CHAPTER 33

# Nursing assessment and management of pain

*Yangama Jokwiro*

## KEY TERMS

acute pain
analgesic
chronic pain
endorphins
epidural infusion
gate control theory
pain
pain assessment tool
pain management
palliative care
patient-controlled analgesia (PCA)
substance abuse
threshold
transcutaneous electrical nerve stimulation (TENS)

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the physiological basis of pain perception
- Describe the factors influencing an individual's perception of, and reaction to, pain
- Describe the differences in approach to pain assessment across the lifespan
- Describe various methods of pain management, including both non-pharmacological and pharmacological approaches
- Apply appropriate principles in planning and implementing nursing actions to prevent and to alleviate an individual's pain

## CHAPTER FOCUS

**Pain** is a hugely subjective phenomenon which has been defined by the International Association for the Study of Pain (IASP) (1979) as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'. However, a timeless definition of pain that has been widely accepted and used by many nurses is that of Margo McCaffery (1968), a highly recognised pain care specialist. Her definition encompasses the idea that 'pain is what the person says it is, and exists when he [sic] says it does' (McCaffery & Pasero 1999:17). Pain is usually the chief reason individuals seek medical help. Nurses, due to their unique position as direct care workers, should be adequately equipped with cross-cultural, interdisciplinary and age-appropriate skills to assess and manage pain effectively. Thus the focus of this chapter, using a person-centred approach, is on the pathophysiology of pain, barriers to effective pain control and perception, assessment and treatment of pain.

## LIVED EXPERIENCE

I am back again in these familiar hospital corridors. I survived the accident and I am grateful to the mighty Lord for that; but this debilitating pain has left me paralysed for life. This time the pain is worse and I hope that I will be looked after by a nurse who understands what I am going through. I hope I don't meet new nurses and I have to go through my history again. The worst feeling is getting to a place of help and not getting the relief that you need.

**Danai, 44, with chronic pain syndrome post MVA**

# FUNDAMENTALS OF PAIN

Pain is a phenomenon as simple as it is complex. For instance, individuals realise that sitting down can help relieve pain but prolonged sitting can then result in more pain. The same applies to activities of daily living such as walking, dancing and playing. What is even more baffling is that doing nothing for too long or being isolated can also result in pain. Individuals master ways to balance the environmental stimuli so that they avoid pain, such as by using a reverse-cycle air-conditioner to control exposure to hot or cold weather. However, it is impossible to always avoid pain as it is part of our daily living. It is also apparent that pain is multifactorial in origin because of the various environmental factors associated with it; thus the experience and responses to pain are unpredictable. The unpredictability of the response to pain is also complicated by individual differences in age, personality, culture, previous experience, gender and race among other factors. This is why a precise clinical description of pain has eluded clinicians for decades.

Melzack and Casey published a model which describes pain in terms of three hierarchical levels: 'a sensory-discriminative component (location, intensity and quality), a motivational–affective component (depression and anxiety) and a cognitive-evaluative component (thoughts concerning the cause and significance of the pain)' (Melzack & Casey 1968). This description recognises that pain perception may not always be associated with diagnosable tissue damage and that it is hugely influenced by psychological and emotional factors. It also recognises that pain as an unpleasant experience does affect the mental status of people. Pain's sensory-discriminative component constitutes its physiological role as a protective signal, a product of evolution and a warning of actual or impending tissue damage. Avoidance of pain appears to be an instinctive reaction to harmful factors in the environment; for example, a newborn will draw away from a painful stimulus (Craft et al 2014). Throughout the life cycle, people will avoid painful stimuli or take actions to withdraw from such stimuli. The sensation of pain can also warn the individual of emotional or stress-related problems, such as a headache caused by tension or anxiety. The ability to relieve or to control pain depends on an understanding of how it occurs and how it is controlled by the brain.

Although the complex mechanisms of the physiology and psychology of pain are not understood completely, there are several theories of pain. The **gate control theory** (Melzack & Wall 1965) is the leading theory and a discussion of the other theories is beyond the scope of this chapter. The gate control theory of pain suggests that neural mechanisms in the dorsal horns of the spinal cord can act like a gate (Melzack & Wall 1965). This theory proposes that activity in the large diameter nerve fibres can close the gate and block pain impulses, resulting in a decrease or elimination of pain sensation. Therefore, according to this theory, it is possible to block pain impulses travelling to the brain by stimulating the large 'A' nerve fibres and 'closing the gate'. This theory may help to explain why cutaneous stimulation (rubbing a sore spot) or acupuncture can relieve pain, because stimulation of non-painful nerve fibres can 'confuse' messages and suppress pain signals.

It is acknowledged that pain can be inhibited along the course of transmission (Figures 33.1 and 33.2) and that endorphins play a complex role in closing the gate to pain (Bryant & Knights 2014). **Endorphins** are naturally occurring substances with opioid qualities, which combine with the same receptors as morphine and other narcotics to produce the same effect (i.e. analgesia) (Bryant & Knights

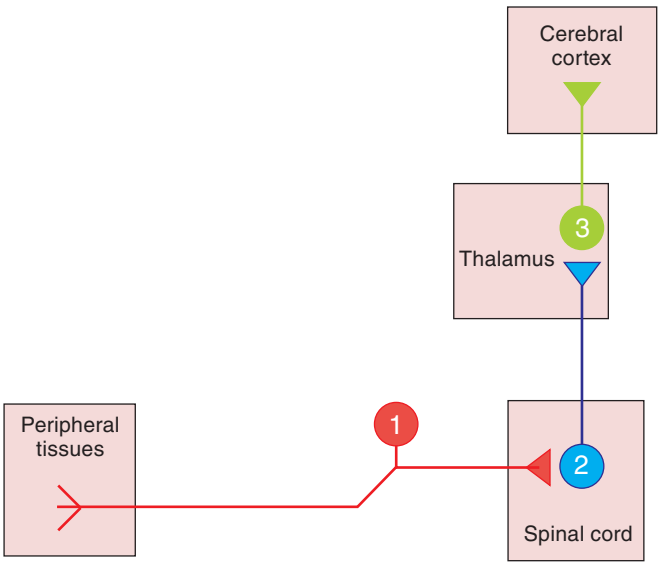

**Figure 33.1** The transmission of pain
*(Craft et al 2014)*

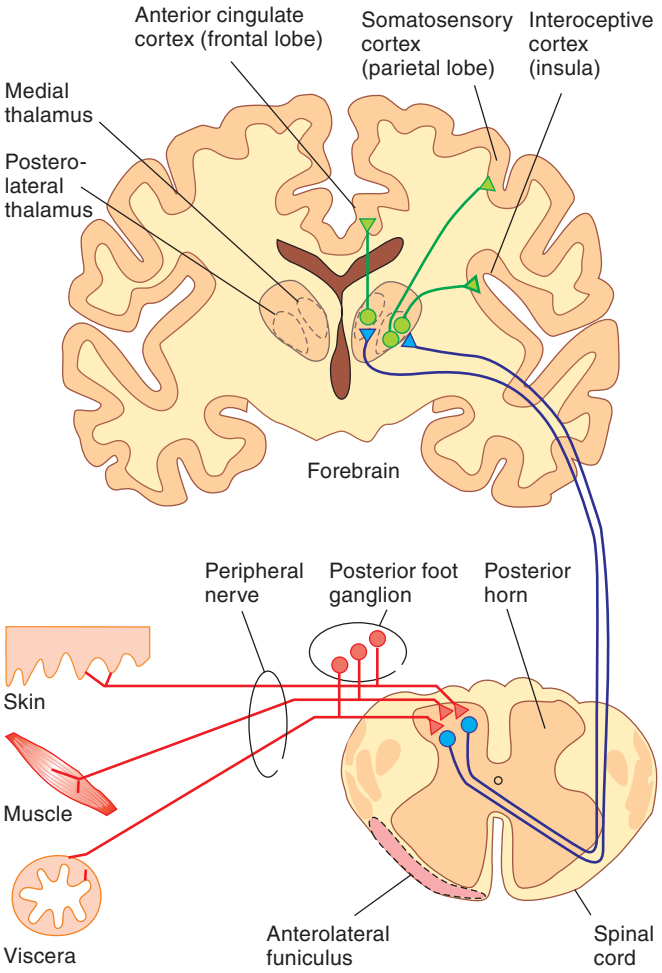

**Figure 33.2** The transmission of pain
*(Craft et al 2014)*

2014). They act as neurotransmitters that mediate the transmission of pain information. As a result of pain or stress, an impulse from the brain may trigger the release of endorphins from pain-inhibiting neurons in the dorsal horn, which block transmission of the pain impulse before it reaches the brain (Figure 33.3). Various studies have shown that plasma endorphin levels increase in states of stress, and also that acupuncture and transcutaneous electrical nerve stimulation (TENS) increase endorphin release (Amir et al 1980; Bowen et al 1987; Belvisi et al 2009; Brown et al 2015; Bryant & Knights 2014). Therefore, although incompletely understood, it is known that the body has some internal mechanisms that help to control pain and our perception of it.

**CRITICAL THINKING EXERCISE 33.1**

Explain physiologically why individuals can become aggressive when they experience pain.

## Classification of pain

In order to manage pain effectively an understanding of the classification of pain is required. The IASP taxonomy of 2014 provides a framework for classification of pain (IASP 2014). It classifies pain according to the cause or pathology involved in its generation. This results in categories such as nociceptive pain, neuropathic pain, psychogenic pain and phantom pain (Table 33.1). The other classification of pain is based on duration (Bryant & Knights 2014). The two main categories in this classification are acute and chronic pain (Table 33.2).

# PAIN MANAGEMENT ACROSS THE LIFESPAN

**Pain management** is the use of pharmacological or non-pharmacological nursing interventions to comprehensively treat discomfort and improve or restore the quality of life. Pain management involves vigilant monitoring of comfort using a multidisciplinary approach and not the mere administration of prescribed analgesics (Brown et al 2015). The major goal is to eliminate pain and improve the quality of life and function. In **palliative care** (see Chapter 38), pain management allows individuals to die with dignity.

The nurse, by virtue of spending 24 hours a day with individuals, is in a position to make the greatest impact in the diagnosis and treatment of pain. As described previously, pain is a hugely subjective experience, and therefore difficult to diagnose objectively. It is thus vital for nurses to be cognisant of the fact that pain is a lived experience, a product of the continuous conflict between the internal and external stimuli and the whole individual (IASP 2014). Therefore, the nurse has an important responsibility to observe the individual for visible evidence of pain, listen carefully to the individual's description of pain and implement measures that prevent or treat pain. In addition, the nurse has a responsibility to monitor and report the individual's response to, and the efficacy of, any prescribed pain management. From a

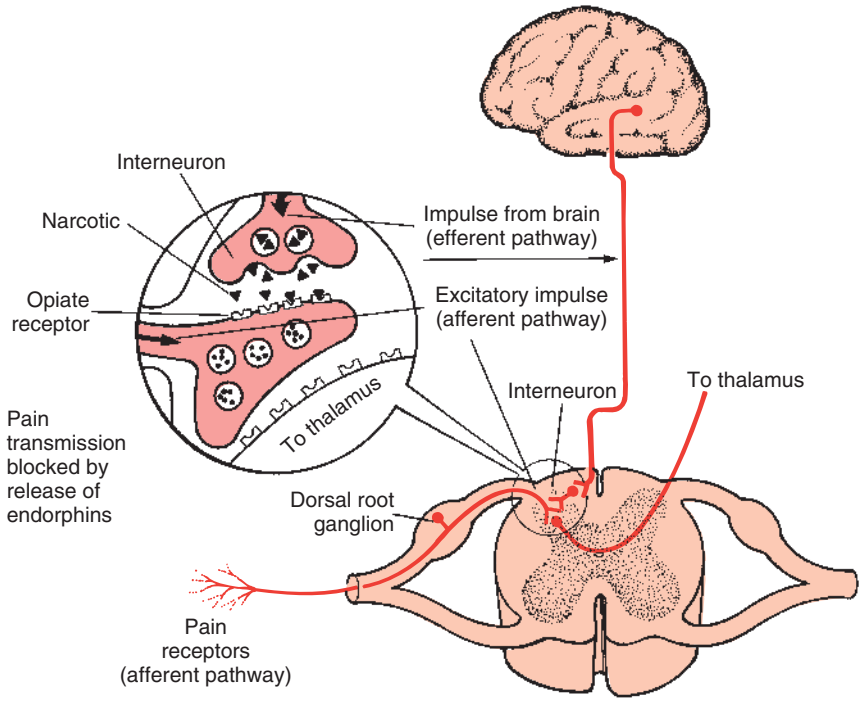

**Figure 33.3** Modulation of pain by endorphins
*(Huether & McCance 2011)*

**TABLE 33.1 | Classification of pain based on aetiology or pathology**

| Type of pain | Pathophysiology |
|---|---|
| Nociceptive | This pain is caused by stimulation of nociceptors (peripheral nerve fibres). These peripheral nerve fibres have the capability to be responsive to noxious internal or external stimuli. Nociceptive pain can be classified as *somatic* (deep or superficial) originating from the skin and musculoskeletal system and *visceral* originating from damaged organs. Nociceptive pain is caused by ischaemia, trauma, chemical irritants and extremes of temperature.<br>When pain receptors are stimulated they send electrical impulses along special pathways to the spinal cord. These pathways may be seen as being similar to a two-lane road, one lane with large diameter fibres for fast message transmission ('A' fibres), and one lane with smaller diameter fibres for slower message transmission ('C' fibres). 'A' fibres have the most insulation, and carry information that reflects throbbing and pricking types of pain. Slow pathways ('C' fibres) have less insulation, and carry impulses that represent burning pain. Pain receptors in the skin and other tissues are free nerve endings, some of which are the peripheral terminations of small diameter 'C' fibres, while others are the slightly larger diameter 'A' fibres.<br>When histamine and other naturally occurring chemical substances are released as a result of tissue damage, pain sensations travel along the nerve fibres. Regardless of the type of pain, and whether travelling slowly or quickly, pain impulses are transmitted to the dorsal root ganglia of the spinal cord, where they synapse with certain neurons in the posterior horns of the grey matter. Pain sensations are then transmitted to various areas of the brain by synapses at the thalamus, where they are perceived and interpreted (Figure 33.2) |
| Neuropathic | Pain resulting from the damage or malfunction of nerve fibres in the peripheral and/or central nervous system. The nerve fibres could be located in the periphery or central sections of the nervous system. The resulting pain is often described as burning or pins and needles |
| Psychogenic | Hugely complex pain which is not fully acknowledged or understood. This pain exists in the absence of known pathophysiology and it is associated with mental and emotional behaviours |
| Phantom | Pain sensation resulting from body parts that have been surgically removed |
| Referred | Pain which originates from visceral organs but is felt on cutaneous areas suggesting some embryonic origin. A good example is cardiac pain which is also felt in the neck and shoulders (Figure 33.4) |

*(Berman et al 2015; IASP 2014)*

**TABLE 33.2 | Classification of pain based on duration**

| Type of pain | Pathophysiology |
|---|---|
| Acute | Pain of rapid onset which varies in intensity and length of time, but is usually time limited and has a predictable management and end. It is often perceived as an incident of high severity and is often able to be precisely located and described. **Acute pain**, if mild, may require no specific intervention, and more severe acute pain can usually be managed successfully. Acute pain may result from injury or infection or occur after surgical intervention. Acute pain includes pre- and postoperative pain, post-traumatic pain, burns pain, acute pain during childbirth, pain as a result of spinal cord injury, acute headache pain, pain associated with HIV/AIDS or sickle cell crisis, pain in trigeminal neuralgia, interventional pain (diagnostic and therapeutic procedures), pancreatitis and other colic pain, pain in myocardial infarction and other major cardiac events, acute on chronic pain. When tissue damage is the cause, pain declines as the tissues heal |
| Chronic<br>—malignant<br>—non-malignant | Pain that has lasted for a period of 3 months or more in the past 6 months and is an ongoing experience that fails to resolve naturally or does not respond well to intervention. It is often no longer considered to be pain that warns of impending danger or tissue damage. **Chronic pain** is constant or intermittent and the individual often has difficulty localising it.<br>Chronic malignant pain includes pain in individuals with cancer, HIV/AIDS, motor neuron disease (MND), multiple sclerosis, end-stage organ failure, advanced chronic obstructive pulmonary disease, advanced congestive heart failure, parkinsonism.<br>Chronic non-malignant pain includes:<br>— chronic musculoskeletal pain such as spinal pain or low back pain, chronic degenerative arthritis, osteoarthritis, rheumatoid arthritis, myofascial and rheumatic pain, chronic headache, migraine pain, bone pain<br>— neuropathic pain (including nerve compression pain, post-nerve injury and post-amputation pain), diabetic neuropathy, complex regional pain syndromes (types I and II), skeletal muscle spasm pain, post-herpetic neuralgia, chronic postsurgical pain<br>— visceral pain (such as distension of hollow viscera and colic pain)<br>— chronic pain in sickle cell anaemia |

