanical means and has the ability to change its load distribution properties with or without an applied load (NPUAP et al 2014). Mattresses should be checked for 'bottoming out'. This means there must be at least 5 cm between the individual's lowest bony prominence and the mattress when the individual is lying supine. Heel protection should place the heel completely off the bed and distribute weight along the calf avoiding additional pressure on the Achilles tendon. Synthetic sheepskins, fluid filled gloves, donut devices or cut-outs should be avoided as they shift the pressure to another body surface area.

## Repositioning

Repositioning is an essential component of pressure injury prevention and care. Repositioning of the individual is designed to relieve or redistribute pressure points. It provides an opportunity to observe the skin condition and offer basic nursing care such as food or fluids and interaction with the individual. Repositioning regimens such as frequency, position and evaluation of the regimen must be documented in the individual's medical records. When lying in bed, individuals should be placed in a 30 degree tilted side-lying position (right side, back, left side) or 30 degree inclined recumbent position. The reduction of pressure and shear at the heel is important. The posterior prominence of the heel sustains intense pressure, even when a pressure redistribution surface is used (NPUAP et al 2014). Because the heel is covered with a small amount of subcutaneous tissue any pressure is transferred at an angle to the bone, increasing the tissue pressure (NPUAP et al 2014). It is challenging to offload pressure shear and friction for heels—the use of appropriate equipment to elevate and offload the heel completely is recommended. When head-of-bed elevation is required avoid a slouched position, which places extra pressure on the sacrum and coccyx. Use aids such as pillows to support the upper body and prevent the individual slipping towards the foot of the bed. An overhead handgrip may be used to lift and relieve pressure from the buttocks and sacral area. More frequent, smaller shifts in position may be necessary for some individuals intolerant of major changes (e.g. post-surgery pain). The individual sitting in a chair is encouraged to lift up from the seat frequently while sitting, to relieve pressure and facilitate tissue perfusion in the buttocks and sacral area. The person is assisted in this action if unable to lift independently. Avoid positioning the individual on medical devices such as drainage tubes; these can create areas of localised pressure. Splints, plaster casts, braces and bandages should be checked regularly and adjusted to relieve pressure. Individual factors need to be considered to be effective in preventing prolonged pressure on any area. Using correct manual handling techniques can avoid shearing when repositioning an individual. The person must be moved safely avoiding dragging the skin along any surface, and surfaces such as bed linen must be kept smooth and dry. In healthcare, annual mandatory competency in use of aids and positioning is suggested to maintain best practice.

### CRITICAL THINKING EXERCISE 29.2

After changing an individual's position, you observe redness over the bony prominences. What type of assessment must you perform to obtain correct information regarding pressure injury risk?

## Pain assessment and treatment

Pressure injuries are painful. The pain caused by pressure injuries can be constant and severe, and may be the most distressing pressure injury symptom (NPUAP et al 2014). Pain may be related to ongoing pressure, friction and/or shear, damaged nerve endings, inflammation, infection, procedures or treatments, or excoriation from incontinence and muscle spasm (NPUAP et al 2014). Assess all individuals for pain related to a pressure injury or its treatment and ensure an appropriate management plan is put in place.

## Wound care including infection management

Wound bed preparation is used as the tool to guide pressure injury wound care. Debridement of non-viable tissue after vascular assessment maximises the healing ability of the wound. In large pressure injuries therapies such as negative pressure wound therapy (NPWT) may be beneficial to reduce the size of the wound and manage large volumes of exudate. Local wound infection is managed aggressively to avoid spreading infection and speed the healing process. More information on this issue can be found in the wound management section of this chapter.

Specific pressure injury assessment tools such as the Pressure Ulcer Scale for Healing (PUSH) Tool (NPUAP 2015) monitor changes in a pressure injury. The PUSH Tool measures three parameters: size of the wound (length × width), exudate amount and tissue type (e.g. necrotic, slough, granulating, epithelialising). Similar to a risk assessment tool, it gives a score for each parameter with the sum giving a total score. It is designed to provide a quick reference to whether the wound is healing.

### CRITICAL THINKING EXERCISE 29.3

Bruce, 77, is admitted to the acute care hospital for a right total knee replacement. He has been fairly immobile for some time because of deterioration in his right knee. Bruce also has diabetes mellitus and is obese. Bruce's postoperative recovery is marked by pain and subsequent wound infection. He experiences a stage III pressure injury to his right heel. What measures could have been taken to prevent Bruce from developing a pressure injury?

## Skin tears

**Skin tears** are injuries caused by shearing, friction or blunt trauma. The skin injury can present as a laceration or skin flap, with separation of epidermis and/or dermis. At highest risk are the elderly due to skin fragility as ageing takes place. Neonates are also at risk because of the immaturity of their skin. These events cause pain and distress to individuals and their families, and in the elderly can often be difficult to heal.

An international consensus panel defined skin tears as:

*A wound caused by shear, friction and/or blunt force resulting in separation of skin layers. A skin tear can be partial thickness (separation of the epidermis from the dermis) or full thickness (separation of both the epidermis and dermis from underlying structures).*

**(LeBlanc & Baranoski 2011)**

### Prevalence

National figures on incidence and prevalence rates of skin tears are difficult to obtain, as there is no national reporting mechanism. These wounds often go unreported, especially in the community (Carville et al 2007; White 2001). In one Australian state survey skin tears were found to be the most prevalent wound in the aged care setting (16%), followed by pressure injuries (10%) (Mulligan et al 2009). Tears were the third most common wound type in the hospital setting, with over half of these being hospital-acquired (Mulligan et al 2009). This correlates with a 16% incidence rate in a 120-bed aged care facility (White et al 1994). Another survey of forty-four aged care facilities found a prevalence rate of 54% (Edwards 1998). White found 64% of RNs working in high care residential aged care facilities reported more than one skin tear a week, with 29% indicating they became aware of between three and five skin tears a week (White 2001).

Skin elasticity and tensile strength decrease as ageing skin loses subcutaneous and dermal tissue and serum composition, which diminishes skin surface moisture.

### Risk factors

Risk factors for skin tears in elderly are complicated by dehydration, poor nutrition and hydration, cognitive impairment, impaired vision or altered mobility and decreased sensation. Further identified risks include age >85; female; long-term steroid use, which thins the skin; a history of skin tears; stiffness and spasticity; dry, fragile skin; polypharmacy; presence of ecchymosis (bleeding into the subcutaneous tissue); dependence for activities of daily living such as use of assistive devices; applying and removing stockings; removal of tape; having blood drawn; transfers and falls; and cardiac, respiratory or vascular comorbidities. There are currently no validated risk assessment tools for the prevention of skin tears.

### Classification for skin tears

Until recently there was only one recognised skin tear classification system, the Payne Martin Classification for Skin Tears (Payne & Martin 1993). This system was later revised to include sub-classifications of three main categories and five types of skin tears (Payne & Martin 1993).

Recent Australian research has developed a new skin tear classification the system, the STAR skin tear classification system, based on consensus from Australian wound nurse experts (Carville et al 2007). This system uses five categories depending on the degree of skin loss (Figure 29.5).

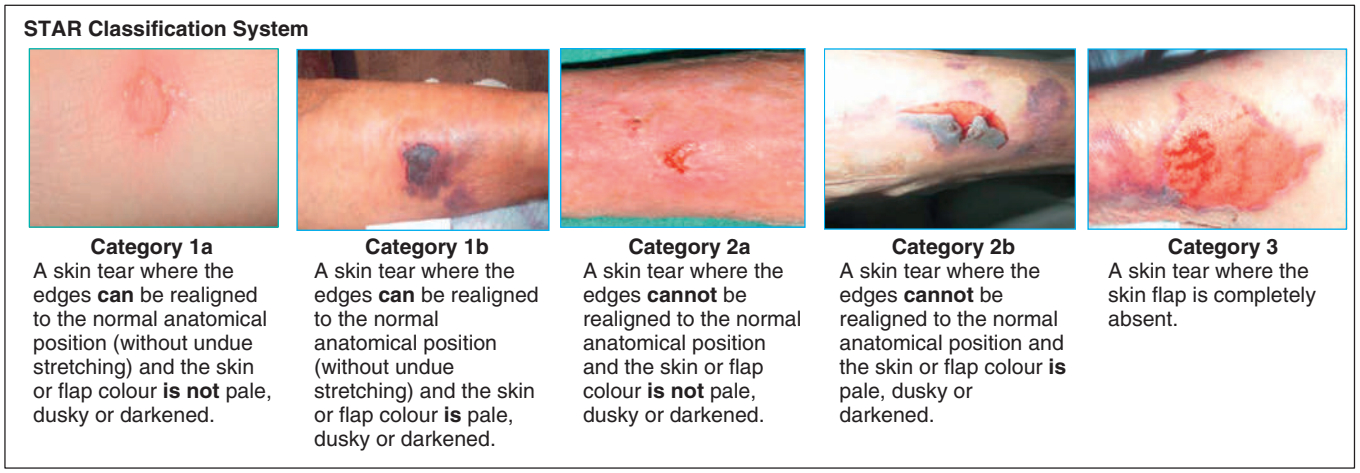

**Figure 29.5** STAR skin tear classification system
*(Carville et al 2007)*

## Skin tear prevention

The majority of skin tears occur during routine care. Any management plans should include strategies that can be adopted by healthcare workers to prevent skin tears from developing and/or prevent further trauma (Stephen-Haynes & Carville 2011). Preventing skin tears should start with early identification of those at risk and should encompass the following identified risk reduction strategies:

- Assess for risk factors
- Practise skin hygiene and responsible bathing: avoid the use of soap; use pH neutral cleansers
- Apply emollients to hydrate the skin and increase suppleness (see Clinical Interest Box 29.10)
- Where adhesive products are used consider the use of silicone-based adhesives or dressings that have a silicone wound contact layer
- Provide appropriate nutrition and hydration
- Use safe clothing that is easy to apply and remove and is protective
- Address environmental risk factors by padding surfaces, removing falls risks and providing uncluttered areas and adequate lighting
- Use correct manual handling techniques for turning, transferring and positioning
- Avoid use of tapes
- Trim individual's finger and toe nails and carer's finger nails (Bianchi 2012).

### CLINICAL INTEREST BOX 29.10 Skin tear research

Recent research by Carville et al (2014) identified that applying moisturising creams twice a day can prevent traumatic wounds from developing by 50%. As we age skin becomes thinner, dryer and more fragile, tears easily and heals more slowly. Skin tears can often lead to chronic wounds such as leg ulcers, which are painful and debilitating. This research demonstrates that by simply applying moisturiser twice a day we can prevent traumatic wounds from developing. With over 430 000 Australians affected by chronic wounds like skin tears, and the cost to the healthcare system approximately $2.6 billion per year, this simple regimen can improve outcomes for individuals.

*(Carville et al 2014)*

## Assessment

Assessment of a skin tear is the same as for other wound types. The cause of the skin tear must be established if possible to implement preventative measures. Full systems assessment, which includes comorbidities, individual's age, medical and surgical history, medications and general health status, will determine the potential for wound healing.

Other factors to consider are:

- Anatomical location
- Wound dimensions (length, width and depth)
- Exudate—type and amount
- Size and depth of skin and skin flap
- Haematoma formation
- Condition of the peri-wound skin (e.g. fragility)
- Pain
- Signs and symptoms of infection where the skin tear is more than a few days old.

The arms and lower leg are reported to be the most common location for skin tears (Payne & Martin 1993).

See Clinical Skill 29.4 for guidelines and information on assessment and management of skin tears.

## Management

Given the lack of available guidelines at this time, best practice wound management principles ensure evidence-based treatment is used in the management of skin tears (Ratliff & Fletcher 2007; Stephen-Haynes & Carville 2011). Essential criteria for creating a management plan are: assessment (as discussed above), documentation, cleansing, moist wound

### CLINICAL SKILL 29.4 Assessment and management of skin tears

**Review and carry out the standard steps for all clinical skills/interventions**

| NMBA Decision-making Framework considerations: | Equipment: |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile dressing pack and dressing materials<br>Additional light source (if required)<br>Gloves<br>Disposable apron<br>Normal saline<br>Waste receptacle<br>Dressing trolley<br>Mask and eye protection as required |
| **Skill activity** | **Rationale** |
| Skin tears can result in partial or full separation of the layers of the skin. They may be caused by friction and/or shearing forces and require treatment to prevent wound contamination and infections. | |

| Dispose of gloves and perform hand hygiene<br>Put on clean non-sterile gloves | Removes microorganisms and prevents cross-contamination |
| Control bleeding (if present), cleanse wound with warm 0.9% sodium chloride solution, remove debris (if required). Realign skin tear | Cleans wound and prepares for dressing application<br>Allows for more accurate wound assessment |
| Apply wound dressing as required<br>Ensure dressing extends over the wound edge by at least 1.5–2 cm<br>Before applying, draw arrow on top of dressing in direction of skin flap and write due date for removal | Covers wound and prevents spread of microorganisms<br>Reduces risk of trauma on removal of dressing |
| Assist the individual to reassume a comfortable position | Promotes comfort of the individual |
| Remove and attend to the equipment appropriately. Perform hand hygiene | Prevents spread of microorganisms |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Medico-legal requirement. Provides information about the wound, allows for the planning and implementation of care, monitors healing, and evaluates care. Allows for the planning and implementation of care |

*(ACSQHC 2012; 2015; AWMA 2010; Berman et al 2015; Crisp et al 2013; LeBlanc 2014; LeMone et al 2014; Lynn & LeBon 2012; NHMRC 2010; NMBA 2013; 2016; Rebeiro et al 2013; Rowley & Clare 2011; Smith et al 2011)*

healing principles, dressing selection and consideration of pain and potential infection.

Treatment regimens are best aimed at using low or non-adherent dressings which, when removed, will not strip the skin. Soft silicone or silicone-impregnated dressings are gentle to the skin and provide security to the skin flap. Foam dressings are also gentler to fragile skin and absorb exudate leaking from the wound. Skin sealants or protectants can be used to create a thin film between the skin and the dressing. Adhesive dressings such as film dressings and hydrocolloid dressings are generally discouraged because of the risk of further damage to the skin on removal.

Skin tears in the elderly do not respond well to suturing or staples, as the skin is too thin and fragile.

### Steps to manage a skin tear

1. Stop the bleeding
   - An alginate dressing can be used with light pressure to control the bleeding
   - Where possible elevate the limb
2. Clean the wound
   - Use warm sterile saline or water to clean the surrounding skin
   - If there is a skin flap gently peel back the flap and clean under the flap and the exposed wound
   - If the skin flap is viable lay the flap over the open area to act as dressing
   - Trim any non-viable flap
   - Categorise the skin tear and document on the individual's record
   - Apply a skin sealant or barrier to the surrounding (peri-wound) skin
3. Apply a dressing
   - Select a dressing based on the assessment of the individual, relevant protocols, the condition of the surrounding skin and any discolouration or bruising
   - If using skin closure strips leave space between the strips to allow exudate to drain
   - Aim to leave the dressing in place for several days to avoid disturbing the wound
   - Foam dressings should be marked with an arrow in the direction of the flap to assist removal
4. Review and reassess
   - Remove the dressing in the direction of the arrow being careful not to disturb the skin flap. Consider using adhesive removers to minimise additional trauma to the skin
   - Clean and reassess the skin flap; trim non-viable tissue
   - Assess for signs of infection and non-healing
   - Redress as necessary and document all care given in individual's records.

Where infection is a concern systemic antibiotics or a topical antimicrobial dressing, such as a silver-containing dressing, may be used to help manage infection.

*Helpful tip*: Applying a crepe bandage or a cotton tubular bandage to secure a non-adherent dressing will reduce the risk of further injury from the use of tape and dressing removal and use of a silicone dressing will also reduce the risk of additional trauma to the skin tear on dressing removal.

## LEG ULCERS

Chronic leg ulceration is a common and often recurrent condition, most commonly affecting the over-60 age group. The point prevalence of chronic wounds is estimated to be around 2% of Australians over 60 years of age (Graves & Zheng 2014). Graves and Zheng (2014) found that the total number of cases of venous leg ulcers (VLUs) in public and private hospitals in 2010–11 was 47 299. The cost on the Australian healthcare system of managing and treating leg ulcers is substantial, with the average cost in 2002 being $29 493 per wound (Santamaria et al 2002). A recent study by Graves and Zheng (2014) identified that the total healthcare cost of venous ulcers in both hospital and residential care settings was estimated to be US$802.55 million. This cost rises with the extended length of time taken to heal these wounds. **Leg ulcers** incur cost in hospital admissions and in the community nursing setting because of the need for frequent home visits (Johnson 2007).

Baker & Stacey (1994) in their seminal research study found that 58% of leg ulcers had been present for more than 3 months and 24% for more than 1 year, indicating the chronicity of the problem. Leg ulceration is not a disease but rather a symptom of an underlying disease process. Leg ulcers decrease an individual's quality of life, often causing severe discomfort, inconvenience and social isolation, as well as incurring loss of productivity in the workforce (Douglas 2001; Rich & McLachlan 2003). Non-compliance with treatment of venous leg ulcers is a common problem, which leads to a failure to heal and recurrence. However, there are many different types of leg ulcers and it is important to differentiate between them so that the correct management strategies can be followed. Leg ulcers caused by underlying venous disease are the most common type.

### Primary causes

Leg ulcers are classified according to the vasculature involved:

- Arterial, involving arteries and arterioles
- Venous, involving veins and venules
- Mixed arterial–venous, involving arteries, arterioles, veins and venules
- Lymphatic, involving the lymphatic drainage system.

### Arterial leg ulcers

The underlying cause of pure arterial ulcers is a lack of arterial blood supply caused by peripheral arterial disease, though this usually presents a more complex problem with coexisting disease such as heart disease or diabetes. A history of cardiovascular disease, stroke or intermittent claudication may indicate arterial disease. Predisposing factors are atherosclerosis, advanced age, diabetes mellitus, hypertension, obesity and smoking. These ulcers are frequently located between toes or at the tip of the toes, over phalangeal heads, metatarsal heads

or on the side of the sole of the foot and above the lateral malleolus. Arterial ulcers can present with a well-demarcated edge and a deep pale wound base. The ulcer may be painful unless diabetic neuropathy is present and the leg takes on a hairless, thin, shiny, appearance with dry skin. The toenails may be thickened and often brittle. The leg is pale when elevated and cool to touch. Pedal pulses are often diminished or absent.

## Venous leg ulcers

Ulcers caused by underlying venous disease are referred to as venous ulcers. They can be defined as a 'full thickness defect of the skin that persists due to venous disease of the lower leg' (AWMA & NZWCS 2011). Venous disease can occur for various reasons, a common cause being a deep vein thrombosis (DVT) that damages the valves or walls of the deep veins on the leg (post-thrombotic damage). Where the valves in the large veins (superficial and deep) are damaged they fail to close properly allowing venous blood to move up and down the vein. Blood is allowed to flow back down the leg (retrograde flow) and this is known as venous reflux. Additional pressure is created in the veins, and fails to fall when the combined actions of the calf muscle pump and foot pumps contract through walking. This is referred to as ambulatory venous hypertension. Over time the raised pressure in the veins causes fluid to leak into the tissues resulting in oedema (accumulation of fluid in extravascular tissue) and eventual skin ulceration.

These ulcers can take weeks or months to heal and accurate diagnosis of the underlying aetiology is essential to ensure correct management. Compression therapy using bandages or stockings is the accepted management option and has been shown to heal venous leg ulcers more rapidly compared to no compression (O'Meara et al 2012). Compression bandages or stockings aid venous return of blood to the heart (orthograde flow) and a reduction in venous reflux (see 'Compression therapy for venous leg ulcers' below).

In obtaining a diagnosis of venous disease the person may have a history of:

- Venous disease, confirmed by duplex ultrasound
- Varicose veins and/or surgery
- Family history of leg ulceration
- Proven DVT or phlebitis
- Surgery/fractures to the affected leg
- Episodes of chest pain/pulmonary embolism.

Predisposing risk factors are:

- Pregnancy
- Obesity.

Leg ulcers with underlying venous disease usually occur on the lower leg. They can be small in the pretibial area and anterior to the medial malleolus or larger and circumferential. These ulcers generally have uneven edges and a ruddy granulation tissue and appear to be superficial compared with the arterial ulcer. Discomfort is relieved by elevation of the leg. Venous ulcers are often accompanied by oedema, with fluid seepage and maceration of the surrounding skin. Pruritus and scale formation occurs. The leg can take on a reddish–brown pigmentation caused by haemosiderin, oedema is present and the leg can be quite firm to the touch. There is usually evidence of old healed ulcers, tortuous superficial veins and the limb may be warm to touch. Foot and leg pulses are present. Table 29.9 outlines the difference between venous and arterial ulcers.

## Diagnostic tools for the assessment of leg ulcers

- Comprehensive medical and surgical history
- Physical examination including palpation of specific relative pulses
- Doppler ultrasound measurements—ankle/brachial pressure index (ABPI)[1]
- Photoplethysmography (PPG) measurement of venous refill
- Transcutaneous oxygen perfusion measurements
- Duplex scans
- Arteriography.

## Arterial leg ulcer management strategies

The management of arterial leg ulcers is very different from the management of venous leg ulcers:

- Consultation with a vascular surgeon is recommended at an early stage
- Treatment of the underlying disease is important
- Angiography or angioplasty may be required
- Chemical sympathectomy may be required
- Bypass surgery or amputation may be required.

## Compression therapy for venous leg ulcers

Compression therapy is indicated in the management of pure venous leg ulcers. The aim is to reduce the venous hypertension in the leg through compression of the veins using strong bandages or stockings. This will return extracellular fluid to the venous system, reducing limb oedema. Compression of the lower leg narrows the major veins reducing the local blood volume and redirecting blood to the heart. It also narrows the diameter of the vessels increasing the velocity of flow through the vein. Compression can be applied as bandages, stockings or pneumatic compression (dynamic compression). These systems compress the entire lower leg and are contraindicated for individuals with poor arterial circulation, as this circulation can be further compromised. Pressure is determined by the tension (stiffness) of the bandage, the circumference of the limb and the width and number of layers applied (Partsch 2012; Thomas & Fram 2003). A pressure of 30–40 mmHg measured at the ankle aims to achieve a reduction in venous hypertension though it does not account for different limb sizes, bandage application techniques, posture and movement of the limb, condition of the bandage or stocking and skill of the bandager. The pressure may decline over a period of time and re-bandaging

[1]The presence of adequate arterial circulation is a not a default diagnosis for a venous leg ulcer. An ABPI may not be a reliable diagnostic tool in clients with diabetes where arterial calcification can prevent arterial compression and falsely elevate the systolic arterial pressure.

**TABLE 29.9 | Differentiating between venous and arterial ulcers**

| Indicator | Arterial | Venous |
|---|---|---|
| Predisposing factors | Arteriosclerosis<br>Advanced age<br>Diabetes<br>Hypertension<br>Smoking | History of deep vein thrombosis (DVT)<br>Valve incompetence in the deep, superficial or perforating veins<br>Obesity |
| Associated changes in the leg and skin | Thin, shiny, dry skin<br>Thickened nails<br>Absence of hair growth<br>Pallor on elevation of legs<br>Limb may be cool to touch | Firm ('brawny') oedema<br>Reddish brown pigmentation<br>Evidence of healed ulcers<br>Dilated and tortuous superficial veins<br>Limb may be warm to touch |
| Ulcer location | Between toes or at tip of toes<br>Over phalangeal heads<br>Above lateral malleolus (for diabetes or high occlusion), over metatarsal heads, on side or sole of foot | Anterior to medial malleolus<br>Pre tibia area<br>Generally lower third of leg |
| Ulcer characteristics | Well demarcated edges<br>Black or necrotic tissue<br>Dry ulcer bed<br>Deep, pale base | Uneven edges<br>Ruddy granulation tissue<br>Slough in wound bed |
| Pain | Exceedingly painful<br>Pain at rest, relieved by lowering leg to a dependent position | Moderate to no pain<br>Discomfort relieved by elevation of leg |
| Surrounding area | May have neuropathy | Leaking exudate can cause maceration and excoriation |
| Foot/leg pulses | Diminished or absent foot | Usually normal |

*(Carville 2012)*

is required. Pressure beneath the bandage is measured in three main ways: working pressure (when the individual is walking), resting pressure (at rest) and a third factor called the static stiffness index (SSI), which is the increase in pressure per centimetre increase in the circumference of the leg, or the difference in pressure between the supine and standing position (Partsch 2005a; 2012). A high SSI (above 10 mmHg) is considered a more inelastic compression system that produces a higher pressure when standing than when lying (Partsch 2005b; 2012).

Venous and mixed vessel disease ulcers are assessed for suitability to have compression therapy; the type and degree of pressure is determined upon completion of investigations and test. A medical practitioner or advanced practice nurse recommends the appropriate compression bandaging system to apply. An initial trial of bandaging is monitored for increased pain, discolouration of the toes, change of sensation (tingling or loss of sensation), increased oedema in the toes and individual compliance. If an individual is unable to tolerate compression bandages safely, lower compression levels can be applied to build tolerance. The type of bandage or stocking must also try to suit the lifestyle and ability of the individual in self-management.

## Compression bandages

Compression bandages are generally divided into elastic and inelastic bandages. This classification is suitable for a more powerful single layer elastic bandage but does not account for multilayer systems that use two or three layers of weak elastic bandages to achieve compression. Elastic bandages are highly extensible and accommodate changes in the shape of the limb with the contraction of the calf muscle when walking. This gives minimal changes in pressure beneath the bandage and sustained compression at rest. Inelastic bandages have minimal extensibility and greater fluctuations in pressure between walking and resting. Pressure is highest with walking as the expanded calf muscle pushes against the rigid bandage (Partsch 2012). Multilayer bandage systems of three or four layers combine inelastic and elastic bandages with a padding layer and/or crepe bandage where the components have different functions of protection, padding and retention. A Cochrane Review found compression increases ulcer healing rates compared with no compression. Multicomponent systems are more effective than single-component systems. Multicomponent systems containing an elastic bandage appear to be more effective than those composed mainly of inelastic constituents. Two-component bandage

systems appear to perform as well as the four-layer bandage (4LB). Individuals receiving the 4LB heal faster than those allocated the short stretch bandaging technique (SSB). More individuals heal on high-compression stocking systems than with the SSB. Further data are required before the difference between high-compression stockings and the 4LB can be established. Multilayer compression systems (compression bandages) appear to be more effective than single layer systems (O'Meara et al 2012).

The application of compression bandages requires advanced skills and knowledge to ensure correct application. A normally shaped leg has a narrower ankle and wider calf circumference. Compression levels are graduated when a bandage is applied with constant tension and overlap, with a higher pressure achieved at the ankle due to its narrower circumference, reducing by approximately 50% when it reaches below the knee (tibial tuberosity).

### Graduated compression stockings (GCS)

Graduated compression stockings have been shown to be as effective as multilayer compression systems (AWMA & NZWCS 2011). They are generally used for individuals with healed ulcers to prevent recurrence. Regular use and replacement is necessary to maintain compression.

### Pneumatic compression

Pneumatic compression is the application of an inflatable boot to the leg continuously, intermittently or in sequential cycles. It is used in the prevention of deep vein thrombosis, though there is some evidence to suggest it may play a role in the healing of venous leg ulcers.

### Preventing recurrence

Venous leg ulcer recurrence may be prevented with the use of long-term compression at the strongest compression tolerated by the individual (Nelson et al 2000) to increase compliance. In individuals with superficial venous insufficiency surgery and compression may be more effective than compression on its own (Barwell et al 2004).

### Personalised education and support

Leg ulcer education is centred on prevention of recurrence, chronic disease management and general health and lifestyle issues such as nutrition. In some areas leg ulcer clubs have been created to promote these aspects of care and to provide support and education about leg ulcers. These clubs also provide and allow ownership of the person's wound and disease (Kapp et al 2010).

Leg ulcers often require long-term complex dressing, regimens including packing of the ulcer to aid healing. See Clinical Skill 29.5.

## BURN INJURIES

Burns are considered one of the most traumatic injuries for a person to sustain. The physical trauma of a burn goes beyond the damage to the skin. A major burn can cause systemic complications in the short to medium term and physical and emotional complications in the medium to long term.

Dry heat, moist heat, chemicals, electricity or radiation can cause **burn injuries**. When a heat source comes in contact with the skin, the transfer of heat causes structural damage. Heat causes coagulation of the protein in tissue cells (cell damage starts at 41°C; protein coagulation at 50°C), and the depth of the burn is related to the amount of thermal energy dissipated in the skin, which is dependent on the temperature and duration of exposure.

After a burn injury, intravascular fluid is lost as the capillaries become more permeable. As the intravascular fluid volume decreases, the venous return and cardiac output fall. The clinical signs of 'shock' become apparent and tissue hypoxia threatens internal organs such as the kidneys. Other changes occur in organ function, in electrolyte levels and in metabolic function. Subsequently, complications of major burns can involve any body system because all systems are stressed during the injury and during healing.

### Classification of burns

Burn injuries are classified according to the depth of tissue injury. Where burn injuries were classified by first, second and third degree the classifications now reflect the anatomical thickness of the skin layers: epidermal, superficial dermal, mid dermal, deep dermal and full thickness (Table 29.10).

### Epidermal burns

In superficial burns only the epidermis is involved, with the basal layer of the epithelium remaining intact. The skin is dry, red (erythematous) and oedematous and the skin is hypersensitive. Superficial burns generally heal within 7 days without scarring and treatment is usually conservative to manage pain, maintain adequate hydration and moisturise the burned area.

### Superficial dermal burns

Partial thickness burns have damage to the epidermis and to the superficial dermis (papillary dermis). They may blister as serum is released from injured blood vessels and have a moist surface. They can be painful, blanch with pressure and have brisk capillary return indicating blood vessels are intact. If the blisters burst, the area beneath is pink, swollen and wet and blanches with pressure. When the superficial dermis has been injured, the raw area is resurfaced with epithelium growing from the undamaged walls of the sweat glands and hair follicles. Healing is usually complete within 14 days if there are no complications with minimal scarring, though there may be reduced pigmentation of the skin.

### Deep partial thickness burns

Deep partial thickness burns (mid dermal burns) extend into the reticular dermis. These burns may blanch with pressure but capillary return is sluggish or absent as blood vessels are destroyed; there is also less leakage of serum. Blisters are not usually present and the burn surface is moist or dry. Deeper partial thickness burns result in diminished sensation, as the dermal nerve endings are destroyed and the burn can be

## CLINICAL SKILL 29.5 Packing a wound

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile dressing pack and dressing materials<br>Additional light source (if required)<br>Gloves<br>Disposable apron<br>Normal saline<br>Additional cotton balls or gauze balls<br>Waterproof sheet (Bluey)<br>10 mL syringe<br>Sterile scissors<br>Sterile gloves<br>Waste receptacle<br>Dressing trolley<br>Mask and eye protection as required |

| **Skill activity** | **Rationale** |
|---|---|
| Wound packing is undertaken to provide a moist cover for the wound to prevent the introduction of microorganisms and to promote healing. Wounds requiring packing heal by secondary intent. The wound packing promotes healing for this type of wound. The type of dressing used also absorbs exudate. | |
| Assess the individual's record to determine previous appearance of wound and any previous dressings<br>Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for pain<br>Assess for any allergies<br>Visually assess the wound for signs and symptoms of infection and dressings used | Determines requirements for equipment and dressing requirements<br>Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Pain may be caused during the procedure<br>Determines any adverse reactions to wound irrigation solution, dressing or tape (if required) |
| Assist the individual to assume an appropriate position of comfort, ensuring that only the wound area is exposed<br>Obtain additional assistance if required | Promotes comfort and facilitates performance of the procedure<br>Assistance is available when required |
| Place the equipment in a convenient location near the bedside. Open procedure pack using corners. Assemble the required equipment, using aseptic technique. Drop sterile equipment into sterile field | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the dressing is being performed<br>Prevents contamination of sterile items<br>Additional items are available for use |
| Perform hand hygiene and loosen wound dressing | Prevents spread of microorganisms and allows ease of removal of wound dressing |
| Put on apron. Perform hand hygiene, apply gloves if required. If other PPE required put on before gloves | Prevents spread of microorganisms |
| Position dressing towel around the wound, remove old dressing and place in waste bag/container | Protects the wound from environmental contamination |
| Dispose of gloves and perform hand hygiene<br>Put on clean non-sterile gloves or sterile gloves if required | Removes microorganisms and prevents cross-contamination |
| Irrigate wound packing (if already present) with normal saline | Allows for packing to be removed without causing removal of healing tissue. Causes less discomfort for the individual |

*Continued*

| CLINICAL SKILL 29.5 Packing a wound—cont'd | |
|---|---|
| Observe the wound for size, union, signs of infection, exudate, odour, inflammation and healing. Assess for pain | Evaluates condition of the wound and stage of healing |
| Cleanse the wound with sterile normal saline in accordance with the practices of the healthcare facility, medical officer's orders or as directed by the nurse in charge. Clean from a clean area towards a less clean area, usually an outward direction | Wound cleansing removes debris from the wound. Avoids transferring wound exudate and normal flora from the surrounding skin into the wound, and thus prevents wound contamination |
| Using forceps, gently pack the wound with the required packing materials. (See medical officer's or wound management consultant's orders.) Ribbon or packing gauze is gently pushed into the wound cavity.<br>**Note:** Do not completely fill the wound with hydrogel or hydrocolloid rope as these will expand as they absorb exudate | Packing allows for secondary wound healing. |
| Using forceps apply an appropriate clean dressing over the wound to provide a moist wound-healing environment and secure it in position | Provides a moist wound environment. Facilitates healing, absorbs exudate, protects the wound from infection and irritation (e.g. from clothing) |
| Remove personal protective equipment and discard with used equipment in an appropriate waste receptacle | Prevents spread of microorganisms |
| Assist the individual to reassume a comfortable position | Promotes comfort of individual |
| Remove and attend to the equipment in correct manner. Perform hand hygiene | Prevents spread of microorganisms |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team. Include date and time, appearance of wound and any exudate, cleansing solution, type of primary and any secondary dressing used, and the individual's response to the dressing. Medico-legal requirement. Allows for the planning and implementation of care |
| *(ACSQHC 2012; 2015; AWMA 2010; Berman et al 2015; Crisp et al 2013; LeMone et al 2014; Lynn & LeBon 2012; NHMRC 2010; NMBA 2013; 2016; Rebeiro et al 2013; Rowley & Clare 2011; Smith et al 2011)* | |

painless. Healing is slower as more skin structures, such as hair follicles, are destroyed. These burn injuries may require early surgical excision of dead tissue and skin grafting to speed recovery to reduce the risk of infection and minimise scarring. These burns will take longer to heal (>21 days).

### Deep dermal burns

Deep dermal burns leave damage to all layers of the skin and the injury may extend to underlying fat, muscle and bone. Epidermal appendages are destroyed and the burn area is painless. The appearance of the burned area can vary and may be white, waxy, tan coloured, red or charred. The area is dry and feels hard. Because all layers of the skin are destroyed early surgical excision of dead tissue and skin grafting or covering with artificial skin is performed, to assist closure of the burn area. Scarring will occur and, depending on the anatomical region involved, there may be functional impairment. These burns also take longer to heal (>21 days).

### Full thickness burns

Burns of this depth leave damage to all layers of the skin, the subcutaneous fat layer, muscle and often bone. The damaged tissue appears charred, firm and dry. There is no pain and limited or no movement of involved extremities. These burns may result from an electrical current or prolonged contact with flame; for example, an unconscious person unable to move from the source of the burn. They require surgical intervention for dead tissue removal and skin grafting. Scarring will occur to the damaged areas.

## Assessing burn severity

An experienced burn clinician should assess burn injuries, especially burns that require admission to hospital. The severity of a burn is largely dependent on its size and depth. Assessing burn depth and size correctly is important as treatment pathways differ depending on the severity of the burn.

## TABLE 29.10 | Burn depth characteristics

| | Superficial epidermal (e.g. sunburn) | Superficial dermal thickness (partial) | Mid dermal thickness (partial) | Deep dermal thickness (partial) | Full thickness |
|---|---|---|---|---|---|
| | | | | | |
| Pathology | Involves epidermis only | Involves epidermis and upper dermis; most adnexal structures intact | Involves epidermis and mid dermis; adnexal structures may be disrupted | Involves epidermis and significant part of dermis, with deeper adnexal structures damaged but viable | Epidermis, dermis and cell adnexal structures destroyed |
| Appearance | Dry and red, blanches to pressure. No blisters | Pale pink. Smaller blisters. Wound base blanches with pressure | Variable pale to dark pink, may have blisters present | Blotchy red or pale deeper dermis where blisters have ruptured | White waxy charred. No blisters. No capillary refill |
| Sensation | Painful | Increased sensation. Very painful and tender | Some nerve endings remain viable; pain is present but less severe than pain of superficial burns | Decreased sensation | No sensation |
| Circulation | Normal, increased | Hyperaemic<br>Rapid capillary refill | Capillary return is present but delayed | Sluggish capillary refill | Nil |
| Colour | Red, warm | Pink | Pale to dark pink | White/pale pink/blotchy red | White/charred/black |
| Blisters | None or (days) later or desquamation | Yes (within hours of injury) | Yes, may be present | Early—usually large blisters which rupture rapidly and slough | Epidermis and dermis destroyed, no blistering |
| Healing time | Within seven days | 7–14 days | 7–28 days | Over 21 days | Does not heal spontaneously |
| Scarring | No scar | Colour match defect. Low risk of hypertrophic scarring | Prolonged healing with possible scarring and contracture. Deeper areas or over a joint may need surgical intervention and referral to a specialist unit | High risk (up to 80%) of hypertrophic scarring | Wound contraction<br>Heals by secondary intention |

*ANZBA (2015); Victorian State Burns Clinical Practice Guidelines (2012)*

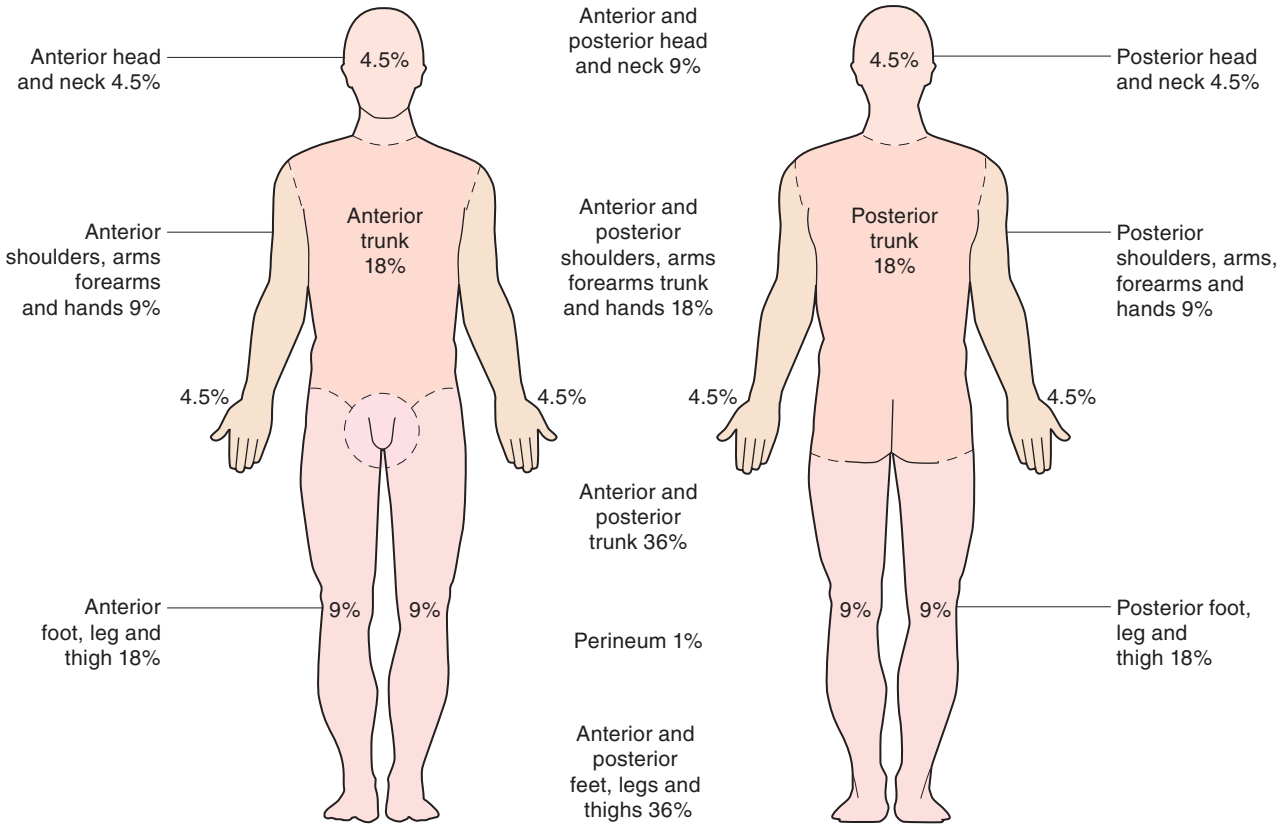

**Figure 29.6** Assessing burn surface area: rule of nines (adults)

Furthermore, the greater the severity, the greater the amount of fluid lost from the body, and the greater the degree of shock that ensues. To assess the size of a burn accurately, a chart is used on which the size is expressed as a percentage of the total body surface.

Two methods exist to calculate burn size: the 'rule of nines' (Figure 29.6) and the Lund–Browder method (Figure 29.7). The rule of nines divides the body into areas that equal 9% which, when totalled, equal 99% with the genitalia accounting for the remaining 1%. For example, the front and back of each leg is 9%, each arm is 4.5%; the upper and lower torso is 9%. This method is quick and easy though less accurate than the Lund–Browder method, which is more accurate as it allows for changes in body proportion with age. The numbers on each body portion on the chart indicate the percentage of body surface for that part. Both types of chart provide a means of determining the extent of the burn or the total body surface area (%TBSA). Areas of erythema are not included in the calculations.

## Causes of burn injury

While there are many ways a burn injury can be sustained, for example, thermal, chemical, electrical, friction or abrasion, all burn injuries cause cell death and tissue ischaemia. The Jackson's Burn Wound Model (Singh et al 2007) describes three areas of tissue injury: *zone of coagulation* (necrosis) nearest the source of injury, where there is irreversible tissue damage; *zone of stasis* (ischaemia), where there is damaged tissue and decreased circulation, but potentially viable tissue; and the *zone of hyperaemia*, in which there is oedema and reversible increased blood flow. Interventions that preserve tissue perfusion in the zones of stasis and hyperaemia potentially decrease burn wound progression or deepening tissue damage (necrosis). Where interventions are suboptimal there is the potential for a partial thickness burn to progress to a full thickness burn in the first 3 to 5 days, thus causing burn wound conversion and making burn depth assessment difficult.

### Thermal burns

Flame and scald burns are the most common types of thermal injury (ANZBA nd; Burns Registry of Australia and New Zealand nd) and are caused by three main mechanisms: conduction (coming into contact with hot objects e.g. hot fluids (scald burns)), radiation (e.g. heat lamp) and convection (e.g. explosion). Scald injuries account for over 38% of burns, flame burns for 32% and contact burns for 16% of all cases. The most common cause for burn injury among children was scalds (57%) followed by contact (20%) and flame (11%) (ANZBA nd; Burns Registry of Australia and New Zealand nd).

### Chemical burns

Chemical burns result from direct contact with the substance or through ingestion or inhalation of acids, alkalis or organic

Percentage of areas affected by growth

| | 0 | 1 | 5 | 10 | 15 | Adult age |
|---|---|---|---|---|---|---|
| A=0.5 head | 9.5 | 8.5 | 6.5 | 5.5 | 4.5 | 3.5 |
| B=0.5 one thigh | 2.75 | 3.25 | 4 | 4.25 | 4.5 | 4.75 |
| C=0.5 one leg | 2.5 | 2.5 | 2.75 | 3 | 3.25 | 3.5 |

To estimate the total of the body surface area burned, the percentages assigned to the burned sections are added. The total is then an estimate of the burn size.

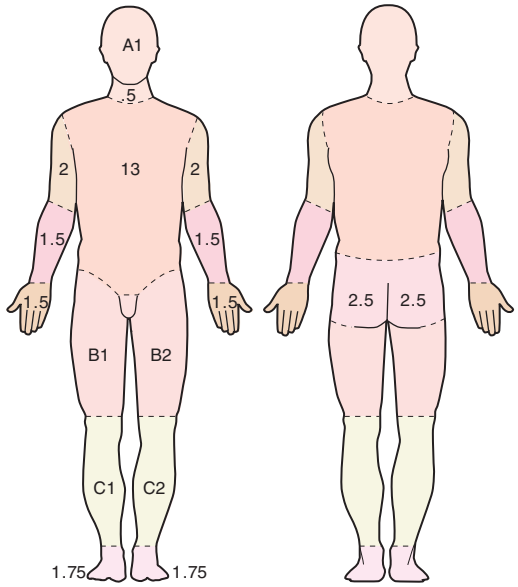

**Figure 29.7** Assessing burn surface area: Lund–Browder method

materials. The severity of the burn depends on the type and concentration (pH) of the agent and the duration of contact. Individuals with chemical burns should have treatment commenced at the scene of the injury. Contaminated clothing should be removed and the area irrigated with clean water, especially burns to the eyes, which require a minimum of two litres of water, before transfer to hospital (Cinat & Smith 2006).

### Electrical and lightning burns

Faulty electrical wiring, contact with overhead power lines and high voltage power cables can all be sources of electrical burns. The tissue damage from these burns can be underestimated due to the internal damage that results, as it is not always visible on admission and the skin can appear normal yet have muscular tissue destruction beneath it. There will be an exit wound as the electrical current has travelled through the body. Cardiopulmonary function must be assessed in these individuals. Lightning burns can cause cardiac arrest and serious nerve damage.

### Friction or abrasion burns

Friction burns are becoming more common, especially in children who injure themselves on exercise machines such as a treadmill. In adults friction burns result from car and motorbike accidents (road rash) (ANZBA nd; Burns Registry of Australia and New Zealand nd).

### Inhalation

There is a risk of inhalation injury in individuals who have been in fires as there is exposure to smoke, especially in an enclosed area such as a house fire. Inhalation injury should also be suspected and assessed in individuals with facial burns, singed nasal hairs and ash in the oropharynx. These burn injuries should always be referred to hospital for full assessment and monitoring.

## Management of the individual with burn injuries

Management is determined by the depth and size of the burn. Effective treatment must be in place in the first 24 hours to reduce the damaging effects of inflammation and to avoid burn wound conversion and deeper tissue injury and it begins with effective first aid. Smaller superficial burns may be managed in the primary health setting. Full thickness and sub-dermal burns should be hospitalised and managed in a specialist burn centre. Nursing Care Plan 29.1 provides an overview of nursing care for an individual with a burn injury.

### First aid for burn injuries

Adequate and appropriate first aid is vital to the successful management of a burn injury. Applying cool running water for the first 20 minutes within the first 3 hours of a burn injury is considered to be best practice for a burn injury (ANZBA 2015; Cuttle et al 2010). It can limit the extent of burn depth, the amount of pain and reduce the area of skin affected by the burn. Individuals with larger burns need to be monitored for hypothermia if cool running water is applied for longer periods. Lotions, creams, butter, aloe vera, toothpaste and ice are all to be avoided as they either mask the full extent of the burn or can interfere with the ongoing management. There is no agreement on the type of burn management a burn-injured individual should receive prior to transfer and consultation should be with the treating burn surgeon.

### When to refer to a specialist burn centre

The Australian and New Zealand Burn Association (ANZBA 2015) provides criteria for when an individual needs to be referred for specialist treatment:

- Burns greater than 10% of total body surface area (TBSA)
- Full-thickness burns greater than 5% of TBSA
- Burns of special areas—face, hands, feet, genitalia, perineum, circumferential limb or chest burns, and major joints
- Electrical burns
- Chemical burns
- Burns with inhalation injury
- Burns with pre-existing illness
- Burns at the extremes of age—young children and the elderly
- Burn injury in pregnant women
- Non-accidental burns
- Burns associated with major trauma.

## NURSING CARE PLAN 29.1

**Assessment:** Skin integrity impaired
Standard 8 Prevention and Management Pressure Injuries—NSQHS standard
**Issue/s to be addressed:** Immobility leads to pressure, shear and friction, and is the factor most likely to put an individual at risk for altered skin integrity. Extremes in age (very young and very old); inadequate nutrition, environmental moisture, (incontinence); and vascular insufficiency potentiate the effects of pressure and hasten the development of skin breakdown.
**Risk factors:**
Pressure on the tissue from impaired mobility, activity or sensation
Tissue integrity that is adversely affected by environmental factors (such as shear or friction forces acting on the skin)
Factors related to the individual (such as nutritional status, oxygen delivery, skin temperature, age and gender, the use of high-risk medicines (i.e. non-steroidal anti-inflammatories) or the presence of chronic disease)
**Goal/s:** The individual's skin remains intact, as evidenced by no redness over bony prominences and capillary refill <6 seconds over areas of redness

| Care/Actions | Rationale |
|---|---|
| Identify risk factors for pressure injuries using an agreed screening tool within 8 hours of admission<br>Undertake a comprehensive skin inspection | Tools can be effective in assisting clinicians to screen for pressure injury risk; this should be combined with clinical judgment<br>Healthy skin varies from individual to individual, but should have good turgor (an indication of moisture), feel warm and dry to the touch, be free of impairment (scratches, bruises, excoriation, rashes) and have quick capillary refill (less than 6 seconds) |
| Update risk and skin assessment daily, as well as when the individual's condition changes, on transfer to another department or facility and prior to discharge | Ongoing assessment is necessary in order to detect early signs of pressure damage, especially over bony prominences |
| Assess the individual's nutritional status | Nutritional screening is the process used to identify individuals who require a comprehensive nutrition assessment. This should be conducted on admission to the healthcare facility or at first visit in community settings |
| Assess skin over bony prominences (sacrum, trochanters, scapulae, elbows, heels, inner and outer malleolus); do not position individual on site of skin impairment | Areas where skin is stretched over bony prominences are at higher risk for breakdown because the possibility of ischaemia to skin is high as a result of compression of skin capillaries between a hard surface and the bone |
| Assess the individual's awareness of the sensation of pressure | Normally individuals shift their weight off pressure areas every few minutes; this occurs more or less automatically, even during sleep. People with decreased sensation are unaware of unpleasant stimuli (pressure) and do not shift weight. This results in prolonged pressure on skin capillaries and, ultimately, skin ischaemia |
| Assess for faecal and/or urinary incontinence and any environmental moisture; if the person is incontinent implement an incontinence management plan to prevent exposure to chemicals in urine and stool that can strip or erode the skin | Keeping skin clean and dry and the use of emollients promote healthy skin that will be resilient to any insults from irritants and shear and pressure. It is important to remember that skin damage from moisture increases the risk of pressure ulceration<br>The urea in urine turns into ammonia within minutes, and is caustic to the skin. Stool may contain enzymes that cause skin breakdown |

## NURSING CARE PLAN 29.1—CONT'D

| Care/Actions | Rationale |
|---|---|
| Assess amount of shear and friction on the person's skin | A common cause of shear is elevating the head of the person's bed; the body's weight is shifted downwards onto the individual's sacrum. Individuals should be positioned and supported to prevent sliding down in bed and creating shear forces. Limit head-of-bed elevation to 30 degrees. Using the knee brake on the bed will also help minimise the person's body slipping downwards in the bed. Common causes of friction include the person rubbing heels or elbows against bed linen and moving the patient up in bed without the use of a lift sheet |
| Assess the individual's ability to move (shift weight while sitting, turn over in bed, move from bed to chair) | Immobility is the greatest risk factor in skin breakdown |
| Assess surface that the individual spends majority of time on (mattress, cushion) | Individuals who spend the majority of time on one surface need a pressure reduction or pressure relief device to distribute pressure more evenly and lessen the risk for breakdown |
| Implement measures to prevent tissue breakdown associated with decreased mobility:<br>• Position the individual properly; use high-specification mattress or pressure redistributing support surface if indicated<br>• Instruct the individual to use overhead trapeze to lift self and shift weight at least every 30 minutes<br>• Lift and move the individual carefully using a turn sheet and adequate assistance<br>• Change the individual's position when in bed at least every 2 hours around the clock | Repositioning of an individual is undertaken to reduce the duration and magnitude of pressure over vulnerable areas of the body and to contribute to comfort, hygiene, dignity and functional ability<br>Regular positioning is not possible for some individuals because of their medical condition, and an alternative prevention strategy such as providing a high-specification mattress or bed may need to be considered<br>The timing of repositioning of the individual is determined by the individual's tissue tolerance; level of activity and mobility; general medical condition; overall treatment objectives; skin condition and comfort |
| Referral to other health professionals as clinically indicated for assessment and treatment | Other interprofessional team members (i.e. physician, nurse, speech pathologist, occupational therapist, physical therapist) should develop and document an individualised intervention plan based on the individual's clinical needs |
| Education—teach the individual and caregiver the cause(s) of pressure injury development:<br>• Pressure in skin, especially over bony prominences<br>• Incontinence<br>• Poor nutrition<br>• Shearing or friction against skin | Information should initially be provided to the person and their family/carer at the time of assessment and care planning, and throughout the episode of care. This ensures they understand the importance of this prevention plan. Reinforce the importance of mobility, turning or ambulation in prevention of pressure injury |

**Evaluation**

The individual's skin remained intact with nil erythema present. Interventions for this care/action were effective in preventing skin breakdown.
The individual was able to demonstrate understanding of pressure injury prevention actions.