*(Berman et al 2015; IASP 2014; National Pain Summit Initiative 2010; WHO 2007)*

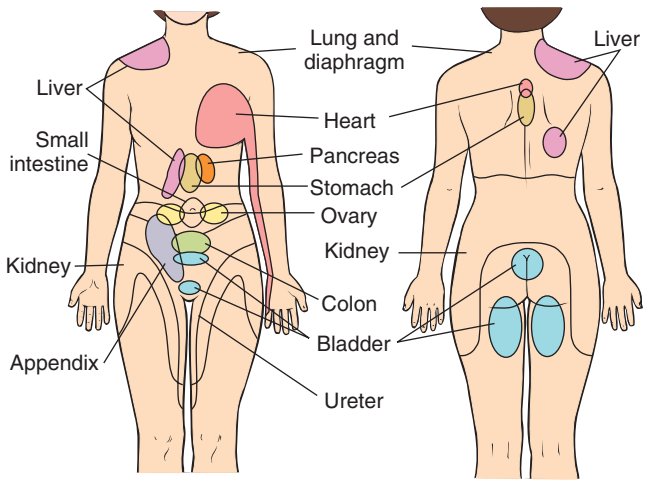

**Figure 33.4** Referred pain sites: cutaneous areas to which pain from certain viscera is referred
*(Craft et al 2014)*

medical point of view, the management of pain includes treating the underlying disease to remove or diminish the cause; treating any other symptoms such as nausea or constipation that may increase the perception of pain; and using non-pharmacological and pharmacological therapy. Specific nursing interventions described later in this chapter include minimising the stimulus that is causing or contributing to the pain, alleviating pain with supportive nursing intervention and assisting the individual self-manage pain. It must be recognised that even the simple provision of information and explanation can have a powerful effect in assisting people to feel in control of their pain-management situation (Craft et al 2014).

## Barriers to effective pain management

There are multiple barriers to adequate pain management; this places individuals at risk of under-treatment. The major problem is that pain management is dependent on a self-report. Individuals recognised to be at risk are those in the extremes of age; that is, children and the elderly. In addition, individuals with psychiatric disorders, who are cognitively impaired, have **substance abuse** problems and those suffering from chronic pain are also at risk of under-treatment of pain. It is therefore important to analyse factors that can influence the perception of pain. The perception of pain is individual and is thus different for each person. Table 33.3 outlines the factors that can influence the perception of pain across the lifespan. In addition, a person may perceive pain differently at different times. Clinical Interest Box 33.1 provides some common biases and misconceptions about pain.

## TABLE 33.3 | Factors influencing the perception of pain across the lifespan

| Factor | Rationale |
|---|---|
| Age | As infants and young children lack the ability to express themselves verbally, their pain, or the degree of pain they experience, may not be recognised or appreciated. Many misconceptions exist in relation to pain in infants, including that infants do not feel pain or are incapable of expressing pain. In addition to the physiological changes, behavioural cues, such as facial activity (including brow bulge, eye squeeze and open lips), crying behaviour and gross motor activity may indicate pain in the infant. Additionally, many children are taught from an early age that they are expected to be brave and that 'only babies cry'. As a result, a child who is experiencing pain may endeavour to hide it. Conversely, a child may invent or exaggerate pain as a method of gaining attention.<br>When older children or adolescents experience pain they may think of it in terms of how it will affect their activities and the attainment of goals. As a result of misunderstanding about their body and illness, young individuals sometimes harbour distressing fantasies about the significance of pain. Consequently, both anxiety and pain are increased.<br>The ability to tolerate pain generally seems to increase with age, and this may be partly due to expectations about what constitutes 'adult' behaviour. Many myths also exist, however, in relation to pain experienced by older adults, particularly those with cognitive impairment. This has resulted in an underestimation and under-management of pain in people with disorders such as Alzheimer's disease. Clinical Interest Box 33.2 provides more information about pain management in individuals with Alzheimer's disease. Common misconceptions include that pain is a natural consequence of growing old, that pain perception decreases with age and that, if the older adult does not report pain, they do not have pain |
| Gender | Many males have been conditioned by society to be strong and brave. Some people consider that any display of emotion by a male, such as crying, is a sign of weakness. As a result of society's expectations of acceptable behaviour, a male may internalise or suppress expressions of pain |
| Culture | Cultural values, attitudes and feelings contribute to the way people react to pain. Some people have a matter-of-fact attitude to pain, with little outward expression of their suffering, while others are more expressive and seek immediate pain relief. Most Western cultures place strong values on the ability to bear pain with silent fortitude, so that external behaviours may not reveal the intensity of pain. People from Latin cultures are permitted to display their suffering openly, such as by crying or moaning, as a socially accepted response to pain. It must also be appreciated, however, that there are enormous differences within every culture and that not every person from a specific culture will react in the same manner. Clinical Interest Box 33.3 provides an example of a cultural experience of pain |
| Emotional state | A person who is emotionally or physically exhausted often has a reduced capacity to tolerate pain. Individual resistance to, and control over, reactions to pain may be lessened. This is often a cyclical phenomenon; continual pain results in anxiety, and anxiety and fear exacerbate pain |
| Environment | There is a relationship between anxiety and pain, and environmental factors can either contribute to or reduce anxiety levels. The environment can act as an anxiety-provoking stressor; for example, if there is an atmosphere of tension or if there is a lack of privacy. Privacy allows a person uninhibited expression of pain, such as crying or moaning. The continued presence of other people, as in a shared ward, results in a sense of loss of privacy. This may be a cause of anxiety and a contributing factor in the perception of, and reaction to, pain. It is therefore important to recognise the many factors that influence pain reactions and to appreciate that each pain experience is unique and personal. Anyone caring for an individual experiencing pain should not judge the appropriateness of that person's reaction to pain, and must be sensitive to individual needs |
| Self-image | A person's self-perception can influence a reaction to pain. For example, a person who has low self-esteem may try to bear pain stoically to be regarded highly by others. Conversely, another person with a poor self-image and feelings of worthlessness may tolerate pain poorly in an attempt to gain attention and recognition. A pain episode may be interpreted by some people as being punished for something |
| Time of the day | Night, with accompanying darkness and reduced sensory input, often increases a person's sensation of pain. Fear and anxiety may be increased and, as a result, so too is the sensation of pain. The latter part of the day may also be when the person is fatigued physically and emotionally |
| Previous experience | Previous episodes of severe pain often cause great apprehension, and individuals can suffer greatly if they anticipate recurrent severe pain. Anxiety may be increased if the previous experience of severe pain was poorly managed. Previous pain experience may at times be useful as a form of comparison when assessing a subsequent pain episode. Overall, the amount of previous pain experiences a person has had may influence their current response to an episode of pain |

*(Adapted from Crisp et al 2013)*

## CLINICAL INTEREST BOX 33.1 Common biases and misconceptions about pain

The following statements are false:

- Substance abusers and alcoholics overreact to discomforts
- Individuals with minor illnesses have less pain than those with severe physical alteration
- Administering analgesics regularly will lead to drug addiction
- The amount of tissue damage in an injury can accurately indicate pain intensity
- Healthcare personnel are the best authorities on the nature of an individual's pain
- Psychogenic pain is not real
- Chronic pain is psychological
- Individuals should expect to have pain in hospital
- Individuals who cannot speak do not feel pain.

*(Crisp et al 2013)*

## CLINICAL INTEREST BOX 33.2 Pain management in individuals with Alzheimer's disease

No evidence exists that cognitively impaired older adults experience less pain or that their reports of pain are less valid than those people with intact cognitive function. It is probable that individuals with dementia and progressive deficits of cognition, particularly those in long-term care facilities, suffer significant unrelieved pain and discomfort. Assessing pain in these individuals is challenging but possible. The best approach is to accept the individual's report of pain and treat the pain as it would be treated in a person with intact cognitive function.

*(Potter et al 2013)*

## CLINICAL INTEREST BOX 33.3 A cultural experience of pain

People from different cultures respond differently to pain. In a more general sense, these responses can be described as stoic and emotive. Stoic individuals tend to bear the pain and withdraw socially as seen in some Northern European and Asian cultures. Emotive individuals express their pain verbally and want to be surrounded by close family members so they can react and validate their pain, as seen in people from Middle Eastern and Mediterranean backgrounds. A person's cultural belief of pain and their personal treatment strategy may lead them to believe, for example, that it is God's will for them to experience pain. Buddhists prefer to use meditation techniques to help relieve their pain.

*(Brown et al 2015)*

As the perception of pain is individual, some will experience pain much earlier than others. Studies have shown that all individuals have a similar sensation **threshold** but that the ways in which different people react to pain may vary tremendously and many factors may be involved (see Clinical Interest Boxes 33.2 and 33.3) (Fillingim et al 2009; Clayton et al 2009; Bryant & Knights 2014). This is demonstrated by behavioural manifestations of pain which express the individual's physiological response and the cultural factors which shape the person's perception of pain. The pain threshold is the point at which a stimulus, such as pressure, activates pain receptors and produces a sensation of pain (IASP 2014).

## Assessing pain

Pain is considered the fifth vital sign alongside classic vital signs such a blood pressure, pulse, respiration and temperature (Lynch 2001). Incomplete assessment of individuals leads to inadequate pain management which in turn interferes with the healing process. The assessment process involves obtaining both subjective and objective data (Table 33.4). The data must be comprehensive, covering both the physiological and the behavioural manifestations of pain (Clinical Interest Box 33.4) (Crisp et al 2013). Assessment begins with a comprehensive pain history and use of the PQRST or PQRSTU mnemonic (Table 33.4) is recommended (Chang & Johnson 2014; Crisp et al 2013). This includes provoking/palliative factors, quality, region and radiation, severity and temporal pattern (onset, duration and pattern). The questions must be designed to enable the individual to describe the pain in their own words. In circumstances when individuals cannot describe their pain, appropriate assessment questions and tools should be used. These circumstances could be younger children, language or cultural barrier and individuals with cognitive impairment (refer to Clinical Interest Boxes 33.2 and 33.3). A nurse should never ignore an individual's statement that they are in pain, and should remember that 'pain is what the person says it is' as described by McCaffery in 1968 (McCaffery & Pasero 1999). An individual can usually sense if the nurse does not believe that they are experiencing pain, and this can increase the sense of helplessness. As a consequence, the person may compensate by under-reporting pain or by anxiously over-reporting. Either reaction aggravates the circle of mistrust–anxiety–more pain (Crisp et al 2013). When assessing an individual's pain, the nurse should obtain sufficient and appropriate information through observation, questioning and conducting a physical examination. (See Case Study 33.1, Nursing Care Plan 33.1 and Progress Note Example 33.1.)

**CRITICAL THINKING EXERCISE 33.2**

Discuss the rationale for ensuring that pain assessment is undertaken in a non-judgmental manner.

## TABLE 33.4 | Assessing pain

### SUBJECTIVE DATA

| Domain | Assessment questions | Rationale |
|---|---|---|
| Pain history | **PQRST**<br>**Provocative**<br>What where you doing when the pain started?<br>What makes the pain worse or what relieves it?<br>What caused it?<br>**Quality**<br>What does the pain feel like?<br>**Region**<br>Where is the pain located?<br>Does the pain move and is it related to any other pain?<br>**Severity**<br>How severe is the pain?<br>**Timing**<br>When did the pain start?<br>How long has the pain been present?<br>Is pain constant or intermittent?<br>**U (You)**<br>How does the pain affect you? | Information should be obtained regarding the onset of pain; for example, whether it was sudden or gradual. The individual should also be asked if the pain increases or decreases at specific times of the day or night; that is, if there is rhythmic variation or pattern in the pain. For example, an individual who has arthritis aggravated by inactivity may experience severe joint pain on waking, but the pain may become less severe throughout the day.<br>Certain physical activities or psychological factors may precipitate pain. For example, chest pain may occur after physical exercise, or abdominal pain may occur after eating. A change of posture may aggravate or relieve pain, and factors such as anxiety or fear may also precipitate pain. It is important to establish factors that aggravate the pain as well as those that modify or bring about pain relief.<br>Quality is the way the pain is described by the person who is experiencing it, and it is important for the nurse to report and record the individual's own words. Some of the terms that may be used to describe the type and quality of pain are gripping, knife-like, burning, prickling, tingling, dull, aching, cramping, gnawing, constricting, throbbing, vice-like, crushing, stabbing and shooting.<br>An individual may be able to locate a painful area specifically by describing it or by pointing to the body area involved, such as the tip of the thumb on the left hand, or they may describe the painful area more generally; for example, all over the abdomen. Pain that radiates from its point of origin should also be noted.<br>The severity of pain is not always evident from a person's reaction, especially with a chronic pain problem, and must therefore be assessed as the individual's own perception. Several measurement tools, or pain scales (Figure 33.5), have been designed to assist an individual to describe the intensity of pain. Healthcare institutions may devise their own measurement tool, or may use a standard tool. One method of assessment is a linear scale from 1–10, on which the individual indicates the intensity of their pain, with 0–1 being no pain at all, and 10 representing severe and intense pain. A similar scale using 'smiley faces' may be used for children (Figure 33.6).<br>This type of measurement device facilitates both assessment and management of pain in many cases. However, the use of pain-scale assessment tools makes the assumptions that the individual has a past experience of pain, that they can understand the scale and verbalise, and that they are not cognitively impaired. With elderly individuals, issues such as poor memory, depression and sensory impairment may also make pain assessment difficult. The Abbey Pain Scale (Figure 33.7) is a measurement of pain in people with dementia who cannot verbalise.<br>It is important to establish how long the pain lasts; for example, whether it is continuous or intermittent |
| Medication history | What medication have you taken to treat the pain?<br>What medications are you currently taking?<br>Have you been prescribed medications in the past to treat this pain? | These questions give invaluable information which can help with diagnosing the cause of the pain. This information can also shape treatment |

*Continued*

## TABLE 33.4 | Assessing pain—cont'd

### SUBJECTIVE DATA

| Domain | Assessment questions | Rationale |
|---|---|---|
| Cognitive dimensions | Is the individual cognitively incapacitated?<br>What is the attitude of the individual?<br>What is your perception of the pain?<br>What is the meaning of the pain? | A person's self-perception can influence a reaction to pain. For example, a person who has a low self-esteem may try to bear pain stoically to be regarded highly by others. Conversely, another person with a poor self-image and feelings of worthlessness may tolerate pain poorly in an attempt to gain attention and recognition. A pain episode may be interpreted by some people as being punished for something |
| Psychological status | How is the individual coping?<br>How do you expect to cope? | A person who is emotionally or physically exhausted often has a reduced capacity to tolerate pain. Individual resistance to, and control over, reactions to pain may be lessened. This is often a cyclical phenomenon—continual pain results in anxiety, and anxiety and fear exacerbate pain |
| Social and family history | What are the social pressures?<br>How is the pain affecting the social role of the individual?<br>Does the individual have any support from the family?<br>How is the family coping? | Assessment should include whether or not the pain interferes with lifestyle or the performance of any activities of daily living; for example, does it affect the ability to eat, move freely or sleep? Are roles and relationships being affected in a significant way by the pain that is being experienced? |
| Cultural and spiritual influences | What is the cultural background?<br>What gives meaning to the individual? | Cultural values, attitudes and feelings contribute to the way people react to pain. Some people have a matter-of-fact attitude to pain, with little outward expression of their suffering, while others are more expressive and seek immediate pain relief |