*(ACSQHC Standard 8 2012; Klopp et al nd)*

## Emergency department management

The aims of initial management are to minimise further tissue damage, stabilise the individual, identify and assess further injuries and initiate fluid resuscitation. Assessment is made regarding the cause of the burn (flame, chemical, electrical), the time of injury, type of first aid given, tetanus history and loss of consciousness. Assessment of burn depth, size and location is then made. Burn management should not preclude resuscitation and emergency management of the individual.

## Hospital management

Once the individual is stabilised management will depend on a range of factors with the main aspects of care being:

1. Ongoing fluid management
2. Burn wound management
   - Prevention of infection
   - Debridement of dead tissue, blisters, loose skin
   - Rapid skin coverage
3. Adequate nutrition
4. Pain relief
5. Promotion of mobility
6. Scar management
7. Psychological support
8. Preparation for discharge.

## Fluid resuscitation

If the burned area is not too great (e.g. less than 15% in an adult, less than 10% in a child), the body generally compensates adequately for the fluid loss, and only the provision of extra oral fluids is indicated. In more extensive or severe burns, fluid loss is a major cause of shock, so fluid replacement is of prime importance. Fluid resuscitation rates are calculated from the time of injury and are based on the size and depth of the burn, age of the individual and pre-existing illnesses and other factors such as dehydration. The medical officer calculates the volume of fluid replacement required and prescribes the type of fluid to be administered. There are various resuscitation formulas; however, these should be used only as a guide to fluid replacement. Intravenous fluid administration is through peripheral and central access in large burns. Extensive full thickness burns may also require a blood transfusion to compensate for a reduction in erythrocyte numbers. Intravenous fluid replacement with electrolytes is continually calculated and adjusted according to need. Individuals with electrical and inhalation injuries have higher fluid requirements.

Monitoring techniques that may be performed to assess fluid requirements include:

- Insertion of a urinary catheter to enable hourly monitoring of urine output. Hydration aims at maintaining a urine output of 0.5–1.0 mL/kg/hour in an adult and 0.5–2.01 mL/kg/hour in a child (Cinat & Smith 2006; NSW Health 2014)
- Advanced monitoring methods including central venous pressure measurements, oxygen consumption and delivery, serum lactate, pulmonary artery catheter measurements and monitoring of base deficit (Cinat & Smith 2006).

## Wound management

Burn wound management is aimed at preventing infection and providing early skin coverage with dressings or skin grafts. The wound can change in depth and appearance over the first few days and treatment plans should reflect these changes. Wound care consists of regular observation, assessment, cleansing and debridement. Showers and bedside cleansing are used to remove old dressings and loose necrotic skin. Occlusive dressings maintain a moist wound environment, enhance the healing process and reduce the risk of scarring as well as reducing exposure to contamination. These are suitable for superficial dermal burns. Deeper burns require an antimicrobial dressing to decrease microbial load and reduce the risk of infection. Moist wound healing produces better cosmetic outcomes with less scarring. Negative pressure wound therapy (NPWT), though used less frequently in burn wounds, is placed over skin grafts to improve graft take (Runkel et al 2010). Permanent and temporary skin covers are discussed below.

Infection prevention is a priority and the most serious threat to further tissue necrosis and wound sepsis. Methods of preventing infection include:

- The use of aseptic non-touch technique (ANTT) principles to prevent cross-infection (see Clinical Interest Box 29.11)
- Topical antimicrobial dressings (silver dressings)
- Systemic antibiotic therapy
- Enhancing natural defences (e.g. by providing a high-protein/kilojoule diet and treating any anaemia).

***Escharotomies*** Eschar is dead tissue which may present in circumferential full thickness burns. The development of eschar causes increased tissue pressure, which may impair circulation and lead to ischaemic necrosis. An escharotomy (release of skin and subcutaneous tissue) is a surgical procedure performed to release constriction of the eschar to prevent secondary ischaemic necrosis. A longitudinal incision is made through the eschar and is extended across joints. As the eschar does not contain nerve endings the procedure is painless, but is still performed under an anaesthetic. It results in open wounds, which provide a portal for infection.

***Prevention of infection*** The burn wound provides an ideal culture medium for a range of microorganisms. Preventing infection is achieved by preventing contamination of the wound and preventing invasion of microorganisms into the tissues and bloodstream. A specialised burns unit may be available where the air is filtered, the individual is received into a bed prepared with sterile linen and isolation techniques are used to protect against infection. When a specialised unit is not available, the individual is generally nursed in a single room using protective isolation techniques.

***Debridement of dead tissue*** In Australia it is now the accepted standard of care for partial and full thickness burn injuries to be treated by early surgical excision of dead tissue (within 72 hours of injury) to prepare the burn area for grafting and primary closure. Blood flow is markedly increased by day 4. The individual must be stabilised and fully resuscitated. Early excision (in the first 24 hours) has been shown to: reduce blood loss in a paediatric population (Desai et al 1990); reduce mortality in individuals without inhalation injury (reduces bacteraemia limiting sepsis and multi-organ failure); and reduce length of hospital stay (Ong et al 2006). It also removes the major route of infection. Serial operations may be required within the first several days.

## CLINICAL INTEREST BOX 29.11 ANTT (aseptic non-touch technique also known as aseptic technique or surgical asepsis)

There are two types of ANTT: surgical and standard. The choice of surgical or standard ANTT is based on ANTT risk assessment and will also determine equipment selection and technique.

Standard aseptic non-touch technique (standard ANTT) is used within wound management procedures. The basic principle is that the key sites (e.g. wound) must not come into contact with any item (hand or equipment) that is not sterile.

Each procedure must be risk assessed. The ANTT technique will vary depending upon the risk assessment (i.e. size of key site and number of wounds and ability to protect key parts). Part of the risk assessment includes determining the length of the procedure and whether key parts and key sites will need to be touched during the procedure.

Sterile gloves are not always required for standard ANTT. Whether sterile or non-sterile gloves are worn depends on whether you can avoid touching the sterile parts of equipment that will come into contact with the susceptible areas (e.g. wound or cannula). If the procedure is complex or the patient is immunocompromised sterile gloves must be worn. If however you can carry out the procedure without touching the key part with your hands, non-sterile clean gloves may be worn.

Use of a dressing pack does not automatically make it a surgical ANTT procedure. Simple wound management techniques could be managed through standard ANTT. However, complex wounds, such as management of a wound drain, may require surgical ANTT.

| | |
|---|---|
| Standard ANTT (clean technique) | • Is a non-touch technique where hands wearing non-sterile clean gloves do not touch the sterile dressing surfaces that will be in contact with the wound bed<br>• Involves 5 moments of hand hygiene<br>• Maintain a clean environment by preparing a clean field, using clean (rather than sterile) gloves and dressing pack. Prevent direct contamination of materials and supplies<br>Examples:<br>• Wounds healing by secondary intention (except for those who are immunocompromised)<br>• Pressure injuries, leg ulcers, old tracheostomy sites<br>• Dehisced wounds (which will already by heavily colonised with environmental micro-organisms)<br>• Simple grazes<br>• Removing sutures |
| Surgical ANTT (aseptic technique) | • Is a strategy used in patient care to reduce exposure to microorganisms<br>• This is to maintain objects and areas as free from microorganisms as possible<br>• Sterile technique involves a surgical hand wash, use of a sterile field, use of sterile gloves for application of a sterile dressing, and use of sterile instruments<br>Examples:<br>• Insertion, re-siting, manipulating or dressing of an invasive device (i.e. intravenous line, central venous catheters, gastrostomy and jejunostomy tubes, tracheostomy tubes, chest drains, urinary catheter or wound drain)<br>Examples:<br>• Suturing of lacerations<br>• Acute traumatic wounds<br>• Where bone is visible<br>• Surgical wounds up to 48 hours postop if immunocompromised<br>• When patients are immunocompromised for both chronic and acute wounds |

*(National Safety & Quality Services 2014, Standard 3; NHMRC 2010; Rowley et al 2010)*

## Primary closure

Specialised dressings, skin closure with skin grafts or skin substitutes can all be used to achieve primary closure of a burn wound. All methods aim to achieve the same outcome of promoting healing, preventing infection and preventing scar development and contraction of scar tissue. Common methods of closure include skin grafting (split and full thickness), application of biological dressings (allografts, xenografts) or biosynthetic dressings.

***Skin grafting*** The ideal burn wound closure is with autograft; that is, using the individual's own skin. It is performed as the treatment of some deeper partial thickness burns and in the treatment of all full thickness burns. Skin grafting promotes healing, prevents infection and prevents the contraction of

scars. It is performed as early as possible in the treatment of some partial thickness burns and in the treatment of all full thickness burns. Split skin grafting involves the removal of thin sheets of the epidermis and some dermis (split thickness skin graft) or all of the dermis (full thickness skin graft) from a donor site, often the thigh, buttocks or back, and placing the skin over the debrided burned area.

In extensive burns the sheets of skin can be 'meshed' to give a net-like appearance and increase the body surface area to be covered. A full thickness graft includes the epidermis and the entire dermal layer, and is generally used when full thickness skin loss has occurred.

Skin from a source other than the individual's own body may be used as a temporary cover for large burned areas, to decrease fluid loss. The donor site is generally covered with a non-adherent dressing, a topical antimicrobial to reduce the risk of infection and graft failure and layers of dressing material to absorb blood and serum that ooze from the wound.

To promote successful transplantation, the graft must be immobilised to prevent displacement. Immobilisation is achieved by one of several methods, such as suturing, and the graft area is covered for protection. Successful 'take' of the graft depends on many factors, including absence of infection in the area, prevention or elimination of haematomas or seromas and adequate blood circulation.

***Skin substitutes*** Common methods of temporary or permanent skin coverage are biological (e.g. allografts, xenograft) or biosynthetic skin substitutes (e.g. Biobrane, PELNAC, Integra, Apligraf). Skin substitutes provide early coverage, reduce the risk of wound contamination and infection and reduce pain and fluid loss. They increase the rate of healing and decrease scarring. They are typically used in full thickness burns and generally consist of a bi-layered structure of an outer epidermal structure and an inner more biologically active dermal layer. They may also deliver growth factors. Some require a secondary procedure with split thickness skin grafting. The outer layer peels off as the wound heals underneath them. Early separation of the outer layer from the regenerated skin indicates an infection or a deeper wound requiring surgical treatment. Some surgeons will place a layer of nanocrystalline silver dressing over the skin substitute to reduce the risk of infection and loss of the dressing.

Skin from a source other than the individual's own body (allograft (cadaver skin) or xenograft (porcine skin)) may be used as a temporary cover for large burned areas, to decrease fluid loss (see Clinical Interest Box 29.1).

Bioengineered skin substitutes (e.g. cultured epithelial autografts) involve new techniques in which sections of the individual's unburned skin are grown in the laboratory, and later used to graft onto their burned areas.

***Non-biological dressings*** Superficial partial thickness burns may be managed with suitable dressings. This method of treatment has expanded over the last several years. The application of silver-containing dressings is used to prevent infection. Silver sulfadiazine (SSD) cream has been the most commonly used burn dressing; however, this treatment in the most part has been replaced by silver dressings (e.g. Acticoat™, Mepilex Ag™) that require less frequent changing, decreasing manipulation of the burn injury and graft site. These dressings are held in position with bandages and can remain in place for 3 to 7 days before being changed. Dressing changes are performed using strict aseptic precautions. For extensive burns the individual is given an analgesic before the dressing change or may be given a general anaesthetic before the procedure is performed. After the dressings have been removed, the wounds are cleansed and further debridement is performed where necessary before the burns are redressed.

***Donor site care*** The donor site is generally covered with a non-adherent dressing and layers of dressing material to absorb blood and serum that ooze from the wound.

## Providing adequate nutrition

In addition to the loss of erythrocytes and protein-rich serum, the hyper-metabolic response of the body to a burn rapidly depletes stores of energy. The individual must be provided with adequate carbohydrates, protein, fats, minerals, vitamins and fluid. Energy and protein requirements are generally assessed using a formula, and oral dietary intake is often augmented by nasogastric feeding or parenteral therapy to meet these requirements. Accurate monitoring of tolerance to the diet enables continual assessment of nutritional requirements. Nursing responsibilities include adherence to feeding protocols, daily calorie counts, understanding the enteral formulas and regular communication with the dietitian.

## Pain management

Superficial burn injury pain can be severe, as nerve endings are exposed. In deeper burn injuries the nerve endings are destroyed, and the person may say the burn does not hurt. Pain management is complex and challenging because the perception of pain has physical and psychological origins. Pain should be recognised from the individual's perspective and is the responsibility of the entire burn team. Inadequate pain management is distressing to the individual, the person's family and the burn team. Analgesic medications are commonly administered together with anxiolytic medications. Nursing measures also include explanation and assurance to the individual to reduce fear, and careful positioning may be beneficial. The nurse has a responsibility to observe the individual continually and to be directed by the person on the level of analgesia required. (More information on pain management is provided in Chapter 33.)

## Promoting mobility

Because of the nature of the injury, and its management, a person with burns may experience prolonged periods of immobility. Thus, the individual is subject to the complications of immobility, such as venous thrombosis, pneumonia, pressure injuries and contractures. (See Chapter 28 for measures to manage problems associated with immobility.) Regular and careful position changes are essential. Individuals must be positioned for comfort and repositioned frequently to

prevent pressure injuries and contractures. Splints and other devices may be used to improve positioning and to prevent contractures. The individual's limbs should be correctly positioned to decrease joint flexion.

Physiotherapy is essential for a person who is immobile, and involves chest physiotherapy and range-of-movement (ROM) exercises. ROM exercises may be performed actively or passively, and the degree of motion should be recorded to document progress. Ambulation is started as soon as possible and the nurse may be required to assist. If skin grafting has been performed, the individual will be required to increase ambulation slowly, as too rapid ambulation may damage new grafts.

### Scar and contracture management

Current management of burn scars comprises a combination of therapies from non-operative interventions to surgery for contracture release. Pressure placed directly over the healed burn tissue is commenced as soon as the new epithelium can tolerate the pressure without causing friction. Individuals with severe and extensive burns will have scarring and will normally have a tailored elastic compression garment applied. These garments are custom made to fit exactly over the burned area. Pressure garments are required to be worn between 6 months and 2 years after healing. Silicone gel sheets are also used to manage scar tissue. These can be worn under a pressure garment or on their own. Other treatments include prolonged stretching and splinting and mobilisation and massage of the scar. It is usual practice for non-operative methods to be applied before surgery is used. Surgery is required for contractures and where vital functional areas are exposed such as the eyelids.

### Providing psychological support

As a burn injury can have a devastating emotional impact on the individual and their significant others, psychological support is an extremely important aspect of care. After the injury, the person will experience various emotions such as fear of death, fear of disability and fear of disfigurement. Feelings of despair, anger, frustration, depression and guilt may all be experienced at any time after the burn. See Case Study 29.2.

Communication between team members caring for the individual is important to achieve adequate support for both them and their significant others. The nurse can help to provide support by:

- Developing a trusting relationship and being available to listen. The nurse should encourage the person to talk through their feelings and fears
- Providing information about all the procedures and equipment in a way that can be understood. Fear will be reduced if information is provided to the individual and significant others in a way that facilitates understanding of the injury, the treatment and the prognosis. People who are experiencing stress often have difficulty in remembering, so information should be repeated whenever necessary
- Assisting the individual to adapt gradually to body changes, and by being supportive when the person views their injury, particularly for the first time
- Supporting the individual's coping mechanisms for as long as necessary. The nurse should understand that any expressions of anger, aggression or intolerance are not being directed at the nurse personally. Rather, it is the person's way of reacting to the injury and its consequences
- Involving the individual in all aspects of care as much as possible, to promote independence and self-esteem.

## Complications of burns

In a severe burn all body systems become involved as the body attempts to maintain homeostasis and complications can involve any body system.

### Shock

Shock is due to loss of fluid from the circulation. The greatest loss of fluid occurs at the site of the burn, but loss also occurs throughout the body. Substances such as kinins, released by the body in response to the injury, increase capillary permeability, allowing serum to escape into the tissues. This loss of serum causes reduced blood volume (hypovolaemia), which may lead to severe shock. As a result of hypovolaemia, cardiac output decreases, blood pressure falls and acute renal failure and death may follow.

### Infection and graft failure

Infection may occur if microorganisms gain entry through areas where the skin has been damaged or destroyed. Although a burn wound is usually sterile initially, the area provides an ideal culture medium for a wide range of microorganisms. Necrotic tissue, oedema and transudate all provide a nutrient medium for bacteria. The individual's resistance to infection is reduced by factors such as shock, anaemia and electrolyte imbalance.

### Septicaemia

Septicaemia occurs when there is bacterial invasion of the tissues and bloodstream, and is a major cause of death in severely burned individuals. Septic shock is a form of shock that occurs in septicaemia, when endotoxins are released from bacteria in the bloodstream. The endotoxins cause decreased vascular resistance, resulting in a drastic fall in blood pressure. Pyrexia, tachycardia, rapid ventilations, confusion and coma may also occur.

### CASE STUDY 29.2

Peter is a 33-year-old man who has been recovering from extensive burns after an industrial accident. He is married and has 2 young children. What are some of the psychosocial issues Peter may face in his recovery from his burns and the associated complications?

### Pulmonary problems

Pulmonary damage can occur from smoke, chemical inhalation or carbon monoxide intoxication. In the acute period, pulmonary oedema may develop, and later pulmonary complications include pneumonia. The cause of death in many burn injury individuals is usually a pulmonary complication/s such as pneumonia (Cinat & Smith 2006).

### Psychological effects

A person who has been severely burned is likely to experience depression, anxiety and difficulty in adjusting to the consequences of injury. The person's significant others are likely to experience similar emotions. If a child has been burned, the parents are also likely to experience severe guilt feelings about the incident.

### Contractures, hypertrophic and keloid scars

Scar formation is a normal part of wound healing and in linear wounds is minimal. In large surface area wounds scars can create problems. Contractures, hypertrophic scarring and keloid formation frequently result after healing of a burn injury. Contractures occur over joints and functional areas. These are characterised by their interference with normal function of any joint that they cross and deformity of mobile structures. True keloid scars tend to extend beyond the margin of the original scar and continue to grow, failing to undergo scar maturation and size reduction. They can also recur after excision. Hypertrophic scars mature and reduce in size. They tend to stay within the boundaries of the original wound and after excision will tend to be a better scar than the original.

### Curling's ulcer

A Curling's ulcer is a duodenal ulcer that may develop in a person with severe burns. It is thought to be the result of stress.

## Preparation for discharge

Before discharge from hospital, it is important that the individual understands that the healed burned and grafted skin is very fragile and will break down more easily than normal skin. The individual must be informed that these areas are very vulnerable to extremes of temperature, irritant substances and physical trauma. As part of discharge preparation the nurse should advise the individual, or the parents of the young child, to:

- Avoid sunlight on the burned areas for at least 12 months. Burned and grafted skin tans unevenly and unpredictably and burns easily. Continuous use of sunscreen (SPF 30 or higher) is recommended
- Use non-irritant soaps and cosmetics on the burn areas
- Exercise care if engaging in activities such as sports in which there is the possibility that the burned areas may be bumped or damaged
- Wear clothing made from soft fabrics that will not irritate the healed burned or grafted areas
- Continue with prescribed management of the areas. Management may include the continual wearing of a tailored compression garment, or application of a cream to the areas. The person may also be required to follow a planned program of exercises designed to improve mobility
- Seek appropriate help, such as psychological counselling, when there is difficulty in adapting to a changed physical appearance.

# SURGICAL WOUNDS

Care of a surgical wound is directed towards promoting healing and preventing infection. In the immediate postoperative period, assessing for haemorrhage is a major responsibility of the nurse. Both the dressing and the bed linen under the individual should be checked for signs of haemorrhage. Any increase in blood staining on the dressing or an increase of blood in a drainage tube or bottle must be reported immediately to the nurse in charge. Strict asepsis is necessary when caring for surgical wounds and the nurse must follow the individual healthcare facility's protocol.

Adequate oxygenation of the tissues is promoted by deep breathing and coughing exercises, and early ambulation to promote full lung expansion will enhance oxygenation of the blood. Adequate circulation of blood to the area should be promoted to transport all the substances required for healing and combating infection. Adequate blood volume can be maintained by ensuring sufficient fluid intake, and circulation can be stimulated by exercises and mobility.

## Healing ridge

To assess healing for a surgical incisional wound it is important to understand how the healing ridge develops (Vuolo 2009). The healing ridge is a build-up of collagen fibres that begins to form during the inflammatory phase of wound healing and peaks during the proliferation phase. You should be able to feel this ridge between days 5 to 9 as you gently palpate the skin on each side of the suture line (Vuolo 2009). The presence of a healing ridge is a sign that healing is progressing (Vuolo 2009). If a healing ridge is not present or is incompletely developed healing isn't progressing as expected and there may be a risk of wound dehiscence.

Movement of the area should be restricted in the early stages of healing. If strain is placed on a wound, the newly formed granulation tissue may tear. The wound area should be stabilised, rested and supported.

## Surgical wound classification

### Clean wound

These wounds are made under aseptic conditions such as surgery, and heal by primary intention. These wounds generally do not require drainage.

### Clean contaminated wound

This is a wound made under aseptic conditions, but involving a body cavity that normally harbours microorganisms, such as the gastrointestinal, respiratory or urinary tract.

### Contaminated wound

This term applies to a wound in which microorganisms are likely to be present, and includes open, traumatic and accidental wounds and surgical wounds in which a break in asepsis occurred.

### Dirty wound

The term 'dirty wound' applies to traumatic wounds that are generally more than 4 hours old. Purulent discharge is evident. The wounds involve perforation of viscera and spillage of contents.

### Infected wound

Wounds that show signs of early infection are red, swollen, hot and painful. If not treated appropriately, cellulitis develops and may lead to conditions such as lymphangitis, lymphadenitis, bacteraemia, septicaemia and possibly even death.

## Surgical wound management

To provide the conditions necessary for healing, the wound must be free of dead or infected tissue, protected against external agents which may delay healing and provided with a moist environment, which is conducive to healing.

Controversy exists about many aspects of wound care, such as the type of dressing applied, frequency of dressing changes, cleansing procedures and solutions used.

See Clinical Skill 29.6: Removal of sutures and staples.

### Surgical site infection (SSI)

SSI is the most common postoperative complication and comprises approximately 20% of all healthcare-associated infections (Milne et al 2012). At least 5% of patients develop an SSI after a surgical procedure (NICE 2008). It is important that healthcare workers identify early signs and symptoms of possible infection and ensure they have put in place the required preventative actions outlined in the NICE guidelines (2008):

- Use an aseptic non-touch technique for changing or removing dressings
- Aim to leave the wound untouched for up to 48 hours after surgery. If you need to clean the wound during the first 48 hours use sterile saline
- Advise individuals that they may shower safely 48 hours post surgery if the suture line is intact and no bleeding or exudate.

Most healthcare facilities develop their own protocols and procedures for wound management and it is the nurse's responsibility to know these procedures and be aware of the protocols and regulations relating to wound care.

The key elements of postoperative wound management include timely review of the wound, appropriate cleansing and dressing, and early recognition and intervention of wound complications (Yao 2013).

**CRITICAL THINKING EXERCISE 29.4**

What discharge instructions would you give an individual about assessing for signs of wound infection?

## CLINICAL SKILL 29.6 Removal of sutures and staples

**Review and carry out the standard steps for all clinical skills/interventions**

| NMBA Decision-making Framework considerations: | Equipment: |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile dressing pack and dressing materials<br>Additional light source (if required)<br>Gloves<br>Disposable apron<br>Normal saline<br>Additional cotton balls or gauze balls<br>Waterproof sheet (Bluey)<br>Suture cutter<br>Sterile clip remover<br>Sterile safety pin<br>Gloves<br>Waste receptacle<br>Dressing trolley<br>Mask and eye protection as required |

| Skill activity | Rationale |
|---|---|
| Sutures and staples are removed once wound healing has occurred. Alternate sutures and staples may be removed with the remainder the following day. | |

*Continued*

| CLINICAL SKILL 29.6 Removal of sutures and staples—cont'd | |
|---|---|
| Assess the individual's record to determine previous appearance of wound and any previous dressings<br>Prior to commencing the procedure introduce self, identify the individual, obtain consent, validate and explain the rationale for the procedure, gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for pain<br>Assess for any allergies<br>Visually assess the wound for signs and symptoms of infection and dressings used | Determines requirements for equipment and dressing requirements<br>Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place<br>Pain may be caused during the procedure<br>Determines any adverse reactions to wound irrigation solution, dressing or tape (if required) |
| Assist the individual to assume an appropriate position of comfort, ensuring that only the wound area is exposed. Provide for privacy<br>Obtain additional assistance if required | Promotes comfort and facilitates performance of the procedure<br>Assistance is available when required |
| Place the equipment in a convenient location near the bedside. Open procedure pack using corners. Assemble the required equipment, using aseptic technique. Drop sterile equipment into sterile field | Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the dressing is being performed<br>Prevents contamination of sterile items<br>Additional items are available for use |
| Perform hand hygiene and loosen wound dressing | Prevents spread of microorganisms and allows ease of removal of wound dressing |
| Put on apron. Perform hand hygiene, apply gloves if required. If other PPE required put on before gloves | Prevents spread of microorganisms |
| Remove any dressing, examine the incision to determine the amount of healing and type of suture/clip used | Removes any exudate and dried blood, thus reducing the risk of infection |
| Removal of each intermittent suture involves:<br>• Starting with alternate sutures, using forceps to grasp the knot and gently raise it off the skin<br>• Cutting the suture as close to the skin as possible, away from the knot<br>• Pulling the cut suture up and out of the skin, ensuring that the exposed portion of the suture is not pulled through the tissues | Allows for assessment of union. Avoids risk of pulling exposed suture through the tissues, which prevents infection |
| Removal of a continuous suture involves:<br>• Using forceps to grasp the first knot and gently raise it off the skin<br>• Cutting the first suture on the side opposite the knot<br>• Cutting the same side of the next suture in line<br>• Lifting the first suture out in the direction of the knot<br>• Repeating the process down the suture line, using forceps to hold each suture where you would grasp the knot if the suture were intermittent | Minimises discomfort and ensures that the sutures are removed in the correct direction |
| To remove staples, position the extractor's lower jaws beneath the span of the first staple | The extractor reforms the shape of the staple and pulls the prongs out of the intradermal tissue |
| Squeeze the handles until they are completely closed then lift the staple away from the skin. Remove alternate staples at first. Repeat the process for each staple | Ensures that the incision has healed before removing all staples |

| CLINICAL SKILL 29.6 Removal of sutures and staples—cont'd | |
|---|---|
| Clean the wound with sterile normal saline to remove any blood or fluid left on the surface | Wound cleansing removes debris from the wound |
| If necessary, apply butterfly strips or tapes across the incision | Keeps the edges of the incision closed |
| Apply a light dressing if necessary | Provides additional support, and promotes union of the wound edges if healing is not complete |
| Remove personal protective equipment and discard with used equipment in an appropriate waste receptacle | Prevents spread of microorganisms |
| Assist the individual to reassume a comfortable position | Promotes comfort |
| Remove and attend to equipment in a correct manner. Perform hand hygiene | Prevents spread of microorganisms |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team. Include date and time, appearance of wound and any exudate, cleansing solution, number of sutures or staples removed, dressing used and the individual's response to the procedure. Medico-legal requirement. Allows for the planning and implementation of care |

## CRITICAL THINKING EXERCISE 29.5

Mrs Cooper, aged 72, attended the emergency department as her GP was concerned that her leg ulcer was infected. Mrs Cooper was admitted for a course of IV antibiotics. She is a widow who lives alone and her family does not live close to her. She is planned for discharge from hospital in the next 48 hours. When does discharge planning need to be started for Mrs Cooper? Explain. Identify some healthcare services that can be utilised to help Mrs Cooper with wound management.

## Summary

The integumentary system consists of the skin and its appendages: the hair, nails, sweat and sebaceous glands. The skin is the largest organ of the body and is composed of two layers. The epidermis is the thin outermost layer composed of epithelial cells, many of which are keratinocytes. Keratin has waterproofing qualities and is also responsible for the formation of hair and nails. Melanin, which is produced by cells in the deeper layer of the epidermis, gives colour to the skin and protects the body against the damaging effects of ultraviolet rays in sunlight. The dermis, or deeper layer of the skin, contains blood vessels, nerve endings, hair follicles and hairs, arrector pili muscles, sebaceous glands and sweat glands. Nails and hair protect certain areas of the body, for example, nails protect the tips of toes and fingers, while hair protects areas such as the scalp. The major functions of the skin are protection, thermoregulation, sensory perception, excretion, immunity, synthesis of vitamin D and to act as a blood reservoir.

Surgical wounds are the result of intervention by the surgeon and can range from an uncomplicated suture line to a more complex wound requiring drainage tubes or skin grafts. A surgical wound must be treated with strict aseptic technique and the nurse must be cognisant of the individual health organisation's protocols.

Pressure injuries result from ischaemic hypoxia of the tissues due to prolonged pressure in an area of the body, usually over a bony prominence. Both intrinsic and extrinsic predisposing factors contribute to the development of a pressure injury. Pressure injuries can be classified as stages I–IV, depending upon the amount of tissue damage. Risk assessment and preventative strategies that are employed by the nurse play an important role in ensuring that the incidence of pressure injuries, which are largely

*Continued*

predictable and preventable, is kept to a minimum. The nurse engages the multidisciplinary team to assist in the prevention of pressure injuries within the vulnerable individual population such as the elderly and frail.

Skin tears are a traumatic injury that can occur especially to the frail elderly population. Preventative strategies that pay particular attention to improving the condition of the person's skin, the environment and equipment used for caring for this vulnerable age group are important.

Leg ulcers are a costly and debilitating disorder and the nurse must be able to differentiate between the different types to employ the correct wound management method. The use of compression bandaging, which can be quite effective in the management of venous leg ulcers, is contraindicated and dangerous for the management of arterial leg ulcers.

Dry heat, moist heat, chemicals, electricity or radiation can cause a burn injury. The depth of tissue injury describes a burn and the size of the burn is estimated by using either the Lund–Browder method or the rule of nines. Complications include: shock, infection, scarring and contracture and adverse psychological effects. Medical and nursing management of an individual with burn injury will vary according to the severity of the injury. The care of the individual involves fluid and electrolyte replacement, prevention of infection, provision of adequate nutrition, relief of pain, promotion of mobility, providing psychological support and promoting healing of the injury.

The effects that disorders of the skin have on the individual range from minor and temporary, to major and life threatening. Some serious skin disorders affect the individual to the extent that self-concept and body image are severely impaired. Disorders of the skin may have a single cause or may result from several interrelated factors, while for some disorders the cause is unknown. Tests used to diagnose skin disorders include direct examination, biopsy, microscopic examination and skin testing.

With any skin integrity deficit, the psychological support for the individual is of major importance. Pain management and nutritional support are also vital. The correct method of wound care is essential and must be given with a clear understanding of the normal healing processes and the effect that certain pathologies have on those processes.

### DECISION-MAKING FRAMEWORK EXERCISE 29.1

A person you have been caring for has an open wound on their lower leg. You are asked to renew this dressing. A dry dressing is requested in their care plan. You remove the dressing with some difficulty as it has adhered to the wound. What actions would you take as an Enrolled Nurse in this situation?

## Review Questions

1. What are the major functions of skin?
2. What are the major factors that affect skin integrity?
3. Describe the four (4) stages of the wound healing process.
4. What factors can affect wound healing?
5. State the benefits of moist wound healing.
6. What are the major manifestations of skin disorders?
7. What are the four (4) stages of a pressure injury?
8. What care is required to prevent and manage pressure injuries?
9. What care is required to prevent skin tears?
10. What is the difference between an arterial ulcer and a venous ulcer?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER 30

# Promotion of health and wellbeing: nutrition

*Lynelle Jenkinson*

## KEY TERMS

adipocytes
anabolism
anorexia nervosa
basal metabolic rate (BMR)
body mass index (BMI)
bulimia nervosa
carbohydrates
catabolism
disaccharides
dysphagia
enteral
essential amino acids
fat-soluble vitamins
monosaccharides
non-essential amino acids
pagophagia
polysaccharides
recommended dietary intake (RDI)
total parenteral nutrition (TPN)

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Identify the three major groups of nutrients
- List the six groups of vitamins required for health
- List the eight major elements or electrolytes required for health
- Identify the functions and common food sources of the essential nutrients
- Describe the physical characteristics associated with a usual nutritional status
- Identify factors and disorders that may affect an individual's nutritional status
- Identify commonly used assessment techniques to measure an individual's nutritional status
- State the components of a healthy balanced diet
- State the principles of good nutrition throughout the lifespan
- Recognise signs and symptoms of poor nutrition
- Describe how the healthy balanced diet can be adapted to meet specific dietary beliefs and/or requirements
- Apply appropriate principles to meet nutritional needs throughout the lifespan, during episodes of illness or alterations in physiological or psychological status
- Assist in meeting an individual's nutritional needs accurately and safely in relation to assisting at mealtimes
- Provide care for an individual requiring enteral and parenteral feeds

## CHAPTER FOCUS

This chapter focuses on the nutritional needs of individuals over the lifespan and how a person's wellbeing can be affected by an alteration in the quantity and quality of absorbed nutrients. Nurses are required to assess and educate individuals to maintain nutritional health status and provide information on how to undertake care related to nutrition. Nutritional practices and requirements may vary according to age, height, sex, religion, culture, socioeconomic factors and physical and psychological status. Nurses must be able to accommodate for all these different factors when they plan, care and provide health education for individuals.

## LIVED EXPERIENCE

Recently I was admitted to hospital for 2 weeks with a chest infection. When I was discharged I weighed only 40 kg since I had lost 5 kg during my stay. Often meals were brought into my room and left on the table out of my reach. When I would call the nurses they would hurry in and shove the tray over to me. I could see they were busy and they would run out of the room before I could ask them if they would be able to help me. Because of my severe arthritis I was unable to open a lot of the packaging the food was in. I could not open the small containers of milk or open the sugar so I could not even enjoy a cup of tea. By the time the kitchen staff came to collect the tray the food was cold and unappealing anyway. After a few days my daughter spoke to the nursing unit manager and nursing staff were encouraged to check I could reach my table and to open all the packaging. The other thing they did was to arrange for modified cutlery to be delivered with each meal. This meant I was able to feed myself with less pain. Another message I would like to give the nurses is that it is important to make sure patients have access to fluid. Each morning my water jug was put on my bedside but was also not within my reach since I was attached to oxygen and an IV drip. This means that I did not drink as much as I should and became very dehydrated which I believe was also not good for my recovery.

**Dulcie, 76 years old**

# NUTRITION OVERVIEW

Food and nutrition have long been recognised as important contributors to health. However, food and nutrition affect more than just the physical aspects of our health and wellbeing. The buying, preparing and eating of food is part of everyday life. For many cultures, including Australia, food is a focus for social interactions with family and friends. For some, it is also an economic concern (Australian Institute of Health and Welfare (AIHW) 2012a). Nutritional care in healthcare facilities requires a coordinated approach involving health professionals, support staff, the individual and their carers.

While eating has a psychosocial and cultural significance in life, the major roles of food intake are to provide nutrients necessary for the development and growth of cells and the replacement of substances required by cells to maintain efficient body function. Information about the ingestion and digestion of food and the absorption of nutrients is provided in Chapter 32. After the digested nutrients have been absorbed into the blood and lymph, they are distributed to the cells for further chemical processing, releasing the energy necessary for body function. The process of metabolism converts the nutrients into chemical forms that produce energy and rebuild body tissue. The two phases of metabolism are: **anabolism** (or constructive phase), when simple substances derived from the nutrients are converted into complex substances that can be used by the cells; and **catabolism** (or destructive phase), when these complex substances are reconverted into simpler forms to release the energy necessary for cell function (Harris et al 2014).

The term nutrition is used to describe all the processes by which the body uses food for energy, maintenance and growth (Gropper & Smith 2013). It is important to recognise that nutritional requirements vary in response to changes throughout the lifespan. Factors that increase the body's metabolic demand include the periods of rapid growth during infancy and adolescence, pregnancy and lactation, increased physical activity and periods of stress, disease or trauma. Metabolic requirements diminish with reduced energy demands, decreased physical activity and age (Brown et al 2014).

Adequate nutrition is partially dependent on the ability of the body to ingest and digest food, to absorb nutrients from the intestine and to excrete waste products. Additionally, the quality and quantity of food consumed has an important influence on an individual's current and future health status. It is important that a diet contains the essential nutrients for each stage of the lifespan in order to maintain health and wellbeing.

The World Health Organization (WHO) defines undernutrition or malnutrition as:

*When the body does not get the proper amount of energy (calories), proteins, carbohydrates, fats, vitamins, minerals and other nutrients required to keep the organs and tissues healthy and functioning well.*

**(WHO 2010)**

Food is not just a source of nutrients. It is important for good social and emotional health as well as physical health. Food and eating are part of the way people live their lives. The eating patterns of individuals and families are constantly being shaped and changed by a variety of factors. Some of these include:

- The kinds of food that is available at the local supermarket or shop
- Cultural, religious and family background
- The amount of time available to shop for, prepare and cook food
- The personal likes and dislikes of household members
- Values, attitudes and beliefs about food and eating
- Knowledge about food and nutrition
- Advertising campaigns and food promotions
- The amount of money that can be spent on the food budget
- Access to transport
- Food fads and fallacies
- Physical or psychological status of the individual such as allergies or an intolerance to specific foods or nutrients; difficulty in chewing or swallowing; level of independence/dependence; disorders that interfere with nutrition which may result in maldigestion, malabsorption or loss of nutrients. These, in turn, can lead to emotional states such as depression or anxiety, which may further impact on the physical or psychological status of the individual (AIHW 2012a).

## NUTRITION ASSESSMENT

Nutrition risk screening should be inclusive of the nursing assessment on admission. It is essential to obtain information about the individual's appetite; food preferences; height; weight; food allergies; dysphagia; chronic diseases; level of activity; assistance required for eating, feeding and drinking; and social or physiological issues. Observation of an individual's general appearance provides information about their general state of health and their nutritional status. Some characteristics of altered nutritional status are presented in Table 30.1. Assessing the individual's eating pattern and their nutritional status may also identify problems or risk factors.

The Academy of Nutrition and Dietetics/American Society for Parental and Enteral Nutrition (Stayner 2012) suggests that the criterion for the diagnosis of malnutrition is for the individual to display two or more of six characteristics:

1. Insufficient energy intake
2. Weight loss
3. Loss of muscle mass
4. Loss of subcutaneous fat
5. Localised or generalised fluid accumulation
6. Diminished functional status as measured by hand grip strength.

In addition to the physical characteristics associated with poor nutritional status, psychological symptoms may be evident. An individual with a poor nutritional status may experience irritability, lethargy, apathy or inability to concentrate. It is possible, however, that these symptoms and the physical signs presented in Table 30.1 may be related to an underlying condition and/or the person's nutritional status.

It is essential to determine the individual's nutrition risk by utilising a validated nutrition risk screening tool. The Malnutrition Screening Tool (MST) (Figure 30.1) is the most frequently reported screening tool utilised in Australian healthcare facilities. (For further information on MST see also Chapter 19.) Others include Subjective Global Assessment (SGA) and the Mini-Nutritional Assessment (MNA) (Ferguson et al 2010). The result of nutrition risk screening must be documented in the healthcare record.

Certain groups of individuals may be more at risk of a poor nutritional status, including those who are:

- Suffering emotional or physical stress
- Impaired cognitively or intellectually
- Alcohol, drug or nicotine dependent
- Post surgical procedure
- Diagnosed with a chronic illness
- Homeless
- Pregnant or lactating
- Older or the young
- Unaware of nutritional values
- Strict vegetarians
- Following 'fad' diets.

Any person identified at risk of malnutrition needs prompt referral to a clinical dietitian for further nutrition assessment or to other health professionals for the management of specific issues which may affect their nutrition status. This includes swallowing, biting, chewing difficulties, impaired upper limb function affecting self-feeding, poor dentition, mental health issues or cognitive issues. To maintain or promote an appropriate intake of food and therefore a good nutritional status, individuals should be encouraged to follow the principles of a balanced healthy diet that provides the body with essential nutrients. However, it is also important when looking after individuals to take into account that while the consumption of food provides for the physiological needs of a person, it can also contribute to their social and emotional needs.

### Nutritional assessment and the older person

When performing a nutritional assessment on an older person it is important that the nurse determines the type, quantity and frequency of food eaten. Unintentional weight loss is associated with a number of poor health outcomes. In the older person this can be attributed to a combination of protein–energy malnutrition, cachexia or physiological anorexia (a result of the ageing process on various body systems) (Soenen 2013). Identification of poor nutrition in older persons can occur on admission to hospital, nursing homes, during follow-up outpatient appointments or at GP clinics. This can lead to improved health outcomes and better quality

**TABLE 30.1 | Characteristics of altered nutritional status**

| Symptom | Nutrients |
|---|---|
| Poor growth | Protein, energy, iron, zinc, iodine, vitamin D, calcium, essential fatty acids, vitamin A |
| Poor immunity | Zinc, selenium, vitamin C, vitamin D, vitamin E |
| Poor appetite | Zinc, magnesium, iron, thiamin, niacin, folate |
| Fatigue/irritability | Protein, zinc, iron, chromium, pyridoxine, B12, folate, vitamin C |
| Moody/depressed | Protein, zinc, iodine, magnesium, thiamin, niacin, pyridoxine, B12, vitamin C, vitamin D |
| Migraine/headache | Riboflavin, B complex |
| Sleep disturbance | Magnesium, calcium, pyridoxine, niacin, vitamin C, vitamin D |
| Poor dream recall | Pyridoxine |
| Impaired memory/cognition | Iron, zinc, iodine, thiamin, niacin, B12, folate |
| Bone/joint pain | Calcium, zinc, iodine, boron, vitamin D, vitamin C, essential fatty acids |
| Diarrhoea | Zinc, iron, excess magnesium, excess vitamin C, niacin, B12, folate, biotin |
| Constipation | Water, dietary fibre, iodine/thyroid, iron, niacin |
| Irregular periods | Iodine/thyroid, iron, zinc, vitamin E, essential fatty acids |
| Mastalgia | Vitamin A, vitamin E |
| Premenstrual syndrome dysmenorrhoea/menorrhagia | Pyridoxine, calcium, magnesium, essential fatty acids |
| **Hair** | |
| Hair loss/dry/brittle/slow growth | Protein, zinc, iron, iodine/thyroid, riboflavin, biotin, essential fatty acids, vitamin A (deficiency or excess) |
| Premature greying hair | Copper, biotin, B12 |
| Dry scalp/flaking | Zinc, magnesium, selenium, biotin, vitamin A |
| **Eyes** | |
| Dark under eye circles | Iron |
| Pale conjunctiva | Iron |
| Impaired night vision | Zinc, vitamin A |
| Twitching eyelid/facial spasms | Magnesium, calcium |
| **Nose/taste/tongue/mouth** | |
| Poor smell/anosmia | Zinc, vitamin A |
| Impaired taste | Zinc, vitamin A |
| Pale tongue | Iron |
| Magenta/blue tongue | Riboflavin, biotin |

*Continued*

**TABLE 30.1 | Characteristics of altered nutritional status—cont'd**

| Symptom | Nutrients |
|---|---|
| Large pale, swollen tongue | Iodine/hypothyroid |
| Smooth bright red tongue | Riboflavin, pyridoxine, B12, folate, biotin |
| Raw, painful dark red tongue | Niacin, B12, folate |
| Berry-like red tongue | B complex |
| Cherry-tip tongue | Niacin, pyridoxine |
| Burning sensation/mouth/throat | Vitamin D |
| Lip cheilosis (burning/soreness) | Riboflavin, niacin, pyridoxine |
| Angular stomatitis | Thiamin, riboflavin, niacin, pyridoxine, folate, B12. iron |
| Bleeding gums | Riboflavin, vitamin C, vitamin K |
| **Nails** | |
| Vertical corrugations (pronounced) | Protein, riboflavin, zinc |
| Pronounced central ridge | Protein, iron, folate |
| Horizontal grooves | Past severe illness, protein, zinc, selenium, calcium |
| Leukonychia (white spots) | Zinc |
| White half moon at base of nails | Pyridoxine |
| Dry, thin, brittle nails | Protein, essential fatty acids, iron, calcium |
| Peeling/splitting nails | Protein, calcium |
| Spoon-shaped/brittle nails | Iron |
| Soft, papery bitten nails | Protein, zinc |
| Growth arrest/thickened nails | Protein, zinc |
| Yellow nails | Vitamin E |
| Eggshell nails | Vitamin A |
| **Muscles** | |
| Muscle pains/aches | Calcium, magnesium, potassium, selenium, thiamin, vitamin C, vitamin E, vitamin D, co-enzyme Q10 |
| Cramps | Calcium, magnesium, iron, potassium, sodium, vitamin D, vitamin C |
| Twitching/spasms | Calcium, magnesium, potassium, pyridoxine, vitamin D |
| Calf muscle tenderness | B complex, vitamin E |
| Weakness/wasting | Protein, thiamin, vitamin D, potassium, calcium |
| Decreased muscle reflexes | B complex, vitamin E |
| **Skin** | |
| Excessive ageing of skin/wrinkles | Vitamin E, essential fatty acids, iodine |
| Perifollicular hyperkeratosis (toad skin) | Zinc, vitamin A, B complex, vitamin C, essential fatty acids |

**TABLE 30.1 | Characteristics of altered nutritional status—cont'd**

| Symptom | Nutrients |
|---|---|
| Shark skin/dyssebacea (sebum plugs in follicles/face/body) | Riboflavin |
| Oily scaly seborrhoeic dermatitis (nasolabial folds/eyebrows/forehead) | Riboflavin, niacin, pyridixine, biotin, copper, essential fatty acids |
| Dry scaly/coarse/itchy dermatitis | Zinc, iodine, niacin, essential fatty acids, biotin, vitamin A, vitamin C, vitamin E |
| Dry 'fish scale' 'flaky paint' especially on the legs | Vitamin A, zinc |
| Hyperpigmentation non-scaly macules/patches | Insulin resistance, vitamin A, zinc, vitamin C, niacin, pyridoxine, B12, folate, essential fatty acids |
| Hyperpigmented scaly dermal patches on face/limbs (pellagra) | Thiamin, niacin, biotin, zinc, essential fatty acids |
| Liver spots (ceroid accumulation) | Vitamin E |
| Eczema | Biotin, zinc, essential fatty acids |
| Psoriasis | Vitamin D, vitamin A, essential fatty acids, zinc |
| Acne | Essential fatty acids, zinc, vitamin A, vitamin C |
| Wound healing | Protein, essential fatty acids, vitamin A, pyridoxine, vitamin C, zinc, biotin |
| **Nerves** | |
| Impaired coordination/balance disorientation/ataxic gait | Thiamin, B12 (neurological changes can occur without haematological changes), niacin, vitamin E |
| Neuropathy (weakness, ataxia, pins and needles, paraesthesia), foot/wrist drop, reduced tendon reflexes, numbness | Thiamin, riboflavin, pyridoxine, B12, carnitine, folate, magnesium, calcium, potassium, essential fatty acids, chromium, iron, vitamin E |
| Postural hypotension | B6/B complex, iron |

*(Wahlqvist 2011)*

of life (Agarwal et al 2013). Nurses should ask the older person about the following:

- Any special diets (e.g. low-salt, low-carbohydrate) or self-prescribed fad diets
- Intake of dietary fibre and prescribed or over-the-counter vitamins
- Use of aperients
- Weight loss and change of fit in clothing
- Amount of money individuals have available to spend on food
- Accessibility of food stores and suitable kitchen facilities
- Variety and freshness of foods.

The ability to eat (e.g. to chew and swallow) needs to be evaluated. Poorly fitted dentures or decreased taste or smell may reduce the pleasure of eating, so individuals may eat less. Individuals with decreased vision, arthritis, immobility or tremors may have difficulty preparing meals and may injure or burn themselves when cooking. Individuals who are worried about urinary incontinence and frequency may reduce their fluid intake; as a result, they may eat less food (Continence Foundation of Australia 2012).

While all older persons are at risk of poor nutrition, individuals diagnosed with dementia are at further increased risk of malnutrition. Throughout the assessment of the older person it is therefore essential that cognitive function be assessed (Alzheimer's Australia 2015).

It is important for the nurse to realise that ageing changes the interpretation of many measurements that reflect nutritional status in younger people. For example, ageing can alter height. Weight changes can reflect alterations in nutrition, fluid balance, or both. Despite these age-related changes, body mass index (BMI) is still useful in older persons. If abnormalities in the nutrition history (e.g. weight loss,

suspected deficiencies in essential nutrients) or BMI are identified, a thorough nutritional evaluation by the medical officer, which includes laboratory measurements, is indicated (Soderhamn 2012).

### CRITICAL THINKING EXERCISE 30.1

Discuss the importance of performing a nutritional assessment.

### CRITICAL THINKING EXERCISE 30.2

Dana is a 24-year-old under investigation by her GP with dizziness, heat intolerance and shakiness. She has had unintentional weight loss of 7 kg over the past 6 months despite a reported healthy appetite and increased calorie intake. Other symptoms reported include intermittent palpitations, hair loss, sweating and irritability. The provisional diagnosis is hyperthyroidism. What care should you arrange to assist Dana in planning, regaining and maintaining her weight?

## Healthy balanced diet

Eating a balanced diet is vital for good health and wellbeing. Food provides human bodies with the energy, protein, essential fats, vitamins and minerals to live, grow and function properly. People need a wide variety of different foods to provide the right amounts of nutrients for good health. Enjoyment of a healthy diet can also be one of the great cultural pleasures of life. The foods and dietary patterns that promote good nutrition are outlined in the Australian Dietary Guidelines (NHMRC 2013a). There are five principal recommendations to be considered equally important in terms of public health outcomes:

1. To achieve and maintain a healthy weight, be physically active and choose amounts of nutritious food and drinks to meet your energy needs
2. Enjoy a wide variety of nutritious foods from the five groups every day (see below)
3. Limit intake of foods containing saturated fat, added salt, added sugars and alcohol
4. Encourage, support and promote breastfeeding
5. Care for your food; prepare and store it safely (NHMRC 2013a).

The total amount of food that a person needs each day to provide themself with the energy and nutrient needs will vary depending on the person's age, sex and activity levels, and whether or not the person is pregnant or breastfeeding. The NHMRC (2006) provides **recommended dietary intake (RDI)** levels for energy and the various nutrients across various conditions, age and sex categories. The RDIs are specified in the nutrient reference values for Australia and New Zealand. RDIs or 'allowances' are the levels of intake of essential nutrients considered adequate to meet the nutritional needs of 97–98% of healthy individuals.

The Australian Guide to Healthy Eating (Figure 30.2) is Australia's current suggested food selection guide based on latest evidence and expert opinion (NHMRC 2013a). The Guide aims to promote healthy eating habits throughout life to assist in reducing the risk of chronic health problems, such as heart disease, obesity and type 2 diabetes. The Australian Guide to Healthy Eating is a visual representation of the Australian Dietary Guidelines. The aim of the Guide is to encourage the consumption of a variety of foods from each of the food groups every day in proportions that are consistent with the Dietary Guidelines and to drink plenty of water. The five foods groups are:

1. Bread, cereals, rice, pasta, noodles
2. Vegetables, legumes
3. Fruit
4. Milk, yoghurt, cheese
5. Meat, fish, poultry, eggs, nuts, legumes.

Furthermore, the Australian Guide to Healthy Eating highlights fats and oils should be eaten only occasionally or in small amounts.

For minimum recommended number of serves from the Australian Guide to Healthy Eating for adults see Figure 30.3.

## Nutritional needs of infants and children

Throughout all stages of development, a healthy balanced diet is necessary to provide the nutrients required for the body's

**Figure 30.2** The Australian Guide to Healthy Eating
*(NHMRC 2013a)*

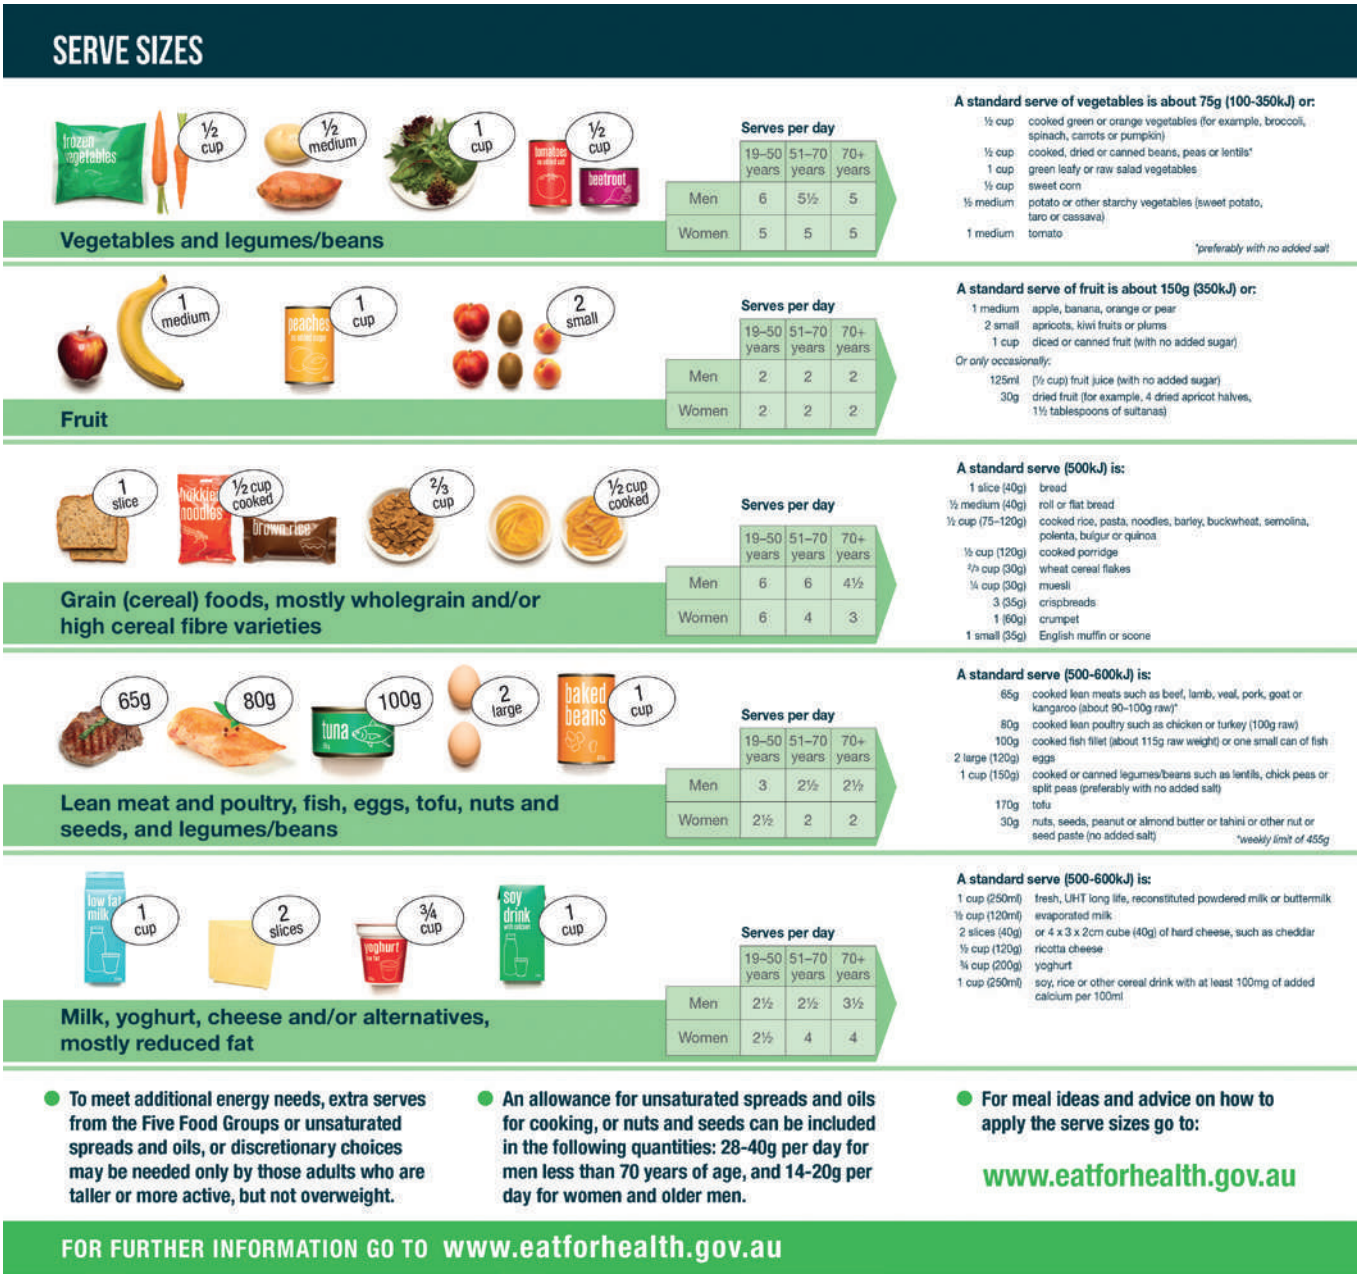

**Figure 30.3** Australian Dietary Guidelines—sample serves for adults *(NHMRC 2013a)*

needs. For information on maternal and newborn nutrition, see Chapter 45.

Breast milk or an appropriate infant formula should remain the main source of milk until 12 months of age (WHO 2013). Based on the currently available evidence it is recommended introducing complementary solid foods from around 4–6 months (NHMRC 2012). There is little evidence that delaying the introduction of complementary solid foods beyond 6 months reduces the risk of allergy (Australasian Society of Clinical Immunologists and Allergists (ASCIA) 2010). When a child is ready to eat solids, the parents/carers should consider introducing a new food every 2–3 days according to what the family usually eats (regardless of whether the food is thought to be highly allergenic). One new food should be introduced at a time so that reactions can be more clearly identified. If a food is tolerated, this should be continued as a part of a varied diet (ASCIA 2010).

The aim of introducing solids is to wean the infant off milk to prevent such problems as failure to thrive, malnutrition and anaemia, and also to educate the palate to different tastes and textures; eating therefore becomes largely a learning process. Rice cereal, pureed stewed fruit and vegetables are

suitable first foods. By 6–8 months of age, chewing movements begin and the infant can be introduced to more coarsely textured foods.

When the infant begins to grasp objects and put them in their mouth, they may be ready to be introduced to finger foods. An infant can take fluids from a cup at about 7–8 months of age. Giving fruit juice to a child from a bottle should be discouraged, as high fructose levels may contribute to the development of jaw and tooth deformity and dental caries, and excessive volumes of fruit juice may result in diarrhoea.

At about 12 months of age the infant should be eating a range of basic foods. The diet should consist of bread and cereals, fruit and vegetables, meat and/or other protein foods, milk and/or milk products and small amounts of butter or margarine. Salt, sugar and fatty foods should be avoided (NHMRC 2012).

**CRITICAL THINKING EXERCISE 30.3**

Ava, a 10-week-old infant, presents to emergency with frequent gagging and vomiting post feeds. Ava's mum, Linda, describes the emesis as large, non-projectile undigested milk with no reports of blood visible. Linda appears tired and describes Ava's frequent episodes of crying, and being unable to be consoled, particularly in the late afternoon. She is concerned that Ava is not tolerating adequate amounts of breast milk and is concerned she may become dehydrated. Ava is examined in the department and has bare weight of 4.2 kg, length 56 cm, head circumference 36.5 cm. What would you discuss with Linda and her medical officer?

## The toddler and preschool child

During this stage of development a child's rate of growth is slower than in infancy and this is normally reflected by a decrease in appetite, although appetite is generally unpredictable during these years. Toddlers are learning to feed themselves and to eat new foods. They should eat a variety of nutritious foods from all five food groups. Toddlers in particular need to ensure adequate iron and calcium intake, with low-fat diets not suitable for children less than 2 years. For minimum recommended number of serves from the Australian Guide to Healthy Eating for children see Figure 30.4.

Foods should be served at regular times in a calm and relaxed atmosphere. Because young children are active, snacks between meals are important. The foods offered for snacks should contribute to the nutritional needs of the child, while foods with poor nutritional value should be avoided. Small hard foods, such as nuts, raw carrots, etc., are potentially dangerous for the young child, as they may be inhaled and obstruct airways.

## The school-age child

During the first 12 months of life the foundation is laid down for good dietary practices. By the time the child is of school age, eating patterns are usually firmly established. As the child grows and develops, their tastes can change, and foods that were previously enjoyed may be refused, while the child may acquire a taste for other foods, due in part to social interaction and their changing physiological needs and subsequent sensory changes.

Nutritional requirements are similar to those for children of preschool age, although kilojoule needs are diminished in relation to body size (Figure 30.4). However, fat and protein reserves are being laid down for the increased growth needs of the adolescent period, and the school-age child should be encouraged to consume a healthy balanced diet consisting of foods from each of the five food groups and should be discouraged from consuming foods that have poor nutritional value. If the child consumes an excessive quantity of food and/or food that is high in kilojoules, and does not exercise, they may be at risk of childhood obesity and subsequent development of conditions such as adult-onset diabetes and cardiovascular disease. The Australian Institute of Health and Welfare (AIHW) (2015b) reported from the 2011–12 Australian Health Survey almost two-thirds (63%) of the population aged 18 and over are overweight or obese (35% overweight, 28% obese). Similarly, in children aged 2–17 results show one quarter (25%) of children are overweight or obese, with 18% being overweight and 7% obese.

While the prevalence of childhood overweight and obesity increased in Western countries during the 1980s to the late 1990s a number of more recent studies have reported a significant plateau in the prevalence of both overweight and obesity since the late 1990s (O'Dea et al 2014). The NHMRC (2013b) suggests a demonstrated association between childhood obesity and adult obesity. Furthermore, childhood obesity has been closely associated in later life with many diseases and conditions such as coronary heart disease, stroke, type 2 diabetes and osteoarthritis (Park et al 2012). Iron-deficiency anaemia is a more immediate nutritional problem in school-age children due to inadequate amounts of iron in the diet.

## Adolescence

From 10 years of age, children's bodies are developing rapidly to prime the body for reproduction. A pre-puberty growth spurt occurs earlier in girls than in boys, as they store more fat, which initiates adolescence faster (see Chapter 13). During adolescence, the need for nutrients including energy, protein, vitamins and minerals increases. During this time there can be major changes in the selection and volume of food; however, it is important to continue choosing nutritious foods across the food groups (NHMRC 2013a). Hormones alter senses such as taste to enable the adolescent to adapt to changing nutrient requirements. Some individuals at this age may be vulnerable to self, peer and social influences that alter their perception of appearance and self-worth and drastically modify their eating habits (see 'Eating disorders' later in this chapter). (See Case Study 30.1.)

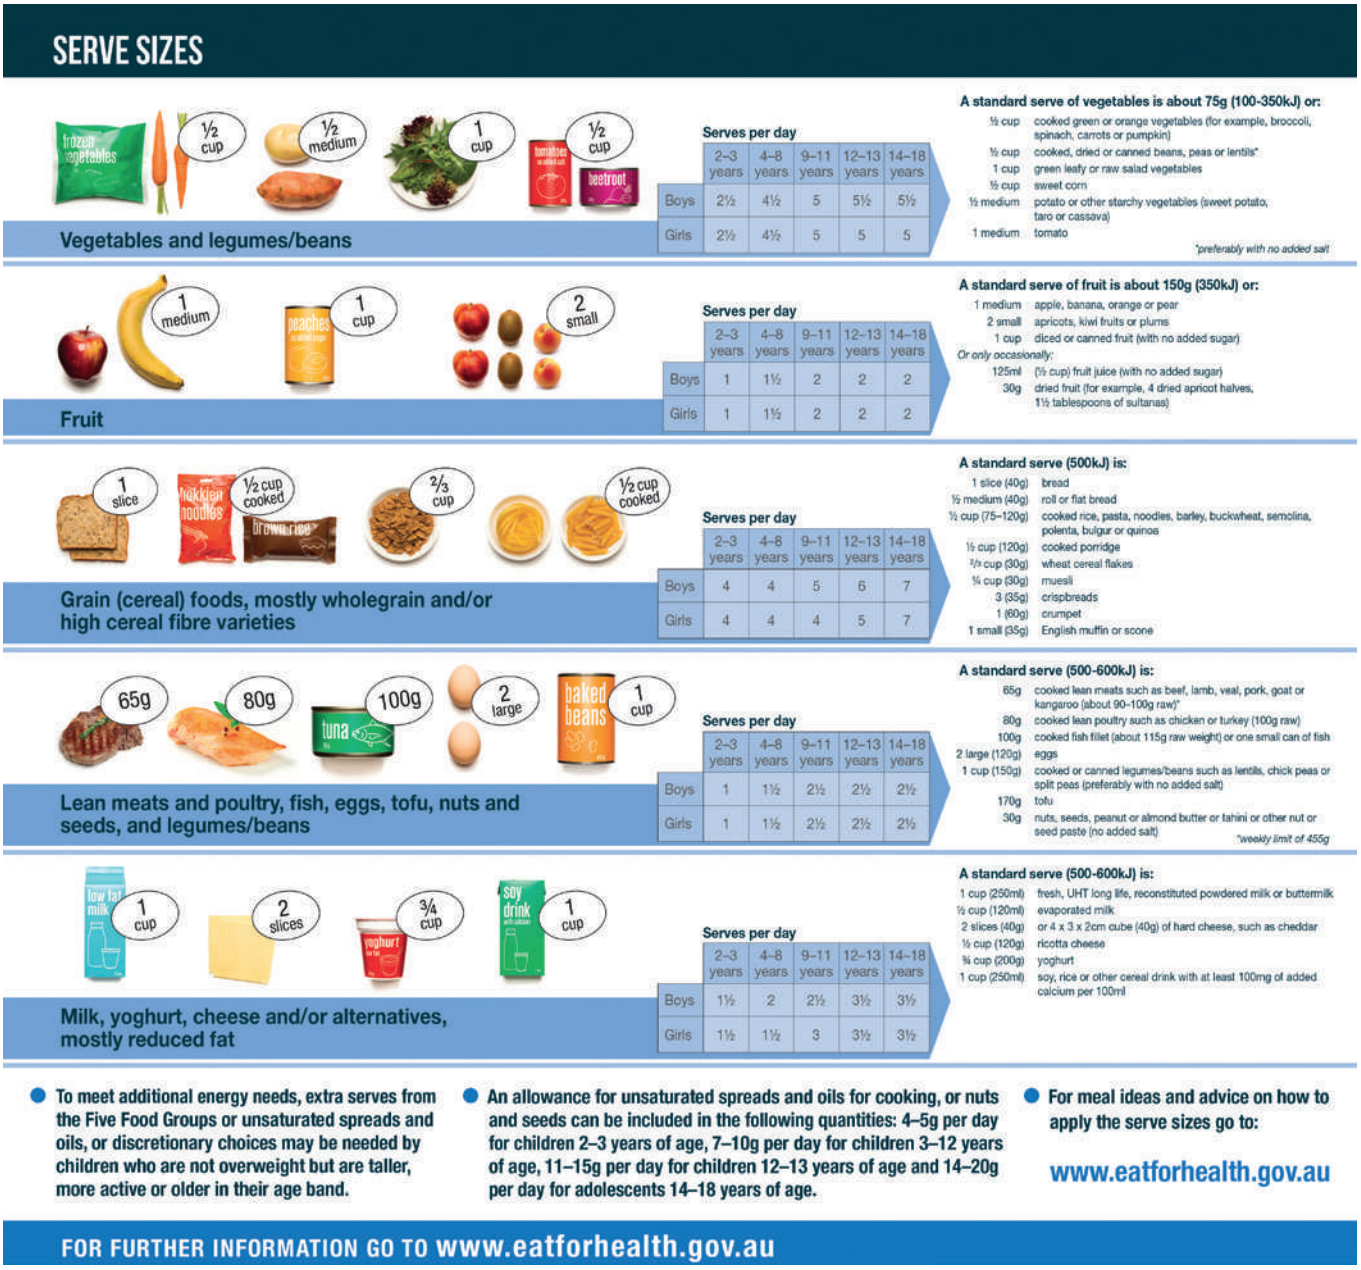

**Figure 30.4** Australia Dietary Guidelines—sample serves for children and adolescents *(NHMRC 2013a)*

## CASE STUDY 30.1

Amelia, a 12-year-old girl, has been brought into hospital for an adenoidectomy and tonsillectomy. While admitting her you discover she weighs 80 kg. She is accompanied by her mother who you notice is also overweight. As a nurse in the team looking after Amelia, it is important that your care of Amelia is person-centred and ensures that Amelia has the best possible health outcomes both in the hospital and on discharge.

1. What are the implications Amelia's weight may have on her short-term and long-term health?
2. Does Amelia's weight have any implications for her pre- and postoperative care? If yes what are these concerns?
3. How would you as the nurse caring for Amelia address her weight issue? Is it appropriate to also involve her parents in this discussion?
4. What nursing advice would you give to Amelia and her family? How would you address an issue like Amelia's diet, which could have health behavioural implications?

## Older persons

The ageing process has significant impact on nutrition due to a decline in biological and physiological function. Older individuals have reduced lean body mass and basal metabolic rate as well as often reduced appetite and energy expenditure. While requirements for some nutrients are reduced, WHO (2015) suggests that requirements for other essential nutrients may increase and recommend a review of the current recommended daily nutrient allowances.

## Energy requirements

In addition to the consumption of foods from the five food groups that provide the essential nutrients, dietary requirements need to be considered in terms of energy requirements. Energy is needed for all the chemical and physical activities of the body, such as muscular activity, production of glandular secretions and the synthesis of substances in cells. The amount of energy required is the amount necessary to maintain physiological processes and depends on factors such as age, sex, climate, body build, height and weight, level of physical activity and usual function or dysfunction.

Energy requirements are increased during periods of rapid growth; for example, during pregnancy, infancy and adolescence and when a person engages in a high level of physical activity. Certain types of body dysfunction, such as hyperthyroidism, can also increase the amount of energy required. Energy requirements are decreased when an individual's level of physical activity is low, with certain metabolic conditions, such as hypothyroidism, and during stages of development when there is little growth, such as old age (WHO 2004).

The two units of measurement that specify the energy value of food are calories and joules. A calorie is defined as the amount of heat required to raise 1 g of water by 1°C. A joule, which is the standard international (SI) unit of energy and heat, is equivalent to the amount of work performed when a 1 kg mass is moved 1 m by the force of 1 newton. One calorie is equal to 4.184 joules. As joules are very small units, it is more convenient to measure food energy in terms of kilojoules. One kilojoule (kJ) is 1000 joules.

The energy values of the three major types of nutrients are:

1. 1 g protein produces about 17 kJ
2. 1 g carbohydrate produces about 17 kJ
3. 1 g fat produces about 38 kJ (NHMRC 2006).

Energy expenditure varies with the level of physical activity a person engages in and ranges from about 5 kJ/min during sleep to about 120 kJ/min during heavy physical activity. When the intake of kilojoules is increased or energy expenditure is decreased, weight gain occurs. Conversely, loss of weight occurs when the intake of kilojoules is decreased or energy expenditure is increased (Nutrition Australia 2012). Basal metabolism is the term used to describe the minimal maintenance of all normal body functions at rest and in the absence of disease. The amount of energy required to support basal metabolism is measured when an individual is awake but at complete rest and has not eaten for at least 12 hours. The measurement is expressed as **basal metabolic rate (BMR)**, according to the number of kilojoules consumed per hour per square metre of body surface area (or per kilogram of body weight) (Harris et al 2014). The BMR is one diagnostic test commonly used to estimate nutritional needs. Variations in the BMR between individuals of the same weight and height may be due to alteration in body composition, such as muscle mass as opposed to fatty tissue, and the presence of certain disease states.

There are two types of measurement that may be used by clinicians when determining body fat and risk of chronic disease. These are the **body mass index** (BMI) and waist circumference.

The BMI is a simple index of weight-for-height that is commonly used to classify underweight, overweight and obesity in adults. It is defined as the weight in kilograms divided by the square of the height in metres ($kg/m^2$). For example, the BMI of a male who is 1.83 m tall and weighs 115 kg is:

$$\frac{115}{1.83^2} = \text{BMI of } 34$$

The value obtained when this formula is used should be rounded to the nearest whole number.

BMI values are age-independent and the same for both sexes. However, BMI may not correspond to the same degree of fatness in different populations due, in part, to different body proportions. The health risks associated with increasing BMI are continuous and the interpretation of BMI grading in relation to risk may vary for different populations. Brown and colleagues (2013) outlined higher health risks associated with lower BMIs for Asian and Pacific Islander people and went on to suggest lower BMI guidelines for these populations.

A BMI value below 20 is common in certain ethnic groups, such as people of Asian descent, and in athletes, but otherwise indicates that a person is underweight. A BMI of 20–25 is within the healthy weight range. A BMI of 25–30 may indicate more muscular build or overweight, while a value of 28–40 is defined as moderate to severe obesity, and a value above 40 signifies morbid obesity (WHO Expert Consultation 2004). For graphical representation of BMI see Figure 30.5.

The waist measurement compares closely with a person's body mass index (BMI), and is another widely utilised scale of predicting an individual's risk of developing a chronic disease. Excessive body fat around the abdomen (central adiposity) is an indicator of internal fat deposits on the heart, kidneys, pancreas and liver. A waist measurement of greater than 94 cm for men and 80 cm for women is an indicator of increased risk of chronic disease development such as type 2 diabetes and cardiovascular disease (AIHW 2012b). An advantage of using waist circumference is that the measurement is not related to the individual's height; however, specific ethnic group waist measurements are yet to be determined. It is believed that they may be lower for Asian

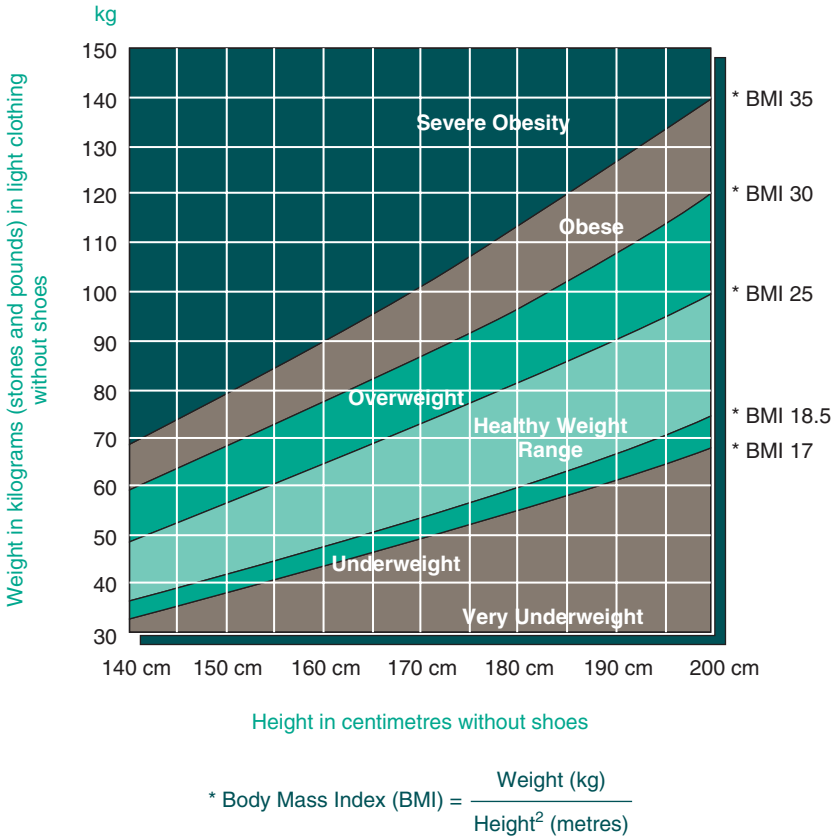

**Figure 30.5** Body mass index for adults
*(NHMRC 2013b)*

men than for Caucasian men and are likely to be higher for Pacific Islanders and African-Americans (men and women). The limited data currently available indicates that the risk factors in Aboriginal populations appear to be similar to those in Asian populations; and the risk factors in Torres Strait Islander populations appear to be similar to those found in Pacific Islander populations (NHMRC 2013b).

Measuring a person's waistline is a simple check for a nurse to perform and for accurate measurement the nurse should ensure that:

- Measurement occurs against the skin
- The person breathes out normally
- The tape measure is snug but does not compress the skin
- The correct place to measure the waist is horizontally halfway between the lowest rib and the top of the iliac crest. This is roughly in line with the individual's umbilicus (belly button) (WHO 2011).

## Glycaemic index

Glycaemic index (GI) classifies carbohydrate foods according to how rapidly glucose is released from them and absorbed into the blood. It has traditionally been used to treat individuals with diabetes mellitus but is now being used for establishing optimal diets for the general populace. The lower the GI the slower the rate of absorption and the slower the rate of insulin release. Complex carbohydrates such as starch provide lower GI nutrients and result in a more stable blood glucose level (Harris et al 2014).

Some simple carbohydrates, such as those found in fruits, have a lower GI value than some complex carbohydrates, such as those found in rice and potatoes. Foods with low-GI values have been used to treat hypercholesterolaemia and obesity. Low-GI foods include multigrain breads, bran, legumes, milk, yoghurt and fruits. High-GI foods, of which there are more than 70, include rice, potatoes, wholemeal and white bread, and some cereals. Further health benefits may be gained by including foods that are high in fibre.

# NUTRIENTS

Nutrients are chemical substances in food that provide energy, build and maintain cells or regulate body processes. The essential nutrients are:

- Carbohydrates
- Proteins
- Lipids (fats)
- Water
- Fibre
- Vitamins
- Mineral salts.

## Carbohydrates

**Carbohydrates** are a group of organic compounds that includes sugar, starch and cellulose. They are composed of one or more monosaccharide (single-sugar) units. Sugars can be classified as either simple or complex and are divided into groups according to the complexity of their molecular structure. Simple sugars, or **monosaccharides**, include glucose, fructose and galactose (Harris et al 2014). **Disaccharides**, which are a combination of two sugars, include sucrose, lactose and maltose. For example, glucose and fructose combine to form sucrose. Complex sugars or **polysaccharides** are a combination of many sugars and include starch, glycogen and cellulose. Before carbohydrates can be utilised by the body cells, disaccharides and polysaccharides must be converted by chemical digestion into glucose.

Carbohydrates provide energy, assist in the metabolism of fat and act as a protein sparer (if there is insufficient carbohydrate in the diet, protein is converted to glucose and used for energy). Carbohydrate foods also supply indigestible cellulose, which adds bulk to the intestinal contents, resulting in stimulation of peristalsis. The major food sources of carbohydrates are:

- Sugars, present in fruits, honey, cane sugar, milk and cereals
- Starch, present in vegetables, cereals and foods made from cereals (e.g. bread and pasta)
- Cellulose, present in vegetables, fruits and cereals (complex carbohydrates).

## Proteins

Proteins are a group of nitrogenous compounds composed of chains of amino acid subunits. Twenty-two amino acids have been identified in humans. Eight of these, the **essential amino acids**, the body is unable to make, and they must be obtained from dietary sources. The remaining 14 **non-essential amino acids** can be synthesised by the body. Before proteins can be utilised by the cells, they must be broken down by physical and chemical digestion into their constituent amino acids. According to the number and type of amino acids present, proteins are classed as either complete (containing all essential amino acids) or incomplete (lacking one or more essential amino acids) (Harris et al 2014).

Proteins build and repair tissue and supply energy (protein that is not needed for growth and repair of tissues is converted into glucose and stored in the liver and muscles as a reserve store of energy). The major food sources of protein are meat, fish, eggs, cheese, milk, poultry and soya beans (complete (or first-class) protein); and cereals, lentils, legumes and nuts (incomplete (or second-class) protein).

## Lipids (fats)

Lipids are a group of substances that are insoluble in water and are composed of fatty acids and glycerol. Fatty acids are classed as saturated or unsaturated. Saturated, or solid, fats are chiefly of animal origin, such as butter, and contain a full complement of hydrogen. Unsaturated, or soft or liquid, fats are chiefly of vegetable origin, such as margarine, and are capable of adding more hydrogen to their molecular structure.

Before fats can be utilised by the body cells they must be broken down by chemical digestion into their constituent fatty acids and glycerol. Fat supplies energy and may be used in the tissues or stored in adipose tissue, which functions to support and protect nerves and organs from trauma, insulate the body to prevent excessive heat loss or gain and as a reserve store of fuel. Fats also supply the **fat-soluble vitamins** A, D, E and K as well as stimulating adolescence, fertility and mood, and suppressing appetite through the action of hormones such as leptin, secreted by **adipocytes** (Harris et al 2014).

The major food sources of fat are animal fats, present in meat, butter, cream, egg yolk, cheese and fish oils, and vegetable fats, present in margarine, cocoa and oils such as olive, safflower, corn and peanut.

## Water

Water is a chemical compound obtained by the body from food and fluid and as a result of the metabolism of protein, fat and carbohydrate in the tissues. Water constitutes about 60% of the total body weight in an adult and is present as intracellular fluid and extracellular fluid. Water is also the basis of all body secretions and excretions.

Water is necessary for the digestion, absorption and metabolism of food, for the production of secretions and for the maintenance of body fluids. Water is also necessary for the regulation of body temperature by evaporation of sweat, and for the elimination of waste products through the kidneys, bowel, skin and lungs.

Water is present in all body fluids and as part of the cellular structure of solid foods. Foods vary in water content; fruit and vegetables contain about 80–90% water, meat contains about 70% and bread contains about 35%.

## Fibre

Dietary fibre, often referred to as cellulose, is the fibrous parts of food that the digestive system has difficulty in digesting. Fibre creates bulk in the stools, which enhances defecation and is used to prevent or minimise symptoms of certain disorders, such as haemorrhoids, diverticular disease, formation of gallstones, simple constipation and intestinal cancer (Harris et al 2014). Foods with high fibre content are fruits, vegetables and wholegrain products. Clinical Interest Box 30.1 provides discussion of the effects of constipation on the older person.

## Vitamins

Vitamins are a group of organic compounds that, with few exceptions, must be obtained from dietary sources. Although they have no energy value, they are essential for normal metabolic and physiological bodily function. The term vitamin was first used in 1912, and letters of the alphabet were assigned to them as they were discovered. Now that more is

### CLINICAL INTEREST BOX 30.1
### Constipation and the older individual

Constipation can occur at any age but is common in the elderly, associated with diminished exercise, fibre and fluid intake, as well as diminished neurogenic gastrointestinal regulation. Measures to avoid constipation are required to reduce the incidence of conditions such as diverticulosis, megacolon, carcinoma, strokes and heart attacks. A nutritional assessment of dietary intake is required, as is examination for any underlying pathologies, such as those causing disorders such as iron-deficiency anaemia from per-rectal bleeding. The clinical features of this anaemia include constipation, lethargy, easy exhaustion, pale conjunctivae and **pagophagia** (craving for ice). Iron is obtained in large quantities from meat, and many older individuals may be unable to obtain and consume or absorb the required amounts. Iron-replacement therapy may be required; however, supplemental iron can result in constipation, false-positive occult blood test and gastrointestinal upset.

*(Rao & Go 2010)*

known about their composition, the chemical name for a vitamin is frequently used.

Vitamins are classed as being either water- or fat-soluble. The water-soluble vitamins are easily destroyed during the preparation and prolonged cooking of food. If they are consumed in excess of the body's need, they are excreted in the urine. Fat-soluble vitamins are oxidised by exposure to air, light and high temperatures. As fat-soluble vitamins are not soluble in water, any excess is stored in the body, and a condition known as hypervitaminosis may occur, which may result in organ failure (Harris et al 2014).

Excessive intake of vitamin A over long periods can result in hypervitaminosis A, a condition characterised by yellow discolouration of the skin (often mistaken as jaundice), loss of appetite and dry itchy skin. Excessive intake of vitamin B may result in allergic-type reactions. Hypervitaminosis D may occur if excessive amounts of vitamin D are taken in and is characterised by nausea, vomiting, diarrhoea, general irritability and severe impairment of kidney function. In normal circumstances a healthy balanced diet will provide the body with sufficient quantities of all vitamins without the need for supplemental vitamin ingestion. Table 30.2 describes the functions and effects of vitamin deficiencies.

### Mineral salts

Mineral salts are a group of compounds that play an important role in metabolism, maintenance of blood pressure, cardiac function, fluid and electrolyte balance, acid–base balance and the regulation of other body processes. Storage and processing of food does not alter its mineral content, although mineral salts may be lost when food is soaked or cooked in water. The elements that mineral salts contain are classed as either major or trace elements; trace elements are present in only minute quantities in the body. A mineral salt that has the property of being a conductor of electrical current is referred to as an electrolyte. The functions and effects of mineral salt deficiencies are listed in Table 30.3.

## DIETS TO MEET INDIVIDUAL NEEDS

A person's normal diet depends on their age, pattern of eating and the food they choose. Dietary requirements may change during illness; for example, an individual may avoid eating foods that cause adverse reactions such as indigestion, nausea or diarrhoea. The diet may also need to be adapted as part of their treatment during certain conditions and disease states.

While acknowledging the factors that influence a person's choice of foods and observing any restrictions to their diet in the management of disease processes, nurses should encourage the consumption of healthy balanced meals following the Australian Healthy Eating Guide principles.

Furthermore, individuals should become aware of the information in the labels of prepared and packaged foods. Notice should be taken of the expiry date and the presence of preservatives and other additives. The listing of ingredients on the packaging denotes the relative quantities of each ingredient, with the major ingredient listed first. The remainder are listed in order of decreasing quantities.

Individuals may choose, or may be prescribed, certain diets, as follows.

### Healthy balanced diet

A healthy balanced diet is one without dietary restrictions or modifications. An individual may select the foods they prefer within the principles of good nutrition and diets based on age, health and cultural or religious beliefs. Some individuals choose to follow a diet in which specific foods or nutrients are restricted or increased, as part of a commitment to a healthy lifestyle. Other people will follow a diet based on cultural or religious commitment.

A healthy approach to eating based on the Australian Dietary Guidelines is depicted in Figure 30.2.

### Vegetarian diets

Individuals may choose to follow a vegetarian diet for health, personal, ecological or religious reasons. Vegetarian diets exclude all flesh foods, such as meat, fish and poultry, and have an intake high in plant foods. The lacto (milk)-ovo (egg) vegetarian diet includes milk, other dairy products and eggs, while a lacto-vegetarian diet includes milk and other dairy products but excludes eggs. The vegan diet (strict vegetarian) excludes all animal-derived products and consists of plant foods only (Nutrition Australia 2011).

### Religious and cultural diets

Certain religious or cultural groups have particular rules concerning the choice, preparation and storage of specific items

## TABLE 30.2 | Vitamins and health

| Vitamin | Functions | Sources | Effects of deficiency |
|---|---|---|---|
| Vitamin A (retinol or carotenes) | Sustains normal vision in dim light, promotes healthy growth of epithelial tissue and bone and therefore raises resistance to infection | Cod liver oil, liver, kidney, egg yolk, milk and dairy products, yellow fruits and yellow and green vegetables | Night blindness, keratinisation of epithelial tissue (and therefore less resistance to infection), stunted growth, zinc deficiency |
| Thiamine (B1) | Nerve function<br>Energy and carbohydrate metabolism | Yeast extract, wholegrain cereals, meats, leafy green vegetables | Polyneuritis, beriberi, Wernicke–Korsakoff syndrome, lack of muscular and mental development |
| Riboflavin (B2) | Energy and protein metabolism, cellular respiration, healthy skin and mucous membranes | Liver, yeast extract, milk and dairy products, eggs, green leafy vegetables | Fissures at the corner of mouth (cheilosis), angular stomatitis, glossitis, dermatitis, failure to thrive |
| Niacin (B3) | Energy utilisation; metabolism of fat, carbohydrate and protein; nervous system function | Liver, bran, meat, fish, yeast extract, legumes | Pellagra (diarrhoea, dermatitis, dementia); glossitis, anaemia |
| Pantothenic acid (B5) | Metabolism of carbohydrates, protein and fat; formation of haemoglobin and acetylcholine | Offal, yeast, fish, meat, egg yolk, apricots | Fatigue, sleep disturbances, headaches, personality changes, irritability |
| Pyridoxine (B6) | Protein metabolism, nervous system function, formation of red blood cells | Liver, fish, meat, wholegrain cereals, bananas, avocado, egg yolk, peanuts | Neuritis, depression, anaemia, EEG and ECG changes, cheilosis, renal stone formation |
| Cyanocobalamin (B12) | Formation of red cells and nucleic acids | All foods of animal origin | Pernicious anaemia, CNS atrophy, vision loss |
| Biotin | Synthesis of fatty acids, metabolism of carbohydrates and fat, gluconeogenesis | Liver, brewer's yeast, fish, offal, soya beans | Lethargy, dermatitis, EEG and ECG changes, hypercholesterolaemia |
| Folic acid (folacin, folate) | Metabolism, DNA and RNA synthesis, formation of haemoglobin | Liver, citrus fruit, offal, nuts, leafy green vegetables | Macrocytic anaemia, malabsorption |
| Vitamin C (ascorbic acid) | Formation of collagen, assists in wound healing, maintenance of capillaries, production of neurotransmitters, aids absorption of iron | Citrus fruits, tropical fruits, berry fruits, tomatoes, potatoes, green vegetables | Delayed healing, bleeding tendencies, scurvy, reduced nervous system and muscle function |
| Vitamin D (calciferol) | Calcium and phosphorus metabolism, immune function | Cod liver oil, fish, butter, margarine, egg yolk, sunlight on the skin | Rickets, osteomalacia |
| Vitamin E (alpha-tocopherol) | Antioxidant action protects the cell membrane, prevents heart disease and delays the ageing process (not yet confirmed) | Wheatgerm, vegetable oil, wholegrain cereals, nuts, legumes | Muscle degeneration, haemolytic anaemia in the newborn, infertility, malabsorption |
| Vitamin K (menadione) | Formation of clotting factors II, VII, IX and X; assists in regulating calcium metabolism | Liver, leafy green vegetables, egg yolk, synthesised by bacterial flora in the gastrointestinal tract | Bleeding tendencies |

*(Mann & Truswell 2012)*

**TABLE 30.3 | Mineral salts and health**

| Mineral | Functions | Sources | Effects of deficiency |
|---|---|---|---|
| **Major elements found in mineral salts** | | | |
| Calcium (Ca) | Formation of bones and teeth, muscle contraction, normal blood clotting, activator for enzymes and neurotransmitters | Milk, yoghurt, cheese, sardines, salmon, sesame seed paste | Osteoporosis, tetany and severe muscle spasms, osteomalacia |
| Phosphorus (P) | Formation of DNA, bones and teeth; nerve and muscle function | Milk, cheese, meat, fish, eggs | Anaemia, weight loss, abnormal growth |
| Sodium (Na)<br>Potassium (K)<br>Chloride (Cl) | Act closely together in the maintenance of osmotic pressure balance between intra- and extracellular fluid; nerve and muscle function, maintenance of acid–base balance | Salt, fruits, vegetables, monosodium glutamate | Cell and tissue fluid abnormality, arrhythmias, muscular weakness |
| Magnesium (Mg) | Activator of enzymes; nerve and muscle function | Cereals, nuts, leafy green vegetables, dried beans | Anorexia, nausea |
| Iodine (I) | Formation of thyroxine | Seafoods, vegetables, iodised salt | Goitre, myxoedema and hypothyroidism, stillbirths and spontaneous abortions, mental and growth retardation, cretinism |
| Iron (Fe) | Formation of haemoglobin, necessary for the transport of oxygen | Liver, red meats, eggs, leafy green vegetables | Iron-deficiency anaemia, pagophagia, lethargy and exhaustion, poor tissue regeneration |
| **Minor (trace) elements found in mineral salts** | | | |
| Zinc (Zn) | Metabolism, collagen formation, component of certain enzymes, healthy skin and hair | Wheatgerm, oysters, meat, cheese, wholegrain cereals | Impaired healing, poor condition of the skin, growth retardation, fatigue, hair loss, behavioural changes |
| Copper (Cu) | Aids iron absorption; nerve function | Shellfish, nuts, wholegrain cereals | Neutropenia, hypochromic anaemia, vascular disorders |
| Cobalt (Co) | Synthesis of vitamin B12 | Leafy green vegetables | Pernicious anaemia due to vitamin B12 deficiency |
| Sulfur (S) | Constituent of amino acids | Protein foods | Deficiency is rare |
| Selenium (Se) | Antioxidant | Fish, liver, cereals | Muscular dystrophy, delayed growth, renal and cardiac degeneration |

*(Whitney et al 2013)*

in the diet; however, individuals may vary in their adherence to religious dietary doctrines and the nurse should not assume that all people who are of a particular faith strictly follow the religious dietary restrictions. Some examples of religious dietary restrictions are:

- Hinduism (Hindu): people of the Hindu faith abstain from eating beef products and follow a vegetarian diet. Stimulants are forbidden
- Islam (Moslem, Muslim): all pork and pork products, alcohol and caffeine are forbidden. Any meat consumed must be from animals slaughtered according to strict rules (Halal). Ramadan, a period of fasting, forbids eating or drinking of any substance from sunrise to sunset for one lunar month
- Jehovah's Witness: dietary restrictions against any foods that are prepared with blood, for example, some meat

pies and blood sausages. Additionally, some Jehovah's Witnesses may refuse to eat meats if they are unsure if the meat presented was not properly bled. There are no specific 'rules' for correct bleeding of an animal so it is best to discuss this requirement with the individual and their family
- Judaism (Jewish faith): foods must be 'kosher' (prepared according to Jewish law) and only certain parts of an animal may be eaten. All pork, shellfish and predatory birds are prohibited. Meat and dairy products are never eaten at the same time and are required to be stored and prepared separately. Certain periods of fasting are observed, such as Yom Kippur, a 24-hour fast. Passover, lasting 8 days, prohibits the consumption of leavened (yeast-containing) bread. Cooking is not permitted on Saturdays (the Sabbath)
- Mormon (Church of Jesus Christ of Latter Day Saints): meat, although not forbidden, is eaten infrequently. Drinks containing caffeine (e.g. tea, coffee and cola) are not permitted. Tobacco is also forbidden
- Roman Catholic: Ash Wednesday and Good Friday are specified days on which abstinence from meat is obligatory. In addition, Roman Catholics are required to fast for 1 hour before taking Holy Communion
- Seventh-Day Adventist: a lacto-vegetarian diet is commonly followed and stimulants such as coffee, tea and alcohol are not permitted (Office of Multicultural Interests 2013).

## Therapeutic diets

A specific diet may be prescribed to rectify a nutritional deficiency, to decrease specific nutrients or to provide modifications in the texture or consistency of food. If a therapeutic diet is prescribed, it is important that the individual understands the reasons for any restrictions or modifications. Information about various therapeutic diets is provided in Table 30.4. Nursing Care Plan 30.1 shows a sample nursing care plan for an individual on a restricted diet.

## Diets for wound healing

Nutrition is intricately interrelated with wound healing. It is important that appropriate nutritional support be provided to individuals as a part of their wound care plan. Malnutrition has a negative impact on wound management including: delayed wound repair, decreased wound strength and increased risk of skin breakdown. Alternatively, nutritional supplementation has demonstrated positive effects of accelerated wound healing (AWMA 2010). Large wounds cause a large increase in an individual's metabolic rate and therefore require altered intake of energy, protein, carbohydrate, fat, vitamin and minerals (Choo et al 2013). It is therefore not therapeutic for persons with chronic wounds to follow restrictive diets until wound repair has been achieved.

The National Safety and Quality Health Standards were developed to improve the quality and standardise care within Australian healthcare settings. Preventing and managing pressure injuries mandates that individuals with pressure injuries must be managed according to best practice guidelines. Improved nutrition is highlighted by the Australian Commission on Safety and Quality in Health Care (ACSQHC) as an implementation strategy to address risk reduction (ACSQHC 2012; 2015). See Chapter 29 for further information on wound healing.

## Diets and mental health

Just as physical health is interrelated with nutrition so too is mental health. For individuals with mental illness a range of factors increase the risk of poor nutrition: specific symptoms of disorder, diet and lifestyle choices, medication side effects, cognition and poor social determinants. General dietary goals of individuals should be based on the Australian Guide to Healthy Eating to improve both physical and mental health. Specific therapeutic diets (e.g. low tyramine) may be appropriate with particular antidepressant medications or to assist treatment of depressive symptoms (e.g. omega-3 fats, folate and magnesium) (ACI 2013).

### CRITICAL THINKING EXERCISE 30.4

Tyra is 30 weeks gestation with her first child. While she is usually healthy she has been experiencing breathlessness, and tiring easily throughout the day. She complains of light headedness, craving ice and leg cramps. Her GP has discussed oral iron replacement therapy; however, she is concerned regarding the side effect of constipation from this treatment. What diet and care would you recommend to Tyra?

### CRITICAL THINKING EXERCISE 30.5

Mel, 24, who is a strict raw vegan, is hospitalised for severe abdominal pain and dysmenorrhoea. She asks you for jugs of ice to chew on, although she is allowed clear fluids. You suspect pagophagia as a result of blood loss. What other signs or symptoms may reinforce your diagnosis of anaemia and what plan would you devise to prove the anaemia and improve her blood count?

### CRITICAL THINKING EXERCISE 30.6

Belinda, 32 is admitted to the medical ward with mastitis. Her 3-week-old baby is rooming in so she can continue breastfeeding. What are some nutritional considerations needed?

# NURSING PRACTICE AND NUTRITIONAL NEEDS

Each institution has its own system for delivering meals, and the nurse should ensure that both the individual and their immediate environment are prepared in readiness for mealtimes in accordance with local facility policy and procedure.

## TABLE 30.4 | Therapeutic diets

| Diet | Description | Indications |
|---|---|---|
| Clear liquid | No solids permitted and only fluids that leave no residue, are non-irritating and non-gas forming are allowed (e.g. water, black tea or coffee, clear soups and fruit drinks) | Obstruction or irritation of the gastrointestinal tract<br>Preparation for colonoscopy<br>Postoperatively before starting on solids |
| Full liquid | All fluids, plus foods that become liquid at room temperature (e.g. jelly and ice-cream) are permitted | Progression from clear liquids<br>Before starting on solids<br>Inability to chew or swallow solids |
| Soft | Semi-solid easily digested foods are permitted, e.g. soup, cooked cereal, milk pudding, mashed or pureed vegetables and fruit, eggs, soft meats and fish | Advancing from a liquid diet<br>Individuals with chewing or swallowing difficulties<br>Certain gastrointestinal disorders |
| Low fibre | Foods that can be absorbed easily and leave no colour or residue are permitted (e.g. clear soup, tender meat, fish or chicken, eggs, refined cereal products, jelly, ice-cream) | As part of preparation for colonoscopy<br>Colitis<br>Before and after surgery on the lower colon |
| High fibre | Foods that contain residue that adds bulk to the faeces and stimulates peristalsis (e.g. fruit, vegetables, nuts, wholegrain products) | Prevention of cancer<br>Prevention and treatment of constipation<br>Hypercholesterolaemia |
| Low kilojoule | The number of kilojoules is reduced below the usual daily requirement. Foods that are low in fat or refined carbohydrate are permitted | Weight reduction |
| High kilojoule | The number of kilojoules is increased above the usual daily requirements. Foods that are high in carbohydrate, protein and fat are included | Weight gain. To replace and repair damaged tissue (e.g. after severe burns) |
| Low cholesterol | Foods that are high in fat and cholesterol are restricted (e.g. butter, cream, whole milk, cheese, egg yolk, meat) | Prevention or treatment of heart disease, atherosclerosis, high serum cholesterol levels |
| Low fat | Foods that are high in fat are restricted (e.g. butter, cream, whole milk, cheese, fatty meat) | Liver or gallbladder disorders<br>Irritable bowel syndrome<br>Weight reduction |
| Low protein | The amount of protein is restricted and fat and carbohydrate is increased | Kidney or liver failure |
| High protein | The amount of protein is increased and foods high in complete protein are included (e.g. meat, fish, eggs, cheese, milk) | To replace and repair damaged tissue |
| High iron | Foods that are rich in iron are included (e.g. liver, red meat, green leafy vegetables) | Prevention and treatment of iron-deficiency anaemia |
| Controlled carbohydrate (diabetic) | The amounts of carbohydrate, kilojoules and protein are controlled to meet nutritional needs, to control blood sugar levels and to maintain an appropriate body weight | Diabetes mellitus |
| Controlled sodium | Foods that are high in sodium are omitted and no salt is added to food | Cardiovascular disease. Certain kidney diseases, liver failure, fluid retention (oedema) |
| Gluten restricted | Foods that contain gluten are eliminated (e.g. wheat, rye, oats, malt, barley). Rice and corn are permitted | Coeliac disease |
| High vitamin | A balanced healthy diet that includes foods that are high in one or more deficient vitamins | Vitamin deficiency diseases (e.g. night blindness)<br>Anaemia (e.g. vitamin B12, folate)<br>Beriberi<br>Scurvy<br>Rickets |

*(Mahan et al 2012)*

## NURSING CARE PLAN 30.1

**Assessment:** Marcus is a 31-year-old male, 198 cm tall and 140 kg. BMI >30, categorising him as obese. His waist circumference is 150 cm. BP 132/86, HR 98, fasting BGL 7.2 mmol, and reports breathlessness on minimal exertion
**Issue/s to be addressed:** Nutrition altered, more than body requirements—overweight, obesity
**Goal/s:** Decreased body mass index to healthy range
Decreased waist circumference to healthy range
Increased activity level to 30 minutes of exercise 5 days per week

| Care/Actions | Rationale |
|---|---|
| Weekly body weight recorded | Weight loss or gain should be recorded to determine effectiveness of care plan |
| Dietitian referral | Dietitians are a member of multidisciplinary team with a detailed understanding of nutrition to assist in weight loss |
| Formulate eating plan with appropriate caloric intake and nutritional needs | Weight loss is associated with a negative calorie input to output balance |
| Educate individual to keep a daily food and fluid diary | Quantification of intake, and a visual record may also help individual to make more appropriate food choices and serving sizes |
| Facilitate water intake 2 L minimum per day | Water assists in the excretion of by-products of fat breakdown and helps prevent ketosis |
| Discuss mindful eating and consciousness of nutritional habits | Non-hungry eating is a commonly recognised symptom in obese individuals |
| Discuss role of regular exercise | The combination of diet and exercise promotes loss of adipose tissue |

**Evaluation**

6 weeks following implementation of care plan Marcus has had weight reduction of 8 kg and waist circumference decrease of 3 cm. He has decreased breathlessness on exertion and increased activity tolerance with walking 30 minutes 5 days per week. He has maintained a food diary of all intake during the time period. He has identified poor portion control as a trigger for his overindulgence. Marcus reports water intake of approximately 1.5 L per day with a reported effort to increase to the recommended 2 L.