### OBJECTIVE DATA

| Domain | Rationale |
|---|---|
| Vital signs | The individual's temperature, pulse, respirations and blood pressure should be measured when pain is first experienced. When acute pain occurs the autonomic response is activated, so that:<br>• Heart rate increases<br>• Blood pressure rises<br>• Breathing often becomes rapid and shallow<br>• Muscles tense<br>• Blood flow to the hands and feet is constricted, and they become cold<br>• The skin becomes pale and sweaty<br>• Nausea and vomiting may occur.<br>These physiological changes are often less observable in a person with chronic pain.<br>Over time the changes are unable to be sustained, and the individual with chronic pain may exhibit a general appearance of not being in pain. The results should be documented, and repeated measurements made to detect any alterations. Any abnormal result or significant variation should be reported immediately |
| Physical examination | The individual should be observed for signs of increased emotional tension, such as irritability, anxiety, depression, aggression, exhaustion or sleeplessness. When an individual experiences pain or a change in the nature of pain already present, the nurse should monitor and assess by making the observations as described. Clinical Interest Box 33.4 outlines some behavioural indicators of the effects of pain. A simple head-to-toe assessment is also warranted to make sure that there are no mechanical objects that may be the cause of pain such as a blocked catheter |
| Investigations | The medical officer may order further investigations which may help diagnose the source of pain |

*(Adapted from Brown et al 2015; Crisp et al 2013)*

## CLINICAL INTEREST BOX 33.4 Behavioural indicators of effects of pain

**Vocalisations**

- Sighing, groaning, moaning
- Grunting, screaming, calling out
- Aggressive/offensive speech
- Noisy breathing
- Asking for assistance

**Facial expressions**

- Frowning, sad or frightened face
- Grimacing, wincing, eye tightening
- Distorted facial expressions—brow raising/lowering, cheek raising, nose wrinkling, lip corner pulling
- Rapid blinking

**Body movement**

- Tense posture, guarded, rigid
- Fidgeting
- Pacing, rocking or repetitive movements
- Reduced or restricted movement
- Altered gait

**Social interaction**

- Aggressive or disruptive behaviour
- Socially inappropriate behaviour
- Decreased social interactions
- Withdrawn

**Changes in activities**

- Appetite change, refusing food
- Increase in rest periods
- Sleep or rest pattern changes
- Increased wandering

*(Royal College of Physicians, British Geriatrics Society, British Pain Society 2007; Edith Cowan University 2007)*

## CASE STUDY 33.1

Mrs Jones is 65 and, up until admission to hospital, has lived alone. She has had rheumatoid arthritis for the past 25 years, resulting in severely deformed hands. She is unable to walk without assistance and is no longer managing at home, despite full community services. Chronic pain is a major issue for her. Mrs Jones states that 'the pain is there most of the time but gets worse when I move suddenly'.

Describe the assessment and management of Mrs Jones' pain.

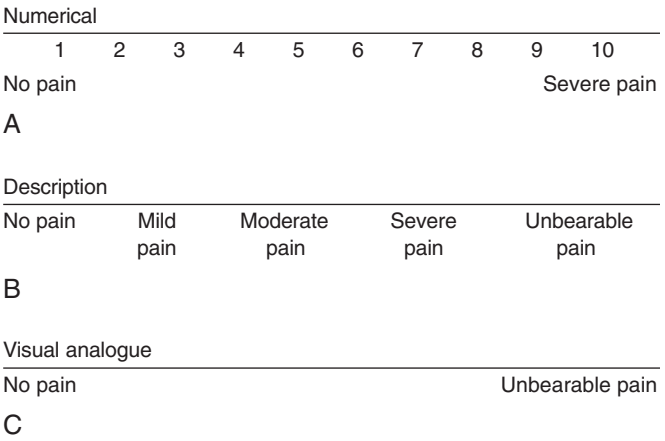

**Figure 33.5** Scales for measuring pain intensity in adults The individual identifies a point on the scale that corresponds to their perception of the severity of the pain

### Pain assessment tools

There are a variety of **pain assessment tools** used for individuals across the lifespan (Figures 33.5, 33.6 and 33.7). The aim of these tools is to standardise and objectify assessment. These tools include:

- Numeric rating scale (NRS) (Figure 33.5A)
- Categorical or verbal descriptor scale (VDS) (Figure 33.5B)
- Visual analogue scale (VAS) (Figure 33.5C)
- Faces scale (Figure 33.6)
- Abbey Pain Scale (Figure 33.7).

## NURSING INTERVENTIONS FOR AN INDIVIDUAL EXPERIENCING PAIN

The nurse has a responsibility to try to eliminate or minimise the stimulus that is causing pain. The nurse should also observe the individual who is experiencing pain, report and document their observations and implement nursing measures accordingly to alleviate pain. Continued assessment and monitoring of the individual is necessary to evaluate the effectiveness of any prescribed therapy (IASP 2014). Particular attention must be paid to individuals who cannot clearly articulate their needs or feelings, such as infants and small children and those with cognitive or communicative impairment (Crisp et al 2013). Pain management, both of non-pharmacological and pharmacological nature, must still be addressed in these situations, and responses evaluated. The nurse also plays an important role in supporting the individual's significant others, who are usually distressed by the pain experience of their loved one, particularly when the pain is chronic or is a result of terminal illness.

The importance of clear and effective communication between the nurse and the individual and significant others cannot be overemphasised. A positive relationship facilitates effective communication, which can affect the individual's response to pain and pain relief. The individual should be

## NURSING CARE PLAN 33.1

**Assessment:** Mrs Jones is 65 and, up until admission to hospital, has lived alone. She has had rheumatoid arthritis for the past 25 years, resulting in severely deformed hands. She is unable to walk without assistance and is no longer managing at home, despite full community services. Chronic pain is a major issue for her. Mrs Jones states that 'the pain is there most of the time but gets worse when I move suddenly'.
**Issue/s to be addressed:** Chronic pain, related to joint inflammation
Impaired home maintenance, related to fatigue
Activity intolerance, related to the effects of inflammation
Deficient knowledge: therapeutic regimen
**Goal/s:** Effective pain management
Minimise joint stress with ADLs
Understanding of the prescribed therapeutic regimen

| Care/Actions | Rationale |
|---|---|
| Assess thoroughly including vital signs, liver function test and renal function test | NSAIDS are nephrotoxic and hepatotoxic |
| Schedule NSAIDs at equal intervals throughout the day | Keeps the pain under control through the day |
| Give morning NSAID dose with milk and cracker biscuits approximately 30 minutes before rising | Allows individual to mobilise when they get up and giving NSAIDs with food protects stomach |
| Performing ROM exercises in shower or bathtub | Reduces joint stiffness by allowing self-lubrication |
| Apply local heat with paraffin dip or compress; use cold packs as needed | Reduces pain and increases joint mobility |
| Provide information about the Arthritis Foundation of Australia | This information is helpful for individuals to access services and support groups |
| Referral to social worker | Helps with household work |
| Provide information about the disease process and its manifestations, prescribed medications with desired and adverse effects, and the importance of balancing rest and activity | Empowers the individual |

**Evaluation**

Verbalises effective pain management strategies.
Uses assistive devices to minimise joint stress with ADLs.
Verbalises a plan to reduce responsibilities for home maintenance.
Expresses a willingness to plan rest breaks during the day.
Demonstrates understanding of the prescribed therapeutic regimen and its importance for both short- and long-term benefit.

## PROGRESS NOTE EXAMPLE 33.1

| | |
|---|---|
| 20/07/2015<br>1020 hrs | Nursing: Admitted Mrs Jones for pain management. GCS 15/15, PERLA and normal power upper and lower limbs. Nil focal neurology. Her vital signs were normal. Her liver function and renal function are within normal limits. She has been referred to social worker and occupational therapy for self-care adjustments and use of assistive devices. She has also been advised on the use of NSAIDs with the pharmacist. Nil other concerns identified.<br>***S. Stewart* (Stewart) EN** |

encouraged to express feelings openly, in an atmosphere of trust. The nurse should learn to listen actively to the individual, so that not only the verbal interactions are heard but any non-verbal cues are also detected and acted on (see Chapter 8). For example, individuals may deny pain or state that they are not experiencing much pain, but the body language and tone of voice may indicate otherwise. To promote peace of mind and to reduce anxiety, individuals should be provided with information about their illness, including expected pain and its management. Individuals should be aware that they have a right to pain relief and that various pain-relieving measures are available. It is important to prevent or reduce the cycle of pain–stress–anxiety–pain. A variety of nursing measures, some very simple, may help to minimise or alleviate pain (Table 33.5).

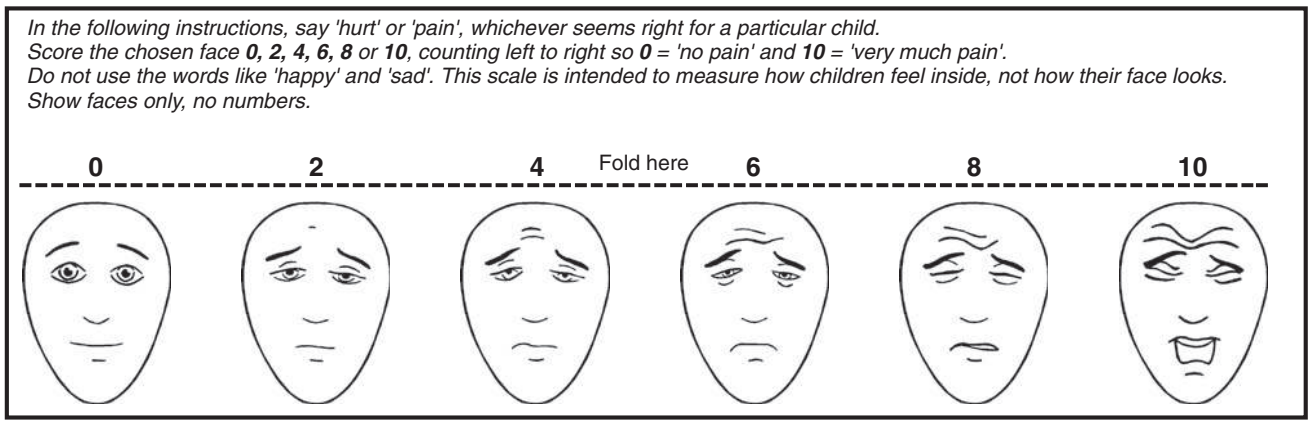

**Figure 33.6** Faces Pain Scale, Revised

*(Faces Pain Scale—Revised (FPS-R). www.iasp-pain.org/fpsr. Copyright © 2001, International Association for the Study of Pain®. Reproduced with permission)*

**CRITICAL THINKING EXERCISE 33.3**

It has been observed that pain in certain groups, especially children and the elderly, is not always well managed, and that these groups may be among the most under-treated for pain. Why do you think this may occur? What can the nurse do to improve this situation?

## Non-pharmacological therapy

Pain management and control may be achieved by a variety of supportive measures other than medication. Non-drug approaches to pain management may include the use of heat or cold, massage and psychological methods.

### Application of heat or cold

The general rule is that heat is for chronic pain while cold is for acute injuries. Heat applied to the skin causes dilation of the local blood vessels and, as a result, may improve the blood supply to an area, relax muscles and relieve spasm, promote healing and relieve pain. Cold applications may also be used to relieve swelling and pain. Cold has a numbing effect that helps to reduce pain in a body part. The use of heat and cold depends on the individual's preferences and hospital policy and if used should include education on potential risks and safe use (Brown et al 2015). Heat packs have been associated with burns, especially wheat or grain filled packs. The Therapeutic Goods Administration (TGA) advises consumers to follow manufacturer instructions and to use heat packs listed on the Australian Register of Therapeutic Goods (ARTG).

### Massage

Massage involves the manipulation of soft tissue and can increase circulation, reduce muscle tension, relax the individual and relieve pain. Cutaneous stimulation often acts to alter the individual's conscious awareness of pain. Aromatherapy and massage using essential oils may also be of benefit in some situations. Soothing touch and gentle rocking motion to promote contact, warmth and closeness may help to relax an infant in pain.

### Psychological methods

Various techniques may be used to promote general relaxation of the individual, and therefore reduce anxiety and relieve pain. Music and art may be used as a sensory distraction or as a soothing method of reducing stress (Brown et al 2015). Other methods of distraction may be helpful to lessen the individual's awareness of painful stimuli, such as encouragement of concentration on slow, deep, rhythmic breathing exercises, or even guided imagery, singing, praying or tapping (Brown et al 2015). Several other methods of non-pharmacological pain management may be prescribed or undertaken. While it is not the role of the nurse to implement these, they may form part of the overall treatment plan, so an awareness of them is required.

### Acupuncture

Acupuncture, which is a form of traditional Chinese medicine, involves the insertion of fine needles into the skin at selected points on the body. It may be used to manage both acute and chronic pain, and there are several theories about how it relieves pain. Some authorities believe that acupuncture achieves analgesia by stimulating the release of endorphins, while others believe that it stimulates the large diameter nerve fibres that effectively close the gate and block pain impulses (Amir et al 1980; Bowen et al 1987; Belvisi et al 2009; Brown et al 2015; Bryant & Knights 2014).

### Transcutaneous electrical nerve stimulation

A specific technique of peripheral nerve stimulation, **transcutaneous electrical nerve stimulation (TENS)**, involves the application of electrodes to trigger points on the skin (Figure 33.8). The electrodes are activated by a battery-powered device to produce a tingling or vibrating sensation in the painful area. The impulses block the transmission of pain impulses to the brain (Brown et al 2015; Bryant &

**Figure 33.7** The Abbey Pain Scale
*(Abbey et al 2004)*

**TABLE 33.5 | Nursing measures to improve comfort**

| Nursing action | Rationale |
|---|---|
| Change of position | At times pain can result from, or be increased by, an uncomfortable posture. The individual should be assisted into a more comfortable position, with appropriate pillows arranged for support. The addition of a sheepskin underneath the back and buttocks may enhance comfort, and the bedclothes should be arranged to meet individual needs. It is important to ensure that the individual's body is in alignment, and the placement of a pillow under a painful limb may further enhance comfort. Correct positioning should ensure that there is no undue stress on incisions, and no tension applied to any tubing present (surgical drain tube or urinary catheter) |
| Meet general comfort needs | The nurse should ensure that all basic comfort needs are provided for; for example, discomfort and pain can result from a distended bladder. The individual may feel more comfortable if the face and hands are washed, hair brushed and teeth cleaned. If not contraindicated, a drink of the individual's choice should be offered. A warm drink in the evening may help to promote settling and sleep. Comfort needs for an infant in pain may include containment (swaddling) to increase feelings of security, and the pacifying effect of non-nutritive sucking |
| Gentle handling | When the individual is being assisted to move, the nurse should ensure that any movements are made gently. Pain is usually increased on movement, so individuals should be permitted and assisted to move at their own pace. As the individual moves, the nurse should ensure that painful areas are supported. An incision can be supported during movement; the individual or the nurse may place a hand over the incision to 'splint' it, or hugging a pillow may provide support on movement |
| Promote rest and sleep | Pain is very tiring, and fatigue increases reactions to pain; therefore, the nurse should ensure that the individual receives adequate and effective rest and sleep. Measures should be implemented during the day, as well as during the night, to facilitate rest; for example, the blinds may be drawn, and all care planned so that repeated interruptions and visits to the individual are avoided. Relaxation reduces anxiety, can enhance the effect of pain relief and facilitates sleep. The individual can be taught and encouraged to practise one of several relaxation techniques, as described later. If appropriate, and with consent, gentle massaging of the neck and back may relieve tension and facilitate relaxation |
| Check dressings and splints | Any dressing, bandage or splint should be checked at regular intervals and, within medical orders, changed or adjusted if necessary. A poorly positioned dressing can irritate a wound, a bandage may be too tight or an inappropriately applied or positioned splint may cause pressure and pain |
| Adapt the environment | The nurse should consider the immediate surroundings and adapt them according to individual needs. While some individuals experiencing pain may prefer to rest in a darkened room, others may prefer that their room is bright and cheerful. An individual may choose to attempt to distract themselves from their pain by watching television or listening to music, or may prefer to lie quietly. The presence of fresh flowers in the room may be a source of pleasure or irritation, and some individuals may find it comforting if there are appropriate paintings on the wall. The nurse should ensure adequate privacy and appropriate ventilation and heating, while adapting the environment to meet individual needs |
| Implement prescribed therapy | The nurse may be responsible for being with the individual during therapy, or may be involved in its implementation. Whenever therapy is prescribed, the nurse should implement measures to promote the individual's comfort and safety. The nurse should also monitor the individual to assess the efficacy of prescribed therapy, and report and document all observations |

Knights 2014). TENS may be indicated for many people, especially those with joint or bone pain. It is normally well tolerated, although skin irritation is sometimes experienced. It should not be used for individuals with cardiac pacemakers as it can interfere with pacemaker function.