The following aspects of nursing practice in meeting patient nutritional needs are in accordance with information taken from ACI (2012) and NSW Department of Health (2011).

## Assisting individuals at mealtimes

### Key aspects related to providing individuals with meals

- Ward mealtime should be coordinated with nursing care to minimise disruptions.
- Nursing care should be planned to ensure that there are no unpleasant sights, sounds, smells or treatments being performed during mealtimes, as these could interfere with appetite.
- Individuals should be offered the use of toilet facilities, and their hygiene needs should be attended to before meals arrive in the ward.
- Individuals who require assistance/supervision during mealtimes should be identified.
- Ambulant individuals may need assistance to a table; non-ambulant individuals should be assisted into a comfortable position. Either sitting upright in bed or out of bed if appropriate.
- Eating areas should be cleared of unnecessary items to provide space for the meal tray; the tray should be placed within reaching distance for the individual.
- When the meals arrive the nurse should ensure that each individual receives the correct meal, prepared in the correct manner according to their dietary, ethnic, cultural or religious requirements and that all the necessary items meet the individual's needs. This includes the provision of adaptive aids, cutlery and drinking devices for eating/drinking.
- Medications that are required before, during or after the meal are administered (e.g. insulin).
- During mealtimes ensure allocation of appropriate staff, carers, relatives and volunteers to meet individual needs (e.g. by cutting food, opening packets, pouring fluids or help with feeding).
- Nursing staff should provide supervision and assistance with eating and drinking where there is clinical risk (e.g. suspected dysphagia, eating disorders).
- If an individual is not able to eat what has been provided, measures should be taken to obtain an alternative meal type or other form of nourishment.
- The nurse should observe the individual's intake of food and fluid, complete clinical assessment of intake and inform nursing, medical or dietitian staff if the individual's intake declines. Intake needs to subsequently be recorded in food and fluid records accurately.

- Following the meal, the nurse should ensure that the individual has the opportunity and equipment to perform normal hygiene (e.g. cleaning of hands, face and teeth or dentures).

Certain individuals may experience difficulty or be unable to feed themselves for a variety of reasons, including age, general weakness, pain due to surgery, paralysis or limitation of movement due to, for example, the presence of arm splints, intravenous lines or casts. An individual who is dependent may experience embarrassment if they require assistance at mealtimes; the nurse should therefore endeavour to make mealtimes as normal and enjoyable as possible. Clinical Skill 30.1 outlines how to assist with eating and drinking.

## Key aspects related to assisting an adult at mealtimes

- Ensure that the individual is comfortable before starting a meal.
- Elimination and hygiene needs should be attended to before a meal is started.
- The individual may require to be assisted into a comfortable position and the table adjusted to the appropriate height.
- The meal should be placed where it can be seen and smelt, to stimulate the appetite.
- Condiments (e.g. salt and pepper) should be provided and may be added to the food, provided the individual is not on a salt-restricted diet.
- The nurse should ascertain whether the individual prefers one food at a time or a combination (e.g. meat alone, or combined with a vegetable). It is also important to ensure that food or fluids are not too hot or cold.
- Suitable utensils should be selected (e.g. an individual may prefer to eat using a spoon rather than a fork). The amount of food placed on the utensil should be easily managed by the individual. The utensil should be placed gently into the front of the mouth, to avoid injury or stimulation of the gag reflex.
- The food should be presented at a rate that meets the individual's needs, giving them sufficient time to chew and swallow each mouthful and to maintain dignity.
- Sips of fluid should be offered during the meal. A flexible straw, rather than a cup or glass, may be easier for some individuals to manage.
- To maintain dignity and to promote independence, the individual should be encouraged to be as independent as possible and may be encouraged, but never forced, to eat a meal.
- Allow the individual to wipe their mouth with a serviette during the meal, or assist if necessary.
- On completion of the meal, the individual's hygiene and comfort needs should be met. The nurse should report and document the intake of food and fluid.

## Key aspects related to assisting a child at mealtimes

Mealtimes in a hospital should be pleasant unhurried occasions and the environment should be one that enables the child to enjoy mealtimes. The nurse should communicate effectively with the parent/carer and child to ensure that the appropriate foods are being served. Some guidelines are:

- Mealtimes should be free from distractions
- Servings need to be small to minimise the psychological reaction to a large-sized serving
- Adequate time should be allowed for the meal to be eaten without hurrying
- The child should be prepared for the meal. Toilet needs should be attended to, nappy changed if necessary, hands and face washed, serviette or bib provided, distractions such as toys put away and the child made comfortable in bed or seated on a chair at a table
- The child should be discouraged from eating in front of the television or electronic devices (Hare-Bruun et al 2011)
- Painful or emotionally distressing procedures should not be performed immediately before or after a meal, and activities should be timed so that a child does not become too tired to eat a meal
- Meals should be served attractively, in amounts appropriate to the age and the condition of each child
- Children should be encouraged to feed themselves, even though they may do it in a 'messy' fashion
- Assistance should be given if the child is unable to manage or to use distractive therapy to maintain input
- Some children may need coaxing, but a child must never be forced to eat (Australian Government Department of Health 2011).

Uneaten food should be removed without comment and the nurse in charge informed. If the child's illness is causing anorexia, other forms of nutrition may be offered. Refusal to eat may be an attempt by the child to gain more attention, or it may be that the foods are different in appearance, presentation, availability of condiments or timing to the meals they are used to eating. Every attempt should be made to provide nutritious foods that the child enjoys. In a clinical setting, a lot of patience may be required to assist a child to eat a healthy balanced diet, particularly if their carers are not present. The child may be apprehensive of their setting, in pain, used to different foods or their diet at home may be of a poor standard.

Children should be observed for any adverse reaction to food and the nurse in charge and/or medical officer informed if a child vomits before, during or after a meal; develops diarrhoea; or develops what may be an allergic reaction to a food, such as a rash, pruritus or breathing difficulties.

## Key aspects related to assisting an individual with dementia at mealtimes

The general nutritional requirements of an individual with dementia are similar to those of others of the same age;

## CLINICAL SKILL 30.1 Assisting with eating and drinking

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| Am I educated?<br>Am I authorised?<br>Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. however, due to cognitive decline they may require a range of interventions to support intake:

- Assistive feeding devices to promote independent provision of food and fluids
- Finger foods may allow the person to regain the enjoyment of eating if they have experienced the loss of adequate manual dexterity to control cutlery
- Encourage support of family and caregivers at meal time
- Specific diet to meet personal food taste
- Contrasting-coloured crockery may assist the individual distinguish food/fluids
- As oral intake diminishes artificial nutrition may be necessary (Evans & Best 2015).

## Key aspects related to assisting an individual with chewing or swallowing difficulties

Some individuals who experience difficulty in chewing or have dysphagia due to, for example, glossitis, stomatitis, cerebral vascular accidents or dental conditions, are at risk of malnutrition because of limitations to the types of foods they can chew and swallow safely. Clinical Interest Box 30.2 provides an example of how gastro-oesophageal reflux can affect the nutritional status of a child. Individuals may require modifications to the consistency of food. Depending on the cause and degree of difficulty, the individual's needs may be met by:

- Referral to a speech pathologist to ascertain the cause of the problem by observing the individual's swallowing reflex and by investigations such as salivagrams, fluoroscopy or barium swallows
- Providing meals comprised of soft foods or thickened fluids
- Initiating the swallowing reflex by gentle pressure on the tongue with the feeding utensil
- Offering all food and fluid carefully and monitoring to avoid or detect aspiration
- Placing the food into the unaffected side of the mouth in individuals with a facial paralysis (e.g. Bell's palsy) or after a cerebrovascular accident. The nurse should ensure that food does not accumulate in the cheek of the affected side (Department of Communities, Child Safety and Disability Services 2013).

## Key aspects related to assisting an individual with visual impairment at mealtimes

- It is important to encourage independence; the nurse should therefore consult the individual about the type of assistance that would be most beneficial. For example, individuals may find it helpful if the nurse describes the meal by referring to the plate as a clock face. The nurse should state where each food on the plate may be located (e.g. the meat at 2 o'clock, the potatoes at 4 o'clock and the beans at 6 o'clock).
- To avoid injury the individual should be made aware of the proximity and location of hot articles (e.g. cups of

## CLINICAL INTEREST BOX 30.2 Gastro-oesophageal reflux and failure to thrive

Failure to thrive is a term used in paediatrics to describe an infant, toddler or child who fails to gain weight when measured against percentile charts for age, head circumference and height. In infancy failure to thrive can be associated with mild to severe alterations in nutritional state as a consequence of numerous clinical disorders.

A common condition is gastro-oesophageal reflux (GOR), which can be due to lax cardiac sphincter muscle or changes in coordination of oesophageal peristalsis. GOR can cause oesophagitis from intermittent bathing of oesophageal tissue in stomach acid. Common symptoms may also include food refusal, diminished intake, prolonged feeding times, distractibility, sleep disorders and continued crying, which may lead some to diagnose an infant as a 'colicky baby'. Diagnosis is made by history and monitoring oesophageal pH over a 24-hour period. Treatments may include thickening agents, post prandial prone positioning while awake, positioning up to 30 degrees from the horizontal while sleeping, peristaltic medications and gastric acid inhibitors. Changing the infant's diet is not suggested (i.e. from breast milk to formula or, if formula fed switching to an alternative formula type).

*(Royal Children's Hospital Melbourne 2010)*

tea or coffee) and the nurse should ask if assistance to pour the fluids is required.
- If the individual is unable to feed themself, they should be asked to indicate when they are ready for the next mouthful.
- Self-feeding should be encouraged at all ages to promote independence and dignity. When an individual is being fed, the nurse should perform the procedure in a relaxed and confident manner, with due regard for maintaining their dignity. A variety of self-help devices are available to assist individuals in feeding themselves (Figure 30.6) (Vision Australia 2012).

### Assistive feeding devices

Self-help feeding devices (Figure 30.6) may be helpful for an individual who has poor vision, limited arm mobility, limited grasp or reduced coordination and include:
- Plate guards, which attach to one side of the plate and are used to assist an individual to place food on the eating utensils
- Angled or swivelling utensils (e.g. forks and spoons that are angled to assist individuals with a limited range of arm or hand movement)
- Weighted utensils for individuals with limited hand control (e.g. Parkinson's)

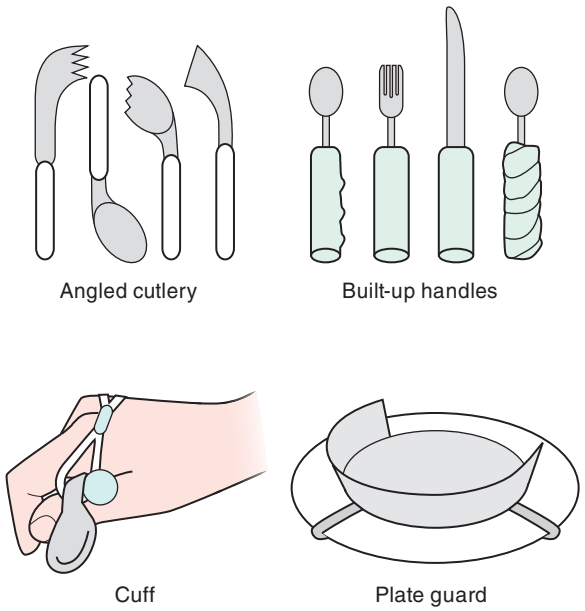

**Figure 30.6** Assistive feeding devices

- Utensils with built-up handles. The thicker handles are beneficial for individuals with diminished grasp or who experience joint pain or discomfort (e.g. arthritis)
- Cuffs, which are placed over an individual's hand, with a spoon or fork inserted into the slot in the cuff. A cuff may be beneficial for an individual with diminished grasp or movement.

## COMMON DISORDERS ASSOCIATED WITH NUTRITION

Although many disorders are related to a specific nutrient deficiency, the common disorders of nutrition may be classified as malnutrition, obesity, eating disorders and nutrient loss as a result of vomiting or diarrhoea.

### Malnutrition

Malnutrition occurs as a consequence of continued poor nutrition status and may be described as the condition in which nutrients are being used or lost by the body in excess of the intake and absorption or utilisation of nutrients. Identifying factors that put an individual at risk is an important step in ensuring that all individuals have their individual nutritional needs met. People who are at risk of malnutrition include those who:
- Are experiencing increased metabolic demands or protracted loss of nutrients (e.g. due to burns, surgery, inflammatory conditions or infections, vomiting, diarrhoea, physical or psychological trauma, hormonal imbalance or prolonged pyrexia)
- Are not consuming oral food or fluid for more than a few days
- Have a BMI value below 20 or who have recently experienced a loss of more than 10% of their normal body weight

- Are alcohol or drug dependent
- Are receiving medications or treatments that have an anti-nutrient or have catabolic properties (e.g. immunosuppressants or anti-tumour agents)
- Have a disorder that results in defective digestion, utilisation or absorption of nutrients (e.g. gastrectomy, diabetes mellitus, Crohn's disease).

The NSW Agency for Clinical Innovation (ACI) reports malnutrition in hospitals is frequently undetected and untreated. From a 24-hour survey across 56 Australian and New Zealand hospitals assessing the nutritional status and dietary intake of adult hospitalised patients, Agarwal and colleagues (2010) found malnutrition rates in Australian acute hospitals were between 30% and 50%.

Early identification of individuals at risk of malnutrition enables early nutrition intervention to be initiated. Adverse consequences of malnutrition include:

- Increased infection rate
- Delayed wound healing
- Increased risk of complications (e.g. pressure injuries, sepsis, falls, adverse drug reactions and interactions, decline in mental health)
- Muscle wasting and weakness
- Dehydration
- Impaired mobility
- Decreased response and/or tolerance to treatment
- Decreased quality of life
- Decreased life expectancy
- Increased use of medication
- Increased length of stay
- Increased re-admission (ACI 2012; Queensland Health 2013).

Treatment includes identifying the cause and providing adequate nutrients. See Clinical Interest Box 30.3 on high rates of malnutrition in the elderly.

## Obesity

Obesity is the condition in which there is an excess of body fat, and is determined by calculating the individual's BMI or waist measurement. Obesity is due mainly to an imbalance of energy intake from diet and energy expenditure (through physical activities and bodily functions). Genetic and environmental factors play a role (AIHW 2015a). Obesity may result from excessive kilojoule intake, metabolic disturbances, side effects of drugs such as steroids, an inadequate expenditure of energy or from a combination of factors. Obesity may have serious consequences, including cancer, premature cardiovascular disease, breathing difficulties, hypertension, diabetes mellitus, gallbladder disease or psychosocial problems (AIHW 2015a). Obese people may also demonstrate undernourishment in essential vitamins and minerals, even though excess food is consumed (Berman et al 2015).

Principles of treatment include reducing dietary intake and any causative drugs or hormones, while planning exercise, dietary and behaviour modification and the administration of medications such as appetite suppressants, hormonal therapy or oral substances containing; for example, cellulose.

### CLINICAL INTEREST BOX 30.3 High rates of malnutrition in hospitalised individuals

Agarwal et al (2010) conducted a ground-breaking Australian study involving 56 hospitals across Australia and New Zealand. The 3122 participants were involved in an audit of nutritional status and dietary intake of adult hospitalised individuals using the Malnutrition Screening Tool. This study revealed alarming levels of malnutrition. In hospitalised persons, based on the International Classification of Diseases (Australian modification), participants were deemed malnourished if their body mass index was <18.5 kg/m$^2$. Malnutrition prevalence was recorded as 32% with a further 41% of the participants deemed 'at risk' of malnutrition. Fifty-five per cent of malnourished participants consumed ≤50% of the food offered with 'Not hungry' the most common reason for poor food consumption. This study highlights the prevalence of malnutrition in the Australian population. With the burden of increased morbidity and mortality surrounding malnutrition as well as the associated financial burden on the healthcare system it is essential nursing staff implement early nutrition interventions and referral to members of multidisciplinary teams.

*(Agarwal et al 2010)*

Surgical interventions are sometimes indicated in instances of morbid obesity. A variety of surgical procedures is available and most are aimed at reducing the capacity of the stomach (Cobbols & Lord 2012). See Nursing Care Plan 30.1 for an example of the nursing care required for obese individuals.

## Eating disorders

The two most recognised disorders of eating are anorexia nervosa and bulimia nervosa. **Anorexia nervosa** is characterised by self-imposed starvation, weight phobia and consequent emaciation. Body image, with a consequential loss of weight, becomes the individual's prime focus and is the result of a belief that their body is too fat, even when extreme emaciation is evident with BMI <18.5 (Brown et al 2014). **Bulimia nervosa** is characterised by episodes of 'bingeing' on large quantities of food, followed by purging with laxatives or self-induced vomiting.

The causes of both disorders are difficult to determine, but most experts agree that they result from an interaction of biological, psychological and sociocultural factors. Treatment, which is difficult and varied, includes behaviour modification, psychotherapy and, in some cases, hospitalisation until the desired weight is achieved (National Eating Disorders Collaboration 2014).

## Nutrient loss as a result of vomiting

Vomiting, if prolonged, may result in significant nutrient deficiency, dehydration and electrolyte disturbance. To correct

the imbalance, oral, enteral, intravenous therapy or total parenteral nutrition (TPN) may be indicated. Vomiting is not a disease itself but is a symptom of disease and may occur as a result of:

- Diseases of the stomach, intestines, liver, biliary system, pancreas or peritoneum
- Hypersensitivity to certain foods
- Ingestion or presence of irritants
- Acidosis, either metabolic or respiratory
- Pain
- Adverse reaction to, or a side effect of, certain medications
- Hormonal changes during early pregnancy
- Disturbances of equilibrium (e.g. travel sickness, vestibulitis)
- Disorders of the central nervous system (e.g. concussion, cerebral oedema, brain tumours)
- Psychological factors (e.g. apprehension, unpleasant sights or smells).

Vomiting (emesis) is the expulsion of the contents of the stomach or small intestine and is a reflex action caused by stimulation of the emesis centre in the medulla oblongata. When this centre is stimulated the glottis and nasopharynx close, the cardiac sphincter of the stomach relaxes and contractions of the diaphragm and abdominal muscles occur. As a result of the increased intra-abdominal pressure, the stomach or intestinal contents are forced upwards and are expelled through the mouth. Vomiting may be preceded by a feeling of sickness (nausea) and accompanied by salivation, sweating and pallor. In conditions such as intestinal or sphincter obstruction, 'projectile' vomiting may occur, in which the vomited material is ejected with great force (Harris et al 2014).

Vomiting should be assessed in terms of the nature of vomiting (effortless or projectile) and the characteristics of the material vomited (vomitus). Observations made of the vomitus may assist in determining the cause of vomiting and include observations of the:

- Consistency: the vomitus may consist of fluid, partially digested or undigested food
- Colour: vomitus may vary in colour from clear to yellow, to brown or green. The presence of bile tends to colour vomitus yellow or green and may indicate propulsion of the contents of the small intestine into the stomach
- Presence of blood: blood may be present as bright red streaks or clots, or may have a 'coffee grounds' appearance. The latter occurs when blood has been partially digested by gastric acid secretions. Vomiting of blood is called haematemesis. Forceful vomiting may induce blood-stained vomit (e.g. Weismann's tear)
- Odour: vomitus is usually sour smelling, but a 'faecal' odour indicates reflux of bowel contents due to an intestinal obstruction (e.g. paralytic ileus)
- Quantity: if possible, vomitus should be measured in millilitres to assess the amount of fluid being lost, particularly if haematemesis is present.

### Key aspects related to care of an individual who is vomiting

- If the individual is sitting, place an emesis bowl under the chin and position a towel to protect clothes and bedding.
- If the individual is lying down, lift and turn the head to one side to reduce the risk of aspiration.
- Ensure privacy, as individuals will feel distressed and embarrassed by the incident.
- Ensure dentures do not become dislodged.
- The nurse should stay with the individual to provide comfort and support, to ensure aspiration is recognised or prevented and to splint an abdominal wound or area of pain to reduce further pain or dehiscence of wounds, if present.
- The vomitus should be removed as soon as the episode is over to reduce the risk of a recurrence caused by the sight, smell or thought of the vomitus.
- Soiled linen or clothing should be changed and removed immediately from the room.
- Hands and face should be washed to refresh the individual and to remove any vomitus.
- Oral hygiene should be attended to by cleaning teeth, plates or dentures and providing a suitable mouth rinse to eliminate any unpleasant aftertaste.
- The individual should be assisted into a position of comfort and permitted to rest quietly.
- If anti-emetics are ordered they should be administered by appropriate nursing staff.
- Assess hydration status including urine output, mucous membranes, thirst, skin turgor and capillary refill.
- Take measurement of individual's blood glucose level to recognise/treat hypoglycaemia (Emergency Care Institute 2015).
- The nurse should report and document (in healthcare record, fluid balance chart) the incident so that appropriate nursing or medical actions may be implemented. An anti-emetic medication may be prescribed by a medical officer and administered to reduce nausea and to prevent further vomiting.

## Alternative methods to meet nutritional needs

An alternative method of meeting nutritional needs may be indicated when an individual is unable to consume food or fluid orally. Alternative methods include total parenteral nutrition (TPN), intravenous therapy and tube feeding via orogastric, nasogastric, nasoduodenal, nasojejunal, gastrostomy, gastroduodenal or gastrojejunal tubes.

### Total parenteral nutrition

**Total parenteral nutrition (TPN)** is sometimes referred to as hyperalimentation and involves the parenteral administration of a complete nutritional preparation that contains high concentrations of essential nutrients and which may include intralipid solutions, containing fats (Harris et al 2014). This method of feeding may be indicated when it is not possible

for the individual's nutritional needs to be met via the digestive tract.

Hypertonic solutions are administered through a catheter that has been inserted into a large vein, such as the subclavian vein. Further information about intravenous therapy can be found in Chapter 26. The solution containing nutrients enters directly into the bloodstream. TPN solutions administered by this route provide a medium for rapid bacterial growth and, because the tubing provides access for the entry of microorganisms, contamination and septicaemia must be prevented. The catheter is inserted by a medical officer using sterile equipment and technique. Care of the equipment throughout the course of treatment requires strict asepsis.

Management of an individual who is receiving TPN is the responsibility of the Registered Nurse (RN), and the individual must be monitored continually to prevent or detect possible complications. Complications that may result from TPN include:

- Hyperglycaemia or hypoglycaemia
- Fluid and electrolyte imbalance
- Catheter-related septicaemia
- Infection of the catheter site
- Extravasation of blood from the vein as a result of catheter trauma
- Air emboli
- Liver failure
- Diarrhoea or constipation.

The nurse may be required to assist with the care of an individual receiving TPN and must be aware of the scope of their role in promoting safety and comfort (Reghim & Zeltoun 2012).

## Intravenous therapy

Intravenous therapy involves the introduction of a solution or solutions into a peripheral or central vein. Information about intravenous therapy is provided in Chapter 26.

## Enteral tube feeding

Naso-enteric tubes are orogastric, nasogastric, naso-duodenal or nasojejunal tubes used to administer a range of nutritional feeds to an individual for a variety of reasons, including:

- Malabsorption (e.g. inflammatory bowel disorders)
- Surgery (e.g. oral or throat surgery)
- Central nervous system disorders (e.g. paraplegia, unconsciousness, pharyngeal paralysis)
- Metabolic disorders (e.g. hyperinsulinaemia, hypoglycaemia)
- Food refusal or **dysphagia**, when the individual is too ill or weak to eat normally.

Selecting the most appropriate device for an individual is multifactorial. The device selection should always include the individual and include consideration of anticipated feeding duration and the individual's clinical condition and social circumstances (Fletcher 2014).

The nurse should be aware of the policies and regulations regarding their role and responsibilities in both insertion and management of **enteral** tubes.

### Nasogastric tubes

Feeds given by a nasogastric tube inserted via the nares into the stomach (Figure 30.7) are normally administered to individuals who experience short-term difficulties in nutrition, or when surgically placed tubes such as gastrostomy tubes (see below) may be contraindicated by the individual's physical condition. For information on insertion of a nasogastric tube see Clinical Skill 30.2. Following insertion it is essential nursing progress notes are completed abiding to institution documentation policies. See Progress Note Example 30.1.

### Nasoduodenal and nasojejunal tubes

Tubes placed into the duodenum or jejunum are used for individuals with gastric disorders that contraindicate gastric placement, such as severe reflux, partial or total gastrectomy and malabsorption.

### Gastrostomy tubes

Feeding via a gastrostomy tube may be indicated if there has been recent surgery or an obstruction in the upper part of the digestive tract, or as a long-term treatment for feeding difficulties. A gastrostomy tube is a hollow tube, often composed of silicone, inserted through the abdomen into the stomach by a surgeon either through an external approach, via an incision through the abdominal wall, or endoscopically via the mouth through the stomach and through the abdominal wall. The opening around the tube may be sutured to prevent leakage or accidental removal (Figure 30.8) or held in place by the use of an inflatable balloon and a flange or similar device that applies pressure to hold the tube against the inside wall of the stomach.

Gastrostomy (percutaneous endoscopic gastrostomy (PEG) and jejunostomy (percutaneous endoscopic jejunostomy (PEJ)) devices are used for long-term nutritional support, generally more than 6–8 weeks (Berman et al 2015). Fluid enteral feeds are normally introduced 24 hours later through the tube, into the lumen of the stomach, duodenum or jejunum. Some tubes may require replacement to prevent or treat occlusion or disintegration; long-term silastic tubes may be left in situ indefinitely. In the event of accidental tube removal, the individual should have a Foley or Malecot catheter available, to enable a medical officer to ensure the stoma's patency and continuity of feed.

Prepared enteral feeds are administered either by:

- Intermittent or bolus feeds, in which a solution is administered at regular intervals (e.g. every 4 hours). Administered to individuals who are able to tolerate volumes at a rate they could normally drink orally. A syringe or giving set is attached to the end of the nasogastric tube and filled with the feed or fluid, which is allowed to flow in slowly by gravity or by the use of an enteral feeding pump. The rate of administration can be adjusted; for example, by the height at which the syringe or set is held at, or by adjusting the enteral pumping rate; or
- Continuous feeds, in which a gravity infusion set or a controlled enteral feeding pump is used that can deliver the fluid at a regulated rate over a predetermined time.

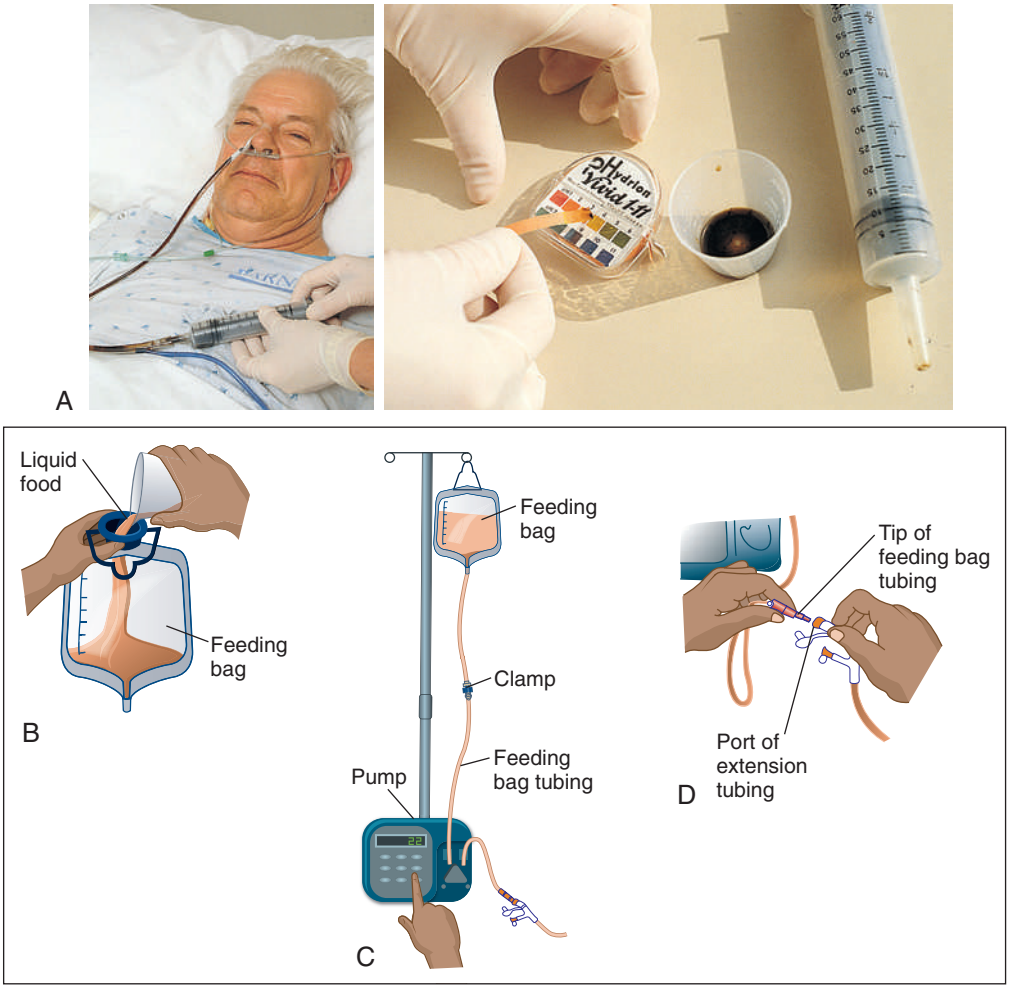

**Figure 30.7** Administering enteral feeds via nasogastric tubes

A: Confirm placement B: Pour formula into feeding container C: Connect tubing through infusion pump D: Connect to NG

(***A:*** *Crisp & Taylor 2013*; ***B–D:*** *Adapted from Fairview Health Services 2016*)

## CLINICAL SKILL 30.2 Inserting a nasogastric tube

**Review and carry out the standard steps for all clinical skills/interventions**

**NMBA Decision-making Framework considerations:**

Am I educated?
Am I authorised?
Am I competent?
If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator.

**Equipment:**

Appropriate-sized gastric tube (large or fine bore tube)
Nasofix or hypoallergenic tape (approx 7 cm × 2.5 cm split in half for 5 cm of its length to look 'Y-shaped'
Lubricant (KY gel) if tube not self-lubricating
10 mL and 20 mL syringes
Water or moist cotton buds (if permitted)
Kidney dish
PPE (non-sterile gloves, goggles and apron)
Yankauer sucker and suction
Emesis bag/bowl
Tissues
Protective sheet
Plastic bag
Equipment for observations ($O_2$ saturation)
Safety pin
Spigot or drainage bag if required
pH indicator paper/strip

*Continued*

## CLINICAL SKILL 30.2 Inserting a nasogastric tube—cont'd

| Skill activity | Rationale |
|---|---|
| Validate the medical orders in the individual's record | Ensures correct procedure is about to take place |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Critically think through the assessment data and problem solving—individual's health status (baseline observations), contraindications and special precautions for nasogastric tube insertion, privacy, comfort measures | Evaluate each aspect and its relationship to other data to help identify specific problems and modifications of the procedure that may be needed for the individual |
| Place the equipment in a convenient location near the bedside. Assemble the required equipment including suction equipment or equipment related to providing nutrition as indicated prior to beginning the procedure<br>Raise the bed to the appropriate working position based on your height | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Assist the individual into the high Fowler's position with neck flexed unless contraindicated<br>Spinal and neurological individuals must be positioned as per medical orders | Facilitates tube insertion and reduces risk of gastro-oesophageal reflux and aspiration<br>Avoids neck extension as it closes oesophagus, opens trachea and promotes aspiration |
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination of tubing |
| Clean nares if necessary and examine nostrils for deformity/obstruction and nasal surgery to determine best side for insertion<br>If nasogastric tube is being reinserted the other nostril should be used | Asking the individual to breathe through one nostril while occluding the other will help ascertain if one nostril has an occlusion<br>Minimises risk of irritation and pressure necrosis around the nose |
| Measure the portion of tube to be inserted by extending it from the tip of the individual's nose to the earlobe and from the earlobe to the xiphoid process<br>Note length and mark this measurement on the tube | Determines the insertion length of the tube to ensure the tube is inserted an adequate distance so that the distal tip rests in the stomach |
| Flush fine bore nasogastric tube with 10 mL of water to activate the Hydromer coating | Ensures easy removal of stylet after insertion and confirms correct positioning |
| Lubricate the first 5–10 cm of the tube with water-soluble lubricant<br>*Note*: Some small-bore tubes self-lubricate when dipped in water | The use of lubricant will ease insertion by decreasing friction |
| Grasp the tube with your hand and gently insert it into the nostril guiding it posteriorly and inferiorly straight back along the floor of the nose<br>Ask the individual to sniff to ease the passage of the tube from nose to oropharynx<br>Have an emesis basin and tissues in the individual's lap<br>Pause a moment if the individual is coughing or gagging | Insertion of the NGT can stimulate the gag reflex |

| CLINICAL SKILL 30.2 Inserting a nasogastric tube—cont'd | |
|---|---|
| Instruct the individual to tilt the head slightly forwards | Flexing the head forwards allows the tube to follow the posterior wall of the nasopharynx and enter the oesophagus rather than the trachea |
| Instruct the individual to swallow while you gently but steadily advance the tube. Coincide advancement of the tube with the individual swallowing<br>DO NOT give sips of water as the tube is being inserted. If the individual has a dry mouth but impaired gag reflex the mouth may be moistened with a cotton bud prior to requesting them to swallow or ask individual to sniff to elevate the soft palate | The muscular movement of swallowing helps advance the tube<br>Minimises risk of aspiration |
| If resistance is met withdraw the tube 1–2 cm and rotate the tube slowly with downward advancement towards the closest ear<br>Do not force the nasogastric tube<br>Abort procedure and attempt other nostril<br>Withdraw the tube immediately if the individual exhibits signs of distress or a change in respiratory status, if individual begins to cough or change colour or if the tube coils in the individual's mouth | Prevents adverse individual outcome such as pneumothorax, aspiration, trauma to surrounding tissues, incorrect tube placement into lungs or cranium |
| Advance tube until the pre-measured mark is reached<br>When the pre-measured mark has been reached secure the tube to the individual's nose using Nasofix or hypoallergenic tape ensuring the tube does not cause pressure on the naris<br>If inserting a fine-bore nasogastric tube do not remove stylet until correct placement has been confirmed by x-ray and documented in individual's health record<br>To prevent tension on the tube place a piece of tape onto the nasogastric tube (distal end) and attach it to individual's clothing | Ensures the tube does not move out of the stomach |
| Perform and document observations and compare to pre-procedure observations<br>Notify the Registered Nurse/medical officer if there is a significant deviation from baseline observations or if there is a change in the individual's condition | Ensures individual has not been compromised by insertion of nasogastric tube |
| Ensure correct position of the nasogastric tube<br>Aspirate 5 to 10 mL of gastrointestinal fluid. Observe amount, colour and test pH using pH indicator paper/strip<br>Obtain post-insertion chest/upper abdominal x-ray<br>The medical officer must document correct placement in the individual's file prior to the administration of any medications, fluids or formula<br>Once correct placement has been confirmed and documented reactivate the Hydromer coating with another 10 mL of water before removing the stylet<br>The stylet must not be reinserted<br>If using a large-bore tube for aspiration attach a spigot or drainage bag to the main lumen of the nasogastric tube | Ensures the tube is in the correct location and not in the trachea<br>Gastric fluid pH is usually 1.0–4.0, indicating the tube is in correct position<br>pH of pleural fluid is usually >6, indicating incorrect position |
| Discard the equipment appropriately<br>Remove gloves. Perform hand hygiene | Prevents cross-infection |

*Continued*

| CLINICAL SKILL 30.2 Inserting a nasogastric tube—cont'd | |
|---|---|
| Lower the bed keeping the individual upright and ensuring individual comfort<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Document in individual's healthcare record reason for nasogastric tube insertion, nostril used, type and size of tube, insertion distance and the external length of the tube (from nostril to tip)<br>Report the procedure and any abnormal findings to Registered Nurse/medical officer | Documentation and reporting increases the communication between healthcare professionals and complies with legal requirements for reporting change |
| *(Agency for Clinical Innovation 2012; ACSQHC 2012; 2015; Berman et al 2015; Crisp & Taylor 2013; Dempsey et al 2014; LeMone et al 2014; NSW Department of Health Policy 2009)* | |

| PROGRESS NOTE EXAMPLE 30.1 | |
|---|---|
| 12/08/2015<br>0810 hrs | Nursing: NG inserted as per Dr Smith orders above. NG size 16F inserted Left naris to 30 cm without difficulty. Placement confirmed with universal paper pH = 4. RN Pepper witness to pH. NG Gastrolyte commenced as per fluid order. Dr Smith aware of same.<br>***L. Jensen* (Jensen) EN** |

Continuous feeds are administered to individuals who have experienced difficulty in tolerating bolus doses, or for individuals with malabsorption, reactive hyperinsulinaemia, diarrhoea or other metabolic problems.

Depending on the institution and the nutrition required, the enteral feed may come pre-packaged, for example in cans, and will not require refrigeration, while other solutions stored in containers such as waxed cardboard or made in-house do require refrigeration.

The nurse should be aware of the policies and regulations in their healthcare setting regarding their role and responsibilities in checking the location of the tip of the nasogastric tube (see Clinical Skill 30.3).

## Care specific to gastrostomy type tubes

For individuals who may be discharged home or to encourage independence with enteral tubes in situ, the individual may be taught how to test, administer and perform the care required independently. Part of the education involves discussing some of the complications and how to deal with them, as described below.

***Care and cleaning of gastrostomy tube and equipment***

*Abdominal distension*. Determine tube position by testing the aspirate with pH-sensitive paper. Before administering an enteral feed or fluid, gas may be vented (released) from the stomach to avoid distension. Venting is achieved by removing a spigot, unscrewing a cap and/or releasing an obstructive clamp, or by inserting a catheter and raising the tube to a vertical position.

*Hanging times*. In a warm environment, feeds can be contaminated by pathogens. For maximum hanging times local policies and procedures should be abided by. Times may vary depending on the individual's condition (e.g. immunocompromised), the type of feed and environment (e.g. hospital setting or person's home).

*Home* Cleaning. Feeding equipment, syringes, etc. can be washed with warm soapy water and left to air dry and can be used for 3 days. The equipment should be washed again in warm soapy water immediately before each use.

*Flushing*. Flush tube pre and post feeding. Flush tube pre and post medications. If the individual is on continuous feeding the gastrostomy tube should be flushed every 4 hours.

***Skin care*** The area around the gastrostomy site requires daily cleaning with warm soapy water to remove build-up of secretions from the stoma site and to prevent infection. Creams and dressings are not recommended if there is no redness or inflammation. The tube and the surrounding pressure device should be rotated in the stoma daily to prevent adhesion or ulceration of the surrounding skin. The skin around the site should be inspected for redness, oozing, swelling or bleeding (Forest-Lalande 2012a).

## Common problems associated with enteral feeding

***Aspiration*** This is the most life-threatening complication (Stayner 2012) and occurs when gastric contents, saliva, food or nasopharyngeal secretions have been inhaled into the respiratory tract. Signs and symptoms of aspiration include tachypnoea, increased work of breathing, wheeze, crackles,

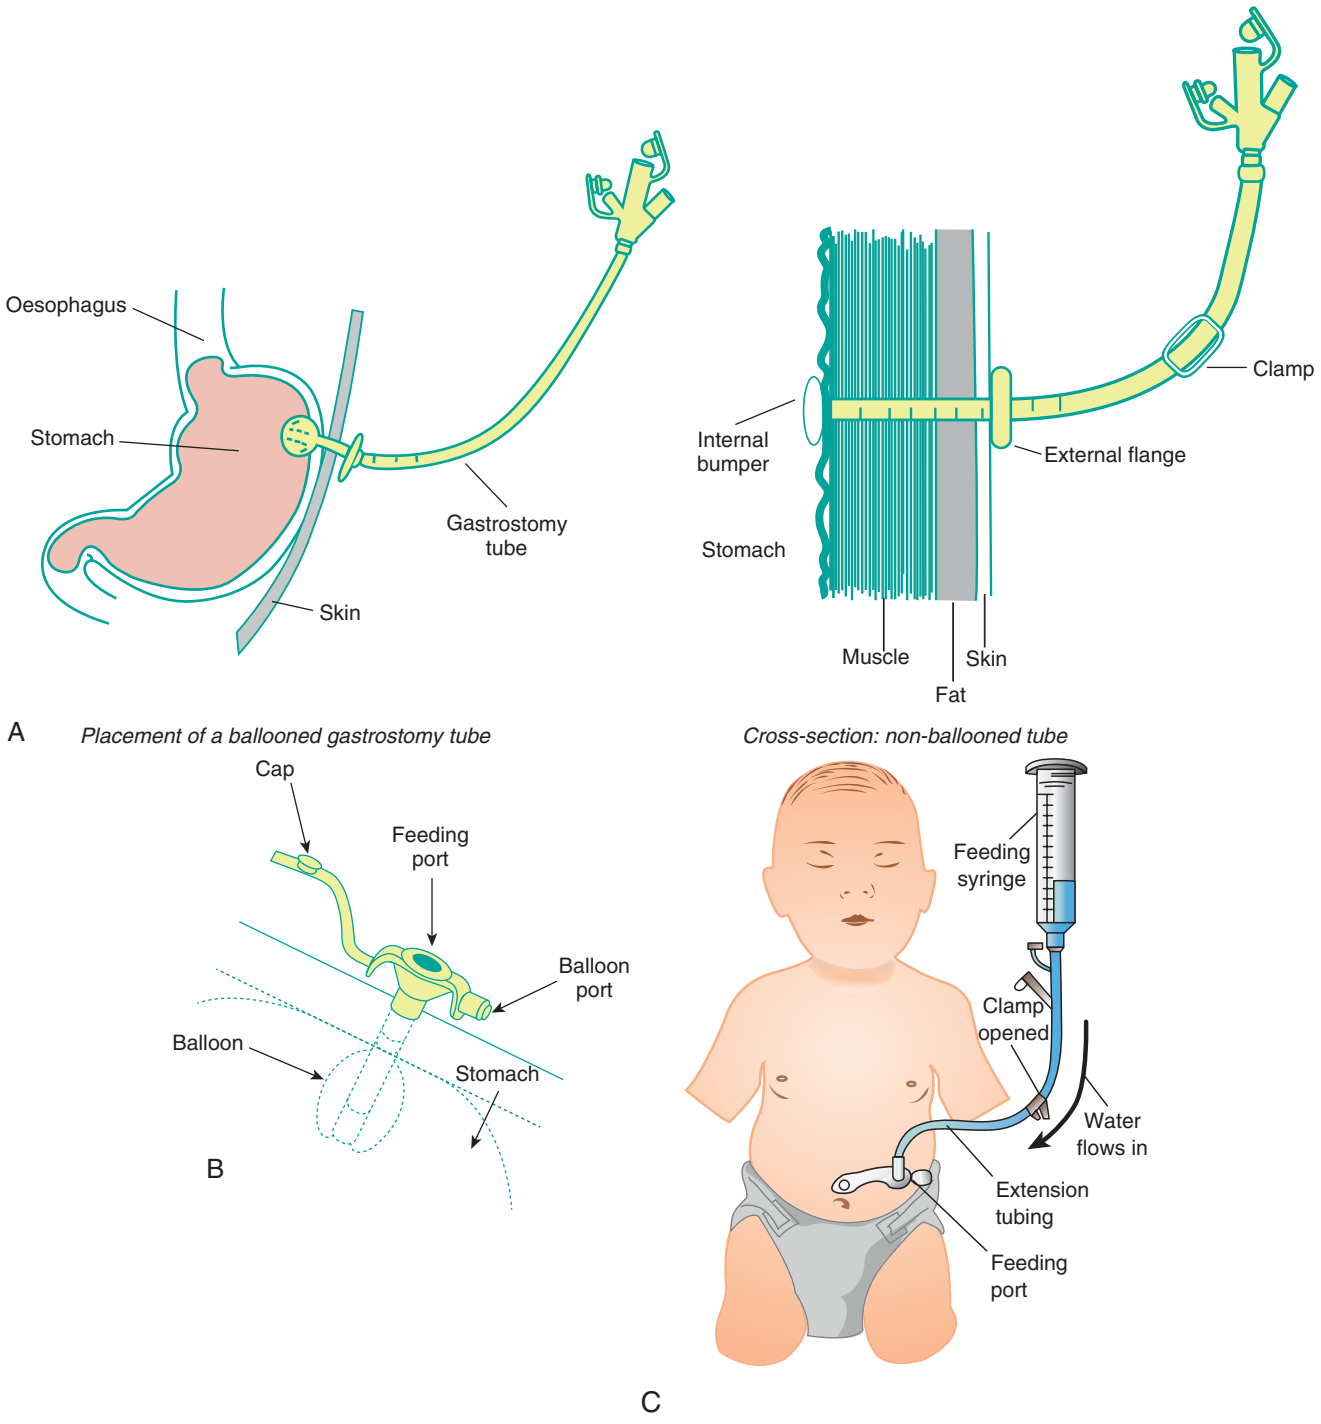

**Figure 30.8** Gastrostomy feeding

## CLINICAL SKILL 30.3 Enteral feed

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| Am I educated?<br>Am I authorised?<br>Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Enteral feeding pump<br>Enteral feeding set<br>Prescribed enteral feed or ready-to-hang formula<br>IV pole<br>PPE (non-sterile gloves, apron, gown)<br>20 mL oral/enteral syringe<br>pH indicator paper/strip<br>Stethoscope<br>Glucometer to obtain blood glucose by finger-stick |

| **Skill activity** | **Rationale** |
|---|---|
| Validate the medical officer and dietitian's order in the individual's record | Ensures correct procedure is about to take place |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Critically think through assessment data and problem solving—provide privacy, correct position of nasogastric tube, documentation of order, individual's baseline weight and laboratory values, electrolyte and metabolic abnormalities such as hyperglycaemia and fluid volume excess or deficit and auscultate for bowel sounds | Evaluate each aspect and its relationship to other data to help identify specific problems and modifications of the procedure that may be needed for the individual<br>Baseline objective data is used to measure the effectiveness of the feeds<br>Absent bowel sounds may indicate decreased ability of GI tract to digest of absorb nutrients |
| Confirm documentation of enteral feeding regimen (type, route, volume and flow rate) by medical officer and dietitian<br>Ensure correct position of nasogastric tube has been confirmed by a post-insertion chest/upper abdominal x-ray and documented by medical officer in individual's health records prior to administration of medications or fluids | Ensures correct feeding regimen<br>Ensures correct position of nasogastric tube prior to administration of medication or fluids |
| Place the equipment in a convenient location near the bedside. Assemble the required equipment including suction equipment or equipment related to providing nutrition as indicated prior to beginning the procedure<br>Raise the bed to the appropriate working position based on your height | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene and don gloves. Other PPE may also be required | Prevents cross-infection and contamination reducing transmission of microorganisms |

## CLINICAL SKILL 30.3 Enteral feed—cont'd

| | |
|---|---|
| Check the tube length measurement at the nostril is unchanged compared to the documented correct tube length confirmed by the medical officer by post-insertion x-ray<br>Placement on chest/upper abdominal x-ray must be confirmed and documented by a medical officer where there is suspicion of tube displacement or if the individual has been retching, vomiting or violent coughing<br>With a torch examine the back of the individual's mouth to ensure tube has not curled up in the back of the throat<br>Aspirate gastric contents to check for gastric residual. Return aspirated contents to stomach unless the volume exceeds 150 mL<br>Measure pH of aspirated GI contents<br>Test pH by using pH indicator paper/strips. Gastric aspirate has a pH <5<br>Observe the aspirate appearance | Check correct tube placement prior to commencement of the formula<br>Presence of gastric secretions indicates that the distal end of the tube is in the stomach. Residual volume of greater than 150 mL may indicate gastric emptying is delayed<br>The pH of fluid aspirated from tube of fasting individuals is helpful in differentiating between gastric and respiratory placement and gastric and small bowel placement<br>Gastric fluid is usually cloudy and grassy green or tan to off-white in colour |
| Individual should be positioned in high Fowler's position or elevate head of bed >30 degrees<br>Where this is contraindicated the individual should be positioned laterally (left side) to protect the airway during and for at least 60 minutes post cessation of enteral feeding | Reduces risk of gastro-oesophageal reflux and aspiration by ensuring individual is safely positioned prior to commencement of feeding |
| A closed enteral feeding system ready to hang is generally used; it has a maximum 24-hour hang time post connection with a giving set<br>Giving set must to be changed at time of a closed enteral feeding system being hung<br>Decanted formula should not be hung for more than 8 hours<br>Ensure non-touch technique when preparing and handling formula and nasogastric tube<br>Enteral feeding delivery set must be replaced at least every 24 hours<br>Time and date should be specified on giving set label | Ensures correct enteral feed and hang time<br>Prevents contamination of formula and nasogastric tube<br>Tubing and formula must be free of contamination to prevent bacterial growth |
| Ensure formula is at room temperature<br>Shake formula container well<br>Close roller clamp at lower end of spike giving set to prevent air entering the tube<br>Connect tubing to container or prepare ready-to-hang container and fill container and tubing with formula<br>Connect distal end of tubing to the proximal end of the feeding tube<br>Hang pack on IV pole and adjust height<br>Connect tubing through enteral feed pump, prime line as per manufacturer's instruction<br>Set flow rate as ordered | Ensures correct administration of formula<br>Cold formula may cause gastric cramping and discomfort |
| Assess individual while feeding is in progress for signs of intolerance to enteral feeding (e.g. vomiting, reflux, nausea, diarrhoea, distension, large residual aspirate volumes)<br>If formula is not tolerated inform Registered Nurse who will assess and notify medical officer and dietitian | Ensures formula is tolerated by individual |
| During continual enteral feeding the nasogastric tube should be flushed with 30 mL of tap water 3 times a day unless clinical indication prevents this volume of fluid. Chart the amount of water used to flush on fluid balance chart<br>Consult with Registered Nurse if the feeding tube is blocked<br>Measure amount of residual aspirate every 4 hours<br>When tube feedings are not being administered cap or clamp the proximal end of the feeding tube after flushing the tube with 30 mL water | Continuous feeding delivers a prescribed hourly rate of feeding which reduces risk of abdominal discomfort<br>Flushing the tube with water reduces the risk of sediment forming and blocking the tubing<br>Individuals receiving continuous feeding should have tube placement confirmed and residual aspirate checked every 4 hours<br>Prevents air entering the stomach between feeds |
| Discard the equipment appropriately<br>Remove gloves/PPE. Perform hand hygiene | Prevents cross-infection |

*Continued*

## CLINICAL SKILL 30.3 Enteral feed—cont'd

| | |
|---|---|
| Lower the bed keeping the individual upright and ensuring individual comfort<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Monitor the cleanliness and effectiveness of the tape securing the nasogastric tube to the nose. Tape should be replaced daily<br>During tape change observe for signs of pressure necrosis around the nose | Ensures the correct tube placement and absence of pressure areas |
| Monitor blood glucose level (BGL) as per facility/organisation policy<br>Document intake on fluid balance chart<br>Monitor intake and output every 24 hours<br>Weigh individual daily until administration rate is reached for 24 hours then 3 times per week<br>Observe return of normal laboratory values<br>Record and report amount and type of feed, individual's tolerance of feed, adverse effects and patency and placement of tube | Monitors individual's tolerance of glucose<br>Ensures accurate intake is recorded<br>Intake and output are indications of fluid balance or fluid volume excess or deficit<br>Weight gain is an indicator of improved nutritional status. Sudden gain of more than 900 g in 24 hours may indicate fluid retention<br>Improving laboratory values indicate improved nutritional status |

*(Agency for Clinical Innovation 2012; ACSQHC 2012; 2015; Berman et al 2015; Crisp & Taylor 2013; Dempsey et al 2014, LeMone et al 2014; NSW Department of Health Policy 2009; Rebeiro et al 2013)*

hypoxaemia, fever, cyanosis and cough. Feed should be immediately ceased and not recommenced until reviewed by medical officer (Stewart 2014).

***Tube occlusion*** Occasionally tubes can become occluded because of inadequate flushing, feeds being too thick or the administration of certain crushed medications. To unblock the tube, a volume of 20–30 mL (adults) of water can be administered into the tube with pulsatile pressure or by massaging the tube—do not milk the tube by stretching the tube and squeezing it (ACI 2014).

***Tube migration/obstruction*** Verify placement and discontinue feeding until medical review.

***Accidental removal*** Rinse tube and replace it as soon as possible—do not recommence feeds until tube position has been verified.

***Balloon burst*** Check balloon volume by withdrawing water into syringe, change tube.

***Bleeding*** Bleeding may indicate the presence of an infection or trauma to the tube. Bleeding is stopped by localised pressure or 'stomahesive' dressing, and the incident documented and reported.

***Redness*** Localised redness with or without swelling may indicate inflammation from acidic gastric contents due to, for example, the tube being too small for the stoma, the flange being too loose on the skin or perishing or bursting of the balloon in the stomach. Any ooze can be checked for acidity using pH-sensitive paper. If acid is detected, a waterproof cream can be applied to prevent further irritation of the skin by acid (Forest-Lalande 2012b). The use of dressings to soak up the fluid or topical antacids may cause further skin breakdown. The size of the tube and the flange's location need to be checked daily to prevent migration. An indelible pen can be used to mark the lower limit of the tube, and the measurement is recorded on the care plan. In some cases an individual may require a tube to be replaced with a larger-diameter one.

Complications with tubes or flanges are reported to a medical officer or a stomal therapist. In some situations, particularly after surgery, primary and/or secondary peritonitis may be caused by inadequate pressure from the flange and balloon and subsequent poor sealing of underlying tissues.

***Diarrhoea*** If the feeds are administered too rapidly or the individual is intolerant to the feed, diarrhoea may develop. This may be minimised by slowing the rate of the feed or changing the feed type. If symptoms persist a medical officer should be contacted.

***Granulation of gastrostomy site*** Granulation of the surrounding tissue occurs as a healing response but can interfere with the comfort of the tube. To prevent granulation the stoma should be washed daily and the tube turned daily (ACI 2014). A literature review conducted by Warriner & Spruce (2012) provided a range of current treatment modalities for hypergranulation including: surgical removal, silver nitrate cauterisation, topical low-dose steroid application, topical antimicrobials and foam dressings.

***Hypoglycaemia*** Individuals who have bolus feeds administered too rapidly, in excessive quantities or who may have a lax pyloric sphincter are at risk of the feeds entering the duodenum too rapidly and causing hyperinsulinaemia and consequential hypoglycaemia. See Clinical Interest Box 30.4 for other electrolyte disturbances that may result.

## CLINICAL INTEREST BOX 30.4 Refeeding syndrome

First discussed in prisoners of war post WWII, refeeding syndrome is the derangement of serum electrolytes, vitamins and fluid resulting from over-aggressive treatment of malnourished individuals. In response to carbohydrate load, insulin is released, leading to increased glycogen, fat and protein synthesis. This triggers sudden uptake of potassium, phosphate and magnesium. This intracellular movement results in hypokalaemia, hypophosphataemia and hypomagnesaemia (Khan et al 2011). Symptoms of lethargy, shortness of breath, muscle weakness, GI upset, ataxia and delirium are indicative of these electrolyte disturbances. Individuals at an increased risk of developing Refeeding syndrome are children, individuals with greater than 10% weight loss in 4 weeks, anorexia for more than 7 days and chronic alcoholism. It is recommended electrolyte abnormalities are corrected prior to commencement of refeeding at a rate of 10–20 kCal/kg/day before gradually increasing over week.

*(Sydney Children's Hospital 2013; Khan et al 2011)*

## Summary

Nutrition is necessary for the development and growth of cells and for the replacement of substances required by the cells to maintain efficient body function. A diet that contains the essential nutrients is essential throughout each stage of the lifespan, and people should be encouraged to follow the principles of good nutrition and to eat a balanced healthy diet. Food provides energy that is necessary for all the chemical and physical activities of the body. Energy requirements vary according to age, sex, body composition and presence of ailments or conditions. Each nutrient performs a specific function, and a nutrient deficiency may result in body dysfunction.

Many factors influence an individual's eating pattern, and choice of foods and illness may necessitate certain changes in dietary intake. Modification of the consistency of food may be indicated, or a specific diet may be prescribed for therapeutic purposes. The nurse should assist individuals to meet their nutritional needs and the nurse may need to assist or feed an individual who is unable to feed themself. If an individual is unable to consume food or fluid orally, an alternative method of meeting their nutritional needs may be necessary.

Problems associated with nutrition should be identified so that appropriate medical, nursing and dietitian care can be planned and implemented to meet the individual's nutritional needs.

## DECISION-MAKING FRAMEWORK EXERCISE 30.1

You are working on a gastrointestinal ward and caring for Kathleen, a 47-year-old woman, day 4 post open laparotomy appendectomy. This morning she has been vomiting and complaining of severe cramping abdominal pain. On taking her vital signs you find she is tachycardic and diaphoretic. Her abdomen is distended and on auscultation has decreased bowel sounds. In response you call the Medical Emergency Team to review Kathleen. The medical officer requests you insert a nasogastric tube (NGT) immediately to alleviate a paralytic ileus. During your course you had NGT insertion demonstrated and had practised in the nursing lab. Since starting on the ward you have assisted with multiple insertions and have almost completed the local hospital accreditation course.

Using the nursing practice decision-making framework:

1. What would your response to the medical officer's request be?
2. What would be the appropriate nursing action to ensure Kathleen receives the requested treatment?

## Review Questions

1. What information should be included in the nutrition assessment of an individual?
2. What are the national Healthy Eating Guidelines?
3. Individuals should be recommended to have a low or high GI diet? Why?
4. List the essential nutrients.
5. What are the common disorders associated with nutrition?
6. What are principles of good nutrition suggested by the NHMRC?
7. What are other diets to meet individual needs?
8. What are potential alternative methods to meet nutritional needs and when should these be considered?
9. What are the common problems associated with gastrostomy tubes?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing care: urinary elimination and continence

*Auxillia E Madhuvu*

CHAPTER 31

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the transport mechanisms in the body related to the urinary system
- Explain homeostasis as related to the urinary system
- Discuss fluids, electrolytes and acid–base balance
- Name the parts of the urinary system and describe the structure and function of each part
- Identify the factors that affect urinary elimination and associated problems throughout the lifespan
- Describe the different types of urinary incontinence and possible causes
- Describe the major manifestations of urinary system disorders
- State the diagnostic tests used to assess urinary system function
- Consider the psychosocial aspects of care from a person-centred and relationship care perspective
- Assist in planning and implementing nursing care for the person with a urinary system disorder

## KEY TERMS

atrophy
bladder
continence
cystitis
enuresis
incontinence
kidney
micturition
pyelonephritis
ureter
urethra
urethritis
urinalysis
voiding

## CHAPTER FOCUS

The urinary system is responsible for maintaining homeostasis and eliminating waste products of body metabolism through the excretion of urine. Many factors can affect the formation of urine and the subsequent excretion of urine and this chapter provides an overview of the main issues. Nursing management of persons with urinary elimination disorders requires an informed understanding of factors impacting on an individual's lifestyle and a care plan to adequately respond to these needs, as well as the sensitivity to sustain the person's sense of dignity and self-esteem throughout.

## LIVED EXPERIENCE

I walked into the emergency department screaming with lower abdominal pain. The nurse opened the door to let me into the examination room. She asked me a few questions, checked my blood pressure and temperature. She asked when I last passed urine and whether it was a lot of urine or just a few drops. 'A few minutes ago', I replied, 'and just a few drops', as I did not want to talk more about my dribbling problem at this stage! She reached out and grabbed a machine to check how much urine was in my bladder. As she pressed on my lower abdomen with the scan I screamed so that other staff members come in to help. The nurse looked puzzled! Another staff member said, 'Quickly, let's put in a urinary catheter.' Within a few minutes the catheter was inserted. What a relief! All the pain went away, it felt like magic. I realised that my urine dribbling which I didn't want to talk about was the actual problem.

**Alfious, age 65**

# THE URINARY SYSTEM

The urinary system (Figure 31.1) filters waste products from the blood and excretes them in the form of urine. The urinary system is also instrumental in regulating the rates of elimination of water and electrolytes from the body. By regulating the volume of the body fluid, the urinary system helps maintain blood pressure and the electrolyte content and pH of the blood. The urinary system consists of the **kidneys**, which filter blood; the **ureters**, which transport urine to the bladder; and the **bladder**, which stores the urine until it is excreted via the **urethra**.

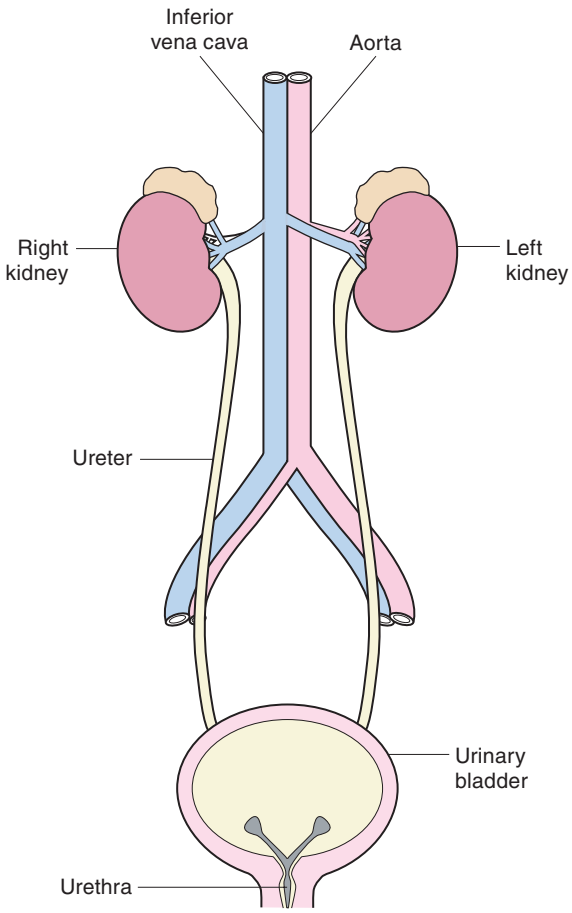

**Figure 31.1** The urinary system

## The kidneys

Each kidney contains at least 1 million nephrons, together with their collecting tubules or ducts. The nephron (Figure 31.2) is the functional unit of the kidney. Each nephron is composed of a vascular and tubular system that allows for the formation of urine. The nephrons are located in the renal tissue, with most in the cortex and some extending deep into the medulla of the kidney.

The adult kidney weighs 120–170 g, is 10–13 cm in length, 5–6 cm wide and 3–4 cm thick. The kidneys are protected and supported by renal fascia and by layers of perirenal fat. They are positioned at approximately vertebral level of T12 to L3, the right kidney usually slightly lower than the left.

The function of the kidneys is to maintain homeostasis. Homeostasis is the process that controls the body's internal environment. External variables may change such as heat, cold, fluid, diet and stress but to sustain the body in a state of equilibrium, receptors in the body identify if something is off balance and trigger a negative feedback. The urinary system maintains homeostasis by:

- Filtering the blood to maintain its normal composition, volume and pH

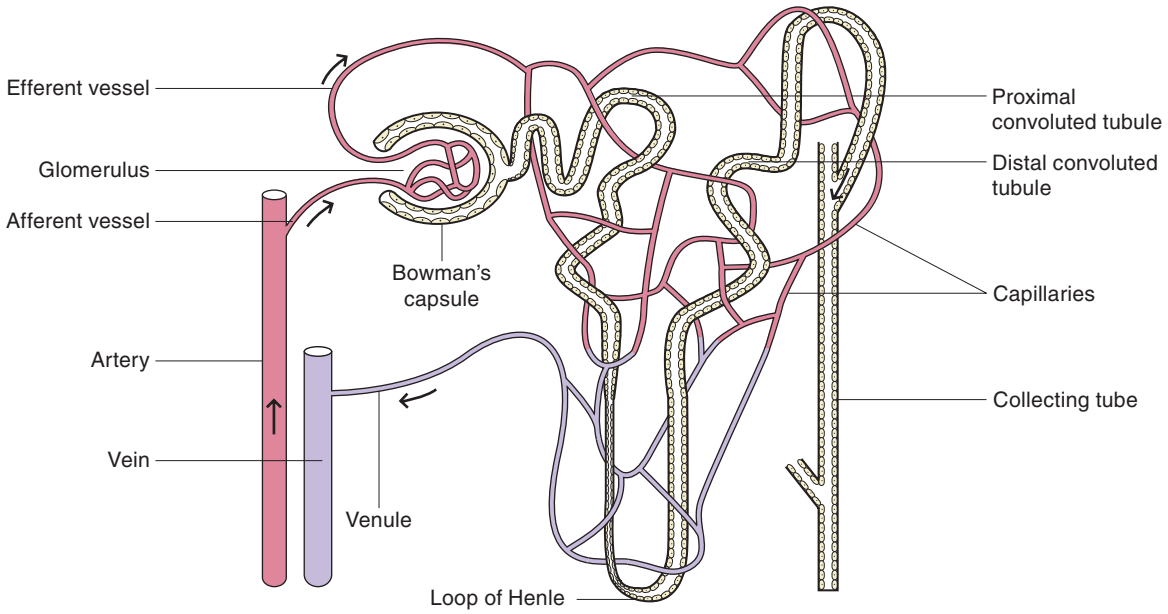

**Figure 31.2** The nephron

- Regulating water balance and electrolytes
- Regulating acid–base balance in the blood
- Eliminating filtered wastes from the blood and reabsorbing required substances back in the blood
- Regulating blood pressure
- Producing erythropoietin in response to hypoxia and reduced renal blood flow (Marieb & Hoehn 2012; Vance & Harold 2010).

In carrying out these functions the kidneys excrete urine. Urine is made up of water and dissolved substances that are in excess of the body's need to function, and includes by-products of metabolism, such as urea. These substances are transported into the bloodstream, which enters the kidney via a branch of the renal artery. The nephron is the functional unit of the kidney. Each nephron is composed of a vascular and tubular system that allows for the formation of urine. The nephrons are located in the renal tissue, with most in the cortex and some extending deep into the medulla of the kidney. The blood is filtered from there through the glomerulus (see Figure 31.2), where glucose, minerals, urea, other soluble substances and water pass through to the renal tubule.

Kidney function is controlled by both the nervous and the endocrine systems which in turn control:

- Adrenaline, secreted by the adrenal, or suprarenal, glands, which helps maintain the high level of blood pressure in the glomerulus
- Antidiuretic hormone (ADH), secreted by the pituitary gland, which controls the amount of water reabsorbed from the tubules
- Aldosterone, secreted by the suprarenal glands, which controls the tubules' reabsorption of mineral salts.

### Composition of urine

In health, with adequate hydration, urine is a clear, amber-coloured slightly acidic fluid composed of 96% water, 2% urea and 2% mineral salts, uric acid and creatinine (Marieb & Hoehn 2012).

## The ureters

The ureters are two narrow, thick-walled muscular tubes, 25–30 cm long, which originate in the renal pelvis of each kidney. They pass down the posterior abdominal wall and into the pelvic cavity to enter the posterior base of the bladder. The ureters enter the bladder at an oblique angle so that, as the bladder fills and contracts, urine is not forced back towards the kidneys. The walls of the ureters consist of an outer fibrous coat that is continuous with the renal capsule, a middle coat of involuntary muscle and a lining of transitional epithelium. The function of the ureters is to carry urine from the kidneys to the bladder, by means of peristaltic action. The involuntary muscle layer in the walls of the ureters contract 1–5 times per minute to force urine into the bladder (Marieb & Hoehn 2012).

## The urinary bladder

The urinary bladder is a hollow muscular organ that acts as a reservoir for urine and is supported by the detrusor muscle. The detrusor muscle is a layer of the urinary bladder wall made of smooth muscle fibres arranged in spiral, longitudinal and circular bundles; its competency is vital to maintaining continence. In the female it is in front of the uterus and in the male it sits in front of the rectum. The walls of the bladder consist of:

- A covering of peritoneum over the upper portion (the fundus)
- A layer of involuntary muscle
- A layer of connective tissue
- A layer comprised of mucous membranes which are formed into folds (rugae) which increase the surface

areas of the bladder walls, enabling the bladder to expand when full and contract when empty.

The trigone of the bladder is a triangle formed by the two ureteric orifices, where the ureters enter the bladder, and the urethral orifice at the neck of the bladder. A band of the detrusor muscle encircles this opening to form the internal urethral sphincter; incompetence of this sphincter may have an impact on continence (Marieb & Hoehn 2012; McCance & Huether 2014).

**Micturition** (or **voiding**) is the act of passing urine. While the normal capacity of the adult urinary bladder is about 450 mL, the bladder is capable of expanding to hold larger amounts. The bladder fills slowly over a period of time and, when it holds about 300–500 mL, a desire to empty the bladder is experienced. Bladder capacity ranges from 600 mL to 1000 mL, depending on the person. A reflex initiated by impulses from stretch receptors in the bladder wall regulates the process of micturition. The sensory neurons transmit the impulses to the spinal cord, where they are relayed to the brain, which in turn stimulates parasympathetic neurons that innervate the bladder wall. When a person is ready to pass urine, these impulses cause the bladder muscles to contract, the internal urethral sphincter relaxes and the desire to urinate is activated. The person is then able to voluntarily relax the external sphincter and void at an appropriate time and place. Urine is usually excreted in amounts of 1–2 L in 24 hours (Marieb & Hoehn 2012).

### The urethra

The urethra (Figure 31.3) is a muscular tube extending from the neck of the bladder to the external meatus. In the female the urethra is about 2.5–4 cm long and opens at the external urethral orifice in front of the vaginal opening. The external sphincter guards this opening. In the male the urethra is about 15–20 cm long and opens at the tip of the penis. The male urethra has a double function: it forms a passage for urine as well as semen. It is guarded by an external sphincter immediately below the prostatic portion of the urethra. The function of the urethra is to provide a passage for urine from the bladder, out of the body (Marieb & Hoehn 2012).

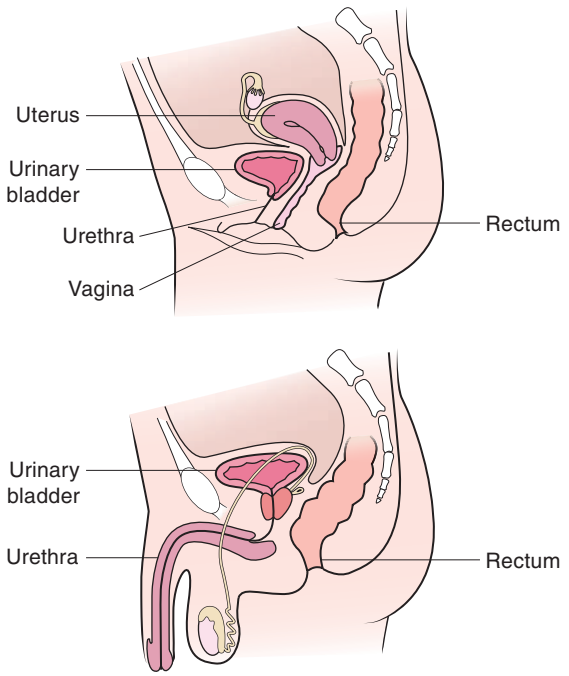

**Figure 31.3** Position of the female and male urethra

## ALTERATIONS IN URINARY SYSTEM FUNCTIONING

The kidneys are essential in the maintenance of homeostasis, as they regulate the rates of elimination of water and electrolytes from the body and contribute to the maintenance of a constant blood pH and blood pressure. The kidneys also eliminate metabolic waste products and toxic substances. Therefore, any dysfunction in the formation or excretion of urine can have major adverse effects on homeostasis (Berman et al 2015).

### Changes in kidney structure

Atrophy of the kidneys because of destruction of the renal tissue can occur in many chronic renal diseases. Kidney **atrophy** is when a kidney becomes smaller in size due to kidney disease or because the kidney is non-functioning. Mostly it has to do with impaired blood supply to the kidneys. Alternatively, the kidneys can become enlarged because of blockage of the ureters, enlargement of the prostate gland or from invasion of the kidneys by neoplastic cells. If there is an obstruction lower down in the urinary tract, the ureters may become enlarged in diameter as they fill with urine that cannot pass the obstruction (Marieb & Hoehn 2012).

### Fluid and electrolyte imbalance

Water accounts for half or more of young adult body weight. It occupies two main cellular compartments: intracellular and extracellular. Intracellular fluid is within the cell and extracellular fluid is outside the cell. Extracellular fluid consists of blood plasma and interstitial fluid. Very small changes in the electrolyte concentration in different fluid compartments will cause water to move from one compartment to another. If the kidneys are unable to concentrate the urine by regulating reabsorption, the loss of a large amount of dilute urine may result in fluid imbalance. If the kidneys fail to excrete sufficient water, an increase in the total circulating fluid volume impedes cardiovascular function. Renal disease may result in abnormal retention or loss of sodium, potassium, calcium or phosphorus (Marieb & Hoehn 2012; Porth 2011).

### Acid–base balance and elimination of wastes

Normal metabolism produces an excess of acids. To compensate, the kidneys excrete acids and return bicarbonate to the plasma and extracellular fluid. An acid–base imbalance (metabolic acidosis) will result if this function is impaired; that is,

if there is an increased amount of acid or a decreased amount of base in the body. Normal arterial blood pH is 7.35 to 7.45. If the pH rises above 7.45 a person is said to be in alkalosis, pH below 7.35 results in acidosis. The kidneys must also continually filter and excrete nitrogenous wastes derived from protein metabolism (Marieb & Hoehn 2012; Porth 2011).

### Urine output

Alterations in urine output may be temporary or long term. Urine output may be decreased, as in obstruction of the ureter or acute or chronic renal failure, or it may be increased, as during the diuretic stage of acute renal failure. The passage of urine along the urinary tract may be impeded by an obstruction, such as a tumour or calculus (Kidney Health Australia 2014).

### Manifestations of urinary system disorders

Disorders of the urinary system may produce signs and symptoms that vary according to the site and severity of the problem.

#### Pain

Pain is more common in acute, rather than chronic, disorders of the kidneys and urinary tract. Pain that originates from the kidneys is generally experienced as a dull ache in the lower back and may radiate to the lower abdominal area. Pain associated with renal colic is sudden and severe. It is felt in the lower back and may radiate to the groin area. Nausea and vomiting frequently accompany this type of pain.

Suprapubic pain may result from spasms or overdistension of the bladder, as in acute retention of urine. An infection of the lower urinary tract, such as **cystitis** or **urethritis** (inflammation of the urethra), commonly causes pain and burning during and/or after voiding. Strangury is the term used to describe slow and painful spasmodic discharge of urine frequently associated with a 'burning' sensation.

### Changes in voiding pattern

There may be an increase in the frequency of voiding, problems controlling the passage of urine, difficulty in initiating micturition or a sense of urgency associated with the need to void.

### Changes in output

Changes in the output of urine include voiding increased or decreased amounts and cessation of the production or secretion of urine.

### Changes in the urine

Abnormalities of the urine associated with urinary system disorders include changes in the normal colour, clarity or odour of urine. The urine may be blood stained or dark amber, cloudy or smoky in appearance. Chronic renal disease can result in pale, almost colourless urine. A foul smelling 'fishy' odour is commonly present when there is a urinary tract infection (UTI) (Berman et al 2015; Kidney Health Australia 2014).

### Other manifestations

A person with a lower UTI commonly experiences pyrexia, malaise, nausea and vomiting, and pelvic and abdominal discomfort, whereas those with renal disease may experience hypertension, oedema, anorexia, nausea and vomiting, skin changes and neurological symptoms such as headache or altered consciousness (Berman et al 2015; Marieb & Hoehn 2012; McCance & Huether 2014).

## CHANGES TO VOIDING PATTERNS

Any change to voiding patterns needs to be recorded to establish a history. There are various terms for changes, listed in Table 31.1, which are universally understood by health professionals but lay terms may need to be used when discussing the symptoms with the individual or their family. The use of a fluid balance chart to record and analyse intake and output is vital for assessment, as is a bladder diary (see example in Figure 31.4), which provides a more in-depth assessment, including activities and dietary and fluid intake, and gives a more holistic view of an individual's voiding pattern (McGloin 2015).

### Nursing interventions

When a person is experiencing altered voiding patterns, the cause must be identified and treated. Difficulty in passing urine may result from an obstruction to the outflow of urine but may also be caused by other factors such as:

- Anxiety, stress, nervousness or embarrassment associated with the need to use toilet aids
- The need to remain in a supine position when using toilet aids
- The effects of medications, anaesthesia or the acute stress of surgery
- Pain following surgery or a burning sensation which can lead to tension in the muscles controlling the urethral opening
- Altered cognitive state
- Being in unfamiliar environment (Nyman et al 2013).

Nursing actions that may be implemented to induce micturition include:

- Using standard precautions for dealing with body fluids
- Relieving pain. If a person is experiencing pain, the cause should be identified and treated. Nursing actions to relieve pain include ensuring that the person is positioned comfortably, checking any splints or dressings to detect whether they are causing the pain and checking for prescribed analgesia
- Ensuring adequate privacy and sufficient time for the person to void. If possible, the person should be left alone to use the toilet aids (e.g. commode, bedpan or urinal) as they may be self-conscious about the need to eliminate in the presence of others. Ensure the person's safety and that the call bell is accessible

**TABLE 31.1 | Alterations in urinary elimination patterns**

| Term | Definition |
|---|---|
| Anuria | The absence of urine production, or a urinary output <100 mL/day (<30 mL/hour) |
| Dribbling | Dribbling of urine from the urethra despite voluntary control of micturition. It may be at the end of micturition or continuous |
| Dysuria | Pain and burning on micturition, usually as a result of an infection or obstruction |
| Frequency | Voiding at frequent intervals (i.e. <2 hourly) |
| Haematuria | The presence of blood in the urine |
| Hesitancy | Difficulty starting micturition |
| Incontinence | The inability to control the passage of urine |
| Nocturia | Excessive or frequent urination at night |
| Oliguria | A decreased urine production resulting in an output <500 mL/day |
| Polyuria | The excretion of an abnormally large volume of urine |
| Retention | The accumulation of urine in the bladder as a result of being unable to empty the bladder completely |
| Residual urine | The volume of urine remaining after voiding |
| Urgency | The feeling of needing to void immediately |

*(Marieb & Hoehn 2012)*

- Ensuring awareness of cultural differences in position and environment for voiding by communicating sensitively with the person
- Being alert for difficulties which may impede normal urination in time or environment; for example, coexisting conditions impairing physical or cognitive functioning
- Assisting the person to assume a natural voiding position. Whenever possible the person should be permitted to use the toilet but, if this is contraindicated, an upright position may assist. Males may find it easier to pass urine if allowed to stand. Refer to Clinical Skill 31.1
- Helping the person to relax. Unless contraindicated, a warm shower or bath, or the pouring of warm water over the genitalia of a female, may stimulate micturition. Further stimulation techniques may include the sound of running water (e.g. turning on a nearby tap)
- Encouraging the person to drink adequate amounts of fluids, unless this is contraindicated. The recommended fluid intake for adults is 1400–2000 mL per day
- Using clear signage to indicate the location of toilet facilities.

If these actions fail to induce micturition and the person is uncomfortable because of a distended bladder, it may be necessary to implement further actions, such as inserting a urinary catheter. After using bedpan, perineal care is required to make sure the person is clean and comfortable. Refer to Clinical Skill 31.2.

## Screening and investigations

### Urine tests

Various sources of information can be collected through the use of daily charts such as fluid balance charts, or bladder diaries which record voiding patterns and which may note, for example, an interrupted stream or difficulties in voiding as well as a history of the person's elimination pattern. As the body's normal metabolism produces wastes that must be eliminated regularly to maintain effective body function, the observation of urine and the person's ability to eliminate it provides the nurse with objective assessment data. The elimination of urine, or voiding, should be voluntary and painless. The frequency with which urine is passed varies with each individual. Factors that affect the frequency of voiding and the volume of urine include fluid input, bladder capacity, response to the need to void and the availability of toilet facilities. The frequency of voiding, and often the amount of urine voided, can be increased by a large fluid input, fear or anxiety, exposure to a cold environment and some disease states, and decreased by a low fluid input, exposure to a hot environment and some disease states.

***Preparation*** Standard precautions apply for all collection of body fluids. If urine is to be collected for a screening

**BLADDER DIARY**

Name: ..... Date: .....

Where were you living/staying at the time you were recording this: at home or other?

.....

This is a record of issues which may interfere or shed light on how your individual urinary system works. Add a comment in the squares if you wish to: this is your record. Begin a new form for each day and continue until you see a pattern emerge.

| Urinary output | Morning | Evening | Night (did you wake up to go to the toilet?) |
|---|---|---|---|
| Amount of urine at each visit to the toilet<br>Large +++<br>Medium ++<br>Small + | | | |
| Accompanying symptoms? e.g. pain, fullness, urgency? | | | |
| Intake:<br>Amount and what did you drink? (coffee, tea, juice, fizzy drink, alcohol?) | | | |
| Food intake:<br>Short description of amount and food type, e.g. curry, ice cream, beetroot, asparagus | | | |
| Has your bowel opened today? | | | |
| Medication:<br>Prescription, over-the-counter and herbal/vitamin remedies | | | |
| Exercise:<br>Short description | | | |
| Further comments:<br>i.e. environment: 'on a long haul flight', 'toilets were revolting, held on', 'bad day, stayed in bed', 'sedentary day in the office' | | | |

**Figure 31.4** Bladder chart

*(Compiled by Sue Brown 2011)*

**urinalysis**, the person is requested to void into a clean bedpan or urinal or a suitable clean receptacle (Figure 31.5). The urine should not be contaminated by faeces or menstrual blood, as a false assessment may result. The urine is transferred from the toilet utensil into a clean container for observation and analysis immediately after collection. Correct and ongoing identification of sample is of paramount importance.

***Observation*** In health, urine is clear, amber in colour and has a faint odour. Menstruation or any other vaginal discharge and certain medications, supplements or foods can alter the colour and odour of urine and certain diseases will vary the condition and clarity of the urine, so it is important to document what is observed and smelt. Further observations should note if the urine is cloudy or if there is sediment present (Table 31.2).

## Urinalysis (routine)

Reagent strips are used to screen urine samples. Should the urine contain pigments, for example, from vitamin supplements (often bright yellow), they may affect the efficacy of the test. Check each container for use-by date, and ensure the strips are dry and that the container has an efficient closure. Each manufacturer may vary slightly in application of the test so check information as to how to read the strip and the time

## CLINICAL SKILL 31.1 Assisting with toileting: bedpan, urinal, commode

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Bedpan traditional or slipper<br>Urinal<br>Commode chair<br>Pan/urinal cover<br>Monkey bar<br>Waterproof sheet/bluey/absorbent pad<br>Toilet paper<br>Gloves<br>Hand hygiene available for individual—water, face washer, towel, disposable wipes |

| **Skill activity** | **Rationale** |
|---|---|
| **Assist with toileting using bedpan/urinal** | |
| A bedpan or urinal is used to assist an individual with toileting when they are unable to move from the bed to the toilet. The individual will have a rest in bed order, or may be too physically unwell to mobilise. | |
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent | Reduces anxiety and gains individual's consent and cooperation |
| Assist individual to comfortable position (sitting or semi-Fowler's) | Provides ease of access to insert bedpan |
| Place waterproof sheet/bluey/absorbent pad under the individual | Absorbent pad will collect any spilt urine and prevent bed from becoming wet |
| Place bedpan under individual<br>Urinal is placed between individual's thighs. Handle is placed away from the mattress. Penis is placed in to the neck of the urinal | Ensures accurate collection of urine or faeces |
| Provide call bell for individual and allow for privacy | Dignity and privacy are maintained |
| Assist individual with use of toilet paper | To remove urine and faecal matter from the perineal area |
| Remove bedpan/urinal and cover | Prevents contents from being viewed during transportation to pan room/flusher |
| Pathology samples or full ward tests taken as required | Collection of specimens for testing to assist with diagnosis of infections |
| Measurements taken as required and documented on fluid balance chart | Measurements required for maintaining fluid balance |
| Hand hygiene performed | Prevents the spread of infection |
| Hand hygiene provided for individual | Prevents the spread of infection. Provides hygiene requirements for the individual |
| Individual made comfortable and curtains opened | Comfort needs are attended to |
| Report and document all relevant information, including type and date of specimen, correctly in the healthcare record and any complications | Medico-legal requirement. Allows for the planning and implementation of care |

## CLINICAL SKILL 31.1 Assisting with toileting: bedpan, urinal, commode—cont'd

### Assist with toileting using commode

A commode chair is used to assist an individual with toileting when they are unable to move from the bed to the toilet or commode chair. The individual may have a sit out of bed order, or a rest in bed order with toilet privileges, or may be too physically unwell to mobilise. Using a commode chair may provide the individual ease of voiding or opening bowels.

| | |
|---|---|
| Commode is placed close to the bed or chair with brakes applied | Provides ease of access. Brakes prevent chair from moving |
| Pan placed into commode chair | Collects urine or faeces |
| Individual is assisted onto the commode | Prevents individual from falling |
| Provide call bell for individual and allow for privacy | Dignity and privacy are maintained |
| Assist individual with use of toilet paper | To remove urine and faecal matter from the perineal area |
| Assist individual into the bed or chair | To maintain safety |
| Hand hygiene performed | Prevents the spread of infection |
| Hand hygiene provided for individual | Prevents the spread of infection. Provides hygiene requirements for the individual |
| Individual made comfortable and curtains opened | Comfort needs are attended to |
| Remove commode and transport to the pan room | Remove from vicinity of individual's bedside. Testing or collection specimen is better undertaken in the pan room. Contents are disposed of in the correct manner |
| Samples or full ward tests taken as required and documented | Collection of specimens for testing to assist with diagnosis of infections |
| Measurements taken as required and documented | Measurements required for assisting with recording of fluid balance |
| Hand hygiene performed | Prevents the spread of microorganisms |
| Report and document all relevant information, including type and date of specimen, correctly in the healthcare record and any complications | Medico-legal requirement. Allows for the planning and implementation of care |

*(Berman et al 2015; Crisp & Taylor 2013; LeMone et al 2011; Lynn et al 2012; Rebeiro et al 2013; Smith et al 2011)*

needed for a result before commencing the test. There are a large number of diseases that contribute to abnormal readings, many of which are not well known or will require a specialist response. Listed below are the common causes for abnormalities:

- The presence of leucocytes and nitrates may indicate the presence of bacteria
- The presence of protein indicates disease or trauma although, as a person ages, the kidneys become less efficient and protein may be detected
- The presence of acetone and glucose may indicate diabetes, although there are other reasons for their presence
- The presence of blood in urine—haematuria—may indicate contamination (e.g. menstrual blood), trauma or infection
- The presence of bilirubin suggests changes or infection to the liver and biliary system.

In health, urine has a pH of between 4.5 and 8.0; that is, slightly acidic (average is 6.0). A value of 7.0 is neutral, below 7.0 is acid, and above 7.0 is alkaline. pH is frequently affected by what the person has ingested; for example, acid food or a vegetarian diet. The pH value will also be altered in the presence of bacteria or renal calculi and an incorrect result will be obtained if the urine has been left standing for some time.

In health, a specific gravity of between 1.005 and 1.030 is usual. Specific gravity is a measure of the concentration of particles in the urine and reflects the ability of the kidneys to concentrate or dilute urine. It will be altered in over- or under-hydration.

Disposal of excreta is via the toilet or specified equipment in a 'dirty utility' space. Equipment is cleaned and sterilised

## CLINICAL SKILL 31.2 Perineal care

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Monkey bar<br>Waterproof sheet/bluey/absorbent pad<br>Toilet paper<br>Gloves<br>Hand hygiene available for individual—water, face washer, towel, disposable wipes |

| **Skill activity** | **Rationale** |
|---|---|
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent | Reduces anxiety and gains individual's consent and cooperation |
| Place bluey or towel under individual's buttocks | Absorbent pad will collect any spilt fluids and prevent bed from becoming wet |
| Assist individual to comfortable position (supine) with legs flexed | Provides access to perineal area |
| Cover the upper body and legs with a towel | Allows for exposure to the genital area and maintains the individual's dignity |
| Apply gloves | Protects self from exposure to body fluids. Gloves form part of the personal protective equipment required for standard precautions |
| Females: wash and dry inner thighs. Wash the labia from the front towards the anus to remove fluids. Repeat procedure if required, rinsing cloth for each pass. Dry area well. Inspect for signs of excoriation, abnormal odour or excess secretions. Position individual onto the side to gain access to the buttocks. Spread the buttocks, clean and dry the anal area. Apply protective ointments and medications as required or ordered | Cleans the area and identifies any abnormal findings |
| Males: wash and dry inner thighs. Wash and dry the penis. If the individual is uncircumcised retract the foreskin to expose the glans. Clean and dry the scrotum. The individual may be required to be positioned onto their side to allow for greater access to the posterior scrotal folds. Spread the buttocks, clean and dry the anal area. Repeat procedure if required, rinsing cloth for each pass. Dry area well. Inspect for signs of excoriation, abnormal odour or excess secretions. Apply protective ointments and medications as required or ordered | Cleans the area and identifies any abnormal findings |
| Remove gloves and perform hand hygiene | Prevents spread of infection |
| Return individual to a position of comfort. Replace bedclothes | Provides comfort and dignity for the individual |
| Remove equipment from the individual's bedside | Leave bedside neat and tidy. Used equipment is disposed of in the correct manner |
| Perform hand hygiene | Prevents spread of infection |
| Report and document all relevant information, including type and date of specimen, correctly in the healthcare record and any complications | Medico-legal requirement. Allows for the planning and implementation of care |

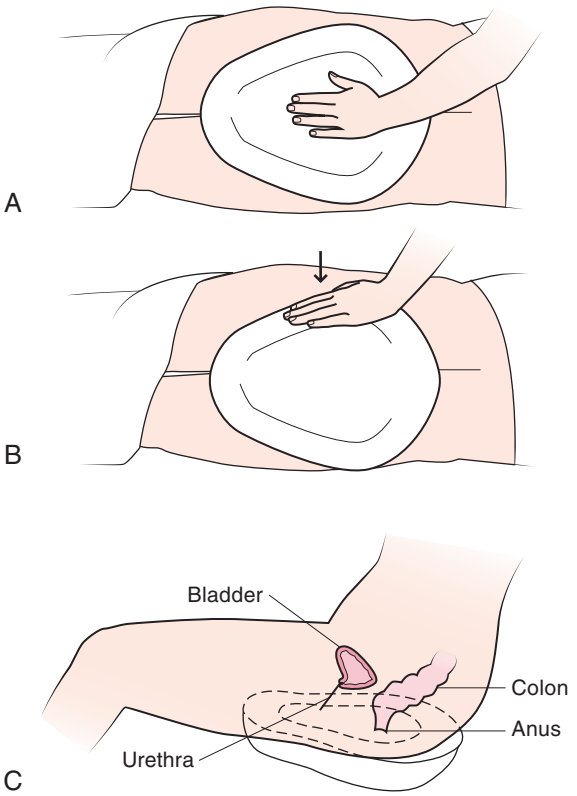

**Figure 31.5** Positioning a bedpan

A: Another method of placing a bedpan is used when the person is unable to help. The person lies on one side and the bedpan is placed firmly against the buttocks B: The nurse pushes down on the bedpan and towards the person C: The person is positioned on the bedpan so that the urethra and anus are directly over the opening

according to facility policy. Standard precautions are maintained throughout the procedure.

Accurate data collection and recording is vital evidence for assessment and diagnosis. Step-by-step method of urinalysis is outlined in Clinical Skill 31.3.

## Urinalysis (laboratory)

Abnormal findings from a routine urinalysis often require further investigation by a laboratory and this will be ordered by the medical officer or nurse practitioner.

Adequate information about the person and the specimen must be provided. The label on the specimen container must contain the person's name, registration number, the date and time of collection and the method used to collect the specimen; for example, catheter specimen of urine. When a specimen is despatched for laboratory analysis it must be accompanied by the appropriate signed request form with type of collection and the specific laboratory tests to be performed.

Specimens must be sent to the laboratory as soon as possible after collection; if delay is anticipated the specimen must be refrigerated as soon as possible. Depending on ambient temperature, urine left for more than 2 hours without some

**TABLE 31.2 | Abnormalities of urine detected by observation**

| Observation | Deviation from normal | Possible cause |
|---|---|---|
| Colour | Pale | High fluid intake, other factors that dilute the urine, such as diuretic medication or disease (e.g. diabetes mellitus) Indication of adequate hydration |
| | Dark or brown | Concentrated urine due to dehydration or presence of bile pigment (e.g. in liver or gallbladder disease), or indication of poor hydration |
| | Smoky | Presence of occult blood |
| | Red | Presence of frank blood |
| | Bright yellow, blue or green | Specific medications |
| | Mucous plugs, viscous, thick | White blood cells, bacteria, pus or contaminants such as prostatic fluid or vaginal discharge may cause cloudy urine |
| Odour | Ammonia | Decomposing urine |
| | Foul-smelling 'fishy' odour | Infected urine |
| | Sweet smelling | Presence of glucose (e.g. in diabetes mellitus) |
| Foreign substances | Pus | Urinary tract infection |
| | Stones, gravel | Calculi in urinary tract |
| Amount | Higher than normal in 24 hours | High fluid intake, diuretic medications, diseases (e.g. diabetes mellitus) |
| | Lower than normal in 24 hours | Obstruction to the flow of urine Diseases that reduce the normal production of urine (e.g. renal failure) |

*(Pagana et al 2013)*

## CLINICAL SKILL 31.3 Urinalysis

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Urinalysis reagent testing strip<br>Paper towel<br>Urine collection container<br>Non-sterile gloves<br>Eye protection as required<br>Waste receptacle |

| **Skill activity** | **Rationale** |
|---|---|
| Urinalysis involves the physical, chemical and microscopic examination of urine. Reagent strips detect and measure various compounds which may be found in urine. | |
| Validate the medical request for specimen collection ensuring no contraindications | Ensures correct procedure is about to take place |
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent | Reduces anxiety and gains individual's consent and cooperation |
| Urine specimen is collected in appropriate vessel or container from the individual and taken to appropriate area for testing | Collection of specimen is required prior to testing |
| Observe urine for colour, amount, odour and presence of any foreign substances | Abnormalities in the urine may indicate renal impairment or presence of microorganisms |
| Prepare testing area by placing absorbent paper towel onto bench top | Paper towel will absorb any fluids spilt |
| Apply gloves | Prevents spread of infection |
| Check test strips are in date, how to read strip and time required for a result prior to commencing | Out-of-date test strips or inaccurate timing may not give an accurate result |
| Uncap bottle and remove reagent strip from bottle. Recap bottle | Prevent contamination of remaining strips in bottle |
| Note the time the reagent strip is inserted into the urine | Not all tests read are read at the same time |
| Dip reagent strip into the collected urine making sure to cover all testing areas on the strip | Allows for accurate testing |
| Holding the test bottle on its side and using this as a guide, without touching the test strip against the bottle, match the test areas of the reagent strip against the bottle when the required reaction time has been reached | Test results are noted against colour matching on the reagent test strip bottle. Touching the strip against the bottle will lead to cross-contamination |
| Dispose of urine sample, test strip, absorbent towel and gloves into correct receptacles | Correct disposal prevents cross-contamination and spread of infection |
| Perform hand hygiene | Prevents spread of infection |
| Document findings in correct charts | Medico-legal requirement. Allows for the planning and implementation of care |
| Report and document all relevant information, including type and date of specimen, correctly in the healthcare record and any complications | Medico-legal requirement. Allows for the planning and implementation of care |

*(Berman et al 2015; Crisp & Taylor 2013; LeMone et al 2011; Lynn et al 2012; Rebeiro et al 2013; Smith et al 2011; Medline Plus 2015)*

form of preservation such as refrigeration is unlikely to produce an accurate result and should be discarded due to decomposition of the urine and increased microbial activity.

If the person is responsible for collecting the urine specimen, the nurse should provide the person with the information necessary to ensure that the collection is performed correctly.

All urine excreted during a timed collection, for example, during a 24-hour period, is collected and sent for laboratory analysis to measure the quantity of various substances present, such as specific hormones. Table 31.3 describes the results of urinalysis.

### Mid-stream specimen

This method of collection is used to obtain a sample of urine that is not contaminated by microorganisms from outside the urinary tract and therefore must be collected in a sterile receptacle. The urine is sent to the laboratory to be tested for the presence of microorganisms and their sensitivity to antibiotics. The aim is to collect the middle portion of the stream of urine. A suggested method of collection is outlined in Clinical Skill 31.4.

### Catheter specimen

A catheter specimen of urine is obtained from a person who has an indwelling catheter. The insertion of a catheter for the sole purpose of obtaining a urine specimen is generally avoided because of the risk of introducing microorganisms into the urinary tract. Collecting a specimen from the end of the catheter that is connected to the drainage tubing should be avoided and best results are achieved if urine is aspirated using a sterile syringe and needle through the sampling port.

### Suprapubic bladder aspiration

The suprapubic bladder aspiration procedure is not commonly used but, when necessary, it is performed by a medical officer,

**TABLE 31.3 | Results of urinalysis**

| Test | Normal values | Deviation | Possible causes |
|---|---|---|---|
| pH | 4.5–8.0 | Elevated (alkaline (above 8.0))<br>Lowered (acidic (below 4.5)) | Urinary tract infection, chronic cystitis, metabolic or respiratory alkalosis, acute and chronic renal failure, low-protein diet<br>Diabetic acidosis, fever, pulmonary emphysema, diarrhoea and dehydration, high-protein diet |
| Specific gravity | 1.005–1.030 | Elevated (above 1.030)<br>Lowered (below 1.005) | Low fluid input, vomiting, diarrhoea, hepatic disease, congestive cardiac failure, presence of abnormal substances in the urine (e.g. protein)<br>High fluid input, diabetes insipidus, certain kidney diseases |
| Protein (proteinuria) | Nil | Present | Kidney infections<br>Acute glomerulonephritis, pyelonephritis, diabetes mellitus (types 1 and 2), acute febrile states, hypertension, congestive cardiac failure |
| Glucose (glycosuria) | Nil | Present | Diabetes mellitus (types 1 and 2), pancreatitis, pain, Cushing's syndrome, hyperthyroidism, administration of corticosteroids, stress |
| Ketones (ketonuria) | Nil | Present | Diabetes mellitus (type 1), fever, starvation, pregnancy, trauma, vomiting and diarrhoea |
| Bilirubin (bilirubinuria) | Nil | Present | Liver disease (hepatitis, cirrhosis), biliary obstruction |
| Blood (haematuria) | Nil | Present | Urinary tract disease or trauma, acute nephritis, renal calculi, renal carcinoma, use of anticoagulants, chronic kidney infection |
| Nitrite | Nil | Present | Urinary tract infections, pyelonephritis, cystitis, urethritis |
| Urobilinogen | 0.1–1.0 | Elevated (above 1.0)<br>Lowered (below 0.1) | Liver disorders (cirrhosis, hepatitis), congestive cardiac failure, blood disorders (e.g. haemolytic anaemia, pernicious anaemia, thalassaemia)<br>Obstruction of the bile duct, antibiotic therapy, cancer of head of pancreas |
| Leucocytes | Very few | Increased | Urinary tract infection, bacteriuria |

*(Pagana et al 2013)*

## CLINICAL SKILL 31.4 Mid-stream urine collection

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile specimen pot<br>Commercially produced specimen pack<br>Biohazard specimen transport bag<br>Gloves<br>Moist towel or wipes<br>Hand hygiene equipment |

| **Skill activity** | **Rationale** |
|---|---|
| Mid-stream urine specimen obtains a urine specimen that is not contaminated by microorganisms from the hands or urethra. Accurate urine collection for a MSU can only be achieved if the individual is able to follow instructions. | |
| Validate the medical request for specimen collection ensuring no contraindications | Ensures correct procedure is about to take place |
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent | Reduces anxiety and gains individual's consent and cooperation |
| Explain to individual how to obtain a specimen that is free of tissue and stool:<br>• Perform hand hygiene<br>• Wash genital area<br>• Female: hold labia open. Males: draw back foreskin<br>• Pass the first part of the stream into the toilet<br>• Collect the urine into the specimen container taking care not to void on the outside of the container<br>• Pass the remaining stream into the toilet. | Promotes cooperation and individual's participation. Where appropriate individual can collect clean-voided specimen independently |
| Specimen container is labelled with the individual's name, date of birth and UR number | Correct specimen is sent for testing |
| Pathology form is checked for the individual's details | Correct form and specimen are sent to pathology department. Correct test will be undertaken in the pathology department |
| Provide individual with equipment to cleanse perineum (see Clinical Skill 31.2 Perineal care). Assist individual if required<br>Perform hand hygiene | Individuals usually prefer to wash their own perineal area when possible. Prevents external microorganisms from contaminating the specimen<br>Prevents the spread of microorganisms |
| Using surgical asepsis, open outer package of commercial specimen kit | Maintains sterility of specimen container |
| Apply gloves | Prevents introduction of microorganisms into urine specimen from nurse's hands |
| Individual voids 30–60 mL of urine into the toilet or toilet utensil | Flushes any residual microorganisms out of the urethra |
| Collect the next 20–30 mL of urine in a sterile container (e.g. sterile kidney dish). If able the individual provides the urine specimen directly into specimen container | Mid-stream specimen is collected. This is the required portion sent for analysis<br>Mid-stream specimens contain fewer microorganisms than the first pass or final stream of urine |
| The individual completes voiding into the toilet or toilet utensil | The remainder of the urine is not required for collection |

| CLINICAL SKILL 31.4 Mid-stream urine collection—cont'd | |
|---|---|
| Pour collected urine specimen into labelled sterile specimen container. If individual voids directly into specimen container, wipe container to remove any urine<br>Remove gloves and perform hand hygiene<br>Ensure individual has facilities for their own hand hygiene | Specimen can be sent for analysis<br>Specimen container is free from urine<br>Prevents cross-contamination |
| Label specimen according to organisation's policies and procedures. Despatch specimen to the laboratory with the request form, or store specimen in refrigerator | Decomposition and cell growth occur if urine is left standing, and may provide a false result |
| Report and document all relevant information, including type and date of specimen, correctly in the healthcare record and any complications | Medico-legal requirement. Allows for the planning and implementation of care |
| Note: Indicate on laboratory slip if individual is menstruating. | |
| *(Berman et al 2015; Crisp & Taylor 2013; LeMone et al 2011; Lynn et al 2012; Rebeiro et al 2013; Smith et al 2011; NHMRC 2010a; 2010b)* | |

using sterile equipment and aseptic technique. It involves the insertion of a needle through the skin over the suprapubic area into the bladder. A quantity of urine is aspirated, placed in a sterile container and despatched to the laboratory. After this procedure the nurse should observe the puncture site for bleeding, and the urine for the presence of blood.