## Hypnosis

Hypnotic analgesia may be achieved when a person enters a state of self-induced relaxation and concentration. During hypnosis, cognitive thinking is bypassed, allowing the individual to become more susceptible to suggestion. The individual enters a passive trance-like state, which is induced by a trained hypnotist, who may use the repetition of words and gestures. Susceptibility to hypnosis varies from person to person.

## Biofeedback

Biofeedback is a method that assists a person to become aware of, and subsequently to control, certain autonomic physiological responses, such as blood pressure, muscle

**CRITICAL THINKING EXERCISE 33.4**

Discuss the rationale/benefits for use of non-pharmacological pain management strategies for:
1. A young child
2. An adolescent
3. An older adult

**Figure 33.8** A transcutaneous electrical nerve stimulation (TENS) device
*(Brown et al 2015)*

tension and heart rate. Through concentration, and with the aid of instruments, the individual can learn to control and modify these processes, which are normally involuntary. The technique of biofeedback is more effective when accompanied by other relaxation techniques.

### Placebo therapy

Placebo therapy involves the administration of inactive substances (such as lactose pills or sterile water), and may be effective for certain people in certain situations. It is thought that placebos relieve pain or other symptoms by causing the body to release endorphins, combined with an expectation that the treatment will be effective (McCaffery & Arnstein 2006). The use of placebos involves a degree of recipient deception and poses many ethical and moral problems (McCaffery & Arnstein 2006). Its use in mainstream pain management should generally be limited.

### Pain clinics

People who experience chronic pain may be helped by attending a multidisciplinary pain clinic. Pain clinics commonly attempt to reduce use of pain medication, help individuals resume normal activities and restore a positive self-image. Management includes a thorough physical and psychological examination before a program is designed for the individual. Approaches to pain management in a pain clinic include psychological counselling, acupuncture, TENS or any of the other methods of pain relief. The individual is taught alternative ways of carrying out the activities of daily living so that associated pain is minimised.

## Pharmacological therapy

Medications prescribed by a medical officer to relieve pain may be either local or systemic, analgesic or co-analgesic. The nurse's role in relation to medication administration involves assessment and monitoring of individual responses to therapeutic treatments ordered. When medications have been prescribed, it may be within the nurse's scope of practice to administer them. Figure 33.9 is a flow chart for pharmacological management of pain.

### Nerve block

Peripheral nerve transmission of pain can be interrupted temporarily by the injection of a local anaesthetic, or permanently by injecting a sclerosing agent into the nerve root area. As the latter method can result in destruction of tissue adjacent to the injected area, other pain-relieving methods are usually preferred, with this being an option in cases when other pain-relieving methods have been unsuccessful.

### Counter-irritants

Counter-irritants, such as mentholated ointments and heat rubs, applied locally to the skin, can produce an inflammatory response, thereby relieving congestion in underlying tissues and reducing pain from the original source.

### Radiotherapy and/or chemotherapy

The pain associated with malignant disease may be relieved by radiation, which shrinks a tumour that is actively causing compression in an area. Chemotherapy (also considered as pharmacological therapy) may sometimes control pain if the tumour is sensitive to the medications used.

### Analgesic

**Analgesic** or pain-relieving medications may be mild (e.g. non-narcotics such as acetylsalicylic acid (aspirin) or paracetamol) or strong (e.g. narcotics such as morphine or oxycodone). Analgesics may be administered via a number of routes, including orally, by injection or infusion (intramuscularly, subcutaneously, intravenously or into the epidural space), or in some instances they may be applied topically (via creams or patches onto the skin) (see Chapter 24). The type, dosage and route of analgesic medications given will be prescribed by the medical officer according to the individual's needs. Good pain control, especially in postoperative and chronic pain situations, is achieved by administering appropriate amounts of the most effective medication at regular intervals, thus avoiding the experience of peaks and troughs of pain. In some cases analgesia is ordered on a 'PRN' (as required) basis, which may be appropriate for intermittent episodes of pain. Clinical Interest Box 33.5 provides a caution related to pain and the older adult.

Analgesics are frequently given intravenously for severe pain, either as a bolus dose (a concentrated dose given in a short period of time) or, preferably, as an infusion, which has the advantage of avoiding repeated injections and establishes

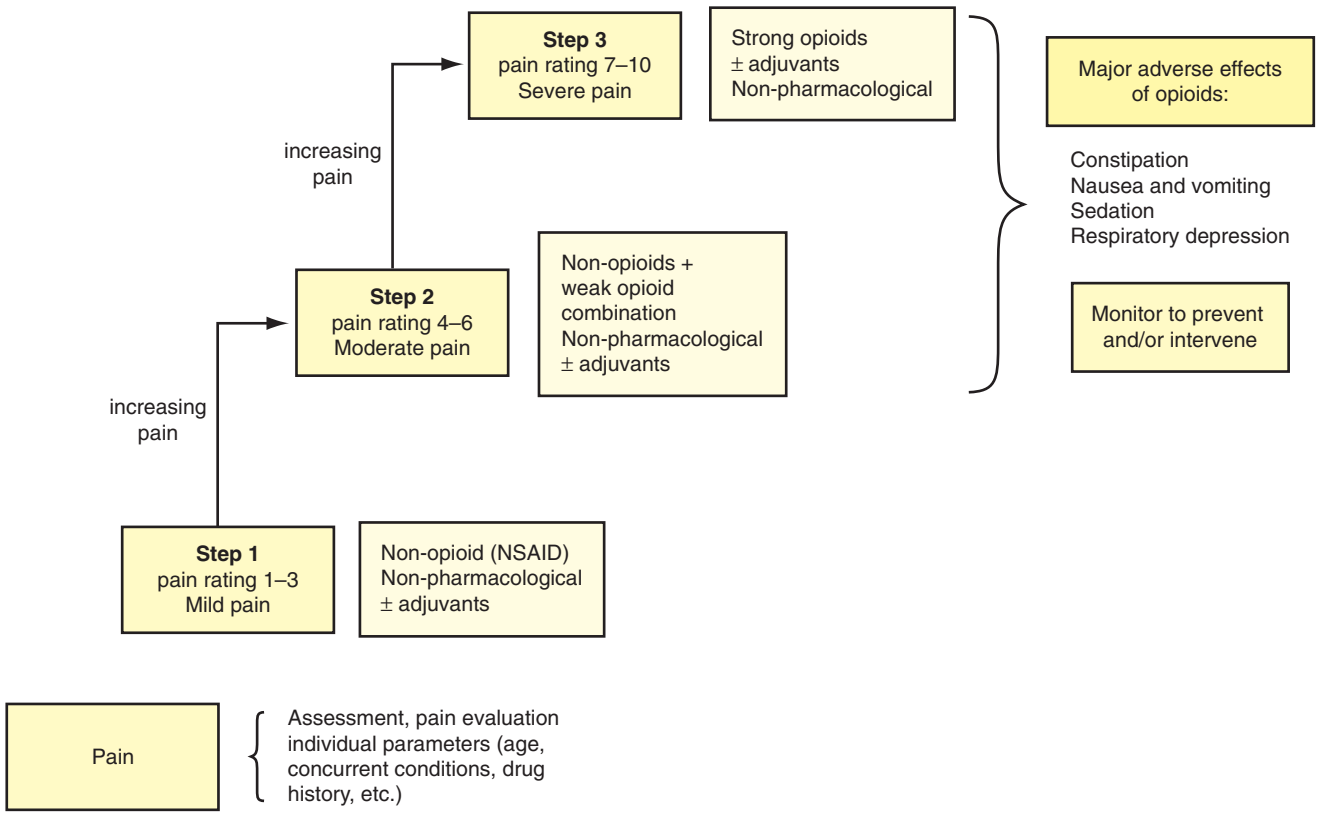

**Figure 33.9** Flow chart for pharmacological management of pain
*(Bryant & Knights 2014)*

## CLINICAL INTEREST BOX 33.5
## Pain and the older adult

Pain is a prevalent in older people and has significant debilitating outcome. This is exacerbated by the existence of multiple commodities and polypharmacy. Nursing older people requires an understanding of the pharmacokinetics and pharmacodynamics of analgesics in older people and the careful monitoring of side effects. Older people are susceptible to confusion if given higher doses of narcotics, for example.

*(Bryant & Knights 2014)*

a constant blood level of analgesic drug, thus avoiding considerable pain between doses. This can be done using an intravenous pump controlled by the individual (patient-controlled analgesia or PCA) or a programmable pump with a catheter placed in the epidural space.

**Patient-controlled analgesia (PCA)** uses intravenous opioids and a programmable pump. A dose of drug is delivered each time the individual pushes a button, within limitations set by the doctor. This allows the individual to choose how often and when to receive the medication, and often enables them to establish a greater sense of control over pain management.

**Epidural** analgesia is an alternative method of pain control that uses a fine catheter inserted into the epidural space of the spine, again connected to a programmable pump. This method of pain relief is effective in controlling pain while allowing the individual to remain alert. It is frequently used in obstetrics, postoperatively and sometimes in individuals with cancer. The primary responsibility of caring for individuals with either narcotic or epidural infusions remains with the Registered Nurse (RN). Nonetheless, response to medications and evaluation of pain control measures are within the scope of practice of all nurses. Table 33.6 outlines nursing measures for an individual with an **epidural infusion**.

**Co-analgesic** medications, while not true analgesics in the pharmacological sense, act to augment pain relief, either alone or in combination with analgesics. Examples of medications that may be used as co-analgesics are corticosteroids and non-steroidal anti-inflammatory drugs, both of which may act to decrease inflammation and oedema (Bryant & Knights 2014). The use of anti-anxiety drugs or drugs producing muscle relaxation may also be incorporated into a treatment plan. Sometimes a dose of co-analgesic medication together with an analgesic can produce greater pain relief than a higher dose of an analgesic alone. Table 33.7 outlines the nursing considerations for an individual receiving specific analgesics and Table 33.8 outlines the actions of analgesics.

## TABLE 33.6 | Nursing care for individuals with epidural infusions

| Goal | Actions |
|---|---|
| Prevent catheter displacement | Secure catheter (if not connected to implanted reservoir) carefully to outside skin |
| Maintain catheter function | Check external dressing around catheter site for dampness or discharge (leak of cerebrospinal fluid may develop)<br>Use transparent dressing to secure catheter and to aid inspection<br>Inspect catheter for breaks |
| Prevent infection | Use strict aseptic technique when caring for catheter (see Chapter 31)<br>Do not routinely change dressing over site<br>Change infusion tubing every 24 hours |
| Monitor for respiratory depression | Monitor vital signs, especially respirations, per policy<br>Use pulse oximetry and apnoea monitoring |
| Prevent undesirable complications | Assess for pruritus (itching) and nausea and vomiting<br>Administer anti-emetics as ordered |
| Maintain urinary and bowel function | Monitor intake and output<br>Assess for bladder and bowel distension<br>Assess for discomfort, frequency and urgency |

*(Crisp et al 2013)*

## TABLE 33.7 | Nursing considerations for an individual receiving analgesics

| Medication | Nursing considerations |
|---|---|
| Salicylates | Medications must be given with food as they can cause GIT bleeding<br>Individuals should also be monitored for bleeding as the medications decrease platelet aggregation |
| Paracetamol | Nurses should make sure the dosage limits are maintained as paracetamol can cause liver toxicity. Care should be taken not to overdose as there are many pharmaceutical preparations that can contain paracetamol, such as Panadeine Forte and Di-Gesic |
| NSAIDs | Medications must be given with food as they can cause GIT bleeding<br>Individuals should also be monitored for bleeding as the medications decrease platelet aggregation |
| Morphine-related products | Monitor vital signs as these medications can cause respiratory depression and hypotension<br>Nurses should also monitor bowels and encourage fluids and fibre as these medications can cause constipation |

*(Adapted from Bryant & Knights 2014)*

## TABLE 33.8 | Action of analgesics

| Drug category | Example | Site of action | Mechanism |
|---|---|---|---|
| Paracetamol | Paracetamol | Damaged cells | Decrease production of prostaglandins from cell responding to inflammation |
| Non-steroidal anti-inflammatory drugs (NSAIDs) | Aspirin<br>Ibuprofen<br>Indomethacin<br>Piroxicam<br>Ketorolac<br>Celecoxib | Damaged cells | Decrease production of prostaglandins from cell responding to inflammation |

**TABLE 33.8 | Action of analgesics—cont'd**

| Drug category | Example | Site of action | Mechanism |
|---|---|---|---|
| Narcotics | Codeine<br>Pethidine<br>Tramadol<br>Oxycodone<br>Morphine<br>Fentanyl | Brain | Bind to natural endorphin stimulant receptor in the brain. This depresses pain perception and can cause profound euphoria |
| Anaesthetics | Lignocaine<br>Ketamine | Brain and peripheral nerve fibres | Block perception and transmission pain |
| Antidepressants | Amitriptyline<br>Venlafaxine<br>Fluoxetine | Brain | Pain is associated with depression |
| Anticonvulsants | Carbamazepine<br>Gabapentin<br>Pregabalin | Brain | Block/modulate transmission of pain |
| Antiemetic | Metoclopramide<br>Ondansetron | Mainly brain but metoclopramide is also a prokinetic | Acute pain is associated with nausea and narcotics can also cause nausea and vomiting |

*(Adapted from Bryant & Knights 2014)*

## Summary

Pain, which is often a protective signal of actual or impending tissue damage, can be both an unpleasant physical sensation and an emotional experience. Each episode of pain is unique and subjective and it is important for the nurse to appreciate that 'pain is what the individual says it is'. Pain may be mild or severe, acute or chronic, physical or psychological.

Pain receptors transmit impulses along nerve fibres to the brain, where the impulses are perceived and interpreted. The body has some internal mechanisms that may be activated to help control pain and its perception, such as the gate control mechanism and the endorphin system.

The perception of pain varies with the individual; therefore, some people will experience pain much sooner and more intensely than others. Many factors influence an individual's reaction to pain, including age, gender, culture, and emotional state, history of pain, self-image, the time of day and the environment. Although each individual's behavioural reaction to pain is different, the physiological responses to acute pain are the same.

The nurse has a responsibility to assess an individual's pain in terms of site, time it occurs, duration, precipitating factors, type, intensity, associated signs and symptoms, body posture, vital signs and emotional manifestations.

The management of pain includes non-pharmacological and pharmacological therapy, and depends on each individual's individual needs. The nurse has a responsibility to eliminate or reduce painful stimuli and to plan and implement supportive nursing measures to help alleviate pain or to assist the individual to manage their pain.