### Straining urine

Stones, or calculi, are insoluble substances formed of mineral salts that may develop in the kidneys. They can range in size from microscopic to the size of grains of sand or gravel to several centimetres in diameter. If it is known or suspected that a person has developed renal calculi, careful observation of the urine is achieved by straining it to detect the passage of stones. Any stones collected are sent for laboratory examination, which reveals their exact composition and helps to identify their cause. The urine is strained by pouring it through a fine substance such as gauze or filter paper.

## Further diagnostic tests

Tests that may be performed to assist or confirm the diagnosis of urinary system disorders include the following.

### Blood tests

Blood may be obtained and tested in the laboratory to assess renal function. The tests most often performed are:

- Serum creatinine measurements, which reflect the ability of the kidneys to excrete creatinine, the waste product of energy metabolism
- Blood urea nitrogen (BUN) levels, which reflect the ability of the kidneys to excrete urea
- Uric acid levels, which may indicate renal dysfunction if elevated
- Measurement of haemoglobin and haematocrit levels, white blood cell counts, serum potassium and phosphorus levels.

### Ultrasound and radiology diagnostic tests

Bladder scans can provide a non-invasive method of assessing residual urine in the bladder and reduce the frequency of catheterisation (Rigby & Housami 2009). These are often portable scans available for use by nurses and other medical personnel and may not require the person to visit a specialist department. More complex ultrasound can identify the size and position of the kidneys and if there are any swellings or cysts associated with them. It will show if there is any dilation (widening) of the tubes which may be the result of blockage. It does not show function.

An intravenous pyelogram (IVP) is an x-ray examination of the urinary tract in which an injection of dye is given into a vein so that the function of the kidneys is shown by passage of the dye through the kidneys and down the tubes (ureters) that drain them to the bladder. A retrograde pyelogram involves the insertion of catheters into the ureters through a cystoscope. Contrast medium is introduced through the ureteric catheters into the pelvis or the kidneys, and x-ray films are taken.

Cystoscopy: the cystoscope is an endoscopic instrument which is passed into the bladder through the urethra in order to inspect its lining. The procedure is carried out either under a general anaesthetic with a rigid instrument or under regional anaesthesia with a flexible cystoscopy.

Computerised axial tomography (CAT) scan of the abdomen may be performed to identify kidney size or structural alterations within the urinary system. It may be done with or without contrast medium.

### Renal biopsy

A biopsy of kidney tissue may be taken for microscopic tissue examination. After injection of local anaesthetic a special biopsy needle is inserted through the skin to obtain a sample from the cortex of the kidney. After a renal biopsy the person

must be monitored closely for haematuria, rapid weak pulse, pallor or low blood pressure, as these may indicate haemorrhage from the biopsy site.

## SPECIFIC DISORDERS OF THE URINARY SYSTEM

Disorders of the urinary system may be classified as congenital, infectious, immunological, degenerative, neoplastic, obstructive, traumatic or those resulting from multiple causes.

### Congenital disorders

Certain disorders may be present at birth, although the manifestations may not become evident for some time. Vesico-ureteric reflux is a mechanical problem that may be congenital or acquired. Abnormal backflow of urine from the bladder to the ureter(s) increases the hydrostatic pressure in the ureters and kidneys. Reflux into the kidneys causes damage to the renal parenchyma and reflux nephropathy. In the congenital form the child is born with a short ureter, which often grows to normal size as the child develops and matures, so that the condition resolves. Acquired vesico-ureteric reflux may be caused by repeated UTIs, by inadequate functioning of the detrusor muscles in the bladder or from a high pressure within the bladder as a result of an obstruction (Hockenberry & Wilson 2010). Symptoms of the disorder generally appear only in the presence of a UTI and there may be no symptoms with chronic infection. The condition may not be diagnosed until signs of renal damage become evident.

Polycystic kidney disease is an inherited disorder characterised by grape-like clusters of fluid-filled cysts that enlarge the kidneys. There are two forms of this disorder, one affecting children and the other affecting adults. In its infantile form the disorder manifests as bilateral masses in the kidney areas, with symptoms of respiratory distress and cardiac failure. Adult polycystic disease is frequently asymptomatic until the person is about 40 years of age. Initial symptoms include hypertension, haematuria and low back pain. UTI is common and progression to renal failure is gradual.

Hypospadias is abnormality or malformation of the penis whereby the urethra is not at the end of the penis but found at any location on the under surface of the penile shaft or scrotum in severe cases. It affects 1 in 150 boys and is usually detected at birth. Symptoms range from penis not being straight, no straight stream of urine and the foreskin being all at the back of the penis (Levitt & Reda 1988; The Royal Children's Hospital 2015).

### Infectious disorders

Infection may occur in any part of the urinary tract, as urine provides an ideal medium for the growth of microorganisms. Most commonly they gain access to the urinary tract by ascending the urethra although, rarely, they may descend from the kidneys to the lower urinary tract.

**Pyelonephritis** is inflammation of the renal pelvis and may be an acute or chronic condition. Acute pyelonephritis results from bacterial infection of the kidneys, commonly as a consequence of a lower UTI. A person with acute pyelonephritis may experience severe pain or a continual dull ache in the kidney region, as well as pyrexia, nausea and vomiting and fatigue. Rigors may be present, and urination may be frequent and painful. The urine is generally cloudy, blood stained and offensive in odour. Chronic pyelonephritis can result in the formation of renal scar tissue, which may in turn lead to chronic renal failure. This condition most commonly occurs in persons who experience recurrent acute pyelonephritis as a result of a urinary tract obstruction or vesico-ureteric reflux.

Cystitis is inflammation of the urinary bladder, and is usually the result of bacterial contamination. Cystitis is more common in females than in males because of the short length and proximity of the urethra to the bowel and vagina. The urine is generally cloudy and offensive and may contain blood cells. Urethritis, inflammation of the urethra, may result from bacterial infection or traumatic irritation such as catheterisation.

Organisms responsible for infections are numerous: *Escherichia coli* is a common infective organism; altered hygiene habits, sexual activity or bowel disorders may contribute to the infective process. Other causative organisms may be transmitted sexually, such as *Chlamydia trachomatis* and *Neisseria gonorrhoea*.

Symptoms of urinary tract infections may include dysuria and the presence of pus in the urine but often manifest differently in different age groups (Carter et al 2014; Bardsley 2014). Table 31.4 outlines the age-related symptoms of UTI.

**TABLE 31.4 | Age-related symptoms of UTI**

| Younger persons (symptoms tend to be specific) | Older persons (symptoms tend to be less specific) |
|---|---|
| Frequency/urge | May/may not be present |
| Continent | Episodes of incontinence |
| Pyrexia/chills | Not always present |
| Burning of micturition | Seldom present |
| Low back/low abdominal pain | Lower abdominal tenderness |
| Lethargy | Lethargy |
| Loss of appetite/nausea | Loss of appetite |
| Mentally alert | Altered mental state |

*www.webmd.com/urinary-incontinence-oab/tc/urinary-problems-and-injuries-age-12-and-older-topic-overview; www.agingcare.com/Articles/urinary-tract-infections-elderly-146026.htm*

## Degenerative disorders

Degenerative disorders include disorders in which there are degenerative changes in the renal structure or changes in the blood vessels that supply the kidneys. Degeneration occurs over a long period, and the person may not experience any symptoms until significant damage has occurred. Nephrosclerosis is necrosis of the renal arterioles, resulting from untreated or uncontrolled hypertension that impairs the blood supply of the kidneys. Renal damage occurs from a combination of fibrosis of the blood vessel walls and the resulting ischaemia. The person presents with high blood pressure, headaches, visual disturbances and altered neurological functioning. The urine contains protein and blood. If untreated, this condition can lead to renal and cardiac failure.

Analgesic nephropathy results from chronic ingestion of substances containing phenacetin. Aspirin–paracetamol combinations have also been found to cause similar renal tubule damage. The person complains of low back pain, haematuria and the symptoms of uraemia (nausea, vomiting, pruritus, muscle cramps). If end-stage renal failure develops, dialysis or kidney transplantation will be necessary (Berman et al 2015).

## Neoplastic disorders

Tumours that arise in the urinary system may be benign or malignant. Kidney tumours are generally malignant and usually well advanced before haematuria, the first and most common sign, appears. Later features include pain as the tumour enlarges and presses on adjacent structures, nausea and vomiting, loss of weight and metastatic symptoms such as bone pain. Wilms' tumour is a rare malignant tumour of the kidneys that occurs primarily in children (Kidney Health Australia 2014).

Bladder tumours are generally malignant, and more common than kidney tumours. Most occur in men over age 50. Evidence shows that prolonged exposure to certain substances such as aniline dyes is associated with increased incidence of bladder cancer. A variety of other carcinogenic substances, such as artificial sweeteners, are linked to bladder cancer. The prime manifestation of a bladder tumour is intermittent haematuria.

Prostate cancer is the most common cancer other than skin cancer in Australian men over the age of 50. Cancer of the prostate is commonly diagnosed through a screening blood test which indicates raised prostate specific antigen (PSA) (Andrology Australia 2015). As the tumour develops it causes the prostate gland to increase in size and causes difficulty in initiating micturition, a feeling that the bladder is not empty after voiding and dribbling of urine after micturition. Acute retention of urine may occur if the flow from the bladder is severely obstructed. Surgical intervention for conditions relating to the prostate can lead to erectile dysfunction and continence issues.

## Obstructive disorders

Obstruction of the urinary tract may be caused by factors other than the presence of tumours and calculi.

Benign prostatomegaly (enlargement of the prostate gland surrounding the male urethra) may compress the urethra and cause urinary obstruction. The cause of hypertrophy of the prostate gland is not fully understood but is probably related to hormonal mechanisms. It is more common in men over age 50. The first sign that there may be prostate problems may be when a man experiences the urge to pass urine more frequently, experiencing hesitancy and/or an interrupted stream. Sexual dysfunction is often experienced as the prostate enlarges. Some men may experience pain at the base of the scrotum and penis (Andrology Australia 2015). A digital rectal examination performed by the person's medical officer can ascertain if the prostate is enlarged.

Hydronephrosis, or dilation of the renal pelvis, may result from obstruction of the urinary tract. The build-up of pressure behind the area of obstruction eventually results in damage to the kidneys, and renal dysfunction. Causes of hydronephrosis include prostatomegaly, urethral stricture, calculi, congenital abnormalities and neurogenic bladder. The person usually presents with dull lower back pain and tenderness, decreased urine flow, dysuria and haematuria. Infection or renal failure can occur if the problem is not corrected.

Calculi are stones that form in the kidneys and urinary tract. Most stones form in the kidneys and pass down into the ureters or bladder. They are usually composed of calcium salts or uric acid. Multiple small calculi may remain in the renal pelvis or pass down the ureter, while a staghorn calculus remains in the kidneys. Although the precise cause is unknown, predisposing factors in the formation of calculi include some medications, dehydration, metabolic factors, infection, prolonged immobility and urinary stasis (Vance & Harold 2010).

The major symptom of calculi is pain, felt as a dull ache while the stone remains in the kidney. Stones which are localised to the kidneys may be treated with extracorporeal shock wave lithotripsy (ESWL). Stones which pass into the ureter may be treated with ESWL or, if lower down, may be removed using ureteroscopy.

If a stone passes into the ureter, the person may experience excruciating colicky pain that is frequently accompanied by nausea and vomiting.

## Traumatic disorders

Injuries to the kidney or urinary tract can have serious consequences. Because the kidney receives a large amount of blood from the abdominal aorta via the renal arteries, even a small laceration can cause massive haemorrhage. Injuries to the kidney include contusion, haematoma and laceration. The renal artery or renal vein may be ruptured. Symptoms include haematuria, back and abdominal pain and symptoms of hypovolaemic shock if the injury is severe. Bladder trauma may be associated with pelvic fractures or result from a blunt or penetrating injury. Symptoms of bladder injury include haematuria, dysuria, decreased urinary output, suprapubic pain and tenderness. Scrotal or perineal swelling may occur if urine escapes from the damaged bladder into surrounding tissues.

## Disorders of multiple cause

Chronic renal failure is the gradual loss of functional nephrons and may be due to several causes, including chronic kidney infections, polycystic kidneys, renal vascular disease, hypertension and obstructive diseases such as calculi, nephrotoxic agents and diabetic nephropathy. The condition produces major changes in all body systems.

It consists of four phases: diminished renal reserve, renal insufficiency, renal failure and end-stage renal disease. During the first phase, renal damage occurs but the person may be asymptomatic. With renal insufficiency the kidneys still function, but urinary concentration is impaired and blood urea levels are elevated. The renal failure stage produces uraemia, metabolic acidosis, electrolyte imbalance and impaired urine dilution. In the end stage, renal function is severely impaired and most other body systems are affected. When renal function is impaired to such an extent that conservative treatment is no longer effective, dialysis therapy and/or kidney transplantation are necessary (Health Insite 2012).

### CASE STUDY 31.1 EXPLORING ONE OF THE DISORDERS OF THE URINARY SYSTEM

Alfred, an 84-year-old, has been to see his doctor for a routine examination. On questioning he revealed that he has been experiencing difficulty with ambulation due to joint pain in his hip. Blood tests show he has slightly elevated PSA and, on digital rectal examination, an enlarged prostate.

On questioning, Alfred admits to having urinary frequency and nocturia, explaining that he often has to get up to 'spend a penny' at night. Upon further questioning he explains that he has noticed increased difficulty with starting and stopping urination and when it does start it is very slow. This has happened over several months but he has been too embarrassed to seek medical advice. Alfred also describes symptoms of joint stiffness and discomfort which make it difficult to do many of the things he once used to do.

1. What do the results of Alfred's blood and physical examination suggest?
2. What is the treatment for the condition and what is the prognosis?

# INCONTINENCE

**Continence** can be defined as the ability to control excretion in a timely and appropriate manner. **Incontinence** is the involuntary loss of urine and can occur at any time. Causes for this distressing symptom can be as a result of infection, changes to the neurological or endocrine system, physiological, pharmacology or psychological changes and other idiopathic causes (Carcio 2014). In children bedwetting (**enuresis**) is a relatively common occurrence which may resolve over time. Persons who experience involuntary leakage frequently lack self-esteem, and may experience physical discomfort and social isolation. Incontinence in adults is categorised into five main categories:

1. Urge: the sudden desire to void resulting in involuntary leakage
2. Stress: the involuntary loss of urine when exercising, coughing or laughing
3. Overflow: incomplete evacuation of urine from the bladder which results in a pool of urine remaining in the bladder. Not only is this a reservoir for bacteria but pressure can build up, resulting in overflow of urine being involuntarily released
4. Transient: sudden onset of incontinence often associated with infection
5. Reflex: loss of bladder control, often the result of neurological trauma or disease.

There can also be a mixed presentation of symptoms. Sensitive probing concerning the history of continence and accurate reporting aid assessment of appropriate initiatives.

## Lifespan issues

Children: micturition is normally under voluntary control by about 2–3 years of age; however, children often experience enuresis into their school years. There are a variety of interventions to assist children experiencing this situation and effective data collection including incidence, external factors such as stress or emotional trauma, absence of infection, pharmacology or disease profiles is necessary. Children frequently outgrow the symptom but the psychosocial implications can have a long-term negative impact.

Adolescence: incontinence can be continuous throughout childhood as a result of infection, toilet avoidance (especially at school), constipation or disease. This stage of development is also a time when some adolescents become sexually active and incontinence related to a bladder infection (cystitis) and associated vaginitis or epididymitis may be experienced. Some adolescents are often reluctant to seek help and the need for sensitivity in responding to this age group is vital (Deshprande et al 2012).

Pregnancy and postpartum incontinence: the effectiveness of pelvic floor exercises in helping to improve the musculature of the pelvic region has long been acknowledged and use of these exercises has resulted in improvement in the post-childbirth incidence of incontinence (Seshan & Sivaram 2012). During pregnancy, mechanical and hormonal factors cause changes in renal physiology, most commonly resulting in frequency of voiding and stress incontinence. Many postpartum changes, including damage to the pelvic floor during vaginal delivery, have long-term continence effects and these are less acknowledged, with many mothers assuming that involuntary loss of urine is normal after the birth of a baby. This condition has an adverse effect on the mother—from physiological, psychological and sexual perspectives (Carcio 2014).

Menopause: urge and stress incontinence increase in women post menopause, and complications such as obesity and type 2 diabetes can exacerbate the symptoms.

Older adults: while continence issues in adolescents and adults are experienced mainly by women, prostatic enlargement in men and the resultant effects of surgery increase the incidence of incontinence in men. The increase in metabolic syndrome in men and women, obesity and neurological changes also contribute to incontinent events. There are frequently mixed aetiologies (causes) in this age group.

## Nursing interventions

Interventions can only be effective when a thorough assessment has been completed. Incontinence issues are highly individualised and the nurse needs to respond to each individual person's needs. Therefore, care plans must be initiated in consultation with the person or their families (see Nursing Care Plan 31.1).

- Use standard precautions for dealing with body fluids
- Use accurate documentation and assessment to aid all health professionals in treatment
- Encourage person to consume fluids unless contraindicated; at least 1500 mL daily, as an inadequate fluid input may further decrease the functional capacity of the bladder
- Recommend weight reduction where applicable
- Establish and maintain Kegel exercise routine (Clinical Interest Box 31.1)
- Use of the NeoControl® or similar chair—which creates therapeutic pulsed magnetic field to provide powerful stimulation of vital pelvic floor muscles—as an adjuvant to pelvic floor exercises. These chairs are being increasingly deployed in the community setting
- Be aware of the person's physical and social environment; for example, wet clothing or bedclothes should be removed immediately and taken from the room to prevent offensive odours. The person should be provided with clean dry clothing and applicable continence aids. Air freshener should be available
- Provide easy access for ambulant persons to the toilet, which should be clearly marked and have suitable rails and/or equipment to assist them to void comfortably. Non-ambulant people should be provided with toilet utensils relevant to their need. Some persons may find it easier to use a commode and men often find it easier to void while standing. Any request for use of toilet facilities should be responded to promptly (Department of Health and Ageing 2015)
- Keep the skin clean and dry as constant moisture on the skin may lead to excoriation and the development of decubitus ulcers. When the person is incontinent their skin should be washed with mild soap and water and gently dried. Particular attention is paid to the genital area, the groin and the crease between the buttocks
- Be aware of the various medications that may be prescribed in the management of incontinence, and their side effects; for example, antibiotics to treat a UTI

### NURSING CARE PLAN 31.1 A PERSON WITH URINARY INCONTINENCE

**Assessment:** Mrs Jones (80 years) had been admitted to the acute ward the previous evening following a fall. This morning the nurse noticed an odour of urine and felt the sheets were damp. Mrs Jones acknowledged she had difficulties getting to the toilet in time and was deeply traumatised by the event. She repeatedly asked the nurse not to tell anyone, and said that she managed well at home.
**Issue/s to be addressed:** Type of urinary incontinence identified (may be mixed in presentation).
**Goal/s:** Person will report relief from urinary incontinence or a decrease in incidence.
Person will gain confidence in ability to self-manage with education and management strategies.
Person will maintain skin integrity and social hygiene effectively.

| Care/Actions | Rationale |
|---|---|
| Maintain standard precautions | To avoid further infections |
| Perform a complete urinalysis | To determine underlying medical disorders and to have a baseline for comparison purposes later |
| Maintain bladder diary for at least 72 hours | To establish continence pattern |
| Review all medications in consultation with the medical officer | To determine if any are thought to be contributing to the incontinence |
| Teach pelvic floor exercises | To help strengthen the pelvic muscles |
| Review person's fluid intake and types of fluid consumed | To check if the person is taking any fluids which might irritate the bladder (e.g. alcohol and caffeine) as this can cause urgency |
| Provide the person with information about the Continence Foundation of Australia | To seek further support |
| Explain continence aids available to allay person's anxiety | |

**Evaluation**

Person reports urinary continence or reduced incidence of incontinence episodes.
Person reports maintenance of pelvic floor exercises at least three times daily.
Person's fluid intake is at least 2 L per day (if not contraindicated by coexisting disease).
Person understands the role and function of the Continence Foundation of Australia.

## CLINICAL INTEREST BOX 31.1
## Pelvic muscle (Kegel) exercises

Exercise program for making pelvic floor muscles stronger:

- Check with a continence adviser or physiotherapist to ensure that exercises are being performed correctly
- Find the right muscles: when passing urine, stop the flow mid-stream. Then relax and finish passing urine. The muscles you tighten and pull upwards to stop the flow of urine are the pelvic floor muscles. Tighten the muscles around the anus by imagining that you are trying to stop passing wind
- Test your muscle strength: women—place one or two clean fingers in the vagina and tighten the pelvic floor muscles; men—press one finger on the area between the anus and scrotum; when the pelvic floor muscles are tightened, this area will move up and away from the finger
- To do the exercise, squeeze the muscle identified and hold for a count of 10 seconds. Relax for a count of 10 seconds. It may take 2 weeks to be able to hold for 10 seconds
- Do the exercise three times a day: 15 in the morning, 15 in the afternoon and 20 at night. Or for 10 minutes three times a day. Try to work up to 25 repetitions at one time. It will take about 2 weeks to notice a difference. Within a month of regular exercise, there should be a decrease in instances of incontinence.

*(adapted from deWit & O'Neill 2013)*

- Continue to screen urine for infection or underlying disease
- Ensure continence aids are suitable, affordable and adequate for the individual. The PadNavigator™ helps you find the right continence pad when a disposable absorbent product has been recommended following a continence assessment (see www.brightsky.com.au/ClinicalSupport.aspx)
- Where necessary provide a referral to a specialist continence nurse and more information such as from the Continence Foundation of Australia
- Assist in changes to lifestyle and planning (e.g. use of the National Toilet Map).

### Specific interventions

- *Stress incontinence*: encourage use of pelvic floor exercises
- *Urge incontinence*: implement planned bladder-retraining regimens to promote continence or to modify incontinence. These regimens often include timed intervals for toileting; for example, the regimen may start at 2-hourly periods and, if continence is achieved, then the timing is increased until a suitable pattern is attained. Kegel exercises may assist in maintaining continence (Continence Foundation of Australia 2015)
- *Enuresis*: use monitoring devices with an alarm system
- Consider a penile sheath (condom drainage) with tube and collection bag for those male persons suffering neurological damage to the bladder. Before any appliance is fitted, the penis must be cleaned and dried and observation made to ensure that the foreskin is not retracted. The appliance is placed over the penis and secured in position. A special adhesive tape is commonly used and care must be taken to ensure that it is not applied too tightly. The tubing from the appliance is connected to either a bedside collection bag or a leg bag. The penis should be observed for oedema and discolouration; if detected, the appliance is removed immediately and reapplied more loosely. At least every 24 hours the appliance is removed and the penis cleaned and dried before reapplication. Use of such appliances should be discontinued if there are signs of skin excoriation, persistent oedema of the penis or UTI. Refer to Clinical Skill 31.5.

### CRITICAL THINKING EXERCISE 31.1

When Mrs Santi arrives at the doctor's surgery following the birth of her third child, she is tearful and anxious. After careful probing you discover that she no longer socialises for fear of being incontinent. Discuss the factors that may have caused this condition. Suggest nurse-initiated tests to assist in assessment. What interventions would you discuss with Mrs Santi?

## CATHETERS

A catheter is a tube that is inserted into the bladder to drain urine. It is inserted through the urethra or, less commonly, through a small incision in the suprapubic area. A catheter may be inserted to empty the bladder then removed immediately, or it may be left in the bladder. A catheter that remains in the bladder may be either clamped and released at specified intervals, or connected to tubing and a bag to enable continuous drainage. A catheter that remains in the bladder is referred to as indwelling. A self-retaining catheter is used for this purpose. It has a small balloon which sits at the neck of the bladder to prevent the catheter falling out, and which is filled with sterile water after the catheter is inserted.

Catheters are graded according to the French scale, and the larger the number the larger the lumen of the catheter. Sizes range from 1 to 30 French gauge (Fg), and the size is selected to suit the person's needs. The Catheter Compass™ helps you select the right catheter for a person when a urological or continence review has resulted in the

## CLINICAL SKILL 31.5 Applying a sheath/condom drainage device

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Condom catheter<br>Urine drainage bag or leg bag and straps<br>Gloves<br>Adhesive tape<br>Basin with warm water, soap, washcloth, towel |

| **Skill activity** | **Rationale** |
|---|---|
| A condom catheter is used for a male individual who is incontinent but can void on his own. | |
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent | Reduces anxiety and gains individual's consent and cooperation |
| Assess the need for and the individual's willingness to use a condom catheter | If the individual is unwilling, he may detach the condom catheter |
| Raise the individual's bed to appropriate working position based on your height<br>Assist the individual to assume an appropriate position of comfort, ensuring that only the wound area is exposed. Provide for privacy | Promotes comfort and facilitates performance of the procedure |
| Assess the condition of the skin on the penis<br>Use measuring device for circumference of penis | Urine incontinence places the skin at risk for breakdown<br>Allows for correct size to be used and prevents leakage of urine |
| Place the individual in a supine position. Cover the upper torso with a blanket, then fold the sheet down so it covers the legs and can be lowered to expose the genitalia | Provides privacy, dignity and comfort for the individual<br>Prevents unnecessary exposure |
| Prepare the urinary drainage bag for easy attachment to the condom catheter. Roll the wider tip of the condom sheath towards the narrower tip | Prepares the system for use |
| Perform hand hygiene. Apply gloves | Prevents spread of microorganisms |
| Wash and dry the penis and surrounding skin | Cleanses the skin before application of the condom device |
| Apply the double-sided elastic tape in a spiral fashion from the base of the penis downwards (or as manufacturer indicates) | Provides a surface on which the condom catheter can be attached without impeding circulation in the penis. Some condom catheters attach with a velcro strip over the sheath |
| Grasp the penis along the shaft. Hold the condom sheath at the tip of the penis and smoothly roll the sheath onto the penis, leaving 2.5–5 cm of space between the tip of the penis and the drainage tube of the condom sheath | Positions the condom catheter on the penis. Allows free passage of urine into the collecting tube and drainage bag |
| Position the penis downwards and connect the drainage tube to the collection bag | Allows urine to flow into the collection bag |
| Return bed to the low position and make the individual comfortable; place call bell within reach | Provides comfort and security |

*Continued*

| CLINICAL SKILL 31.5 Applying a sheath/condom drainage device—cont'd | |
|---|---|
| Remove gloves and perform hand hygiene | Prevents spread of microorganisms |
| Document the date, condition of the genital area, size and type of sheath applied, type of drainage collection attached to the sheath, amount, colour and character of urine obtained in bag, and the individual's tolerance of the procedure | Medico-legal requirement. Allows for the planning and implementation of care. Documents use of condom drainage |
| Check the penis after 30 minutes and then every 2 hours to ensure catheter is not twisted | Ensures that the catheter is not too tight and impairing circulation; twisting of the catheter impedes urine flow |
| *(Berman et al 2015; Crisp & Taylor 2013; LeMone et al 2011; Lynn et al 2012; Rebeiro et al 2013; Smith et al 2011)* | |

recommendation of an intermittent or indwelling catheter (see www.brightsky.com.au/ClinicalSupport.aspx). It is important that a suitable size is selected to avoid leakage of urine around the catheter, or trauma to the urethra or bladder. Indwelling catheters are for single use only.

## Reasons for catheterisation

One of the most common nosocomial infections in hospital is urinary tract infection and many of these can be attributed to catheterisation (Lo et al 2014). As a result, catheterisation is now performed only when considered absolutely necessary, which may include when:

- Monitoring renal function and output hourly during a critical event
- Facilitating a bladder washout or instilling medication
- A post-surgical event occurs
- Acute/chronic retention occurs
- Using investigative procedures such as urodynamic studies.

Use the Bright Sky Catheter Compass™ to help you identify the type of catheter that best suits the person (see www.brightsky.com.au).

## Insertion of a catheter

The procedure of catheter insertion is called catheterisation and is performed using sterile equipment and aseptic technique. Standard precautions are maintained by all personnel involved. As a catheter can cause trauma to the urethral or bladder mucosa and is a potential source of UTI, it is inserted only when absolutely necessary.

In addition to preparing the equipment, it is necessary to prepare the person by ensuring adequate lighting and privacy, placing the person in a supine position with legs extended and promoting comfort and privacy during the procedure. Refer to Clinical Skill 31.6.

## Bladder irrigation

Bladder irrigation or washout may be performed to ensure patency of the catheter, to remove sediment or blood clots or to introduce an antibiotic or bacteriostatic agent. Bladder irrigation may be continuous or intermittent. To prevent urinary tract obstruction continuous irrigation may be necessary to flush out small blood clots that can form after prostate or bladder surgery. During bladder irrigation, sterile equipment and aseptic technique are used to avoid introducing microorganisms. A triple lumen catheter is needed to perform bladder irrigation. One lumen is used to introduce the irrigating solution into the bladder, a second lumen allows the fluid to drain out and the third lumen allows the instillation of fluid into the balloon that holds the catheter in the bladder.

For continuous irrigation, a container of irrigating solution is suspended on a stand and the tubing from the container is attached to the catheter. Drainage tubing from the catheter is attached to a urine collection bag positioned below the level of the person's bladder. A clamp is used to regulate the rate at which the solution flows into the bladder. During irrigation the inflow and outflow tubing is checked to ensure the free flow of fluid. The outflowing fluid is checked for changes in the appearance and presence of blood clots. Both the inflowing and the outflowing fluid must be measured and documented and the collection bag emptied as necessary. The outflow volume should be greater than the inflow volume—allowing for urine production.

Intermittent irrigation involves the gentle introduction of small amounts of prescribed solution. Using a syringe, the solution is introduced into the distal end of the catheter. Small amounts, 30–50 mL for example, are introduced in succession and usually allowed to drain out by gravity. The technique is repeated until the prescribed amount of solution has been used, or until the return fluid is clear. The solution being introduced and returned is measured and documented, and the return fluid observed for changes in appearance or presence of blood clots.

## Intermittent catheterisation

Intermittent catheterisation is either a one-off procedure to assess the urine within the bladder, or the insertion and removal of a catheter several times a day to empty the bladder. Intermittent catheterisation is widely used in neurogenic bladder dysfunction such as spinal cord injury, spina bifida,

## CLINICAL SKILL 31.6 Catheterisation of females

**Review and carry out the standard steps for all clinical skills/interventions**

**NMBA Decision-making Framework considerations:**

1. Am I educated?
2. Am I authorised?
3. Am I competent?

If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator.

**Equipment:**

Bactericidal alcohol hand disinfection
Procedure trolley/suitable clean surface if in community setting
Catheter pack (basic) containing:

- 1 sterile field 60 × 60 cm
- 2 long trays
- 1 paper dressing towel
- 8 cotton balls
- 2 non-woven swabs 7.5 × 7.5 cm
- 2 fenestrated drapes 50 × 50 cm
- 1 pair exam gloves
- 2 aqua dressing forceps
- Pre-connected catheter drainage

OR
Selection of appropriate catheters (smallest bore catheter possible)—it is advisable to take a spare catheter in addition to the one you want, and one of a different/smaller size
Sterile single-use lubricant (water soluble)
1 pair of sterile gloves
1 pair unsterile gloves
Universal specimen container, if required
Cleansing solution 0.9% sodium chloride
10 mL sterile water (inflation of balloon) or as recommended by manufacturer of catheter
Disposable plastic apron/protective clothing
Sterile catheter drainage bag
Disposable waterproof sheet for bed protection
Catheter drainage bag stand, if required
Sterile 10 mL syringe
Goggles
Catheter securing device (e.g. flexi-track)

| Skill activity | Rationale |
|---|---|
| Identify individual<br>Introduce yourself, explain the procedure to the individual<br>Gain consent<br>Take individual's history | Reduces anxiety and gains individual's consent and cooperation |
| Manage environmental factors prior to commencing procedure | Reduces the risk of contamination by movement, touch and proximity |
| Provide written information to individual | Encourages individual to report any problems that may occur while catheter in situ<br>Individual is more relaxed |
| Perform hand hygiene | Reduces risk of infection |
| Clean appropriately sized trolley, and allow time to dry | Ensures key parts are adequately contained in aseptic field<br>Reduces risk of infection<br>If surface is left wet, asepsis is compromised<br>Prevents cross-contamination |
| Gather equipment and inspect packaging for damage; check sterility, indicators and expiry dates; place equipment required on the bottom shelf | Ensures equipment is sterile<br>Top shelf acts as a clean working surface |

*Continued*

| CLINICAL SKILL 31.6 Catheterisation of females—cont'd | |
|---|---|
| Perform surgical hand scrub as stated by manufacturer | Reduces the risk of healthcare-associated infection and cross-contamination<br>ABHRs are more effective, quicker to use and better tolerated by hands than an antiseptic hand wash, and can be accessed at the point-of-care |
| Open the outer cover of the catheterisation pack, ensuring aseptic technique is maintained, and slide the pack onto the top shelf of the trolley | Aseptic technique aims to prevent pathogenic organisms, in sufficient quantity to cause infection, from being introduced to susceptible sites by hands, surfaces and equipment |
| Open other sterile equipment onto tray, ensuring aseptic technique is maintained:<br>• catheter<br>• 10 mL syringe for balloon inflation<br>• urinary drainage bag | Prepares equipment<br>Sequencing |
| Don goggles | Prevents cross-contamination and catheter-associated urinary tract infection (CAUTI) |
| Perform hand hygiene | Prevents cross-contamination and catheter-associated urinary tract infection (CAUTI) |
| Don sterile gloves | Prevents cross-contamination and catheter-associated urinary tract infection (CAUTI)<br>Sterile gloves are used to minimise the risk of contamination |
| Organise catheter pack contents and other equipment on sterile field ensuring aseptic technique is maintained<br>Connect the catheter to the drainage bag<br>Separate trays<br>Place forceps on field<br>Place swabs in one tray<br>Place cotton balls/swabs in other tray<br>Place 1 × fenestrated drape on field<br>1 paper dressing towel on field<br>Place gloves on field | Maintains an aseptic continuously closed urinary drainage system which will reduce the risk of cross-contamination<br>Creates a protective field |
| Remove sterile gloves and perform hand hygiene | Hands may become contaminated via small defects in gloves or on removal |
| Add other sterile equipment to opened pack that is required ensuring asepsis is maintained<br>Pour saline or cleansing solution into receiver with cotton balls<br>Pour 10 mL water into receiver for inflating balloon<br>Squeeze the lubricating gel into receiver with swabs and water (the lubricant does not need to be antiseptic or anaesthetic) | Decreases risk of contamination if receivers are organised and placed in a position that can be easily utilised<br>The lubricant dilates and lubricates the urethra |
| Perform hand hygiene | Prevents cross-contamination |
| Position the individual<br>Place the individual in the dorsal position, with knees flexed and separated, and feet slightly apart on the bed. If individual is able to position herself she may stay in supine position until required<br>Ensure that the individual is not exposed and maintain warmth | Provides a clear view of the urethral meatus<br>Provides comfort and maintains dignity |

| CLINICAL SKILL 31.6 Catheterisation of females—cont'd | |
|---|---|
| Place a waterproof sheet under the buttocks | Protects the sheet |
| Don gloves | Prevents cross-contamination |
| Carefully pick up receiver with cleansing solution and cotton balls and place between individual's legs | Applies manual handling principles |
| Separate the labia minora so that the urethral meatus is visualised<br>If there is difficulty in identifying the urethral orifice, consider re-positioning the individual (e.g. raising the buttocks; ask individual to place hands on buttocks, therefore lifting buttocks slightly, or turning to left lateral position ensuring you have good lighting) | Reduces risk of introducing microorganisms from the genital/anal area into the urinary tract<br>Provides better access to urethral orifice and helps to prevent labial contamination of the catheter |
| Clean both the labia and around the urethral orifice with sterile normal saline using single downward strokes | Avoids contamination with bacteria from perineum and anus |
| Remove tray and put in waste (bin) | Prevents cross-contamination and decreases risk of contamination field |
| Remove gloves<br>Perform hand hygiene<br>Don sterile gloves | Prevents cross-contamination<br>Sterile gloves can touch sterile field |
| Apply fenestrated drape | Creates and extends protective field |
| Place paper dressing towel across the individual's thighs | Reduces risk of equipment becoming contaminated during the procedure and extends sterile area |
| Fill the syringe with 10 mL of water and place in receiver | Syringe is ready when required |
| Dip tip of catheter into the lubricant | Facilitates easier and more comfortable insertion |
| With your non-dominant hand separate the individual's labia with the swabs, and give traction upwards<br>Pick up the catheter with dominant hand and insert in the meatus. Gently advance the catheter along the urethra until it reaches the bladder and urine flows out.<br>Insert the catheter 2 cm deeper<br>Urine should be visible in drainage tube | Gives a good view of the meatus and minimises the risk of contamination of the urethra<br>Less risk of contamination, and ready for insertion<br>Inadvertent inflation of the balloon in the urethra causes pain and urethral trauma<br>Length of catheter inserted must be in relation to the anatomical structure of the urethra. The average female urethra is about 3.8 cm long |
| If catheter is not to be left in, remove it gently when urine ceases to flow, or the required amount of urine has drained<br>Document amount, colour, odour | Catheters are not left in any longer than necessary, and are removed gently to avoid discomfort |
| If a self-retaining catheter is being used, connect the syringe with the correct amount of sterile water to the port on the catheter, ensure syringe is firmly in place, inflate the balloon slowly with a gentle constant force, having first ensured that the catheter is draining adequately according to manufacturer's instructions | Inflated balloon keeps the catheter in the bladder. Inadvertent inflation with the balloon in the urethra causes trauma and pain<br>Use of less than recommended number of millilitres can result in asymmetrically inflated balloon |
| Remove fenestrated drape and equipment from bed<br>Legs may be straightened | Ensures comfort |

*Continued*

| CLINICAL SKILL 31.6 Catheterisation of females—cont'd | |
|---|---|
| Ensure the drainage bag is kept lower than the catheter and the individual's bladder<br>Never allow the tubing to loop or kink; position the drainage bag at the foot of the bed<br>Support the bag in a holder if required at the end of the bed<br>Ensure bag is not touching the floor; clip tubing to secure tubing to the sheet | Failure to keep drainage bag below the level of bladder and upright can slow emptying of bladder, causing individual discomfort and potentially increasing the risk of contamination of the collection system<br>Position drainage bag in such a way as to avoid individual contact<br>Improperly arranged tubing can kink or hang lower than the drainage bag, leading to impeded flow of urine<br>Urine flows from catheter, along the tubing and into the bag. Avoids blocking the flow of urine through the tubing |
| Secure the catheter to the individual's inner thigh<br>The securement should be placed where the catheter is stiffest, typically just below the bifurcation<br>Ensure that the catheter does not become taut when individual is mobilising | If the catheter is not secured properly, it may migrate from its intended point of stabilisation<br>Stabilising urethral catheters can reduce adverse events such as dislodgement, tissue trauma, inflammation and urinary tract infection<br>Movement-induced trauma can lead to urinary tract infections and tissue necrosis |
| Ensure that the labia are cleaned after the procedure | To avoid skin irritation |
| Help the individual into a comfortable position. Ensure that the individual's skin and the bed are both dry | If the area is wet or moist, secondary infection and skin irritation may occur |
| Measure the amount of urine | To be aware of bladder capacity for individual<br>Monitors renal function and fluid balance |
| Take a urine specimen for laboratory if required | To rule out UTI at time of cauterisation and monitor CAUTI |
| Dispose of equipment in a plastic clinical-waste bag and seal the bag before moving the trolley | To prevent environmental contamination |
| Document:<br>Catheter type/balloon/gauge/length<br>Batch number/lot number<br>Expiry date<br>Date of insertion<br>Reason for catheterisation or changing catheter<br>Individual's reaction to catheterisation and any complaints due to catheter in situ<br>Problems with catheter insertion and type of problem<br>Description of urine, colour and volume drained<br>Specimen collected<br>Identity of person inserting catheter | To provide a point of reference or comparison in the event of later queries |
| *(Australia and New Zealand Urological Nurses Society 2013; Australian Commission on Safety and Quality in Health Care (ACSQHC) 2010; 2011; 2012; 2013; Australian Nursing and Midwifery Council 2002; Berman et al 2015; Crisp & Taylor 2013; Geng et al 2012; Gould et al 2008; Gray 2008; Hanchette 2012; Wound, Ostomy and Continence Nurses Society 2012; Joanna Briggs Institute 2010; Lynn et al 2012; NHMRC 2010a; 2010b; Rebeiro et al 2013; Rowley & Clare 2011; Vahr et al 2013; White et al 2013; World Health Organization 2009)* | |

multiple sclerosis or motor neuron disease. Intermittent catheterisation reduces the incidence of UTI and improves quality of life and allows for self-catheterisation, giving greater independence to the person (Newman & Wilson 2011). Side effects can include bleeding, urethritis, stricture and the potential for UTI. Men may have difficulty inserting the catheter past the prostate while women may have difficulty identifying the urethra (Bardsley 2014).

## NURSING INTERVENTIONS

- Use standard precautions when addressing all catheter care needs
- Maintain accurate and frequent records of catheter care and status of output
- Use accurate documentation and assessment to aid all health professionals in treatment
- Maintain skin integrity

- Support person in accessing further information: persons may find the changes to body image profoundly distressing and assistance may be required in areas of psychosocial and sexual support
- Encourage fluids if medically approved
- Encourage mobility where feasible
- Perform a routine urinalysis to screen for infection or for further underlying disease
- Ensure disposal of urine is via the toilet or as per facility protocol.

Nursing care after the insertion of an indwelling catheter is similar for both male and female persons and is planned and implemented to promote comfort, maintain the flow of urine and minimise the possibility of a UTI. The nurse needs to ascertain whether the catheter is to be clamped and released at specified intervals to provide intermittent drainage or if it is to be connected to a drainage bag for continuous drainage. If intermittent drainage has been prescribed, the end of the catheter is clamped. At specified intervals, for example, every 4 hours, the clamp is released to enable the urine that has accumulated in the bladder to drain. Aseptic technique should be used during this procedure to prevent the entry of microorganisms into the open catheter. An intermittent drainage regimen is commonly implemented before removal of an indwelling catheter, to promote and restore any lost bladder tone.

If continuous drainage has been prescribed, actions to promote free flow of urine and prevent stasis of urine include:

- Standard precautions to be observed at all times and constant awareness of increase for potential of infection in catheterised patents considered at all times
- Positioning the tubing so that it is not obstructed or kinked in any way (see Clinical Interest Box 31.2)
- Maintaining the tubing and drainage bag at a level below the person's bladder
- Ensuring that the person has a fluid input of at least 2000 mL daily, unless this is contraindicated
- Taping the catheter to the inner thigh to reduce movement of the tube to prevent ascending infection. If continuous drainage is being used, the system should remain closed and sterile. If it is necessary to disconnect any part of the system, an aseptic technique must be used. To promote comfort and reduce the risk of ascending infection, the urethral meatus and catheter near the point of entry should be cleansed at least twice daily and whenever necessary, for example, after a bowel action. Cleansing should be performed by wiping in the direction away from the urethral meatus to avoid contaminating the urinary tract. An uncircumcised male's foreskin should be retracted before cleansing, and replaced after cleansing
- Observing the urine at least 8-hourly and any deviations from normal reported immediately. Any inflammation of the urethral meatus, or pain or distension over the bladder area, should also be responded to swiftly. The nurse should observe for signs that urine is not bypassing or leaking around the catheter. This may be caused by bladder spasm, blockage of the catheter or tubing or insertion of a catheter of incorrect size. If leakage occurs it should be reported and documented. To test the patency of a catheter or to remove clots or sediment, a Registered Nurse may perform irrigation of the catheter or the bladder after review by a medical officer
- Taking care not to allow the urine to be drained too rapidly when a catheter is being used to drain urine from an over-distended bladder; for example, during acute retention of urine. Decompressing the bladder too quickly may result in bladder trauma or physiological shock; therefore, no more than 1000 mL should be released at any one time
- Using urine meters (burettes) in conjunction with drainage systems when precise measurements of urine output, such as hourly measurement, are required. A meter is commonly a rigid plastic container attached to the drainage system and is calibrated to measure small volumes
- Using disposable closed drainage sets consisting of tubing and a collection bag. The collection bag is emptied at specified intervals or when it is almost full, and the tubing left in position until the entire set is changed or removed (Figure 31.6). The bag is emptied by releasing the valve at the bottom of the bag, using aseptic technique to avoid introducing infection
- Observing the key steps related to emptying and changing collection bags as outlined in Clinical Skill 31.7.

### CLINICAL INTEREST BOX 31.2 Tubing positioning

If an individual with an indwelling catheter reports that they have a feeling to void, ensure that you investigate this. The problem could be caused by the catheter being kinked, twisted or blocked.

## Removal of a catheter

Depending on how long a catheter has been in position, the medical officer may prescribe bladder retraining before its removal. Bladder retraining involves clamping the catheter for specified periods, such as 2–4 hours, then releasing it to empty the bladder. This technique is repeated for several hours to help restore the bladder's muscle tone. Removing a catheter requires aseptic technique. Key aspects related to the procedure and after care include:

- Obtaining a specimen of urine for laboratory analysis if necessary, before the catheter is removed
- Ensuring that all water from the balloon is withdrawn before removing the catheter

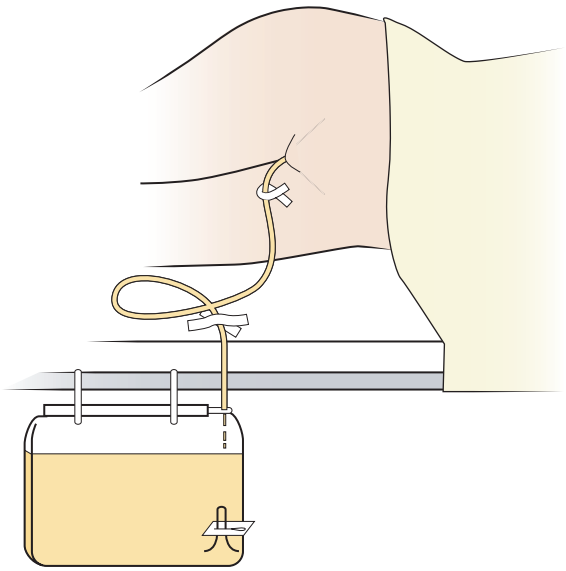

**Figure 31.6** Closed urinary drainage system
*(deWit 2005; redrawn from Potter & Perry 2008)*

- Gently withdrawing the catheter from the urethra, using aseptic technique. If this appears to be difficult ask the patient to relax and gently cough. The catheter may also need a slight rotation to aid withdrawal
- Offering a bedpan or urinal immediately after the catheter is removed, as catheter removal often creates a desire to void
- Encouraging the intake of fluids to stimulate urine production, to dilute the urine and to help decrease any discomfort the person may experience on resuming voiding
- Observing and documenting urine output after the catheter is removed. If the person is voiding only small amounts, the bladder may not be emptying completely, and the medical officer should be informed
- Observing for and reporting any difficulty with voiding, incontinence, dribbling or bladder distension
- Documenting the date and time the catheter was removed and the person's response to the procedure
- Disposing of equipment in line with facility protocols. Refer to Clinical Skill 31.8.