### DECISION-MAKING FRAMEWORK EXERCISE 33.1

You are an Enrolled Nurse who has just commenced working in the Greenslopes Hospice. You have been asked to assist Craig with his breakfast. You notice that Craig has medications sitting on his tray in a cup. Craig tells you they are his pain-relief tablets and he likes to take them with his breakfast. He cannot take them on his own and asks you to assist him in taking them.

What action should you take? Use the decision-making framework to assist your decision utilising the following headings:

1. Identify individual need/benefit
2. Reflect on scope of practice and nursing practice standards
3. Consider context of practice/organisational support
4. Select appropriate, competent person to perform the activity

## Review Questions

1. What is pain?
2. What are the different types of pain?
3. Explain why individuals can feel pain in limbs that have been removed.
4. List potential nursing issues that could affect someone with chronic pain.
5. What are the nursing considerations for someone receiving a narcotic medication?
6. What is the difference between Panadol and aspirin? Explain the side effects of NSAIDs.
7. Why do we feel pain?
8. Explain why rubbing/massage can relieve pain.
9. If Individuals experience psychogenic pain should we dismiss it as attention seeking?
10. What would be the general psychosocial impact of chronic pain on a middle-aged individual?
11. How do age, culture or background and gender affect the individual's perception of pain?
12. What is the pain threshold?
13. How different would the perception of pain be in an individual who already suffers from chronic pain?
14. What is the appropriate assessment tool that could be used to assess:
    a. Children in pain
    b. Adult individuals who do not speak English
    c. An individual with dementia

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER
34

# Nursing assessment and management of sensory health

*Jodie Hughson*

## KEY TERMS

ageusia
anosmia
cacogeusia
chemoreceptors
convergence
diplopia
dysgeusia
hyperopia
hypogeusia
hyposmia
myopia
nystagmus
otalgia
parosmia
presbycusis
presbyopia
proprioception
refraction
tinnitus

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define key terms
- Describe the position and structure of each sense organ
- Describe the physiology of taste, smell, sight and hearing
- Describe the factors affecting sensory functions in the sense organs
- Describe the major manifestations of disorders of the eye and ear
- Describe diagnostic tests that may be used to assess eye and ear function
- Plan and implement nursing care for the person with altered sensory function

## CHAPTER FOCUS

The sensory abilities of taste, smell, touch, sight and hearing enable the person to 'sense' changes in their external and internal environments. This is an essential requirement for maintaining homeostasis so we can interact with the world around us (Crisp et al 2013). Perception of stimuli has its origin in the five special sense organs, which are adapted to receive specific stimuli: tongue (taste); nose (smell); skin (touch); eyes (sight); and ears (hearing and maintenance of balance). Receptors in the sensory organs pick up stimuli from the environment and transmit information to the brain via pathways in the nervous system. In the brain the information is processed and interpreted (Patton & Thibodeau 2014). A person's senses are essential for growth, development and survival. A person can initiate protective reflexes only if they can see or sense a change or danger. Sensory stimuli give meaning to events in the environment. Alterations in sensory function may lead to dysfunctions of sight, hearing, smell, taste, balance or coordination.

As the eyes and ears are the two major structures by which an individual receives information about the external environment, this chapter focuses on the care of these two organs. The eye is the means by which light is reflected from objects and travels to the retina so that an image is formed. Nerve endings in the retina transmit electrical impulses along the optic nerve to the brain for interpretation. The ear is the means by which soundwaves are collected and amplified. Nerve endings in the inner ear transmit electrical impulses along the auditory pathways to the brain for interpretation. The auditory system is also responsible for maintenance of balance (Patton & Thibodeau 2014).

## LIVED EXPERIENCE

I had a stroke at age 62 years and it has left me legally blind. I used to go to the car races every weekend but I can't do that anymore. When it first happened I felt like I had lost my independence and everything I used to love to do, but I have learnt to adjust and have found other interests and ways to maintain my independence. I wish I had lost any other sense but my sight, but now I listen to the car races and the football and I am enjoying these things again.

**Syd, 68 years old**

## CLASSIFICATION OF SENSE ORGANS

Sense organs can be classified as special and general sense organs. Special sense organs such as the eye and the ear are characterised as being large and complex organs, or having localised groups of special receptors for specific and specialised detection of stimuli. The general sense organs are for detecting stimuli such as pain and touch. They have microscopic receptors and are distributed throughout the entire body (see Table 34.1). An example of a general sense organ is the skin (Patton & Thibodeau 2014). Receptors in general sense organs are scattered over almost the entire body. The skin over different parts of the body will respond differently because of the differing numbers of touch receptors. Touch receptors are distributed closely together over the fingertips and far apart across the back and torso. Stimulation of some receptors will lead to the sensation of vibration, while others give the sensation of pressure, pain (pain receptors) or temperature (thermoreceptors).

Many general receptors are present in deep tissue; there are stretch receptors in your stomach that signal when it is full. There are important chemoreceptors in the aorta that detect changes in blood pH and carbon dioxide levels (Crisp et al 2013).

## ALTERED SENSES

People become accustomed to certain sensory stimuli and when these change, the individual may experience discomfort. Factors that contribute to alterations in behaviour are as follows.

### Sensory deprivation

Sensory deprivation is thought of as a decrease or lack of meaningful stimuli. Because of reduced stimulation, a person becomes more acutely aware of the remaining stimuli and often perceives these in a distorted manner. The individual often experiences alterations in perception, cognition and emotion.

### Sensory overload

Sensory overload generally occurs when a person is unable to process or manage the amount or intensity of sensory stimuli. Factors that can contribute to sensory overload are:

- Pain, dyspnoea and anxiety
- A noisy healthcare setting, intrusive diagnostic studies, contact with many strangers
- Nervous system disturbances, certain medication.

Sensory overload can prevent the brain from ignoring or responding to specific stimuli. Some signs of sensory overload can include feelings of fatigue, irritability, anxiety, disorientation, reduced cognitive function and inability to concentrate (Patton & Thibodeau 2014).

### Sensory deficits

A sensory deficit is impaired reception, perception, or both, of one or more of the senses. Impaired hearing and sight are sensory deficits. When only one sense is affected, other senses

## TABLE 34.1 | General sense organs

| Type | Main locations | General senses |
|---|---|---|
| **Free nerve endings** | | |
| (Naked nerve ending; several types exist)  | Skin and mucosa (epithelial layers) | Pain, discriminative touch, tickle and temperature |
| **Encapsulated nerve endings** | | |
| Bulboid (Krause) corpuscle | Skin (dermal layer), subcutaneous tissue, mucosa of lips and eyelids, and external genitals | Touch and possibly cold |
| Lamellar (Pacini) corpuscle  | Subcutaneous, submucous and subserous tissues; around joints; in mammary glands; and external genitals of both sexes | Pressure and high-frequency vibration |
| Tactile (Meissner) corpuscle  | Skin (in papillae of dermis) and fingertips and lips (numerous) | Fine touch and low-frequency vibration |
| Bulbous (Ruffini) corpuscle | Skin (dermal layer) and subcutaneous tissue of fingers | Touch and pressure |
| Golgi tendon receptor  | Near junction of tendons and muscles | **Proprioception** (sense of muscle tension) |
| Muscle spindle   | Skeletal muscles | Proprioception (sense of muscle length) |

*(Patton & Thibodeau 2014)*

may become more acute to compensate for the loss. However, sudden loss of eyesight can result in disorientation. When there is a gradual loss of sensory function, people often develop behaviours to compensate for the loss; for example, a person with gradual hearing loss in the right ear may unconsciously turn the left ear towards the speaker. Persons with sensory deficits are at risk of both sensory deprivation and sensory overload (Berman et al 2015).

## FACTORS AFFECTING SENSORY FUNCTION

A range of factors affect the amount and quality of sensory stimulation, including a person's developmental stage, culture, level of stress, medications, illness and lifestyle. These are outlined in Clinical Interest Boxes 34.1 and 34.2.

### CLINICAL INTEREST BOX 34.1 Factors that influence sensory function

**Age**

- Infants are unable to discriminate sensory stimuli. Nerve pathways are immature
- Visual changes during adulthood include presbyopia (inability to focus on near objects) and the need for glasses for reading (usually occurring from age 40–50)
- Hearing changes, which begin at age 30, include decreased hearing acuity, speech intelligibility, pitch discrimination and hearing threshold. Tinnitus often accompanies a hearing loss as a side effect of drugs. Older adults hear low-pitched sounds the best but have difficulty hearing conversation over background noise
- Older adults have reduced visual fields, increased glare sensitivity, impaired night vision and reduced accommodation, depth perception and colour discrimination
- Older adults have difficulty discriminating the consonants (*f, s, th, ch*). Speech sounds are garbled and there is a delayed reception and reaction to speech
- Gustatory and olfactory changes include a decrease in the number of taste buds in later years and reduction of olfactory nerve fibres by age 50. Reduced taste discrimination and reduced sensitivity to odours are common
- Proprioceptive changes after age 60 include increased difficulty with balance, spatial orientation and coordination
- Older adults experience tactile changes, including declining sensitivity to pain, pressure and temperature

**Medications**

- Some antibiotics (e.g. streptomycin, gentamicin) are ototoxic and can permanently damage the auditory nerve; chloramphenicol can irritate the optic nerve. Narcotic analgesics, sedatives and antidepressant medications can alter the perception of stimuli

**Environment**

- Excessive environmental stimuli (e.g. equipment noise and staff conversation in an intensive care unit) can result in sensory overload, marked by confusion, disorientation and the inability to make decisions. Restricted environmental stimulation (e.g. with protective isolation) can lead to sensory deprivation. Poor-quality environmental stimuli (e.g. reduced lighting, narrow walkways, background noise) can worsen sensory impairment

**Comfort level**

- Pain and fatigue alter the way a person perceives and reacts to stimuli

**Pre-existing illness**

- Peripheral vascular disease can cause reduced sensation in the extremities and impaired cognition. Chronic diabetes mellitus can lead to reduced vision, blindness or peripheral neuropathy. Strokes often produce loss of speech. Some neurological disorders impair motor function and sensory reception

**Smoking**

- Chronic tobacco use can cause the taste buds to atrophy, lessening the perception of flavours

**Noise levels**

- Constant exposure to high noise levels (e.g. on a construction job site) can cause hearing loss

**Endotracheal intubation**

- Temporary loss of speech results from insertion of an endotracheal tube through the mouth or nose into the trachea

*(Crisp et al 2013)*

## CLINICAL INTEREST BOX 34.2 Cultural considerations affecting sensory function

An individual's culture often determines the amount of stimulation that a person considers normal. The normal amount of stimulation associated with ethnic origin, religious affiliation and income level also affects the amount of stimulation an individual desires and believes to be meaningful.

It is important for nurses to be sensitive to what stimulation is culturally acceptable to each individual; for example, in some cultures touching is comforting, whereas in others it is offensive.

*(LeMone et al 2014)*

## ASSESSING SENSORY FUNCTION

Nursing assessment of sensory perceptual functioning includes:

- Nursing history: a guide to assessing a person's sensory perceptual functioning
- Mental status, including level of consciousness, orientation, memory and attention span
- Physical examination: the person's specific visual and hearing abilities; perception of heat, cold, light touch and pain in the limbs; and awareness of the position of body parts
- The person's environment: assess for quantity, quality and type of stimuli
- Social support network: the degree of isolation a person feels is significantly influenced by the quality and quantity of support from family and friends (Berman et al 2015).

Clinical Interest Box 34.3 provides further detail.

## CLINICAL INTEREST BOX 34.3 Interview to assess a person's sensory perceptual functioning

### Visual

- How would you rate your vision (excellent, good, fair or poor)?
- Do you wear glasses or contact lenses?
- Describe any recent changes in your vision.
- Do you have any difficulty seeing near or far objects?
- Do you have any difficulty seeing at night?
- Have you ever experienced blurred vision, double vision, spots moving in front of your eyes, blind spots, light sensitivity, flashing lights or halos around objects?
- When did you last visit an eye doctor?

### Auditory

- How would you rate your hearing (excellent, good, fair or poor)?
- Do you wear a hearing aid?
- Describe any recent changes in your hearing.
- Can you locate the direction of sounds and distinguish various voices?
- Do you experience any dizziness or vertigo?
- Do you experience any ringing, buzzing, humming or crackling noises or fullness in the ears?

### Gustatory

- Have you experienced any changes in taste (e.g. difficulty in differentiating sweet, sour, salty and bitter tastes)?
- Do you enjoy the taste of foods as you did previously?

### Olfactory

- Have you experienced any changes in your sense of smell?
- Do things (foods, flowers, perfumes, etc) smell the same as previously?
- Can you distinguish foods by their odours and tell when something is burning?
- Have you experienced any changes in appetite? (Changes in appetite may be related to an impaired sense of smell.)

### Tactile

- Are you experiencing any pain or discomfort?
- Have you experienced any decrease in your ability to perceive heat, cold or pain in your limbs?
- Do you have any numbness or tingling in your extremities?

### Kinaesthetic

- Have you noticed any difficulty in perceiving the position of parts of your body?

*(Berman et al 2015)*

**CRITICAL THINKING EXERCISE 34.1**

Pain and anxiety are two factors that contribute to sensory overload. Identify four (4) different nursing interventions that you could implement to help alleviate these contributing factors. Why do you think these will help?

# SPECIAL SENSE ORGANS

## The taste receptors

The chemical receptors (**chemoreceptors**) that generate the nervous impulses that result in the sense of taste are called the taste buds. Taste buds are scattered in the oral cavity, with most concentrated over the surface of the tongue and a few found on the soft palate and the inner surface of the cheeks. These chemoreceptors respond to substances present in food and generate nerve impulses that are transmitted to the brain for interpretation. The upper surface of the tongue is covered with small projections (papillae), some of which contain a taste bud. Each taste bud consists of sensory and supporting cells situated in the epithelium and opening into the surface through a small gustatory pore.

Between the cells of the taste bud lie the endings of afferent nerve fibres derived from several cranial nerves. Taste buds on the anterior two-thirds of the tongue connect with fibres of the facial (seventh cranial) nerve. Taste buds on the posterior one-third of the tongue are associated with the fibres of the glossopharyngeal (ninth cranial) nerve, while pharyngeal taste buds send impulses to the brain via the vagus (tenth cranial) nerve (Marieb 2015).

These taste buds can differentiate sweet, salty, sour and bitter stimuli. The tip of the tongue is the most sensitive to sweet and salty substances; the edges of the tongue are most sensitive to bitter substances. Substances must be in solution (saliva) so that they can reach every opening in a taste bud and stimulate the nerve ending. Molecules pass into solution on the surface of the tongue and combine with the surface membranes of the receptor cells. Transmitter substances are released, which evoke action potentials on the sensory nerve fibres. Fibres from the seventh, ninth and tenth cranial nerves carry the taste impulses via the brainstem to an area of the cerebral cortex where the taste is experienced (Patton & Thibodeau 2014).

The sense of taste is intricately linked with the sense of smell, and the sense of taste depends on stimulation of the olfactory receptors (see Figure 34.1). Both senses have a protective function; for example, in detecting substances that may be harmful. Interruption of the transmission of taste stimuli to the brain may cause taste abnormalities. Taste abnormalities may result from trauma, infection, vitamin or mineral deficiencies, neurological or oral disorders and the effects of drugs. Because tastes are most accurately perceived in a fluid medium, mouth dryness may interfere with taste. Alterations in taste may include **ageusia** (a complete loss of taste), **hypogeusia** (a partial loss of taste), **dysgeusia** (a distorted sense of taste) and **cacogeusia** (an unpleasant taste) (Daroff et al 2012).