## CLINICAL SKILL 31.7 Emptying collection bags

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Gloves<br>Jug<br>Goggles<br>Waterproof apron/gown |
| **Skill activity** | **Rationale** |
| To empty a bag, maintain an aseptic continuously closed urinary drainage system (i.e. minimise unnecessary opening of the system), but empty catheter bags frequently enough to maintain urine flow and prevent reflux. | |
| Perform hand hygiene<br>Don disposable gloves when handling the system<br>Don goggles<br>Don waterproof gown | Effective intervention for preventing healthcare-associated infection (HAI) in procedures that generate splashes or sprays<br>Emptying catheter bag requires protective eyewear/full-length face shield<br>Gloves can protect both individuals and healthcare workers from exposure to infectious agents that may be carried on hands<br>As part of standard precautions, don waterproof gown (single-use plastic aprons are recommended for general use when there is the possibility of sprays or spills to protect clothes that cannot be taken off) |
| Place the jug below the valve and release valve, avoid splashing and prevent contact of the drainage spigot with the non-sterile collecting container | Allows urine to drain from the bag into the jug |
| When the bag is empty, tighten the valve | Prevents subsequent drainage of urine out of the bag |
| Remove the jug, observe the urine and measure | Assists in evaluating the individual's urinary status |

## CLINICAL SKILL 31.7 Emptying collection bags—cont'd

| | |
|---|---|
| Empty urine from jug into sluice, rinse the jug, place the container in the pan washer, remove PPE and wash if required, return them to their home, perform hand hygiene | Prevents cross-contamination |
| Report any deviations from normal and document accordingly | Appropriate care can be planned and implemented |
| Ensure the drainage bag is kept lower than the catheter and the individual's bladder<br>Never allow the tubing to loop or kink<br>Position the drainage bag at the foot of the bed<br>Support the bag in a holder if required at the end of the bed<br>Ensure bag is not touching the floor, clip tubing to secure tubing to the sheet | Failure to keep drainage bag below the level of bladder and upright can slow emptying of bladder, causing individual discomfort and potentially increasing the risk of contamination of the collection system<br>Position the drainage bag in such a way as to avoid individual contact<br>Improperly arranged tubing can kink or hang lower than the drainage bag, leading to impeded flow of urine<br>Urine flows from catheter, along the tubing and into the bag. Avoids blocking the flow of urine through the tubing |
| Ensure the catheter is secured to the individual's inner thigh. The securement should be placed where the catheter is stiffest, typically just below the bifurcation | If the catheter is not secured properly, it may migrate from its intended point of stabilisation<br>Stabilising urethral catheters can reduce adverse events such as dislodgement, tissue trauma, inflammation and urinary tract infection<br>Movement-induced trauma can lead to urinary tract infections and tissue necrosis<br>Prevents movement and urethral traction |
| Measure the amount of urine | To be aware of bladder capacity for individuals<br>Monitors renal function and fluid balance |
| Document procedure in healthcare record<br>Description of urine, colour and volume drained<br>Inform the individual how to care for the device | To provide a point of reference or comparison in the event of later queries |
| *(White et al 2013; NHMRC 2010a; 2010b; Geng et al 2012; Vahr et al 2013)* | |

## CLINICAL SKILL 31.8 Removal of indwelling urinary catheter

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable gloves<br>Goggles<br>Syringe for deflating balloon<br>Disposable pad (to protect bed)<br>Gauze swabs/disposable wipes |
| **Skill activity** | **Rationale** |
| Check volume of water that was inflated into balloon (this will be written in nursing progress note from insertion and is also located on the port for balloon inflation/deflation) | To confirm how much water is in the balloon<br>To ensure balloon is completely deflated before removing catheter |
| Position individual and place waterproof sheet in area where spillage may occur | Absorbent pad will collect any spilt urine and prevent bed from becoming wet |

*Continued*

| CLINICAL SKILL 31.8 Removal of indwelling urinary catheter—cont'd | |
|---|---|
| Perform hand hygiene | Prevents spread of infection |
| Open syringe ensuring asepsis is maintained<br>Slide the plunger of the syringe up and down the barrel of the syringe several times to 'loosen it up' | Prevents spread of infection<br>Ensures withdrawal of plunger occurs and it does not adhere to the front of the syringe barrel |
| Back off luer lock or slip tip syringe to 0.5 mL and insert into the inflation port<br>Allow the pressure within the port to force the plunger back and fill the syringe with water<br>Do not use suction on the syringe but allow the solution to come back spontaneously | Auto-deflation and excision of inflow channel are best methods of catheter deflation<br>Painless urinary catheter removal<br>Pressure profilometry shows balloon cuffing is associated with increased balloon retention force<br>Increase in balloon retention force increases the tube friction force (exponential relationship) |
| Check amount of fluid in syringe corresponds to that which was inserted at insertion<br>Remove syringe and discard contents | Ensures balloon is completely deflated before removing catheter |
| Ask individual to breathe in and then out: as individual exhales, gently remove the catheter, placing it on the waterproof sheet or wrapping the catheter in your glove. (Male individuals should be warned of discomfort as the deflated balloon passes through the prostatic urethra) | Relaxes pelvic floor muscles |
| If catheter does not easily come out, stop, inform RN | Failure of balloon to deflate<br>Trauma to urethra if catheter removed while water in balloon |
| Clean meatus using gauze/disposable wipe, clear away equipment, make the individual comfortable | Provides comfort and dignity for the individual |
| Remove gloves and perform hand hygiene | Principles of 5 moments |
| Dispose of catheter and drainage system in appropriate waste | Reduces risk of cross-contamination to others |
| Inform individual to notify you when they void and amount<br>May need to scan bladder with bladder scanner to assess whether there is any residual urine | Ensures they have voided post removal of IDC<br>Monitors residual in bladder |
| Report any deviations from normal and document accordingly | Ensures appropriate care can be planned and implemented |
| Document procedure in healthcare record stating time of removal, description of urine, colour and volume drained, amount in stating R/O IDC | Provides a point of reference or comparison in the event of later queries |
| *(White et al 2013; NHMRC 2010a; 2010b; Chung & Kirkland 2012; Geng et al 2012; Vahr et al 2013)* | |

## SPECIALIST UROLOGY NURSING ACTIVITIES

The nurse may be required to assist in the preparation of a person before specific diagnostic procedures and to monitor their condition afterwards. Catheterisation may be necessary to obtain a specimen of urine or to treat acute urinary retention.

### Urinary diversion

A person whose bladder has been removed, for example because of malignancy, will require urinary diversion. Various surgical techniques that divert the flow of urine are available (Figure 31.7):

- Ureterosigmoidostomy involves the implantation of the ureters into the sigmoid colon, resulting in urine being passed via the rectum

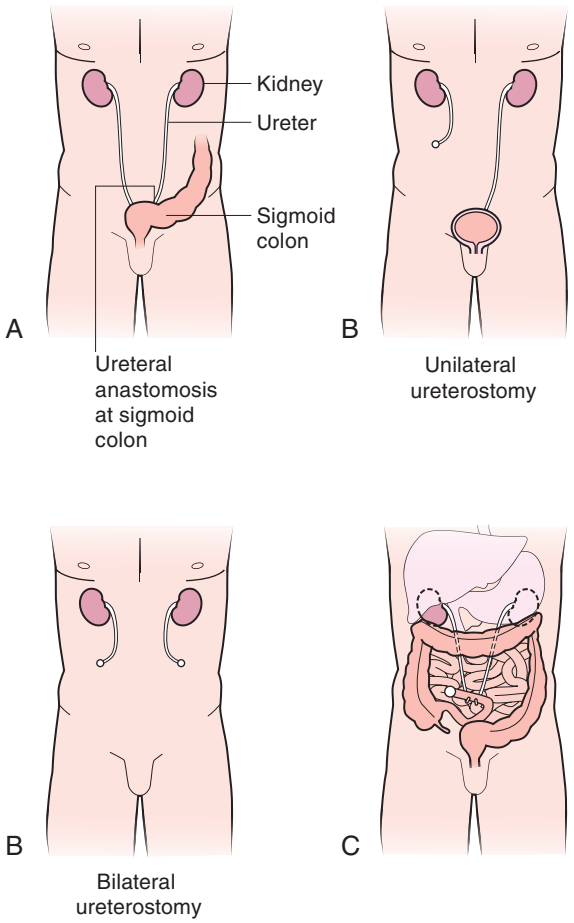

**Figure 31.7** Urinary diversion

A Ureterosigmoidostomy B Cutaneous ureterostomy C Ileal conduit

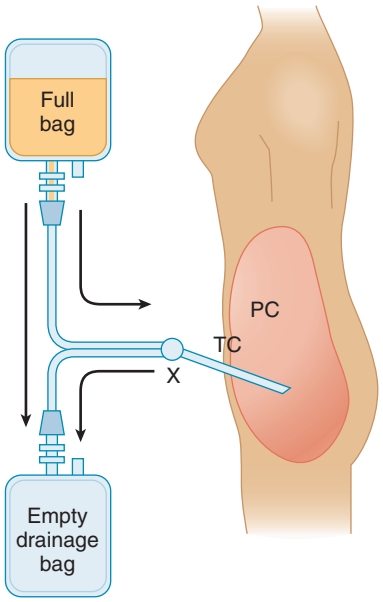

**Figure 31.8** Peritoneal dialysis

*(Greenberg 2009)*

- Cutaneous ureterostomy involves bringing the ureters through the abdominal wall, with urine draining out through the stoma(s) into an ostomy appliance
- Ileal conduit involves resection of part of the ileum. Both ureters are implanted into the proximal end of the ileal segment, and the distal end of the ileum is brought through the abdominal wall to form a stoma. The urine then drains out through the stoma into an ostomy appliance. This particular surgical technique is generally considered to be the most satisfactory if urinary diversion is required.

Care of the person with a urinary stoma is similar to the care required by a person who has a stoma created for the passage of faeces. The main aspects of care are the selection and management of ostomy appliances, care of the stoma and surrounding skin and provision of psychological support.

## Dialysis

Chronic kidney disease (CKD) and dialysis treatment is a serious health issue requiring a multifaceted approach to treatment, including medication, monitoring of fluid and diet intake and a plan which incorporates the concerns and impact on family and carers (Lemmon & Nurse 2015). Dialysis is a specialised nursing function which centres on delaying the progression of disease, preventing further complications and administering and maintaining the dialysis program. It involves the transfer of solutes across a semi-permeable membrane, and the removal of waste products, excess salts and fluid from the blood. The method of dialysis is determined by the person's condition and may be performed by the person at home if the facilities are available, in a specialised unit or a in mobile dialysis unit in rural and remote settings.

There are two types of dialysis: peritoneal dialysis (Figures 31.8 and 31.9) and haemodialysis.

In peritoneal dialysis the person's peritoneum provides the semi-permeable membrane. The procedure may be performed on an intermittent or continuous basis. A catheter is placed in the abdominal cavity, and dialysate is instilled through the catheter. Through diffusion and osmosis, waste products together with excess electrolytes and fluid are transported from the blood into the dialysate.

In haemodialysis the semi-permeable membrane is contained within a dialysis machine. Haemodialysis is performed an average of three times per week for a period of 4–6 hours. This method requires regular and convenient access to the person's blood circulation. Several systems are available that provide this access, including an arteriovenous shunt or the creation of an arteriovenous fistula. An arteriovenous shunt is an artificial passageway that allows blood to flow from an artery to a vein without going through a capillary network (Figure 31.10A). An arteriovenous fistula is created surgically

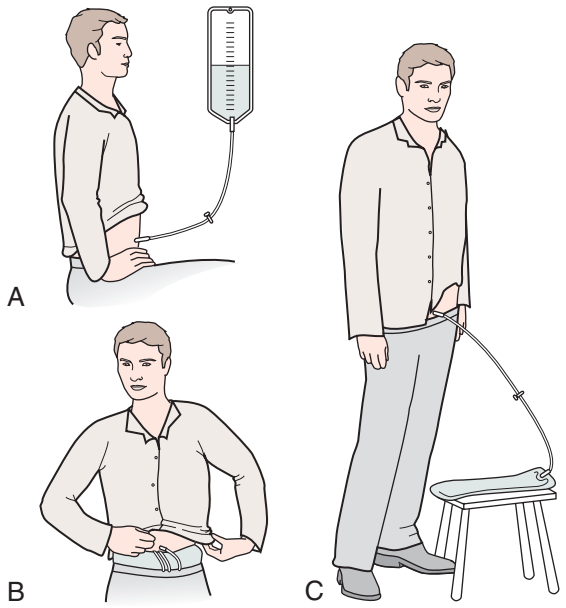

**Figure 31.9** Continuous ambulatory peritoneal dialysis (CAPD)

A: A bag of dialysate is attached to a tube in the person's abdomen so that the fluid flows into the peritoneal cavity B: While the dialysate remains in the peritoneal cavity, the individual can roll up the bag, place it under their clothes and go about their normal activities C: The bag is unrolled and suspended below the pelvis, which allows the dialysate to drain from the peritoneal cavity

to provide vascular access for haemodialysis (Figure 31.10B). During haemodialysis, the person's blood is passed through the artificial kidney (haemodialysis machine) and then returned to the person's own circulation. The person's blood is anticoagulated during haemodialysis to prevent clotting in the tubing and machine. Although dialysis is a lifesaving treatment, it is nonetheless accompanied by risk.

## Nursing intervention

Once a person commences dialysis they have to deal with considerable changes to their lifestyle. These changes may impact on the person psychologically, resulting in depression, anxiety, feelings of guilt and fear of death. They may have to deal with changes in the role in family, changes in employment status, financial concerns and a reduced social network (Rayyani et al 2014). Many persons self-manage their dialysis. The time and support needed varies greatly from person to person; the nurse's role is to be in partnership with the person to generate optimum health outcomes by:

- Creating a connection with the person to promote self-esteem, dignity and independence
- Planning support and care with person, carers and health professional team which is both person-centred and relationship-centred
- Maintaining standard precautions when addressing all care needs
- Maintaining accurate and frequent records of care

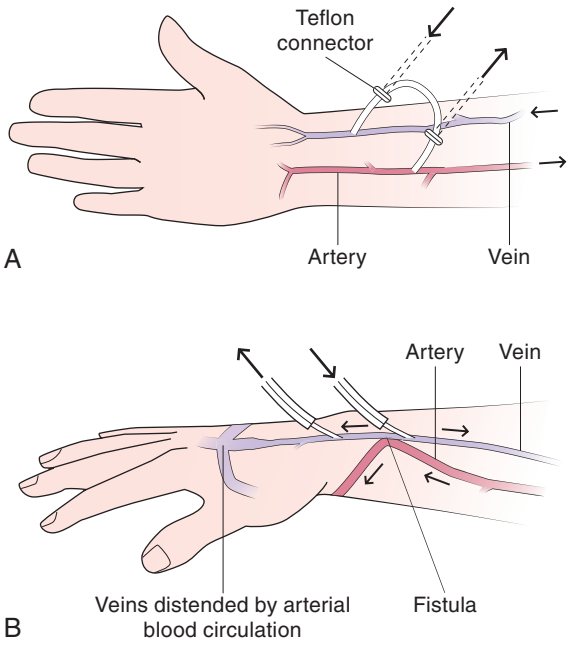

**Figure 31.10** A: Arteriovenous shunt B: Arteriovenous fistula *(Game et al 1989)*

- Using accurate documentation and assessment to aid all health professionals in treatment
- Monitoring vital signs, weight and urinalysis
- Encouraging therapeutic lifestyles, such as stopping smoking, safe alcohol intake and increased sustainable exercise
- Encouraging maintenance of and providing support for diet and/or fluid restrictions
- Relieving pain: if a person is experiencing pain, the cause should be identified and treated. The nurse should report any complaints of pain immediately to the Registered Nurse or medical officer
- Frequently assessing puncture sites for peritoneal dialysis and haemodialysis fistulae sites for infection and bleeding. Table 31.5 outlines the complications of dialysis.

### CRITICAL THINKING EXERCISE 31.2

Mr Dobson has been admitted to a surgical urology ward to commence treatment for renal failure. He lives in a small town 150 km from the nearest medical centre. What aspects would you need to consider in his long-term care? How would you commence a care plan based on person-centred care for this person? Where would you direct him for long-term information on his condition?

## Renal transplant

Renal transplant is a surgical procedure replacing an individual's failed kidney with a healthy kidney from a donor. The recipient's own kidney may be either left or removed.

The donor ureter is anastomosed either to the recipient's ureter or to the recipient's bladder. The transplanted kidney usually begins to produce urine within a very short time after the operation.

Close monitoring of the person after surgery is essential to assess renal function and to detect early signs of rejection of the new kidney. To help prevent graft rejection, which may occur within 1–30 days or up to several years after the transplant, immunosuppressive drugs are administered. As immunosuppressive drugs increase the risk of infection, protective isolation techniques may be implemented. A successful kidney transplant enables the person to lead a life free from the restrictions associated with dialysis therapy. However, immunosuppressive therapy will need to be continued as well as close monitoring of renal function and general health status. There are ethical, cultural and religious divides concerning the transplantation of organs and these issues need to be treated with sensitivity (Lemmon & Nurse 2015).

**TABLE 31.5 | Complications of dialysis**

| Peritoneal dialysis | Haemodialysis |
|---|---|
| Peritonitis | Haemorrhage, from heparinisation or from accidental disconnection of the apparatus |
| Obstructed catheter due to fibrin clot formation | Infection, at the insertion site or from contaminated equipment |
| Excessive protein loss | Thrombosis at the insertion site |
| Hyperglycaemia, if the dialysate contains high level of dextrose | Oedema of the hand or ischaemia of the fingers, as a result of the shunt or fistula |
| *Candida* or herpes zoster infections | Air embolism |
| Abdominal hernia or uterine prolapse, due to persistently raised intra-abdominal pressure | Hypotension from fluid and sodium removal |
| Psychological reactions to the therapy (e.g. anger or depression) | Psychological reactions to the therapy (e.g. anger or depression) |
| Perforation of abdominal structures by the catheter | Hypothermia or hyperthermia as a result of a malfunctioning thermostat on the machine<br>Hypertension (e.g. from fluid overload) |

*(Tzanakaki et al 2014)*

## DECISION-MAKING FRAMEWORK EXERCISE 31.1

You are the Enrolled Nurse who is looking after Jane Stewart post abdominal hysterectomy. Jane complains that she can't pass urine and has abdominal pain with a scale of 8/10. You did bladder scanning and there is 800 mL urine in the bladder. You have informed the medical officer who ordered an indwelling catheter to be inserted. You have only inserted a catheter once as a student and you don't feel confident. (Review Progress Note Example 31.1 as a sample of how this case information would have been documented.)

Jane is in excoriating pain.

1. What are you going to do in this situation?
2. Is your decision in the person's best interest and why?

## PROGRESS NOTE EXAMPLE 31.1

| | |
|---|---|
| 24/06/15<br>1430 hrs | Nursing: Ms Jane Stewart at 1230 hrs complained that she was not able to pass urine and had an abdominal pain score of 8/10. Bladder scanning showed 800 mL in the bladder (refer to print out). Dr Williams was informed and ordered size 12FG indwelling catheter to be inserted. Catheter size 12FG inserted aseptically by RN Judson at 1330 hrs. Catheter drained 750 mL of urine straight away. Catheter left in situ, urine output to be measured hourly, fluid balance chart implemented. Ms Stewart stated she felt so much better and reported no pain.<br><br>***E. Lewis* (Lewis) EN** |

## Summary

The urinary system is essential for homeostasis. It is the means by which the body rids itself of a variety of metabolic wastes and maintains fluid and electrolyte balance. The urinary system consists of the kidneys, the ureters, the urinary bladder and the urethra. The kidneys filter the blood to maintain its normal composition, volume and pH. In carrying out this function, the kidneys secrete urine.

Urine forms by the processes of filtration, selective reabsorption and secretion. Urine is composed of water, urea, mineral salts, uric acid and creatinine. When the kidneys form urine it passes down the ureters by peristaltic action to the bladder. It is then stored in the bladder until micturition is initiated and is excreted from the body through the urethra. Micturition is initiated when the bladder walls are stretched, usually when the bladder holds about 300 mL of urine. Urine is a waste product of metabolism, and regular elimination is necessary for the maintenance of normal body function. Elimination of urine is affected by various factors ranging from the intake of food and fluids to the changes that occur as a result of certain disease states.

As part of the assessment of a person's elimination status, urine is observed and tested in the ward or sent to the laboratory for analysis. The nurse must ensure that specimens are collected and tested correctly so that accurate results are obtained.

Problems associated with the elimination of urine may occur, and the implementation of certain nursing actions may be necessary to assist the person to meet elimination needs. All procedures must be thoroughly understood so that the desired effects are achieved and safety and comfort are promoted.

Normal functioning of the urinary system may be impaired as a result of changes in kidney structure, changes in the ability of the kidneys to secrete and excrete urine or alterations in the passage of urine through the urinary tract. The major problems associated with urinary system disorders are pain, changes in voiding pattern or urine output and changes in the urine. Disorders of the urinary system can be classified as those that are congenital, resulting from multiple causes, infectious, immunological, degenerative, neoplastic, obstructive or traumatic in origin.

Diagnostic tests used to assess urinary system function include laboratory analysis of urine, blood and tissue, radiological examination and endoscopy.

Care of the person with a urinary system disorder includes preventing and managing altered elimination of urine, promoting comfort, maintaining skin integrity and maintaining nutritional and fluid status. Nursing activities include observation and collection of urine and assisting in the care of a person who requires intervention to eliminate urine.

Of primary importance is the need to support the person in what can be an intensely embarrassing time which impacts on their personhood. Sensitivity, education, maintenance of dignity and appreciation of the psychosocial changes often experienced by persons with chronic conditions are key to successful nursing outcomes. As the act of urination is a personal one, cultural differences are often not expressed or understood in the wider multicultural societies of Australia and New Zealand so the nurse needs to investigate these differences with understanding and compassion.

## Review Questions

1. All of the following are normally found in the excreted urine except:
   water
   glucose
   urea
   mineral
2. List indications for urinalysis:
   on admission
   when suspecting UTI
   on discharge
   when a patient is on FBC
3. Why do urinary tract infections occur in women more than in men?
4. List the disorders that affect urinary elimination.
5. List different types of urinary incontinence.
6. Describe at least three (3) different aids used for incontinence.
7. List at least six (6) diagnostic tests that may be performed to determine urinary function.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing care: bowel elimination and continence

*Kelly Gray*

CHAPTER 32

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define key terms relating to the digestive system
- Describe the anatomical position and structure of the digestive system
- Describe the physiological functions of the various areas of the digestive system
- Explain how the presence of bile influences the colour of faeces
- Describe normal faeces and the defecation process
- Identify the factors that affect bowel elimination
- Identify appropriate nursing actions to assist the individual to meet their bowel elimination needs
- Perform procedures described in this chapter accurately and safely, including the observation, collection and testing of faeces, assisting individuals with bowel elimination and changing ostomy devices
- Briefly describe the specific disorders of the digestive system
- Describe the diagnostic tests that may be performed to assess digestive system function
- Consider the psychosocial aspects of care from a person-centred and relationship care perspective
- Employ critical thinking to provide care for individuals with alterations in bowel elimination

## KEY TERMS

colon
colostomy
constipation
defecation
diarrhoea
endoscopy
enema
faeces
flatulence
haemorrhoids
hepatitis
ileostomy
impaction
incontinence
peristalsis
peritoneum
stoma
stomatitis
suppository

## CHAPTER FOCUS

The digestive process enables consumed food and fluids to be broken down into nutrients and electrolytes that can be absorbed by the body for cell energy and function. Various factors that influence normal bowel elimination are explored in this chapter. Observation of the individual's ability to eliminate faeces, together with observation of the faeces, provides the nurse with an objective assessment of the individual's bowel elimination status. As a result, nursing care may be planned and implemented in conjunction with the individual and other healthcare providers to meet bowel elimination needs in a dignified and appropriate manner.

## LIVED EXPERIENCE

I have suffered with constipation all my adult life and have needed to use laxatives regularly. After a conversation with the practice nurse at my medical clinic I now realise that changes to my diet and eating habits, exercising more and altering and increasing what I drank, like having more water, have had a positive impact on my bowel health.

**Rosa, 50 years, Financial Manager**

# THE DIGESTIVE SYSTEM

The digestive process enables consumed food and fluids to be broken down into nutrients and electrolytes that can be absorbed by the body for cell energy and function. This process is achieved through five basic activities: ingestion, movement of the food, digestion, absorption and defecation (Lloyd Jones 2015). Any condition that causes a change in these activities can have a detrimental impact on the person's health and quality of life. Healthy bowel function is maintained by routine elimination habits, a nutritional diet with the recommended amount of fibre and fluid intake and daily mild exercise to stimulate colonic motility. The various factors that can affect normal digestion and bowel elimination are explored in this chapter. Observation of the individual's ability to eliminate **faeces**, together with observation of the faeces, provides the nurse with an objective assessment of the individual's bowel elimination status.

## The digestive process

The digestive system is comprised of the gastrointestinal (GI) or alimentary tract and the accessory organs of digestion which include salivary glands, the liver, pancreas and gallbladder (Kozier et al 2014; Johnstone et al 2014). The GI tract is a muscular tube about 9–10 m in length, which extends from the mouth to the anus (Figure 32.1). The structure of the GI tract is similar for most of its length and consists of an outer covering, middle layers of involuntary muscle and connective tissue and an inner mucous membrane lining (Johnstone et al 2014) (Figure 32.2).

The inner mucous membrane lining which can be found in the mouth and the oesophagus, acts as a protective surface against scratches or grazes which can be caused by food travelling through the oesophagus (Johnstone et al 2014). This layer also secretes mucus into the digestive tract.

The submucosa is composed of connective tissue which contains many large blood and lymph vessels. This layer allows the gastrointestinal tract to stretch to allow food to pass through it (Johnstone et al 2014). It also contains muscles that propel the food through the tract (Johnstone et al 2014).

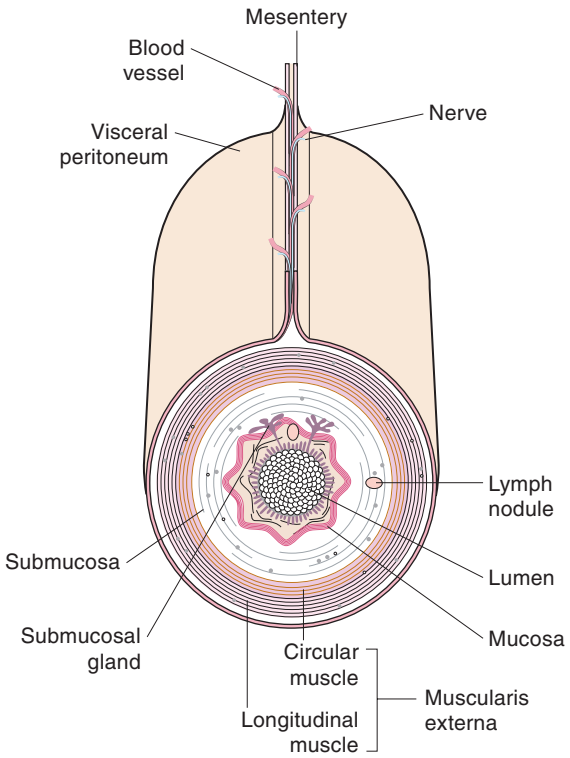

**Figure 32.1** Structure of the alimentary canal

The outer covering of the GI tract consists of fibrous tissue (the serosa) or, in the abdomen, the peritoneum. The **peritoneum** is a double-layer serous membrane that secretes serous fluid to prevent friction between the abdominal organs. The peritoneum forms a lining for the abdominal cavity (parietal layer) and a covering for most of the abdominal organs (visceral layer). The mesentery, which is formed by the

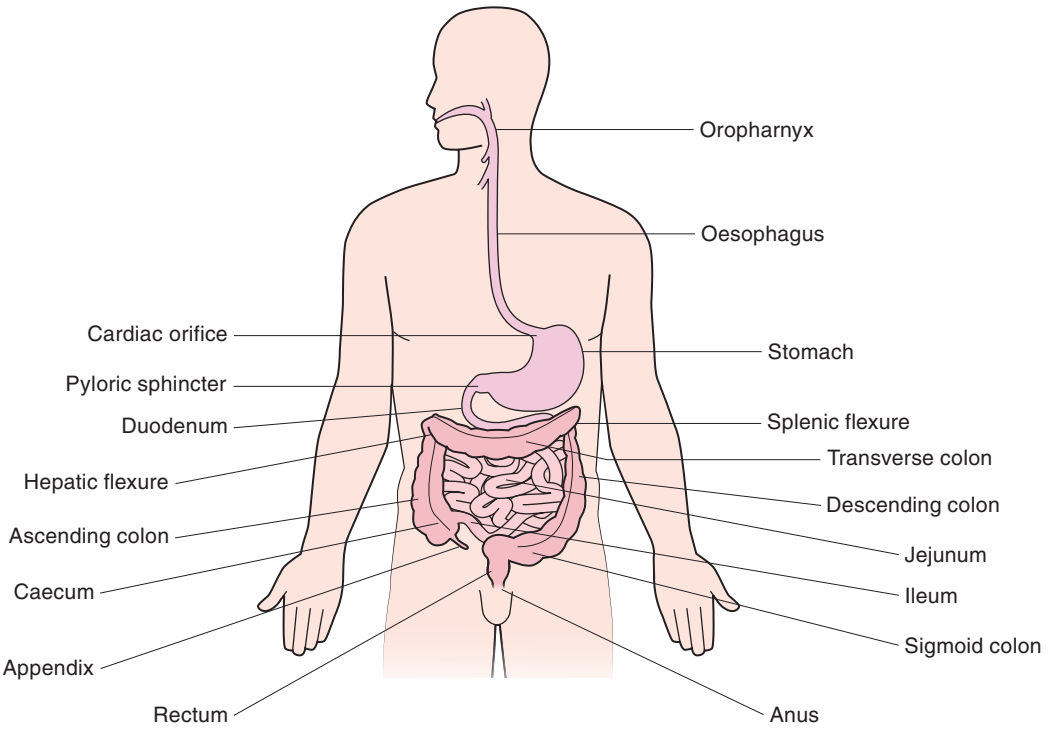

**Figure 32.2** The parts of the alimentary canal

peritoneum, covers the intestines and attaches them to the posterior abdominal wall.

The organs that make up the GI tract are the mouth, the oropharynx, the oesophagus, the stomach, the small intestine and the large intestine.

## The mouth

The process of ingestion usually begins in the mouth. The mouth, or oral cavity, has boundaries of muscle and bone and is lined by mucous membrane. The lips protect its anterior opening and keep food in the mouth (Johnstone et al 2014). The cheeks form the lateral walls, the hard palate forms its anterior roof and the soft palate forms its posterior roof. It also contains the uvula, a finger-like muscular projection hanging down from the midline of the soft palate which prevents food from entering the nasopharynx during swallowing (Johnstone et al 2014).

***Components of the mouth*** The mouth contains the tongue, the teeth and the salivary glands. Once food is placed in the mouth, the teeth break down the food into smaller particles through chewing. The teeth are embedded in the maxillae and the mandible. All teeth have the same basic structural organisation but differ in shape and size. Each tooth is made up of an ivory-like substance called dentine; a central pulp cavity containing blood and lymphatic vessels, nerves and connective tissue; and a thin layer of enamel covering the crown. In children there are 20 deciduous (milk) teeth, consisting of 10 in each jaw; in adults there are 16 permanent teeth in each jaw. In each jaw there are four incisors, used for biting; two canines, used for tearing; four premolars, used for crushing; and six molars, used for grinding. A wisdom tooth is the third molar tooth and it is the last tooth to erupt. Wisdom teeth usually erupt from ages 18 to 25 years.

The salivary glands (an accessory digestive organ), of which there are three pairs, pour secretions into the mouth. Saliva is a watery fluid containing ions, mucin and the digestive enzyme salivary amylase. Salivation is largely initiated by sensory stimulation, including the presence of food in the mouth, and by taste and smell. Saliva has the following functions:

- Moistens and softens food
- Contains mucin, which acts as a lubricant to aid swallowing
- Moistens the mouth
- Has an antibacterial activity
- Enables molecules to dissolve on the surface of the tongue and stimulate the taste buds
- Contains the enzyme salivary beta-amylase, which begins the chemical digestion of starch.

The salivary glands produce approximately 1 L of saliva per day (Patton & Thibodeau 2013).

The tongue consists of a mass of voluntary muscle and is covered by squamous epithelium. On the upper surface of the tongue there are many small projections called papillae, which contain taste buds, the sensory endings of the nerve that perceives taste (Johnstone et al 2014). The taste buds also stimulate secretions from the stomach, pancreas and gallbladder in preparation for the digestion of food (Johnstone et al 2014). The tongue is a very mobile organ which is important in the chewing (mastication) of food, the formation of a bolus and swallowing the formed bolus of food, and is also essential for speech.

## The pharynx

The next phase of digestion involves the movement of food. From the mouth the food is moved into the pharynx. The pharynx is a tube that begins behind the nose and ends at the top of the oesophagus and trachea (Sander & Dark 2014). The pharynx is divided into three sections: the oropharynx, the laryngopharynx and the nasopharynx. The oropharynx and the laryngopharynx are shared by the respiratory and the digestive systems (Johnstone et al 2014).

The oropharynx is the muscular canal forming the passage between the oral cavity and the major parts of the GI tract. Food is moved from the mouth into the oropharynx through swallowing (Johnstone et al 2014). The laryngopharynx is a common passageway for both food and air. The epiglottis prevents food from entering the trachea and this ensures that food progresses through to the oesophagus (Johnstone et al 2014). If food is inhaled this will cause coughing and, in severe cases, respiratory distress.

## The oesophagus

The food continues its movement through the digestive system by moving from the pharynx to the oesophagus. The oesophagus is a muscular tube about 20–25 cm long, extending from the pharynx above to the stomach below (Johnstone et al 2014). It lies behind the trachea, is midline through the neck and thorax, and passes through the diaphragm to join the stomach. The oesophagus has an outer layer of fibrous tissue, a layer of involuntary muscle, a layer of connective tissue and a lining of mucous membrane. The function of the oesophagus is to carry food to the stomach by means of peristaltic action.

**Peristalsis** is a wave-like progression of alternate contraction and relaxation of the muscle fibres of the oesophagus or intestines, by which contents are propelled along the GI tract. The mucosa of the oesophagus secretes mucus which acts as a lubricant and assists in the movement of food (Johnstone et al 2014). At rest, the opening between the oesophagus and pharynx (oesophageal sphincter) is closed. During swallowing the muscles contract causing the sphincter to open, allowing the bolus of food to pass down into the oesophagus. A wave of contraction in the circular muscle layer then propels the bolus down to the stomach (Lloyd Jones 2015). The bottom end of the oesophagus acts as a functional sphincter; as the peristaltic wave approaches the sphincter, the muscle relaxes and allows food to enter the stomach. The sphincter then closes again and prevents regurgitation of gastric contents back into the oesophagus (Lloyd Jones 2015).

## The stomach

The stomach is where the process of digestion begins. The stomach (Figure 32.3) is located in the upper left quadrant of the abdomen and is commonly described as being 'J shaped'. However the size and shape of the stomach can vary according to its contents. The stomach looks small when empty but can increase in size in response to the amount of food the individual consumes (Johnstone et al 2014). The stomach is divided into five areas: the cardia, the fundus, the body, the antrum and the pylorus (Marieb & Hoehn 2013). The cardia is the first section of the stomach closest to the oesophagus. A functional sphincter called the cardiac sphincter allows food from the oesophagus to enter the stomach. The fundus is the upper rounded portion of the stomach, the body is the main part of the stomach, and the antrum is the lower part of the stomach. The pylorus acts as a valve to control emptying of the stomach contents into the small intestine.

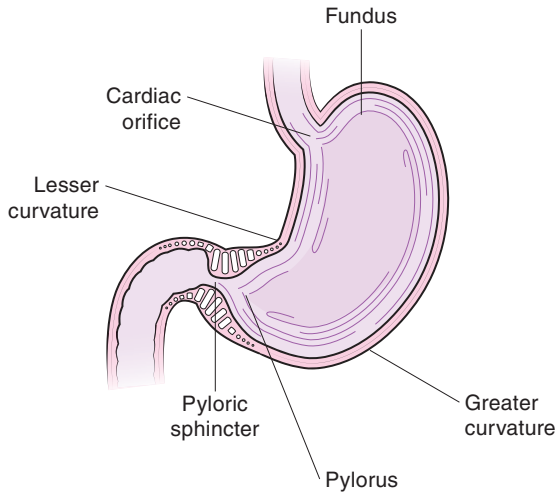

**Figure 32.3** The stomach

Within minutes of entering the stomach mechanical and chemical breakdown of the food occurs (Lloyd Jones 2015). Contraction of the stomach muscles mixes the food with gastric juices and assists in breaking down the ingested food. The body produces an estimated 2 L of gastric secretions a day (Waugh & Grant 2014) which include:

- Hydrochloric acid, which is released in response to the hormone gastrin, and activates pepsins, providing an optimal pH for pepsin activity, and destroys bacteria
- Intrinsic factor, which is vital for the absorption of vitamin B12 from the diet, which is needed for the development of erythrocytes
- Mucus, which is secreted by the surface cells of the stomach mucosa and forms a lining that protects the mucosal cells from the gastric contents
- Gastric enzymes (pepsinogens), which are inactive until exposed to hydrochloric acid, when the active pepsins are released. Pepsins act as a catalyst in the chemical breakdown of protein, forming polypeptides and free amino acids.

The secreted gastric juices break down the food into chyme which has a semi-solid consistency (Johnstone et al 2014). The contractions of the stomach muscles move the chyme to the pyloric sphincter where small amounts of chyme are pushed through into the small intestine (Johnstone et al 2014). The stomach acts as a temporary reservoir for food, stores the food and later releases it at a rate that is optimal for digestion. The rate of emptying of the stomach depends on the:

- Consistency of the chyme
- Degree of opening of the pyloric orifice

- Force of the peristaltic contractions
- Type of food in the stomach (fats tend to delay emptying, while carbohydrates are usually emptied quickly).

The average time for the stomach to empty after a meal is 4–6 hours. The gastrocolic reflex is a physiological reflex controlling peristalsis; it involves an increase in motility of the colon in response to fullness in the stomach and digestion in the small intestine. This reflex is responsible for the urge to defecate following a meal.

## The small intestine

The process of digestion continues in the small intestine and this is where the majority of absorption also takes place. The small intestine is a coiled muscular tube about 5–6 m in length, extending from the pyloric end of the stomach to the large intestine (Johnstone et al 2014). The small intestine is divided into several anatomically recognisable areas: the duodenum; the proximal section, which is the widest section and is about 20 cm long and curved; the jejunum, which is the middle section and is about 2.5 m long; and the ileum, which is the distal section and is about 4 m in length (Johnstone et al 2014).

Intestinal glands in the mucous membrane secrete an intestinal juice containing enzymes to complete the digestion of food. An opening in the duodenum (ampulla of Vater) allows for the entry of the common bile duct, carrying bile from the liver, and the pancreatic duct, carrying pancreatic juice. The absorption of nutrients such as iron, calcium and fat-soluble vitamins A, D, E and K from the ingested food takes place in the small intestine (Lloyd Jones 2015). At the junction of the ileum and the caecum of the large intestine is the ileocaecal valve, which prevents a backward flow of contents from the large to the small intestine.

The wall of the small intestine is capable of several different types of movement:

- Peristalsis, which ensures an onward movement of the contents of the intestine
- Segmentation, which ensures mixing of the intestinal contents. Segmentation contractions occur regularly, causing the chyme to be broken up into segments. Breaking the chyme into segments increases the surface area of chyme that is in contact with the mucosal membrane of the small intestine, thus increasing the rate of absorption (Johnstone et al 2014). Chyme enters the caecum through the ileocaecal valve, which is normally closed but opens briefly to allow a small amount of chyme through with each peristaltic wave.

## The large intestine

By the time chyme enters the large intestine most of the absorption has taken place (Lloyd Jones 2015). The main function of the large intestine is the formation and expulsion of faeces (Johnstone et al 2014). The large intestine is a muscular tube about 1.5 m in length and 6 cm in diameter, which extends from the end of the ileum to the anus (Figure 32.4) (Johnstone et al 2014). Lying in the abdominal and pelvic cavities, the large intestine may be divided into regions that are distinguished by their anatomical structure and position:

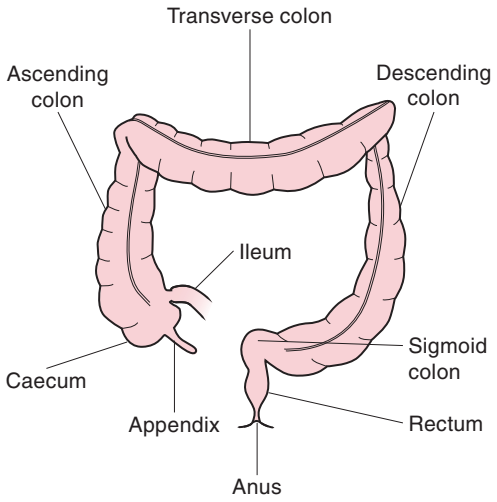

**Figure 32.4** The large intestine

- The caecum, a blind-ended sac about 6 cm long and 7.5 cm in diameter, leads into the ascending **colon** and has the appendix attached. Studies suggest that the appendix is part of the immune system within the body
- The ascending colon, which is about 15 cm long and passes up the right side of the abdominal cavity to the lower surface of the liver
- The transverse colon, which is about 50 cm long and crosses the upper abdomen from right to left then curves in the vicinity of the spleen
- The descending colon, which is about 25 cm long and passes down the left side of the abdomen to the left iliac region
- The sigmoid colon, which is variable in length and is the S-shaped continuation of the descending colon and lies in the pelvic cavity
- The rectum, a straight tube about 12 cm long that forms the last section of the large intestine
- The anal canal, the terminal part of the rectum, about 4 cm in length. The canal opens on to the external skin at the anus. The anal canal contains the internal and the external anal sphincters. The sphincters seal off the end of the alimentary canal and are normally constricted.

As well as the formation and expulsion of faeces the large intestine also:

- Absorbs large amounts of water and some mineral salts
- Produces microorganisms (mainly bacteria) that are necessary for the normal functioning of lymphatic tissue in the large intestine and thus resistance to infection. These bacteria also synthesise vitamins B and K
- Secretion of mucus to lubricate faeces.

Though absorption of water takes place in the large intestine, water makes up 60–70% of the weight of faeces

(Santiago et al 2014). The forming faeces also contain fibre, indigestible cellular plant and animal matter, dead and live microbes, digestive enzymes, epithelial cells from the walls of the gastrointestinal tract together with the mucus they secrete, fatty acids and bile pigments. Faeces also contain dead cells shed from the intestinal lining as well as waste products such as bile pigments and toxic substances.

## The accessory digestive organs

The accessory digestive organs are vital in the digestive process. Although food does not pass through these organs, digestion could not occur without these organs. The accessory organs secrete enzymes into the GI tract which are actively involved in the process of digestion. An enzyme is a substance, usually protein in nature, that initiates and accelerates a chemical reaction. The accessory organs are the salivary glands, the pancreas, the liver and the biliary tract.

### The pancreas

The pancreas is a soft gland, lying across the abdominal cavity behind the stomach (Hendry et al 2014). It is divided into a head, which fits into the curve of the duodenum; a central portion, or body; and a tail, which extends out to the spleen. The pancreatic duct runs centrally through the length of the pancreas, while smaller ducts carry the pancreatic juice secreted by the pancreas into the central duct. The pancreatic duct joins the common bile duct from the liver to enter the duodenum (Figure 32.5).

The bulk of the tissue in the pancreas is composed of exocrine cells, which produce pancreatic juice. The pancreas secretes about 1200 mL of pancreatic juice daily. The overall function of pancreatic juice is the digestion of nutrients. The pancreas is simulated to release the pancreatic juices by the presence of chyme in the duodenum (Hendry et al 2014). Scattered among the exocrine tissue are groups of hormone-secreting cells, the islets of Langerhans, which contain four distinct cells of which the beta cells are crucial to the production of insulin.

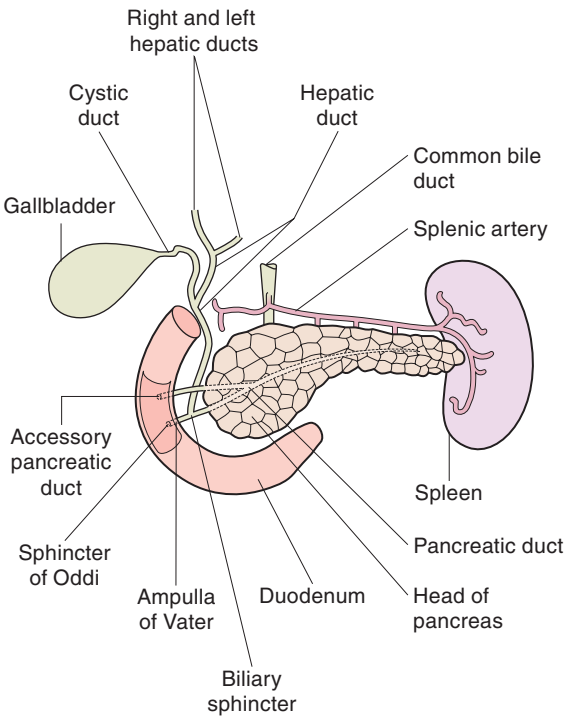

**Figure 32.5** The pancreas and neighbouring structures

### The liver

The liver is the second largest organ in the body after the skin (Bostock-Cox 2014). The liver is an organ situated in the right upper quadrant of the abdominal cavity, immediately beneath the diaphragm (Patton & Thibodeau 2013). The greater part of the liver lies in the right upper abdomen but the organ extends across to the left upper abdomen (Figure 32.6). The liver is divided into two parts: a large right lobe and a much smaller left lobe.

The liver has many functions but those involved in the digestive process include:

- Producing bile—a watery fluid containing a variety of organic and inorganic substances, but no enzymes. Bile aids in neutralising stomach acids and emulsifying fats (Penny 2013). As much as 1 L of bile may be secreted by the liver per day and stored in the gallbladder before it is released into the duodenum.
- Storing carbohydrates, proteins, fats and vitamins which are converted into nutrients and then released either in bile or in the bloodstream (Penny 2013).

The biliary tract, which transports bile from the liver to the duodenum, consists of the left and right hepatic ducts, the common hepatic duct, the cystic duct, the gallbladder and the common bile duct (Figure 32.7).

### The gallbladder

The gallbladder is a small, pear-shaped, muscular sac that lies on the inferior surface beneath the right lobe of the liver (Hendry et al 2014). The main function of the gallbladder is to store and concentrate bile until it is needed for digestion (Hendry et al 2014). When chyme that contains fats or lipids enters the duodenum, the gallbladder contracts and releases bile to digest the fats (Hendry et al 2014).

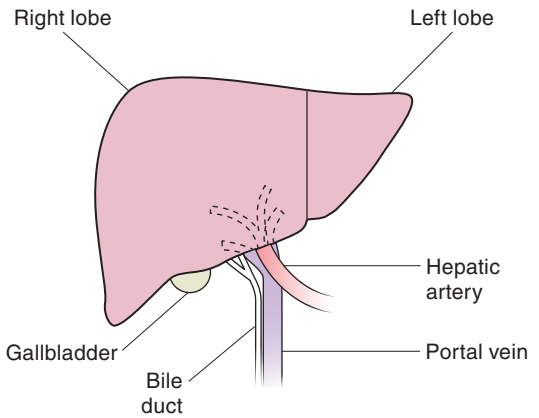

**Figure 32.6** The liver

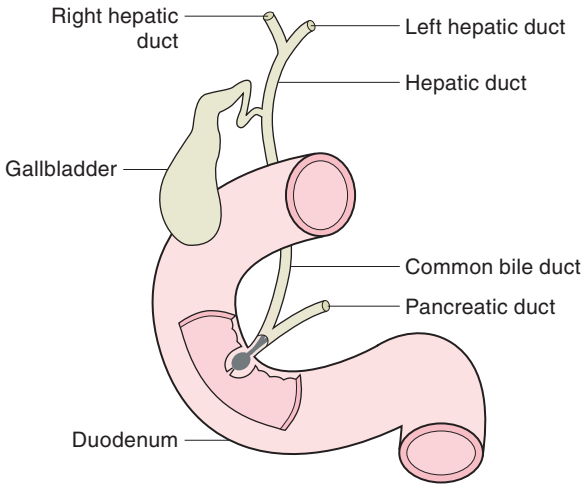

**Figure 32.7** The biliary tract

## Faecal matter and defecation

The frequency of bowel actions depends on the individual. A normal range can be from three times a day to three times a week (Commonwealth of Australia 2013). Faecal matter varies significantly in appearance, depending on diet and health. It is usually brown in colour which results from a combination of bile and bilirubin.

Most of the time the rectum is empty of faeces; however, when a mass movement forces faeces into the rectum the desire to defecate is initiated. Faeces collect in the sigmoid colon before entering the rectum. As the faecal mass enters the rectum the defecation reflex and the desire to defecate are initiated. If it is not convenient, **defecation** can be delayed temporarily, as within a few seconds the reflex contractions cease and the rectal walls relax (Kozier et al 2014; Marieb & Hoehn 2013). An individual with a good bowel function is able to:

- 'hold on' for a short time after feeling the urge to defecate
- start a bowel action once they are ready to (i.e. once they are sitting on the toilet)
- completely empty the rectum when they have a bowel action (Commonwealth of Australia 2013).

## Meeting elimination needs

The individual's elimination status is assessed by obtaining information about elimination practices, bowel actions and their medical and surgical history (Gardiner & Wallace 2014). A list of any medications the individual is taking should also be perused as some medications can affect bowel elimination (Gardiner & Wallace 2014). The nurse should enquire about the individual's usual pattern of defecation and whether they have experienced any recent alterations to this pattern (see Clinical Interest Box 32.1). Information should also be obtained about the individual's usual fluid and dietary intake so that, whenever possible, it can be maintained or improved to facilitate normal elimination. Information about their usual level of activity should also be sought for the same reason. The nurse should identify early signs of any problems associated with elimination so that appropriate care can be implemented to assist the individual to meet their elimination needs. The nurse should also be aware of the numerous factors that affect bowel elimination:

- Age: developmental changes affect bowel elimination throughout life. As the body develops and changes, so do the size of the small and large intestines, amount of secretions and rate of peristalsis. Infants have developing digestive tracts, so complex foods are poorly digested, peristalsis is rapid and control of the bowel is not coordinated by the neuromuscular system until 2–3 years of age. During adolescence, the rate of gastric secretions increases and as ageing increases the rate of peristalsis is reduced. The slowing of nerve impulses delays the sensation to defecate and can lead to constipation
- Cultural influences: the use of different toilet equipment, where and when defecation is deemed to be appropriate, as well as dietary input all impact on the individual's ability to maintain their usual elimination pattern. Changes to environment plus the challenges and/or anxieties associated with assimilating into a new or different culture may similarly alter the elimination patterns. Adherence to fasting practices will also affect elimination patterns
- Privacy: ensuring adequate privacy and sufficient time for the individual to pass faeces. If possible, the individual should be left alone to use the toilet aids (e.g. commode or bedpan) as they are generally self-conscious about the need to eliminate in the presence of others. Ensure the individual's safety and that the call bell is accessible
- Position: any interference from the usual body position (e.g. due to surgery or changed environment) can lead to difficulty defecating and the inability to empty the rectum properly (Commonwealth of Australia 2013). Children, older people or those with a disability may require special needs
- Routine: changes to normal routine can cause an interruption to the individual's normal gastrocolic reflex

### CLINICAL INTEREST BOX 32.1 Clinical consideration when assessing bowel patterns

Some individuals may be embarrassed when nurses ask them about their bowel functioning. Therefore it is important to ensure that questioning is conducted in an appropriate way, place and time. Nurses should adapt their use of terminology to the individual they are dealing with. For example, the nurse may ask a child 'Have you had a poo today?' instead of 'Have you used your bowels today?'

*(adapted from deWit & O'Neill (2013))*

- Diet and fluid intake: any changes to diet will affect elimination. An inadequate fluid intake can result in hardening of the stool contents and discomfort when defecation occurs. The recommended fluid intake for adults is 1400–2000 mL/day. This may be contraindicated in individuals with cardiac and renal disorders
- Physical activity: physical activity promotes peristalsis, while inactivity reduces motility of the bowel. It is recommended that all individuals perform regular mild exercise to promote regular bowel elimination
- Infection: the infection process can directly affect the protective lining of the gastrointestinal tract
- Pain: pain on defecation may be due to the presence of lesions such as haemorrhoids or anal fissures. *Tenesmus* is the term used to describe persistent ineffectual spasms of the rectum accompanied by the desire to empty the bowel; it may be associated with disorders such as inflammatory bowel disease
- Psychological state: the psychological state of a person influences the motility and secretions of the gastrointestinal tract. If a person is angry, anxious or stressed, the secretions and motility of the bowel are increased and can lead to diarrhoea. Alternatively, a person who is depressed will have reduced secretions and motility of the bowel, which could lead to constipation
- Pregnancy: as the fetus develops in size during pregnancy, the pressure it exerts on the bowel is increased, impeding the movement of faecal matter through the bowel
- Medication: laxatives are used to soften the stool to ease the discomfort in defecating. Excessive or chronic use of laxatives leads to reduced bowel muscle tone and less responsiveness to the normal stimulation of defecation. There are also numerous medications that affect the bowel and careful scrutiny of drug regimens is required
- Surgery and anaesthetics: anaesthetics stop bowel peristalsis. Direct and prolonged surgery and nerve damage to the bowel can lead to a prolonged period of reduced peristalsis.

## Promoting a healthy bowel elimination program

A program to promote bowel elimination is an important part of the nursing care plan for an individual. The goal of a bowel management program is to assist the individual to evacuate the bowel comfortably and completely at a determined time without laxative support, by promoting privacy, regular mild exercise, high-fibre foods and an adequate fluid intake. It is important for nurses to support the individual with their bowel elimination while hospitalised as failure to do so may result in a delayed discharge (Knowles et al 2015). With the appropriate support the individual's overall lifestyle can become healthier, and general wellness and outlook improve (see Clinical Interest Box 32.2).