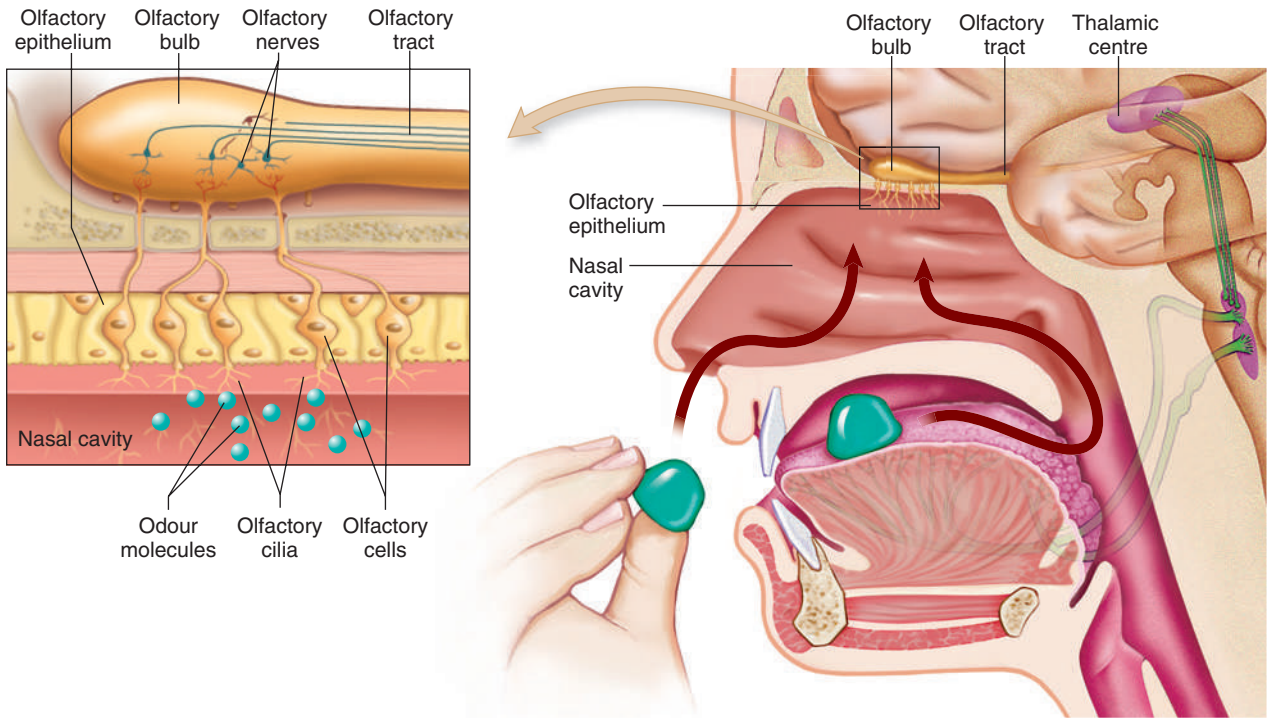

**Figure 34.1** Olfactory structures
*(Patton & Thibodeau 2014)*

## The smell receptors

The chemoreceptors responsible for the sense of smell are located in a small area of epithelial tissue in the upper part of the nasal cavity (Figure 34.2). These chemoreceptors are known as the olfactory receptors. They respond to airborne chemicals and generate impulses that are transmitted to the brain for interpretation. These receptors adapt quickly when exposed to an unchanging stimulus, which means that the person can become accustomed to an odour when constantly exposed to it.

Permanent alterations in the sense usually result when the olfactory neuroepithelium or part of the olfactory nerve is destroyed. Permanent or temporary loss can occur from inhaling irritants such as acid fumes that paralyse nasal cilia. Conditions such as ageing, Parkinson's disease and Alzheimer's disease may alter the sense of smell. Alterations in smell include **anosmia** (a total loss of sense of smell), **hyposmia** (an impaired sense of smell) and **parosmia** (an abnormal sense of smell) (Patton & Thibodeau 2014).

There is a close relationship between the sense of smell and the sense of taste, and therefore they are not always distinguishable. The sensations of smell and taste play an important part in stimulating the secretions of digestive juices (Berman et al 2015).

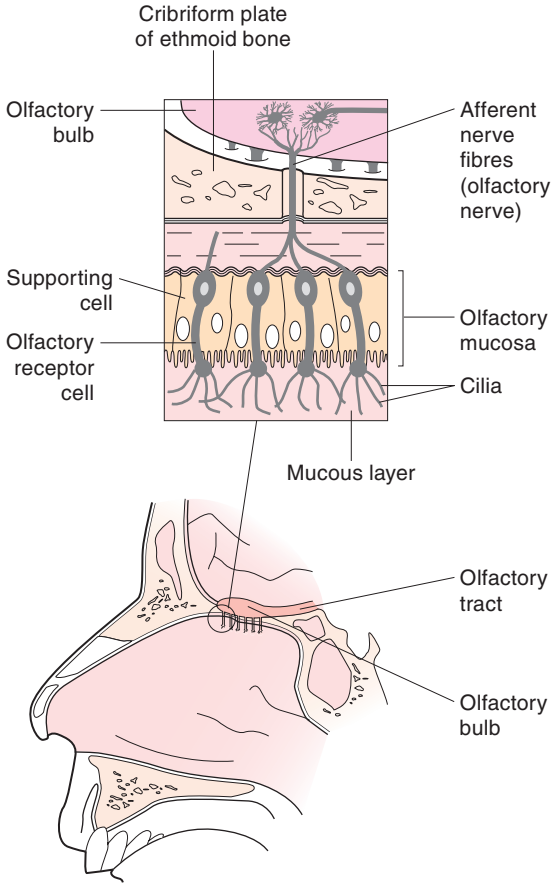

**Figure 34.2** The location and structure of the olfactory receptors in the nose

The nurse plays an important role in promoting the sense of taste and stimulating the sense of smell when caring for a person with altered sensory function. Health education regarding good oral hygiene practices will enhance taste perception. Discuss with the person which foods are the most taste appealing. If taste perception is improved, food intake and appetite will also improve. Taste perception is increased when food is seasoned. The person's sense of smell can be stimulated by pleasant aromas such as flowers, perfumes and food.

# THE EYE

## Structure of the eye

The eye is a spherical structure (Figure 34.3) about 2.5 cm in diameter, consisting of three principal layers (Patton & Thibodeau 2014).

### The outer layer

The outer fibrous layer consists of the sclera and the cornea, which is a transparent structure continuous with the sclera. About five-sixths of the outer surface is made up of a tough white opaque fibrous layer (sclera), while the cornea comprises the anterior one-sixth. Both the sclera and the cornea consist of layers of collagen fibres. In the cornea the fibres are regular in size and arrangement, which accounts for its transparency. The cornea functions as a refracting and protective layer through which light rays pass en route to the brain (Levin et al 2011).

### The middle layer

The middle pigmented vascular layer is composed of three structures: the choroid, the iris and the ciliary body. The choroid is a layer of tissue that lies between the sclera and the retina. It is composed largely of blood vessels, and contains highly pigmented cells that absorb light and prevent it from being reflected within the eyeball.

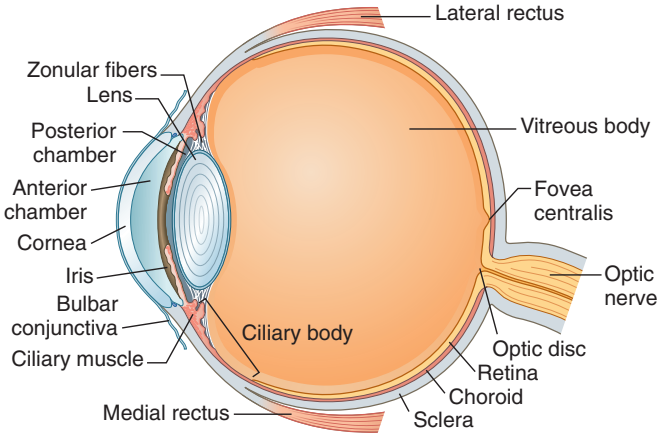

**Figure 34.3** The eye cut in horizontal section

*Ophthalmic Assistant, The Ninth Edition © 2013, Elsevier Inc. All rights reserved*

The iris is a pigmented circular membrane between the cornea and the lens, and gives the eye its colour. Sphincter and dilator muscles within the iris regulate the central aperture (the pupil). By either dilation or constriction of the pupil, the amount of light entering the eye is regulated. The pupil appears black because light rays entering the eye are absorbed by the choroid and are not reflected.

The ciliary body is a thickened area of the choroid, lying anterior to the choroid, extending to the root of the iris. A circular array of fibres stretches from the ciliary body to the lens to hold it in place. The ciliary body controls focusing of the lens and contains glands that secrete aqueous humour (Bruce 2011).

## The innermost layer

The innermost layer is a thin structure called the retina. The retina lines the inner wall of the posterior portion of the eyeball and is comprised of a number of layers. The two main layers are the pigmented layer (the outermost layer of the retina, lying next to the choroid, and whose cells contain melanin) and the rod and cone layer, which lies next to the pigmented layer and is highly sensitive to light.

Rods and cones (specialised nerve endings) are distributed as a tightly packed mass throughout the retina, except at a point where the ganglionic fibres converge to form the optic nerve. This area, which is about 1.5 mm in diameter, is termed the optic disc. Since it possesses no photosensitive cells it is also known as the 'blind spot'. The prime function of rods and cones is to absorb light. Rods can be stimulated by dim light and allow perception of shapes and movement in dim light. Rods also provide far peripheral vision. Cones are specialised for fine visual discrimination of colour perception. There are three types of cones: one type responds mostly to blue light, another to red light and the third type responds to green light (Patton & Thibodeau 2014).

In the centre of the retina is an oval yellowish area, the macula lutea, and in the centre of the macula lutea is a small depression, the fovea centralis. The photosensitive cells in the centre of the retina are more exposed to light than the rest of the retina; therefore, visual acuity is at its highest here (Levin et al 2011).

## Extraocular structure—accessory structures

Extraocular, or accessory, structures of the eye are portions of the eye outside the eyeball. These structures consist of the eyebrows, eyelids, eyelashes and lacrimal apparatus. The eyeball is anchored into position by several structures, including the extraocular muscles, the conjunctiva and the eyelids. The eyeball is surrounded and protected by a bony orbit, the eyebrow ridge and some fatty tissue. The eyeball is lubricated by the lacrimal glands.

The extraocular muscles bring about rotational movements of the eyeball. The muscles arise from the orbit and consist of four rectus muscles, which are attached to the sclera, and two oblique muscles. The oblique muscles are arranged so that for part of their length they lie around the circumference of the eyeball. The eyebrows and eyelashes are short coarse hairs that shade the eyes and protect the eyes from dust and sweat. The eyelids consist of connective tissue covered by skin and lined with mucous membrane. The lining is reflected over the eyeballs, and is called the conjunctiva. The eyelids protect the eye from foreign bodies and excessive light, as well as distributing tears by blinking (Patton & Thibodeau 2014).

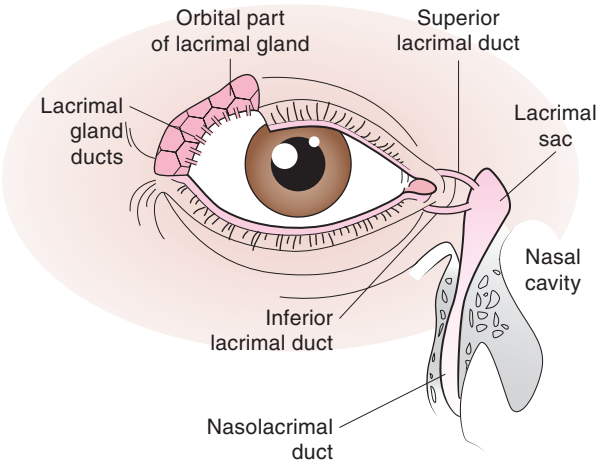

**Figure 34.4** The lacrimal apparatus of the eye

The lacrimal apparatus consists of the lacrimal gland, which is situated over the eye at the upper outer corner and secretes tears, which constantly wash over the conjunctiva (Figure 34.4). Tears leave the gland via several small ducts, and pass over the front of the eye eventually draining into the lacrimal sac, which is the expanded end of the nasolacrimal duct. Tears are secreted on to the anterior surface of the eyeball and are spread over it by the blinking movements of the eyelids. An antimicrobial substance in tears protects the eyes against microorganisms. Excess tears drain down the nasal cavity. The lacrimal glands are stimulated in response to chemical and mechanical irritants, thus producing tears to wash away irritants. Tears may also be produced as a result of emotion such as sadness or happiness (Hendry et al 2012).

## The refractive media

The refractive media are the transparent parts of the eye, and have the ability to bend light rays at the surfaces of two transparent media. The refractive media are the cornea, the lens, the aqueous humour and the vitreous humour. The cornea functions as a refracting and protective layer through which light rays pass en route to the brain (Levin et al 2011).

The lens is a transparent, biconvex encapsulated structure suspended from the ciliary body posterior to the iris. The lens is an elastic structure and this allows its shape to change when the eye is focused. The function of the lens is to refract (bend) light rays and to focus them on the retina.

Aqueous humour is a clear watery fluid that fills the cavities around the lens. These cavities are called the anterior and posterior chambers. Aqueous humour is derived from the plasma in the capillaries of the ciliary body, and passes into the posterior chamber. It then passes forwards through the

pupil to the anterior chamber, where it is absorbed into the ciliary veins. The rate of secretion and re-absorption is balanced so that intraocular pressure is regulated. Aqueous humour serves as a refractory medium and provides nutrients to the lens and cornea (Hendry et al 2012).

Vitreous humour is a clear jelly-like substance that fills the intraocular space from the posterior lens to the retina. Because it does not regenerate, any significant loss of vitreous humour—for example, as a result of injury to the eye—may distort other ocular structures. Vitreous humour helps to maintain the shape of the eyeball, helps keep the retina in position and helps with the refraction of light rays (Marieb 2015).

## The physiology of sight

Light travels from its source to various objects, where it undergoes reflection. This reflected light can then travel towards the eye, where it passes through the cornea, aqueous humour, the lens and the vitreous humour, before forming an image on the retina. Nerve endings in the retina transmit electrical impulses along the optic nerve to the brain. A coordinated process of refraction, accommodation, regulation of pupil size and convergence makes normal binocular vision possible (Patton & Thibodeau 2014).

### Refraction

**Refraction**, or bending of light rays, occurs as the light waves pass through the cornea, aqueous humour, the lens and the vitreous humour. At the lens the light is bent so that it converges at a single point on the retina (Hendry et al 2012).

### Accommodation

Accommodation is the process whereby the curvature of the lens is altered so that the eye is able to focus light from objects at different distances. As an object moves closer to the eye the curvature of the lens increases so that the image remains in focus on the retina (Crisp et al 2013).

### Regulation of pupil size

The diameter of the pupil influences image formation, and the muscles of the iris respond to changes in light intensity. An increase in light intensity initiates constriction of the pupil, whereas a decrease in light intensity causes dilation of the pupil. Adjustment of pupil size therefore regulates the amount of light entering the eyes. Too much light may damage the retina, and too little fails to stimulate it (Patton & Thibodeau 2014).

### Convergence

**Convergence** is the medial movements of the two eyeballs so that they are both directed towards the object being viewed. Convergence allows light rays to fall and stimulate two identical spots on the retinas, resulting in the perception of a single image.

After an image has been formed on the retina by the processes of refraction, accommodation, regulation of pupil size and convergence, light impulses are converted into nerve impulses by the rods and cones. The light breaks down the photosensitive chemical in either rods or cones, which stimulates electrical impulses to the brain for interpretation.

Nerve impulses travel from the retina along the optic nerve. The optic nerve emerges from the back of the eyeball and passes to the optic chiasma, an area at the base of the brain.

The fibres then form the left and right optic tracts, which continue to the visual areas of the brain in the occipital lobes. Here, further processing occurs so that the image is given meaning (Trattler et al 2012).

# DISORDERS OF THE EYE

Healthy vision requires three processes:

1. Formation of an image on the retina (refraction)
2. Stimulation of rods and cones
3. Conduction of nerve impulses to the brain.

Normal eye function can be altered by a malfunction of any of these processes. Some of the pathophysiological causes of disruption of eye function can be congenital, degenerative, infectious, neoplastic or traumatic. The effects may be mild and temporary, severe or permanent. Disorders of vision include alterations in visual acuity, ocular movement, accommodation, refraction and colour vision (Berman et al 2015).

## Refraction disorders

Focusing a clear image on the retina is essential for good vision. In the normal eye, light rays enter the eye and are focused into a clear, upside-down image on the retina. The brain rights the image in our conscious perception but cannot correct an image that is not sharply focused. If the eyeballs are elongated, the image focuses in front of the retina, giving the retina a fuzzy image; this is known as **myopia** or nearsightedness. This can be corrected by refractive eye surgery or by using contact lenses or glasses. If our eyeballs are shorter than normal, the image focuses behind the retina, also producing a fuzzy image; this condition is known as hypermetropia, **hyperopia** or farsightedness. (See Figure 34.5.) This can also be corrected by eye surgery or glasses (The Fred Hollows Foundation 2015).

As we age we develop an inability to focus the lens properly; this is known as **presbyopia**, and is the reason most people once they pass through middle age require reading glasses. The lens becomes firm and loses its elasticity; the ageing lens loses its ability to focus light rays and near objects appear blurred. People may also state that they are experiencing 'halos' which are coloured rings encircling bright lights, caused by alteration in the ocular media. Small moving spots or flecks seen before the eyes are commonly called floaters, and may be due to the ageing process as the vitreous material degenerates. Floaters may also be caused by retinal laceration, diabetic neuropathy or hypertension. Visual changes also include double vision, or **diplopia**. Photophobia may be caused by inflammation of the cornea or the iris and ciliary bodies. An irregular, uneven curvature of the cornea or lens,

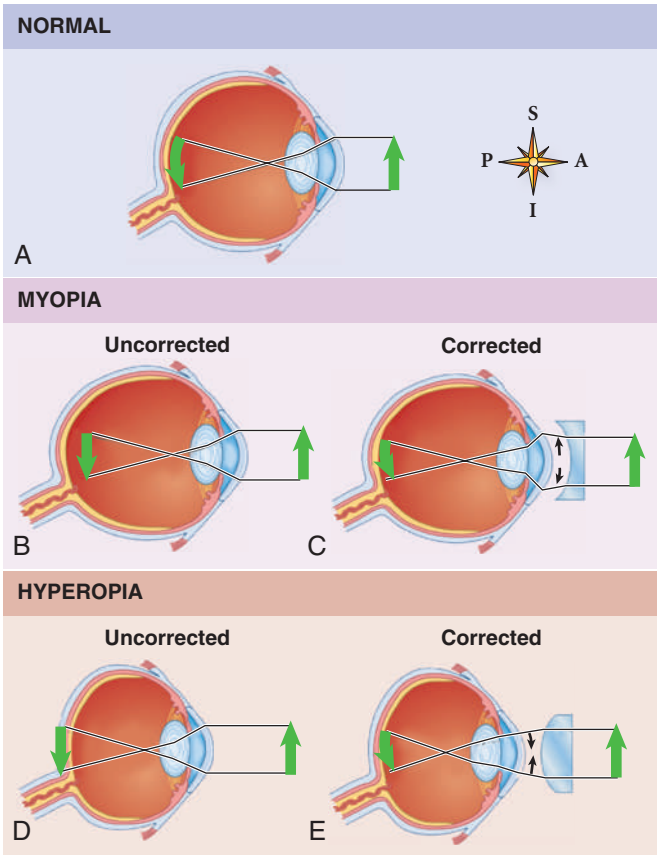

**Figure 34.5** Structure & function of the body
*By Kevin T. Patton, Gary A. Thibodeau. (2016, 15th edition)*

astigmatism, can also be corrected by glasses (Patton & Thibodeau 2014).

### Cataracts

There are three classifications of cataracts: congenital, traumatic and age-related. By definition a cataract is a clouding of the lens in the eye. Cataracts generally develop bilaterally, with each progressing independently, with the exception of congenital and traumatic cataracts. Causes include the ageing process, inflammation, malignancy, metabolic factors, toxins, heredity and trauma. Manifestations generally begin with a decrease in visual acuity. The person complains of not being able to see clearly. They may also complain of blurred vision, glare and a decrease in colour perception. As the cataract progresses, the pupil appears milky white. Surgical removal of the cataract from the lens is indicated when activities of daily living are affected (Trattler et al 2012).

See Nursing Care Plan 34.1 and associated Progress Note Example 34.1 for an individual admitted for cataract surgery.

## Infectious disorders

Infections of the eye and its associated structures also have the potential to impair vision, sometimes permanently.

### Stye

A hordeolum (stye) is a localised staphylococcal infection of a sebaceous gland of the eyelid. This gland is the base of a hair follicle or eyelash. Manifestations include localised inflammation, swelling and pain (Trattler et al 2012).

### Blepharitis

Blepharitis is inflammation of the eyelid margins. It may be caused by bacterial infection or an allergic reaction to smoke, dust or chemical. Seborrhoea, a disorder of the sebaceous gland, may also cause blepharitis. Manifestations include itching, burning, redness of the eyelid margins, chronic conjunctivitis and yellow purulent discharge crusts on the lashes (Trattler et al 2012).

### Conjunctivitis

Conjunctivitis is the inflammation of the conjunctiva and may be caused by excessive exposure to wind, sun, heat, cold, allergens or chemicals, or by bacterial, viral or fungal infection. Manifestations include itching, burning, excessive tearing and pain. Allergic conjunctivitis may cause considerable swelling (Trattler et al 2012).

### Trachoma

Trachoma is a chronic form of keratoconjunctivitis that causes permanent damage to the cornea which, if untreated, can result in blindness. The condition results from infection by *Chlamydia trachomatis* and is associated with poor personal and community hygiene and lack of available clean water. There is a high incidence of trachoma in Australian Indigenous people. Manifestations, which may not become apparent for years, are similar to those for severe conjunctivitis. There is corneal inflammation and scarring, due to the eyelids turning inwards, which causes the lashes to rub against the cornea. Severe corneal scarring may result in blindness (The Fred Hollows Foundation 2015).

### Keratitis

Keratitis is inflammation of the cornea and is frequently caused by trauma or infection. It usually affects only one eye, and frequently presents as a secondary infection to an upper respiratory tract infection involving cold sores (herpes simplex infection). Manifestations include opacity of the cornea, irritation, excessive tearing, blurred vision, redness and photophobia (Trattler et al 2012).

### Orbital cellulitis

Orbital cellulitis is an acute infection of the orbital tissues and eyelids that does not involve the eyeball. The condition is generally secondary to infection of nearby structures. If orbital cellulitis is not treated, the infection may spread to the sinuses and meninges. Manifestations include unilateral eyelid oedema, inflammation of the orbital tissues and eyelids, pain, impaired eye movement and purulent discharge from indurated areas (Tabbara et al 2015).

## NURSING CARE PLAN 34.1

**Assessment:** Mrs Tan has been admitted for cataract extraction and intraocular lens replacement
**Issue/s to be addressed:** Health education regarding the upcoming procedure
Poor vision
Discharge planning
**Goal/s:** Mrs Tan verbalises understanding of upcoming surgery and expected outcomes
Mrs Tan has daily needs assisted as required
Mrs Tan is given appropriate postoperative care
Mrs Tan understands the importance of going home to a supportive environment; family/support persons are informed

| Care/actions | Rationale |
|---|---|
| Provide preoperative health education to ensure the individual understands the procedure. Ensure this is culturally appropriate and offer verbal and written instructions in language of choice. If required obtain assistance from interpreter service | Mrs Tan will feel less anxious and more prepared for surgery if all aspects of the surgery are explained in the best mode for her |
| Offer Mrs Tan assistance with daily activities including hygiene and nutrition. Ensure layout of room is explained, ensure call bell is accessible and any excess furniture or belongings are removed. Provide any nutritional aids or support such as explaining what food is where on the plate and bright-coloured utensils | Due to cataracts Mrs Tan has poor vision and being in an unfamiliar environment will require some assistance with activities of daily living. Keeping environment clutter free and explaining the layout will minimise the risk of injury. Maintaining nutrition while in hospital will aid in recovery |
| Postoperative observations as per surgeon's instructions. Perform eye care as per surgeon's instructions. Mobilise as soon as able | Post-anaesthetic observations and mobilisation are required to ensure there are no adverse side effects |
| Provide Mrs Tan and her carers with culturally appropriate information on what to expect post discharge. Have transport arranged for her on discharge and ensure she has support at home for the initial postoperative period | Being prepared for discharge prevents risks of re-admission as Mrs Tan understands what to expect once she is at home. Ensuring transport will ensure Mrs Tan's safety and to expedite discharge |

**Evaluation**

Mrs Tan and her family/carers verbalise a thorough understanding of the procedure and she appears and purports to be relaxed and comfortable.
Mrs Tan is able to perform all her required daily activities while in hospital and expresses her satisfaction.
Mrs Tan recovers from surgery as per expected outcome without any complications.
Mrs Tan and her family verbalise their understanding of what to expect on discharge and provide details of transport mode home.

## PROGRESS NOTE EXAMPLE 34.1

21/10/2015
0700 hrs

Nursing: Mrs Tan has been admitted for removal of cataracts and insertion of intraocular lens. She is visually impaired. She requires assistance with her daily activities and meals. She has been seen by the surgeon—refer to notes. She has expressed some nervousness about her operation. A thorough explanation of the procedure has been provided to her and her family. To assist in her adjustment staff need to spend time explaining their activities to Mrs Tan before they are carried out.

***J. Hughson*** **(Hughson) EN**

## Disorders of the retina

Damage to the retina impairs vision because even a well-focused image cannot be perceived if some or all of the light receptors do not function properly; for example, in retinal detachment when part of the retina falls away from the tissue supporting it. The condition can result from normal ageing, eye tumours or a sudden blow to the head. Common warning signs are:

- Sudden appearance of floating spots
- Odd 'flashes of light' that appear when the eye moves.

If left untreated the retina may detach completely and can cause total blindness (Patton & Thibodeau 2014).

### Diabetic retinopathy

Diabetes mellitus may cause a condition known as diabetic retinopathy which causes small haemorrhages in retinal blood

vessels to disrupt the oxygen supply to the photoreceptors. The eye responds by building new, but abnormal, vessels that block vision and which may cause detachment of the retina (Trattler et al 2012). See Clinical Interest Box 34.4 for more information on diabetic retinopathy.

## Glaucoma

Another common condition that can damage the retina is glaucoma. This is excessive intraocular pressure caused by abnormal accumulation of aqueous humour. As fluid pressure against the retina increases, blood flow to the retina slows. The reduced blood flow causes degeneration of the retina and thus a loss of vision. There are various forms of glaucoma: primary open-angle, primary closed-angle, secondary, congenital and absolute. Generally speaking, glaucoma progresses slowly and may or may not be symptomatic. It rarely affects persons under 40 years of age. The condition may be caused by over-production of aqueous humour or obstruction to the outflow of aqueous humour, both of which result in accumulation of fluid and a rise in intraocular pressure. Manifestations of primary open-angle glaucoma are gradual and progressive; the person is unable to perceive changes in colour and experiences blurred vision and persistent aching eyes. Manifestations of primary closed-angle glaucoma occur suddenly. The person experiences intense pain, loss of vision, nausea and vomiting. The affected eye appears red, and the pupil is fixed, dilated and unresponsive (Hendry et al 2012).

The manifestations of secondary glaucoma are similar to those of the primary form depending on the cause. Congenital glaucoma is a rare disorder generally associated with other abnormalities, and manifests as a large-diameter cornea. Absolute glaucoma is the end result of any uncontrolled glaucoma resulting in blindness (Trattler et al 2012).

Clinical Interest Box 34.5 provides information on glaucoma prevention and preservation of sight.

## Degenerative diseases of the retina

Macular degeneration is the most common cause of untreatable blindness in developed countries. It is becoming more common throughout the world as the average age of the population increases. Macular degeneration is caused by degenerative changes in the central part of the retina. The exact cause of the degeneration is unknown, but the risk of developing this condition increases with age after reaching 50 years. Other risk factors are cigarette smoking and a family history of the disorder.

Manifestations include loss of central vision, and activities that require fine detailed vision becoming impossible. The disease usually develops slowly and painlessly, and both eyes are generally affected. Vision may be improved in some cases by laser surgery. In extreme cases, it can cause legal blindness; however, most people usually retain good peripheral vision (The Fred Hollows Foundation 2015).

## CLINICAL INTEREST BOX 34.4 Diabetic retinopathy

Diabetes is becoming more common throughout the world, particularly in the developing world, where lifestyle and diet are rapidly changing.

As diabetes becomes more prevalent around the world the number of people with diabetic retinopathy is also becoming more common and has the potential to become a leading cause of blindness.

### What is diabetic retinopathy?

Diabetic retinopathy is a condition in which the retina is damaged by sustained and poor control of high blood sugar levels due to diabetes. It can cause reduced vision and blindness, particularly in its later stages.

### What causes diabetic retinopathy?

Diabetic retinopathy is damage to the tiniest blood vessels of the retina, the capillaries, by the high and abnormally varying levels of blood sugar associated with diabetes. The site of damage is mainly the lining or endothelial cells of these vessels. These cells are necessary for the normal functioning of the capillaries including actual blood flow.

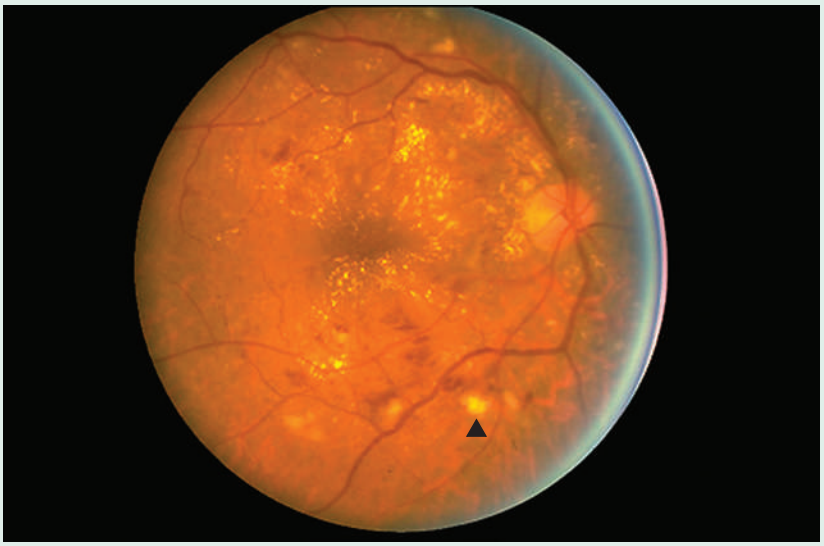
This damage causes three basic problems:

1. Leakage from the capillaries. The accumulation of fluid, protein, fat and whole blood from leaking, damaged capillaries in the retina disturbs the retina's delicate organisation and complex functions. This leakage is prone to occur at the macula, the part of the retina that is most critical for sharp vision.
2. Poor blood circulation. Because of damage to endothelial cells, the capillaries can fail to deliver oxygen and nutrients to the retina and also fail to remove toxic waste products. This causes reduced function or failure of parts of the retina, affecting vision.
3. Growth of abnormal new vessels in the retina. The lack of oxygen and perhaps some other metabolic features of diabetic retinopathy can stimulate new blood vessels to grow on or out from the surface of the retina. These often cause serious problems because they can bleed, sometimes massively, and they promote the formation of scar tissue which can stretch or distort the retina. In advanced cases, this process can pull the retina off the internal surface of the eye (traction retinal detachment). If this occurs, the affected eye will almost always lose all useful vision.

*Continued*

## CLINICAL INTEREST BOX 34.4 Diabetic retinopathy—cont'd

Most people who have diabetic retinopathy start with mild signs as described above, but may progress to the more severe stages.



Diabetic retinopathy, funduscopy. Note the extensive hard exudates (▲), typical of the 'background retinopathy' of diabetes mellitus.