### CLINICAL INTEREST BOX 32.2 Nursing assessment relating to bowel problems

- Past history
- Vital signs, weight, height and BMI
- Assessment of stool, habits and frequency
- Hydration and nutrition status
- Mobility
- Hygiene
- Medications
- Coexisting medical conditions
- Psychosocial (including cultural influences) and environmental factors
- Cognitive function
- Continence status
- Skin integrity assessment

*(Burch 2013b; Gardiner & Hilton 2014; Thomas 2014)*

### Diet

The role of diet is pivotal for a functioning digestive system and the individual's overall health. It is important that the individual includes adequate dietary fibre in their diet. Fibre is important in bowel function as it absorbs water and makes stools bulkier (Commonwealth of Australia 2013). While a high-fibre diet is indicated with constipation, a low-fibre diet is required in the presence of diarrhoea. Specialised diets are often required such as gluten- or dairy-free diets and the potential for poor nutritional intake is increased if bloating, pain or nausea is present. Adequate fluid is also required, particularly in the presence of certain drugs, but fluids known to increase constipation such as alcohol and coffee should be used judiciously. Diet is complex, due not only to the disease process but also as a result of cultural norms, the individual's age and the normal likes and dislikes we all experience. While it is difficult to meet all individuals' needs, an effort to ensure adequate nutrition is of paramount importance for health and wellbeing (Stewart 2014).

### Monitoring elimination

Daily bowel charts recording the bowel movement within a 24-hour period and analysis of a pattern over a week or month will demonstrate any changes. Use of a bowel diary which adds further information such as fluid and diet as well as activities and changes to lifestyle will allow the individual to identify issues which may impact on their elimination changes or habits (Gillibrand 2012).

### Examining faeces

To detect and identify abnormalities, faeces are examined by observation (see Table 32.1 and the Bristol Stool Chart (Figure 32.8)), by chemical testing in the workplace or by analysis in the laboratory. Laboratory analysis of faeces

**TABLE 32.1 | Common characteristics of altered presentation of faeces**

| Colour | Odour | Presentation | What it may mean |
|---|---|---|---|
| Grey, 'clay coloured' | Strong | Within normal range | Flow of bile blocked |
| Dark/Black | Strong | 'Tarry', 'sticky' | Intestinal bleeding |
| Dark/Black | Slight | 'Tarry' | ? taking iron pills or other drugs? |
| Pale yellow | Strong | 'Greasy' | Pancreatic malfunction |
| Pale yellow | Slight to strong | | Use of 'diet pills' |
| Fresh blood | Slight | Within normal range | Haemorrhoids |
| Red | Slight | Within normal range | Ingestion of foods (e.g. beetroot) |
| Green | Strong | Within normal range or loose | Rapid transit through the intestines |
| Meconium | None | Viscous and sticky | Only evident in new born babies; disappears in the first few days of life |
| Mucus | | | Inconsistent or increasing amounts may indicate underlying disease (e.g. Crohn's disease, ulcerative colitis) |
| Undigested food | | | If occurs infrequently and with no other symptoms (e.g. diarrhoea), unlikely to be of concern |

*(Jarvis & Watt 2012; Reid-Searl & Hewerdine 2010)*

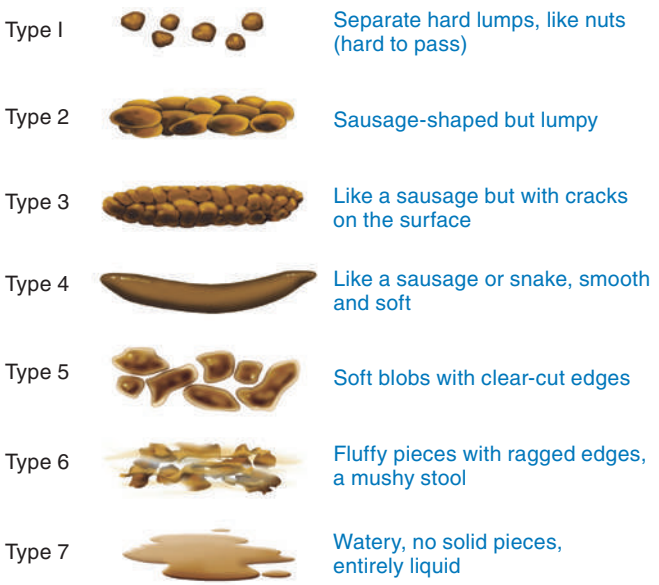

**Figure 32.8** Bristol Stool Chart
*(© The Rome Foundation)*

provides information about the condition and functioning of the digestive system. Testing the faeces for abnormalities involves analysing the specimen for the presence of blood, parasites and/or their ova, bile, fat, pathogenic microorganisms or pancreatic enzymes (Santiago et al 2014).

### Environment

Evacuation is for most adults an intensely private function, preferably done away from people listening. Infants of every culture instinctively adopt a squatting position to evacuate faeces and this was the manner for centuries for most people and is still the preferred method in many parts of the world. The invention of indoor plumbing altered this for much of the developed world, and the porcelain toilet is now considered the norm in most places in Australia. The individual's sitting position on the toilet may need investigation to optimise a relaxed and natural posture to aid elimination (Commonwealth of Australia 2013).

## Common problems associated with elimination of faeces

### Constipation

**Constipation** is the infrequent passage of dry hard stools and is often the result of some deficiency in the three elements necessary for normal bowel activity: dietary fibre, adequate fluid input and sufficient physical activity (Gardiner & Hilton 2014). It affects people regardless of age, race, gender or socioeconomic status (Hussain et al 2015) but is more prevalent in females and those over the age of 65 (Gardiner & Hilton 2014). Constipation can cause psychological and physical distress, serious pain and embarrassment (Thomas 2014). When constipation occurs, the individual often strains

to produce hard dry stools, has a sensation of not emptying their rectum completely, experiences sensations of an obstruction or blockage, has less than three bowel actions a week and may be required to manually assist with the evacuation of faeces (Gardiner & Hilton 2014). Constipation is often accompanied by abdominal distension and discomfort, nausea, headache and diminished appetite (Gardiner & Hilton 2014). Natural measures to prevent constipation include:

- Sufficient dietary fibre: foods such as wholegrain cereals, fruit and vegetables contribute bulk and induce peristalsis (Gardiner & Hilton 2014)
- Adequate fluid input: at least 1500 mL/day is necessary to help keep the intestinal contents in a semi-solid state for easy passage and excretion
- Responding to the desire to empty the bowel as soon as practicable (Gardiner & Hilton 2014)
- Maintaining a regular time for bowel movement
- Maintaining regular exercise (Gardiner & Hilton 2014)
- Relaxing and assuming a natural position when having a bowel action. Some people find the use of a small footstool to promote thigh flexion helpful (Commonwealth of Australia 2013)
- Avoiding undue anxiety about bowel habits. While some people have a bowel action every day, it is quite normal for others to have a 2- to 3-day interval between bowel actions.

Other measures to assist elimination from the bowel may be necessary, including:

- Laxatives: substances taken orally that promote evacuation of the bowel by increasing bulk, softening the faeces or lubricating the walls of the colon (see Table 32.2) (Gardiner & Hilton 2014)
- Suppositories: small solid masses medically ordered and inserted into the rectum to promote the evacuation of faeces (Day et al 2014)
- **Enemas**: the introduction of fluid through the anus into the lower colon to promote the evacuation of faeces (Day et al 2014).

### CASE STUDY 32.1

Rosa, 86, is admitted with severe constipation. While you are interviewing Rosa she states that she has managed her constipation in the past with laxatives, and that she restricts her fluid intake because she suffers with urinary incontinence. She has not been as mobile since her right knee replacement 1 month ago.

1. What do you think may be contributing to Rosa's constipation?
2. What key changes can you suggest to Rosa to maintain a regular bowel elimination program?

## Suppositories

**Suppositories** may be ordered and inserted into the rectum to promote the evacuation of faeces or to facilitate rectal administration of a drug (see Chapter 24).

Suppositories prescribed to promote a bowel action are composed of various substances, such as glycerine. Evacuant suppositories act by softening and lubricating the faeces to facilitate easy passage and excretion, or by increasing

**TABLE 32.2 | Laxatives in common use**

| Category | Example | Action | Route | Time frame |
|---|---|---|---|---|
| Bulking agents | Metamucil, Normacol | Increase weight and water absorbent properties of the faeces | Oral | 48–72 hours |
| Stimulant laxatives | Senna, Durolax, Dulcolax | Increases intestinal mobility | Oral | 6–12 hours |
| | Suppositories | Inserted rectally | Rectal | 10–20 mins |
| Faecal softeners | Liquid paraffin<br>Coloxyl | Oil softens the faeces | Oral | 24–72 hours |
| Osmotic agents | Magnesium salts (Epsom salts) | Increase the water content of faeces | Oral | 0.5–3 hours |
| | Lactulose<br>Duphalac<br>Actilax | | Oral | 4–72 hours |
| | Glycerine suppositories | | Rectal | 15 mins |
| | Microlax enema | Inserted rectally to draw water into the rectum to produce a bowel movement | Rectal | 30 mins |

*(Gardiner & Hilton 2014; Day et al 2014)*

peristalsis through the irritation of intestinal sensory nerve endings. The nurse must be aware of the different types of suppositories available and work within the scope of practice regarding the checking and administration of drugs. Types of medications that may be administered rectally by suppository include those used to relieve constipation, and medications used for the treatment of nausea and pain.

## Enemas

To give an enema is to introduce a solution into the rectum and sigmoid colon (see Clinical Skill 24.3 in Chapter 24). Most commonly it is ordered and administered to promote the evacuation of faeces and alleviate constipation, to prepare a bowel for diagnostic procedures or surgery or to begin a bowel training program.

## Impaction

**Impaction** occurs when the faeces remain in the rectum for a long time and a large hardened mass develops that is difficult and often painful to expel (Halawi et al 2012). There are certain groups of individuals who are more at risk of impaction including residents of nursing homes, those with advanced neurological diseases or renal failure, those who are immobile and those who have a poor intake of fibre or fluids (Halawi et al 2012). Liquid faeces continue to build up behind the obstruction and may move around the obstruction leading to faecal overflow (Halawi et al 2012).

***Treating impacted faeces*** When the condition occurs it is a result of prolonged constipation, poor bowel habits, inactivity, dehydration, use of constipation-inducing drugs or incomplete bowel cleansing after a barium swallow or enema. If measures to promote a bowel action, such as a suppository or enema, are ineffectual, surgical removal of the mass may be prescribed. If medically approved, encourage fluids and exercise once evacuation is complete and the individual is rested (Kozier et al 2014; Crisp et al 2013).

## Flatulence

Excessive formation of gas in the stomach and intestines is called **flatulence**. If the gas is not expelled, the intestines become distended and the person may experience abdominal discomfort and swelling. Flatus is the term used for gas in the intestine that is expelled through the anus. Flatulence may result from swallowed air, the consumption of gas-forming food or liquid or bacterial action within the intestines.

## Diarrhoea

**Diarrhoea** is the discharge of frequent, loose unformed stools resulting from the rapid passage of contents through the intestines. Perceptions of what constitutes diarrhoea may be influenced by familial, social and cultural factors so it is essential that a clear history is elicited from the individual (Gordon 2013). The person with diarrhoea may be exhausted from frequent defecation and the presence of accompanying abdominal distension and pain. If diarrhoea is prolonged, the absorption of nutrients and fluids is impaired and the person begins to show signs of fluid and electrolyte loss (Calder & Hall 2012). Diarrhoea is a symptom of various conditions, including:

- Irritation or inflammation of the gastrointestinal tract; for example, due to pathogenic infection (Calder & Hall 2012), highly spiced foods or medications that increase intestinal motility
- Disorders of digestion or absorption
- Disorders that affect secretion and function of bile or pancreatic juice, such as in obstructive jaundice
- Emotional states such as anxiety or stress.

Diarrhoea should be assessed in terms of the frequency of defecation and the characteristics of the faeces. The cause of diarrhoea must be investigated and treated. Key aspects related to the care of an individual with diarrhoea include:

- Reducing intestinal peristalsis: dietary management of an adult individual involves the withholding of food until the diarrhoea diminishes, then the gradual resumption of food. Foods low in fibre may be provided initially to reduce stimulation of the intestines
- Administering any prescribed medications: anti-diarrhoeal medications may be prescribed, as may antispasmodic preparations, to reduce abdominal cramps and pains
- Maintaining fluid input to replace lost fluids and to prevent dehydration. Oral fluids are given if tolerated, or fluids may be administered intravenously (Gordon 2013). Input and output should be observed and documented as part of the individual's fluid balance assessment
- Ensuring that the individual has adequate privacy whenever toilet facilities are being used, and that used toilet utensils are removed from the room immediately
- Ensuring that the individual's hygiene needs are met: after each bowel action the anal area and buttocks should be cleansed with a mild soap and thoroughly dried. A protective cream may be applied to reduce discomfort, and the area should be observed for signs of excoriation (Gillibrand 2012)
- When using a bedpan or commode chair, the individual may be embarrassed by the odours associated with diarrhoea, so measures to eliminate odours should be taken. Any soiled linen should be changed and removed from the room immediately. The room should be well ventilated, and room deodorants may be used with discretion
- Implementing isolation precautions should be considered until diagnosis of the cause (e.g. pathogenic infection) to prevent cross-infection.

### CRITICAL THINKING EXERCISE 32.1

John, 22 years of age, returned with long-term diarrhoea from a 6-month stint volunteering in a developing country. What are the nursing implications of this and how would you help him?

### CRITICAL THINKING EXERCISE 32.2

Francine, an elderly individual, is admitted with a history of 3 days of diarrhoea. What are the possible causes of diarrhoea? What is your primary concern for this individual? What key information should be charted regarding the bowel actions?

## Faecal incontinence

Faecal **incontinence** is the inability to control the excretion of faeces (Mayer et al 2013). Risk factors for faecal incontinence include increasing age, poor physical or mental health, anorectal procedures, diarrhoea and female gender (Mayer et al 2013). Having a vaginal birth may lead to damage of the anal sphincter, causing faecal incontinence in 33–50% of women who experience such an injury (Tan et al 2013). Management includes continence pads, lifestyle modification, pelvic floor training and drug therapy (Nazarko 2013). Surgical intervention is an option in some cases (Nazarko 2013). The cause must be identified and treated, the person's hygiene needs attended to and measures taken to maintain the individual's dignity and self-esteem.

## Artificial openings into the intestine

As a result of certain disorders such as obstruction or tumours in the bowel, the passage of faeces through the rectum and anus may not be possible (Burch 2013a). In these instances, the surgical creation of an artificial opening, called a **stoma**, takes place. Faecal elimination occurs through the stoma, which may be created as a temporary or a permanent measure. There are two different types of stomas that can be created: a colostomy and an ileostomy. A **colostomy** is formed when the large bowel or colon is pulled through a surgical incision made in the abdomen (Burch 2013a). The faecal matter produced from this type of stoma is soft and formed (Burch 2013a). An **ileostomy** is formed from the ileum and produces loose stools (Burch 2013a).

## Care of individual with a stoma

A stoma may be created in order to be used permanently or temporarily. A temporary stoma may be created to divert faecal contents to allow the bowel to rest; for example, as part of the treatment regimen in an inflammatory bowel disease. A permanent stoma is indicated principally in colorectal cancer after a partial or total colectomy has been performed. The site is selected according to which part of the bowel is affected and with consideration of the individual's physique, clothing, occupation and any other factors that may influence the individual's ability to successfully manage the care of the stoma.

In many healthcare institutions a stoma therapist liaises with the individual and surgeon to select the most appropriate site. The site of the stoma (Figure 32.9) will determine the consistency of the faecal matter excreted through it. The closer the stoma is to the small intestine, the more liquid the faeces will be. Figure 32.10 illustrates the types of colostomy or ileostomy that may be created. An ileostomy will produce approximately 300–800 mL of faecal matter daily requiring the stoma appliance to be emptied 4–6 times a day (Burch 2013b). The colostomy should be active daily with multiple episodes of flatus being noted (Burch 2013b). The stoma appliance will require changing on a regular basis (see Clinical Skill 32.1: Changing an ostomy appliance).

Care of the individual with a stoma includes the selection and management of appliances (Figure 32.11), care of the

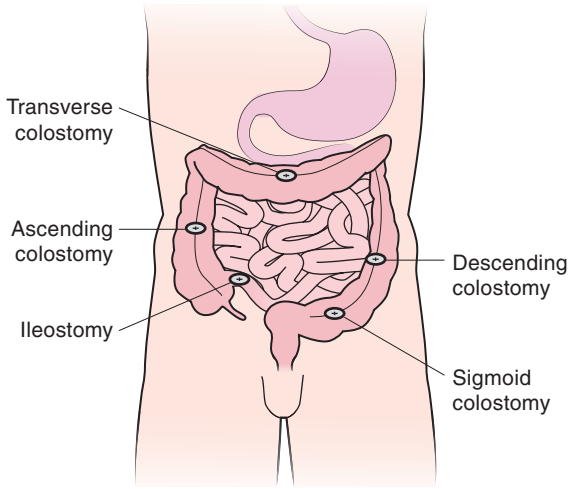

**Figure 32.9** Stoma sites

### NURSING CARE PLAN 32.1

**Assessment:** Individual experiencing faecal incontinence
**Issue/s to be addressed:** Risk of skin excoriation
**Goal/s:** To maintain skin integrity

| Care/Actions: | Rationale: |
|---|---|
| Ensure skin is cleaned after each episode of incontinence<br>Use barrier cream on sacral area<br>Stay hydrated and eat a well balanced diet | Reduces risk of skin irritation and excoriation<br>Acts as a protective barrier for skin<br>Adequate nutrition helps to maintain skin integrity |

**Evaluation**

Skin should be checked regularly for signs of irritation and excoriation.
Skin integrity intact.

## PROGRESS NOTE EXAMPLE 32.1

| | |
|---|---|
| 22/5/2015<br>1430 hrs | Nursing: Individual assisted with changing of the colostomy appliance. Skin surrounding stoma is intact and free of irritation. Stoma is pink and has been active today. Formed stools passed. Nil mucus or blood noted in stool. |

***J. Grey* (Grey) EN**

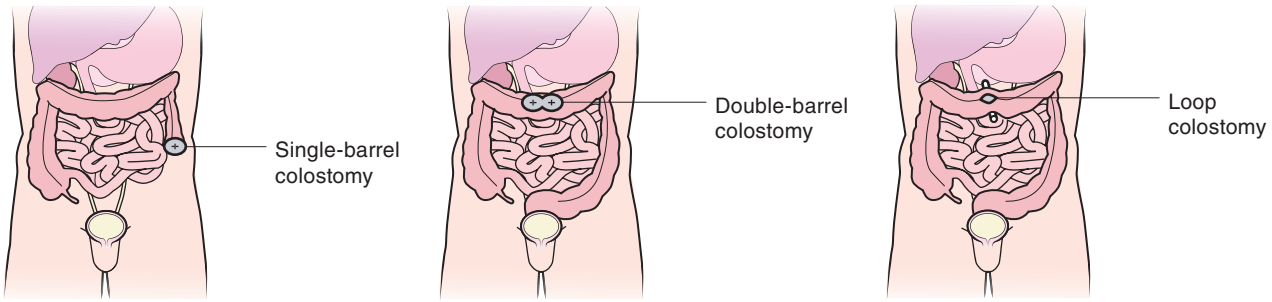

**Figure 32.10** Types of colostomy

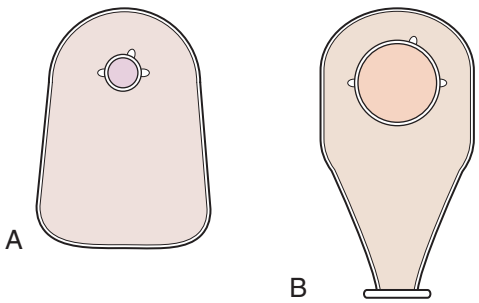

**Figure 32.11** Ostomy appliances
A: Non-drainable stoma bag B: Drainable stoma bag

stoma and surrounding skin, colostomy irrigation, meeting nutritional needs and providing psychological support (Burch 2013b). A stoma therapist may be available to assist in the preparation of the individual and their significant others before the operation and also plays a major role in providing support and education after the operation. Dietary changes may be necessary and are made in partnership with the individual, stoma therapy nurse and dietitian (Burch 2013b).

When planning care considerations the individual's altered body image and/or the impact on intimate relationships need to be responded to in a sensitive, private and dignified manner. When sexual dysfunction as a result of altered body image, depression or illness impacts on the individual and their partner they may need referral to a professional.

For the latest information and research findings on this subject, see the Australian Council of Stoma Associations website: www.australianstoma.com.au.

See Progress Note Example 32.1 as to how you might document the changing of a colostomy appliance.

# DISORDERS OF THE DIGESTIVE SYSTEM

## Specific disorders

Any changes to the nutritional status of the individual will impact on their elimination process and may be ongoing, depending on the nature of the disease process. There are many and varied disorders of the alimentary tract but the following are some of the disorders commonly encountered in practice.

### Stomatitis

**Stomatitis** is a term that refers to inflammation of the mouth (Sargeant & Chamley 2013). It may be a primary condition or a symptom of another disease. Inflammation may affect the lips, tongue, gums, mucous membranes or palate. Stomatitis is characterised by pain, bleeding, swelling, ulceration and halitosis and can often be managed with good oral hygiene and by treating the underlying disorders that are contributing to the condition, such as vitamin deficiencies (Sargeant & Chamley 2013).

### Parotitis

Parotitis is inflammation of the parotid glands (Barskey et al 2013), which may also be related to poor oral hygiene, dryness of the mouth or infection. Infectious parotitis (mumps) is an acute viral disease (Barskey et al 2013). Parotitis may also result from a calculus in the parotid gland.

### Dry mouth

Dry mouth can result from dehydration, mouth breathing, medical conditions such as diabetes and stroke and is a common side effect of many drugs including antihistamines, diuretics and sedatives (Sargeant & Chamley 2013). The

## CLINICAL SKILL 32.1 Changing an ostomy appliance

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Pouch, clear drainable colostomy/ileostomy in correct size with attached skin barrier<br>Pouch closure device<br>Adhesive remover<br>Disposable gloves<br>Deodorant<br>Gauze pads or washcloth<br>Towel or disposable waterproof barrier<br>Basin with warm water<br>Scissors<br>Skin barrier paste<br>Sealant wipes |

| **Skill activity** | **Rationale** |
|---|---|
| Explain the procedure to the individual and provide privacy | Reduces anxiety and embarrassment |
| Place the equipment in a convenient location and raise the bed to appropriate working height | Facilitates performance of the procedure in an organised manner |
| Perform hand hygiene and put on gloves | Prevents contamination |
| Remove the old appliance gently and place it in a plastic bag. Remove the skin barrier (if applicable) | Avoids damage to surrounding skin surface |
| Wipe the stoma and surrounding skin, using swabs and warm water. Pat dry | Cleanses the skin of mucus and faecal drainage |
| Inspect the stoma and surrounding skin. The stoma should be pink or red, and free from excoriation | Deviations from normal must be reported immediately so that appropriate action can be planned |
| Apply the skin barrier to the surrounding skin | Protects the skin |
| Remove the adhesive backing and place the new appliance over the stoma. Ensure that it is secured firmly in position with no gaps exposing the skin around the base of the stoma | Prevents leakage of faeces |
| Assist the individual into a comfortable position and attend to their needs. Restore the bed height, tidy the bed and surrounding area | Promotes comfort |
| Remove the equipment and attend to it in the appropriate manner. Perform hand hygiene | Prevents odour and cross-contamination |
| Document and report the procedure | Appropriate care can be planned and implemented |

*(Black 2014; Burch 2014a; 2014b)*

condition can be associated with thrush, a condition caused by the *Candida* fungus, and which is a common complaint in children and older individuals.

### Gastro-oesophageal reflux disease

Gastro-oesophageal reflux disease (GORD) occurs when gastric acid refluxes back into the oesophagus (Talalwah & Woodward 2013a). Symptoms include persistent heartburn and acid regurgitation, dry cough, halitosis and nausea. In severe cases the symptoms include weight loss and severe chest pain (Talalwah & Woodward 2013b). A hiatus (diaphragmatic) hernia—the herniation of the stomach through the diaphragm into the thoracic cavity—may be one cause of GORD. Changes to diet and lifestyle may aid the individual. Certain prescription medications, and in some cases surgical intervention, may also be required (Talalwah & Woodward 2013b).

## Gastritis

Gastritis is inflammation of the gastric mucosa and may be acute or chronic (Smith 2013). Acute gastritis is associated with irritation of the mucosa related to the ingestion of irritating foods, alcohol, caffeine or certain medications. It may also be caused by food poisoning, microorganisms or psychological stress. Chronic gastritis is commonly associated with an underlying disorder such as a gastric ulcer, chronic alcohol abuse or malignancy. Many people with chronic gastritis have no symptoms, while others experience anorexia, a feeling of fullness, eructation (burping) and vague epigastric pain (Smith 2013). The same symptoms appear in acute gastritis, and the individual may also experience abdominal cramps, nausea, vomiting and diarrhoea. Haemorrhage may occur, presenting as haematemesis (vomited blood) and/or occult blood in the faeces or melaena. A common cause of gastric ulcers is the infection caused by *Helicobacter pylori* (*H. pylori*). Investigations for *H. pylori* include breath tests, as well as blood and stool tests (Smith 2013).

## Gastroenteritis

Gastroenteritis is inflammation of the stomach and intestines. It is an acute disorder characterised by diarrhoea, nausea, vomiting and abdominal cramps (Beckett & Bright 2013). Gastroenteritis has many causes, including the ingestion of bacteria, amoebae, parasites, viruses, toxins or food allergens; and drug reactions. The symptoms vary according to the cause, the extent to which the digestive tract is involved and the age of the individual. Viral gastroenteritis is easily spread and is more common in colder months (Beckett & Bright 2013). The symptoms of viral gastroenteritis appear 12–48 hours after exposure of the virus and include nausea, vomiting and diarrhoea (Beckett & Bright 2013). Infants, older adults and debilitated individuals are more vulnerable to the rapid loss of fluid and electrolytes that occurs with the condition.

## Haemorrhage

Gastrointestinal haemorrhage may occur as a result of a variety of disorders. Common causes of bleeding from the upper digestive tract are peptic ulcer disease, oesophageal varices, malignancy and erosive gastritis (Kyaw & Chan 2014). Upper gastrointestinal haemorrhage may be accompanied by haematemesis or melaena. Causes of bleeding from the lower digestive tract include haemorrhoids, fissures, inflammatory bowel disease, polyps, diverticular disease and malignancy. Haemorrhage from the lower intestinal tract may present as bright-red blood excreted through the anus, or as occult blood present in the faeces. If blood loss is severe, the signs and symptoms of hypovolaemic shock will be evident.

## Peptic ulcer

A peptic ulcer is a localised area of erosion occurring in the stomach or duodenal (the beginning of the small intestine) lining (Regidor 2013). The most common cause of peptic ulcer is a stomach infection associated with the *H. pylori* bacteria but a small percentage are caused by anti-inflammatory drugs such as aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) (Tang & Chan 2012). Malignancy may also be a cause of perforation into the lining of the stomach or duodenum. Symptoms vary in each individual but may include pain described as gnawing, dull, aching or 'hunger-like'; fullness; bloating and nausea (Crosby & Dexter 2013).

## Cholecystitis

Cholecystitis is the acute inflammation of the gallbladder wall and is caused by stones in the cystic duct in 90% of cases (Thomas 2013). The gallbladder becomes dilated and filled with bile, pus and blood. Risk factors for cholecystitis include increasing age, female gender, obesity or rapid weight loss, certain ethnic groups and pregnancy (Thomas 2013). Symptoms include right upper quadrant pain that may radiate to the right shoulder or back, nausea, vomiting and loss of appetite (Thomas 2013). Cholelithiasis is the term used to describe the presence of stones or calculi in the gallbladder (Felicilda-Reynaldo 2012). Choledocholithiasis is the presence of gallstones in the common bile duct (Felicilda-Reynaldo 2012). Major manifestations of choledocholithiasis are similar to those of cholecystitis. If a stone obstructs the common bile duct, jaundice may be evident. Gallstones may be formed by cholesterol that is supersaturated in fat and crystallises or by unconjugated bilirubin that binds to calcium, or a combinations of these products (Felicilda-Reynaldo 2012).

## Hepatitis

**Hepatitis**, which is inflammation of the liver, may be viral or non-viral in origin. Viral hepatitis is classified as infection with hepatitis A virus (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV) or hepatitis E (HEV).

Hepatitis B, C and D usually occur as a result of parenteral contact with infected body fluids. Hepatitis A and E are typically caused by ingestion of contaminated food or water (World Health Organization (WHO) 2015). The individual may have few symptoms or may experience headaches, fatigue, anorexia, pyrexia, dark urine, pale faeces, liver enlargement, jaundice and pruritus. Healthcare workers are at risk of contracting hepatitis B and C through body fluids and therefore standard precautions must be scrupulously adhered to at all times.

Hepatitis A is a viral infection of the liver generally spread via the faecal–oral route, either through contaminated food or water or direct contact with an infectious person (Galmes-Truyols et al 2013). The course of the infection is usually short term and a vaccination against hepatitis A is available.

Hepatitis B (serum hepatitis) is generally transmitted parentally by contact with infected blood. The virus may also be spread via contact with body secretions such as saliva, vaginal secretions, menstrual blood and semen and from infected mother to her baby, during passage through the birth canal or via breast milk (Peate & Jones 2014). The incidence of hepatitis B is higher in people who receive blood or blood products, use or share contaminated needles or engage in unprotected sexual practices (Peate & Jones 2014). The

infection may persist for an extended time, resulting in chronic liver failure and cirrhosis, but the majority of people with hepatitis B will recover. The World Health Organization (2015) reports that there are 240 million people worldwide who are chronically infected with hepatitis B and an estimated 780 000 die annually from the virus. Adult vaccination against hepatitis B involves three doses given over 6 months.

Hepatitis C is a virus that is a major contributor to liver-related morbidity and mortality (Jack 2014). It is spread through blood-to-blood contact such as blood transfusions and shared needles, and can lead to cirrhosis and end-stage liver disease (Jack 2014). Medical treatment in countries where there is no access to single-use sterile equipment for procedures, or testing of donated blood for viruses, can also be a risk factor for contracting the virus (Jack 2014). There is no vaccination currently available for hepatitis C (Jack 2014).

Hepatitis D is most commonly seen in developing countries and is caused through a defective virus that needs the hepatitis B virus to exist (Ahn & Gish 2014). Vaccination against hepatitis B can also protect individuals from the D strain of the virus (Ahn & Gish 2014).

Hepatitis E is a viral disease more common in developing countries. The highest rates of hepatitis E infection occur in regions where there is poor sanitation and sewage management that promotes the transmission of the virus, such as Central and South-east Asia, North and West Africa and Mexico. In most cases it will resolve (Hepatitis Australia 2013).

Non-viral hepatitis generally results from exposure to certain toxins and medications and excessive use of alcohol. Manifestations of the disorder are similar to those of viral hepatitis.

**CRITICAL THINKING EXERCISE 32.3**

Maria has arrived in ER pointing to her epigastric region and moaning in pain. Her ECG is normal. What would be your first considerations in preparing her for investigations?

## Diverticular disease

Diverticulosis is characterised by asymptomatic sac-like protrusions (diverticula) in the colon wall where the mucosa herniates at weakened points (Reddy & Longo 2013). Faecal matter becomes trapped in the pouches and the resulting inflammation is called diverticulitis (Reddy & Longo 2013). Diverticulitis causes mild to severe abdominal pain, some nausea and altered bowel habits (Reinhard 2014). In severe cases, the diverticula can rupture, producing abscesses or peritonitis (Reddy & Longo 2013). It increases in incidence with ageing and there is no gender bias in presentation but cultural factors are thought to impact on the disease process as a result of the highly refined diet found in the developed world (LeMone et al 2013; Reinhard 2014).

## Irritable bowel syndrome

Irritable bowel syndrome (IBS) is defined as a chronic functional gastrointestinal disorder with symptoms of bowel dysfunction, often accompanied by abdominal pain and bloating (Barboza et al 2014). The condition is thought to result from food intolerance, psychological distress or in the presence of increased gastrin levels and affects more women in the developed world than men. Treatment may involve the use of antispasmodics, antidepressants, lifestyle coaching, an increased intake of probiotics and altered dietary intake (Barboza et al 2014).

**CRITICAL THINKING EXERCISE 32.4**

Julianne, 28, has been diagnosed with IBS. What are the classic symptoms affiliated with IBS? What individual education points can you cover with Julianne to assist her in managing IBS?

## Coeliac disease

Coeliac disease is an abnormal response to gluten by the immune system, causing small bowel damage. Symptoms include diarrhoea and malabsorption which prevents uptake of essential nutrients. Treatment requires a continuing gluten-free diet to resolve the symptoms (LeMone et al 2013).

## Hernia

A hernia is the protrusion of an organ or the fascia of an organ through the wall of the cavity that normally contains it (Hammond 2014). Various types of hernias are named according to their location: umbilical, inguinal, femoral, intestinal and incisional; the last occurring at the site of an abdominal incision. If the protrusion can be pushed back into the cavity the hernia is said to be reducible (Hammond 2014). The major complication of an intestinal hernia is strangulation, when the blood flow to the protruding loop of bowel may be obstructed resulting in necrosis. Repair of the hernia involves surgery to place mesh over the hernia orifice thus preventing the protrusion of the organ (Hammond 2014).

## Bowel obstruction

Bowel obstruction is a mechanical or functional obstruction of the intestines, preventing the normal digestion process (Lynch et al 2012). Obstructions may be caused by adhesions, impacted faeces, hernias, tumours, inflammation, neurological disorders or by medication effects (Lynch et al 2012). If the obstruction is at the distal end of the intestine, vomiting may occur, and the vomitus will have a faecal odour caused by bacterial overgrowth in the intestinal tract. The individual generally experiences abdominal pain, distension and vomiting, and is usually unable to pass flatus or faeces. Further manifestations of bowel obstruction may include fluid and electrolyte imbalance because of progressive dehydration and plasma loss (Lynch et al 2012). Complications

of intestinal obstruction include peritonitis, ischaemia and necrosis of the bowel (Lynch et al 2012). The aim of treatment is to alleviate pain, nausea and vomiting and to restore normal bowel function, which may require surgical intervention. Other obstructions may resolve with bowel rest, where the patient is kept nil by mouth and hydration maintained with intravenous fluids (Lynch et al 2012).

### Haemorrhoids

**Haemorrhoids** are distended veins in the anal area, and can be internal or external (Anderson 2013). Internal haemorrhoids commonly present with prolapse or painless rectal bleeding. External haemorrhoids cause bleeding and can cause acute pain if thrombosed. Haemorrhoids commonly result from increased pressure in the anal area related to constipation, straining to defecate, obesity, pregnancy and prolonged sitting or standing (Anderson 2013). The individual commonly experiences pain in, and bleeding from, the anus, particularly during defecation. Pruritus of the anal area may occur in the presence of external haemorrhoids and topical creams are available to alleviate this symptom. Surgery may be an option in severe cases (Anderson 2013).

### Anal fissure

An anal fissure is a crack in the lining of the anus and, like haemorrhoids, is associated with increased pressure in the anal area (Abramowitz et al 2012). Sudden occurrence is characterised by a tearing or burning pain during or immediately after defecation, and by the appearance of a few drops of blood. An anal fissure may heal spontaneously or it may partially heal and recur. A chronic fissure produces scar tissue, which may impede normal defecation (LeMone et al 2013).

### Rectal prolapse

Rectal prolapse is the protrusion of one or more layers of the mucous membrane of the rectum through the anus. Prolapse may be partial or complete—with displacement of the anal sphincter and rectum (Skinn & Gardiner 2013). A rectal prolapse occurs when there is a weakening of the pelvic floor, a poorly attached rectum to the sacrum or a floppy rectum or sigmoid colon (Skinn & Gardiner 2013). Risk factors for this condition include increasing age, chronic constipation and straining on defecation as well as childbirth (Skinn & Gardiner 2013). When a rectal prolapse occurs protrusion of tissue from the rectum is evident, and the individual may experience a sensation of rectal fullness, bleeding and pain due to ulceration of the exposed tissues (Jarvis & Watt 2012).

## Inflammatory and infectious disorders

Inflammatory and/or infectious disorders of the digestive system may be related to internal or external irritation or to the proliferation of pathogenic microorganisms.

### Appendicitis

Appendicitis is the acute inflammation of the vermiform appendix. The individual typically presents with acute abdominal pain starting in the mid-abdomen, later localising to the right lower quadrant (Murphy & Berman 2014). Symptoms may include fever, anorexia, nausea, vomiting and elevation of the neutrophil count (Murphy & Berman 2014). The condition commonly results from an obstruction of the lumen of the appendix, for example, by a faecal mass, or as a result of inflammation and oedema due to a viral infection. The obstruction causes inflammation, which can lead to infection, necrosis and perforation. If the appendix perforates, the contents spill into the abdominal cavity, causing peritonitis (Murphy & Berman 2014).

### Peritonitis

Peritonitis is inflammation of the peritoneum and may be associated with many conditions. Causes of peritonitis include end-stage liver disease, ruptured appendix and abdominal trauma (Cabrera & Schub 2014). The peritoneum becomes inflamed and oedematous, which generally results in decreased intestinal motility and intestinal obstruction. Peritonitis adversely affects the GI, endocrine and cardiovascular systems (Cabrera & Schub 2014). The onset of peritonitis may be acute, or slow and progressive. The inflammatory process causes accumulation of fluid in the abdominal cavity, leading to abdominal distension and rigidity, severe pain, nausea and vomiting. As a result of loss of fluid and electrolytes into the abdominal cavity, the individual displays signs of hypovolaemic shock. Other potential complications include septic shock, acute renal failure, liver failure, respiratory failure, abscess formation and abdomen compartment syndrome (Cabrera & Schub 2014). Treatment commonly includes antibiotics, analgesics, anti-emetics, surgery and supportive care such as supplemental oxygen, blood transfusions and intravenous fluids (Cabrera & Schub 2014).

### Pilonidal sinus

A pilonidal sinus occurs when a hair tunnels inwards, gathering sebaceous oils and other debris (Rice 2014). This causes a localised infected tunnel in the natal cleft (Rice 2014). A pilonidal sinus causes pain and infective symptoms and often requires a surgical incision with drainage. The condition is exacerbated by friction, warmth and moisture and is more common in young males (Rice 2014). Nursing care includes keeping the area dry and clean and ensuring the individual routinely removes hair from the area (LeMone et al 2013).

### Inflammatory bowel disease

Inflammatory bowel disease (IBD) describes a chronic autoimmune disorder of the gastrointestinal tract characterised by inflammation with active and remission periods (Bettany & Gardiner 2013). The two main conditions associated with IBD are Crohn's disease and ulcerative colitis (Bettany & Gardiner 2013). Although the precise cause of inflammatory bowel disease is unknown, factors that have been implicated include a familial tendency, infection, autoimmune reactions and psychological stress. The effect of the disease causes altered mobility and fatigue, as well as changes to perception of body image and alteration in quality of life (Bettany & Gardiner 2013).

Ulcerative colitis primarily affects the superficial mucosal layers of large areas of the colon. The inflammation associated with the disorder destroys tissue, causing ulceration and necrosis (Bettany & Gardiner 2013). Symptoms may be intermittent or continuous and include abdominal pain and diarrhoea. The faeces are generally watery and may contain blood and mucus (Bettany & Gardiner 2013). Complications of ulcerative colitis include haemorrhage and bowel obstruction (Bettany & Gardiner 2013).

Crohn's disease can affect any part of the digestive tract from the mouth to the anus but most commonly affects the small intestine and/or colon (Crohn's and Colitis Australia (CCA) 2015a). There may be healthy sections of the intestine between the diseased sections. Crohn's disease can affect all layers of the intestinal wall and can lead to complications such as strictures, abscesses, fistulae and fissures (CCA 2015a). Symptoms vary according to the site and extent of the lesions and, in acute episodes, the individual experiences abdominal pain and cramps, flatulence, diarrhoea, nausea and vomiting and pyrexia (Bettany & Gardiner 2013). The faeces may contain large quantities of blood and mucus. Chronic or prolonged episodes of inflammatory bowel disease lead to nutritional imbalances, marked weight loss and an increased risk of colon cancer (CCA 2015b; Bettany & Gardiner 2013).

## Neoplastic disorders

Neoplasms of the digestive system may be benign or malignant. Cancer may develop in the mouth, oesophagus, stomach, intestines, rectum, liver or pancreas. The manifestations of cancer of the digestive system vary according to the site.

Polyps are projections of the mucosal surface of an organ and may develop in the stomach or intestine (Islam et al 2013). Most polyps have no risk of cancer but a certain subset has malignant potential (Islam et al 2013). Polyps may be asymptomatic or they may cause diarrhoea, haemorrhage or the manifestations of intestinal obstruction (Islam et al 2013). Familial colonic polyposis is a hereditary disorder characterised by numerous polyps, and has a high association with colonic malignancy.

Colorectal cancer is the most common cancer of the digestive system and is the third most commonly diagnosed cancer worldwide (World Cancer Research Fund 2015). It can develop with few, if any, early warning symptoms. Symptoms of bowel cancer include:

- Bleeding from the anus or any sign of blood after a bowel motion
- A recent and persistent change in bowel habit; for example, looser bowel motions, severe constipation and/or needing to go to the toilet more than usual
- Unexplained tiredness (a symptom of anaemia) and weight loss
- Abdominal pain, especially of recent onset (Commonwealth of Australia 2015).

Screening tests for occult blood assist in early diagnosis of colorectal cancers, improving treatment options and chances of survival. Regular screening can also reduce death from bowel cancers by 15–25% and prevent between 300 and 500 deaths per year (Commonwealth of Australia 2015).

## Traumatic disorders

Trauma to parts of the digestive system may be related to injury or to irritation, such as the ingestion of a corrosive substance. Abdominal trauma may be localised or it may involve more than one abdominal structure. When a part of the digestive system is damaged the processes of digestion, absorption and elimination may be impaired. As a consequence, alterations in nutritional, electrolyte and fluid status occur. Depending on the type and extent of injury, the manifestations include external bruising, abdominal distension, pain, altered bowel sounds and haemorrhage, either internal and concealed, or presenting as haematemesis and/or melaena. Complications of trauma to the digestive system include haemorrhage, shock, infection, peritonitis and obstruction (Kozier et al 2014; Crisp et al 2013).

## End-of-life care

Management of constipation and incontinence in end-of-life care is a priority. Lack of appetite, inadequate intake and high opioid usage contribute to constipation and potential discomfort (Gardiner & Hilton 2014). Abdominal massage and fluid management adaptive to the individual's altered needs may assist, as well as appropriate continence aids to ensure the individual is comfortable and their dignity is maintained.

**CRITICAL THINKING EXERCISE 32.5**

Lee has end-stage dementia and is under a palliative care plan. What aspects of her bowel elimination care need considering?

## Diagnostic tests

Certain tests may be performed to assist or confirm the diagnosis of digestive system disorders.

### Digital rectal examination

A digital examination is done with a gloved finger placed into the anorectal region to identify any physical abnormalities or constipation (Gardiner & Hilton 2014). This is an invasive and uncomfortable procedure and the individual needs privacy and reassurance.

### Screening

Screening is recognised as one method in the early detection of bowel cancer (Commonwealth of Australia 2015). Individuals are now able to screen for unseen blood in their stool which may be an indicator of a disease process. Faecal occult blood test (FOBT) involves placing small samples of stool on special cards and sending them to a pathology laboratory for analysis. The results are then sent back to the individual and their designated medical officer (Cancer Council Australia 2015).

### Laboratory tests

Specimens that may be obtained from the individual for laboratory analysis include blood, faeces, gastric or peritoneal fluid, urine and samples of tissue. Laboratory tests include:

- Histology, microbiology and cytology of stools
- The blood may be tested to determine haemoglobin level, haematocrit, leucocyte count, serum electrolytes, bilirubin levels, glucose levels or pancreatic enzyme levels
- The faeces may be tested to identify bleeding disorders, biliary obstruction, infections and disorders of digestion or absorption
- Gastric fluid analysis involves examination of gastric secretions, and may be performed by examining a specimen of vomitus or by testing a sample of the gastric contents aspirated via a nasogastric tube
- Peritoneal fluid analysis assesses a sample of peritoneal fluid obtained by abdominal paracentesis. The test may be performed when bleeding or infection is suspected by a medical officer. Abdominal paracentesis involves the insertion of a trocar and cannula through the abdominal wall to aspirate a quantity of peritoneal fluid
- The urine may be tested to detect the presence of any abnormal substance (e.g. bilirubin) which may be excreted in the urine as a result of a digestive system disorder
- Biopsy: specimens of tissue may be obtained during endoscopic examinations or surgery. The specimens are examined microscopically for changes in cellular structure, to confirm diagnosis or to determine the cause of a disease (e.g. malignancy) (CCA 2015b; Kozier et al 2014; Crisp et al 2013).

### Radiological examination

Several different types of radiological investigation may be performed:

- Plain x-rays may be taken to aid in the diagnosis of abdominal masses, bowel obstruction, trauma to abdominal organs and ascites
- Computerised tomography (CT) scanning involves the direction of a narrow x-ray beam at parts of the body, from various angles. Contrast medium is often administered intravenously to enhance visualisation. A computer reconstructs the information as a three-dimensional image on a screen
- Ultrasound involves the use of soundwaves to visualise body structures. A transducer is passed over the area, such as the abdomen, and receives echoes, which are bounced off body structures. The echoes are converted into electrical impulses, which may be viewed on a screen or photographed
- Fluoroscopy (visualisation with motion) involves use of a contrast agent (e.g. barium sulfate) which can be visualised as it passes through and outlines structures in the digestive tract. Fluoroscopic examination of the digestive tract includes barium swallow, barium meal and barium enema
- Defecating proctogram is an x-ray of the rectal region during defecation. A simulated stool is an oral contrast agent, composed of barium and a liquid, starchy substance and the individual is required to pass this agent.
- **Endoscopy** is the visual examination of part of the digestive tract using a flexible fibreoptic endoscope. The endoscope also provides a channel for the introduction of instruments for the purpose of obtaining a sample of tissue for microscopic examination. The various forms of endoscopy derive their names from the part of the body being examined:
  - oesophagoscopy (the oesophagus)
  - gastroscopy (the stomach)
  - duodenoscopy (the duodenum)
  - proctoscopy (the anus and rectum)
  - sigmoidoscopy (the sigmoid colon)
  - colonoscopy (the colon) (Kozier et al 2014; Crisp et al 2013).

**CRITICAL THINKING EXERCISE 32.6**

William, 50, is admitted for a colonoscopy because of a family history of bowel cancer and because he has had intermittent presence of blood in his bowel actions. What education can you provide William with about this procedure?

## Care of the individual with a digestive system disorder

Although specific nursing actions and medical management may vary depending on the disorder, the main aims of care are to:

- Maintain standard precautions
- Monitor and maintain accurate bowel frequency and stool form scale (see Clinical Skill 32.2: Stool assessment/collection)
- Ensure accurate documentation and assessment to aid all health professionals in treatment
- Ensure hygiene needs are met; for example, that handwash or sanitisers are available following bowel action
- Maintain skin integrity and appropriate personal hygiene
- Ensure environment is clean, fresh and appropriate to age and ability of the individual
- Encourage appropriate fluids and diet
- Encourage appropriate and realistic exercise
- Ensure the individual is in partnership with the health team in care planning and support individual in accessing further information
- Investigate culturally sensitive issues specific to the lifestyle of the individual
- Maintain individual dignity and support self-image deficits through exploration of potential for altered

## CLINICAL SKILL 32.2 Stool assessment/collection

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Faecal specimen container<br>Pathology request form<br>Bedpan<br>Gloves |

| **Skill activity** | **Rationale** |
|---|---|
| Explain the procedure to the individual and ensure privacy | Reduces anxiety and embarrassment |
| Check the individual's identity band and ensure this information matches the identity on the pathology request form | Ensures the sample is obtained from the correct individual |
| Perform hand hygiene and follow infection control procedures | Prevents cross-infection |
| Provide the individual with a bedpan. Encourage the individual to void prior to providing the stool sample | Ideally the stool sample should be uncontaminated by urine although this might not always be possible |
| Visually assess the stool sample. The size, shape, colour and consistency of the stool should be observed | Changes in the size, shape, colour and consistency of the stool can be a sign of an underlying medical condition |
| The specimen must be labelled with the individual's identifying details, and the date and time the sample was collected | Unlabelled samples will not be processed by the laboratory |
| Using the scooped lid of the faecal specimen container, place a portion of the stool into the container. Place the lid on the container. | All stool samples must be placed into the faecal specimen container |
| The sample is placed the appropriate pathology bag and sent to pathology | The sample will be processed in the laboratory |
| Document and report the procedure | Appropriate care can be planned and implemented |

*(Black 2014; Burch 2014a; 2014b)*

relationships, both physical and emotional, with significant others. Consider the issues such as teasing, bullying, altered physical relationships and carer expectations and stress.

It is vital that infection control principles are adhered to when handling any bodily fluids. The Australian Commission on Safety and Quality in Health Care (ACSQHC 2012) has recognised the importance of infection control and made the reduction of harm through healthcare-associated infections an area of priority in its goals for healthcare. Nurses have a central role to play in this by using effective, evidence-based hand hygiene practices and educating individuals to do the same (ACSQHC 2012).

Specific nursing activities include implementing measures to assist elimination from the bowel, observing and collecting excreta, and care of an individual with a stoma.

## Summary

The functions of the digestive system are to ingest and digest foods so that nutrients can be absorbed into the bloodstream, and to eliminate wastes from the body. Normal functioning may be impaired as a result of alterations in swallowing, secretory function, motility, digestion, absorption or elimination. Disorders of the digestive system can be classified as those occurring from multiple causes, from inflammation or infection, as a result of neoplasms, obstruction or as a result of injury. Diagnostic tests used to assess digestive system function include laboratory

## Summary—cont'd

analysis of body fluids, excretions or tissues; radiological examinations; and endoscopy. Care of the individual with a digestive system disorder includes preventing and managing altered elimination, promoting comfort, maintaining skin and mucous membrane integrity and maintaining nutritional and fluid status. These tasks need to be balanced by supporting the individual through often undignified and embarrassing procedures. Maintaining their self-esteem and encouraging a team approach from all healthcare providers to ensure an optimum lifestyle for the individual is crucial for satisfactory person-centred outcomes.

### DECISION-MAKING FRAMEWORK EXERCISE 32.1

Mr Smith, an individual with a spinal cord injury, has been admitted for a surgical procedure. During his admission he reports to you that he has not had a bowel action for 4 days. Mr Smith states that he is usually unable to completely empty his rectum and requires his wife, who is his carer, to assist him in manually emptying his rectum. He asks if you could perform this procedure as he is experiencing rectal pain. You have never performed this procedure before and do not feel confident in doing so. Mr Smith reassures you that it is easy and he will talk you through the process.

Using the decision-making framework:

1. What is your response to Mr Smith?
2. What is your next action?

## Review Questions

1. What factors may impact an individual's ability to ingest food?
2. Describe the digestion process in the large intestine.
3. Consider the psychosocial impact of bowel disease on the individual and their family.
4. Describe the different types of hepatitis.
5. Describe how assessment of faeces assists in the application of laxatives.
6. Identify the factors that affect bowel elimination.
7. Outline five (5) causes for the onset of diarrhoea in an individual.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/