*Robbins and Cotran Atlas of Pathology, Third Edition. Copyright © 2015, 2010, 2006 by Saunders, an imprint of Elsevier Inc.*

### Symptoms of diabetic retinopathy

Often in mild diabetic retinopathy a person will have no symptoms. Once the disease becomes more advanced they may experience:

- Blurred vision
- Floaters
- Sudden catastrophic loss of vision in one or both eyes.

### Contributing factors

#### Length of disease

The longer the person has diabetes, the more likely it is that they will develop diabetic retinopathy. Once it is present it tends to worsen as time passes. It is rare to see much diabetic retinopathy in people who have had diabetes for less than 5 years but it does happen at times. Diabetes can remain undiagnosed for a period of time; therefore, people can have diabetes longer than they realise and it is possible for diabetic retinopathy to be present at the time of diagnosis of diabetes.

#### Blood glucose levels

The poorer the control of blood sugar levels, the more likely it is that diabetic retinopathy will develop and the more likely it is that it will worsen.

#### Other vascular risk factors

Control of blood lipids (e.g. cholesterol) and blood pressure are also very important in the delay of onset of diabetic retinopathy. Lifestyle choices play a big part in the control of these factors. Healthy eating, weight control and exercise should be encouraged, along with quitting smoking and reducing or ceasing alcohol intake.

### Prevention and slowing progression

Diabetics should have regular eye examinations from time of diagnosis. This is the single most important measure in the prevention of blindness from diabetes.

### Treatment

Treatment of diabetic retinopathy should begin as soon as possible, before significant symptoms are evident and before the disease has progressed too far. This represents one of the great challenges in the care of diabetic retinopathy in both developed and developing countries.

#### Laser treatment

The current treatment for most people is laser. Laser treatment is usually applied through a special contact lens in an outpatient setting and the individual can go home after having it. The treatment is not usually painful. The affected areas

## CLINICAL INTEREST BOX 34.4 Diabetic retinopathy—cont'd

of the retina are treated with tiny laser burns, particularly where there is significant leakage of fluid, especially at or near the macula, or where there are areas of ischaemia.

The aim of treatment is to help prevent further leakage, to promote reabsorption of fluid from the retina and reduce the stimulus to new vessel growth. Where there is severe ischaemia or when new blood vessels are already present, treatment aims to cause the new vessels to regress and prevent any further vessels from developing.

Often treatment is required to be repeated a number of times. In advanced diabetic retinopathy laser treatments may fail to improve sight significantly and disease progression may continue, often leading to blindness in both eyes.

### Surgical interventions

Surgical interventions may be indicated in very advanced cases of diabetic retinopathy where there has been severe bleeding in the eye, scar formation or retinal detachment. However, this intervention is usually only undertaken when all other treatments have failed to stop progression of the disease.

### Other treatment

There are new and emerging forms of treatment including injecting drugs into the eye to reduce swelling in the retina and suppress new vessel growth. These are similar drugs to those used in the treatment of some forms of macular degeneration but at present are too costly for routine use in some countries.

*(Batterbury et al 2009; Tarr et al 2013)*

## CLINICAL INTEREST BOX 34.5 Glaucoma prevention and preservation of sight

Routine eye screenings are recommended for early detection of glaucoma. Although it cannot at this time be predicted, prevented or cured, in most cases glaucoma can be controlled and vision preserved by early diagnosis. The person needs to be aware that certain prescription and over-the-counter medications can cause increased intraocular pressure and should not be taken without consulting their doctor. The person who has experienced an episode of acute angle-closure glaucoma is taught about the risks, warning signs and management of future attacks. Persons need to understand the importance of lifetime therapy and periodic eye examinations with intraocular measurement in controlling the disease and preventing blindness. The nurse should assess the person's compliance with routine health screening.

*(Hendry et al 2012)*

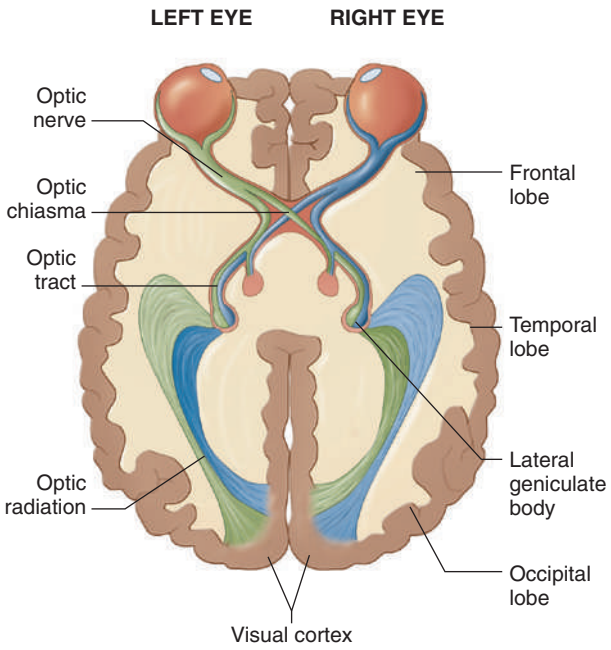


**Figure 34.6** The optic (visual) pathway

*(Thibodeau & Patton 2010)*

Degeneration of the retina can cause difficulty in seeing at night or in dim light. This condition, nyctalopia or night blindness, can be caused by a deficiency in vitamin A. Vitamin A is needed to make photo pigment in rod cells. Photo pigment is a light-sensitive chemical that triggers stimulation of the visual nerve pathway. A lack of vitamin A may result in a lack of photo pigment in rods, a condition that impairs dim-light vision (Patton & Thibodeau 2014).

## Disorders of the visual pathway

Damage or degeneration in the optic nerve, the brain or any part of the visual pathway can impair vision (see Figure 34.6). This can include damage from stroke, multiple sclerosis or trauma among others. Damage to the visual pathway does not always result in total loss of vision; depending on where the damage has occurred only part of the visual field may be affected (Patton & Thibodeau 2014).

# OTHER DISORDERS OF THE EYE

## Congenital disorders

### Strabismus

Strabismus is a condition of eye deviation in which the eyes fail to look in the same direction at the same time. The eyes may have uncoordinated appearance and the person may experience diplopia. Congenital strabismus is an anomaly in which there is a defect in the position and fusion ability of the two eyes. The condition is usually easily observed and, in addition to crossed eyes, the person may squint, tilt the head or close one eye to improve vision (Batterbury et al 2009).

### Ptosis

Ptosis, drooping of the upper eyelid, may be unilateral or bilateral. Congenital ptosis results from the failure of the levator muscle in the upper eyelid to develop. Manifestations are usually very obvious; the lid appears smooth and flat, and the person may tilt the head back to compensate if the lid droops over the pupil (Batterbury et al 2009).

## Neoplastic disorders

Benign or malignant tumours may arise in the tissues surrounding the eye, but neoplasms of the eyeball are rare (Batterbury et al 2009).

### Choroidal melanoma

A choroidal melanoma is a malignant tumour of the middle of the eyeball. The major symptom is visual distortion. There is generally no pain unless glaucoma develops (Trattler et al 2012).

### Retinoblastoma

Retinoblastoma is a congenital hereditary neoplasm that develops from retinal germ cells. It is the most common malignancy of the eye in childhood. Manifestations include diminished vision, strabismus, retinal detachment and an abnormal papillary reflex. The tumour grows rapidly and may invade the brain and metastasise to distant sites (Batterbury et al 2009).

## Traumatic disorders

### Abrasions

Abrasions are superficial scratches on the eyelid, conjunctiva or cornea. Corneal abrasions may be caused by foreign bodies or over-wearing of contact lenses. Manifestations include excessive tearing, pain, a sensation of something in the eye and photophobia.

### Lacerations

Lacerations may involve the eyelids or the eyeball. Lacerations of the eyeball may lead to intraocular infection, cataract formation of loss of vision. Manifestations of a lacerated eyeball include severe pain and shock.

### Contusions

Contusions of the eyeball involve a bruising injury in which intraocular damage occurs. The injury may result in bleeding into the anterior chamber (hyphema) or into the vitreous of surrounding tissues. Contusions generally result from a severe blow to the eye, such as from a fist, golf or squash ball. Manifestations include impaired vision, pain, bruising of the tissues surrounding the eye and blood in the anterior chamber.

### Foreign bodies

Foreign bodies may enter the conjunctiva or cornea, or they may penetrate and perforate the eyeball. Examples of foreign bodies that gain entry include eyelashes, dirt and small particles of metal, dust and glass. Manifestations include irritation, pain, excessive tearing and photophobia.

### Burns

Burns to the eye may result from exposure to a chemical, radiant energy or high temperatures. The extent of damage to the eye depends on the duration of exposure and the causative agent. Manifestations include extreme pain, excessive tearing, photophobia, inflammation or destruction of tissue and visual impairment (Batterbury et al 2009).

## Health promotion and education

The nurse is in a key position to educate individuals and their families about the ways by which eyesight can be protected and preserved in children. For adults, screening of visual function is imperative to detect problems early. Regular eye examinations are important, especially for persons with a family history of eye disorders and for persons who are more vulnerable to ocular complications such as diabetes mellitus. Recommended screening guidelines are structured on the basis of age. People under 40 years of age should have periodic eye checks as required. Those aged 40–64 should have a complete eye examination every 2 years, and those aged 65 years and over should have a complete eye examination every year. Examination of the eyes is also recommended if a person experiences any disturbances of vision, pain, sudden appearance of floaters, photophobia, purulent discharge, trauma to the eye or pupil irregularities. Prevention of eye infection includes washing the hands before touching the eyes, and not sharing eye make-up, eye drops or ointment (Crisp et al 2013).

Education is particularly important for persons involved in high-risk occupations and activities. Education should focus on strategies for prevention and first aid measures. Teach people what immediate care to give to prevent permanent loss of sight, such as immediately flushing the eye with copious amounts of water if a chemical splash occurs. Prevention of injury includes wearing eye protection when working with chemicals or when the eyes may be exposed to dust,

wood, metal or glass fragments. Protective eye wear should also be worn during recreational or sporting activities in which sticks or balls may contact the eye, such as squash. Excessive exposure to strong sunlight or sunlamps should be avoided, as these may damage the eyes. A common form of cataract, which can result from frequent exposure to intense sunlight, can largely be prevented if sun hats and good quality sunglasses are worn.

Prevention of eye fatigue includes using adequate illumination when reading or writing, resting the eyes often during prolonged use and reducing screen glare when using a visual display unit such as a computer screen. The nurse should inform the person and family of the importance of follow-up treatment and stress the importance of complying with prescribed activity restriction to prevent further eye damage, and of safe and careful application and correct storage of prescribed eye drops or ointments (Vision Australia 2015).

See Clinical Interest Box 34.6 for information on childhood screening.

**CRITICAL THINKING EXERCISE 34.2**

David Michaels is a 50-year-old man with hypertension. On his admission his blood pressure was 185/105 and he revealed that he had been seeing black spot floaters and flashing lights at times. He also was complaining of blurred vision. What health education would you provide to him on discharge?

**CLINICAL INTEREST BOX 34.6**
**Childhood preventative screening**

The most common visual problem during childhood is refractive error, such as nearsightedness. In early childhood parents may be alerted to a visual problem by reduced eye contact from their infant or the infant's failure to react to light. Recommended screening guidelines are usually structured on the basis of age, and preventative screening occurs in pre-school-age children (ages 4–5 years), where the nurse's role is one of detection and referral.

At school entry (age around 5 years):

- Examine eyes and observe for fixation, following, nystagmus, strabismus
- Test visual acuity
- Test hearing; perform otoscopy on children failing audiometry to determine appropriate action
- Address parental concerns regarding vision and hearing.

For more information visit Department of Education and Early Childhood Development: www.education.vic.gov.au/edulibrary/public/stuman/wellbeing/hwsfdp.pdf

## Diagnostic tests

Tests used to diagnose eye disorders may be classified as subjective, objective or special procedures. Subjective tests require oral responses from the person that must be interpreted by the examiner. Objective tests are those in which the examiner obtains precise measurements or directly visualises the interior of the eyes.

## Subjective eye tests

A visual acuity test evaluates the person's ability to distinguish the form and detail of an object. Visual acuity is measured by the use of a Snellen chart. The person is required to read letters on this chart from a distance of 6 metres. Generally, the smaller the symbol the person can identify the sharper their visual acuity.

Colour vision tests evaluate the person's ability to recognise differences in colour. The most common colour vision tests use plates made up of patterns of dots of primary colours, superimposed on backgrounds of randomly mixed colours. A person with normal colour vision can identify the patterns.

Accommodation tests evaluate the ability of the eyes to adjust to the curvature of the lenses. The examiner may perform this test by questioning the person concerning their visual acuity, while placing trial lenses before their eyes. Alternatively the test can be performed using an ophthalmoscope.

Visual field tests evaluate the functions of the retina, optic nerve and optic pathways. The person's peripheral and central visual fields are assessed when the examiner moves an object from outside the field into the field, on a radial line, until the person states that they can see the object. Tangent screen examinations detect visual field loss. In this examination, a screen is used and test objects from 1–50 mm in size are placed on the screen. Each eye is individually tested for visualisation of the objects.

## Objective eye tests

Intraocular pressure is assessed using a tonometer. A topical anaesthetic is instilled and the examiner places the tonometer on the apex of the cornea to determine pressure in the eye. An alternative method involves the use of an 'air-puff' tonometer that does not contact the eye. Tonometry serves as a valuable screening test for early detection of glaucoma.

Ophthalmoscopic examination involves the use of an ophthalmoscope to view the interior structures of the eye. The ophthalmoscope examines the fundus, or interior aspect, of the eye, allowing magnified examination of the optic disc, retinal vessels, macula and retina.

Slit-lamp examination allows the examiner to visualise in detail the anterior segment of the eye. Before the examination, dilating eye drops (mydriatics) may be instilled. The person sits with their chin on a rest and their forehead against a bar attached to the lamp. Slit-lamp examination helps determine corneal abrasions, dermatitis and cataracts.

Fluorescein staining is a technique in which staining the eye's surface with dye provides a better view of the anterior portion of the eye. The test is generally performed when the

conjunctival or corneal abrasions are suspected. Surface defects absorb more dye than normal areas.

### Special procedures for assessing the eye

Fluorescein angiography involves rapid-sequence photographs of the fundus after intravenous injection of a contrast medium. Fluorescein angiography records the appearance of blood vessels inside the eye.

A culture to determine the microorganism causing ocular infection may be obtained by passing a sterile swab over the conjunctival surface.

Computerised tomography (CT) of the orbit may be used to detect abnormalities such as intraocular foreign bodies or retinoblastoma. Contrast dye is injected and the eyeball scanned.

Ocular ultrasonography involves the transmission of high-frequency sound waves through the eye, and measurement of their reflection forms the ocular structures.

Ultrasonography can identify abnormalities that are undetectable through ophthalmoscopy, and may be used to locate intraocular foreign bodies.

## Care of the person with an eye disorder

While the general care of the person with a disorder of the eye is directed towards helping them to meet their needs, the three main aspects of care are:

1. Maintaining a safe environment
2. Education
3. Providing local eye care.

### Maintaining a safe environment

Any visual impairment or loss renders the individual susceptible to injury; therefore, the nurse has a responsibility to protect them from environmental hazards. These hazards may include such things as low levels of lighting, poor colour contrast or badly positioned furniture. The nurse should describe the layout of the room to the individual. If the individual is ambulant, the nurse should encourage them to locate the various pieces of furniture so that they become familiar with their position in the room. Leave furniture and personal belongings in the same position in the room. Ensure that any doors are either fully closed or open, as a visually impaired person can easily by injured if a door is left ajar.

Nurses can foster independence in the hospitalised visually impaired person by encouraging self-sufficiency in completing activities of daily living, and improving self-esteem as the person attempts and masters activities.

### Education

Education involves assisting the individual to adjust to a visual impairment. The nurse should initially describe to the individual with the alteration to visual function what has occurred. The person who is experiencing visual loss that is either temporary or permanent needs assistance to adjust to the physical and psychosocial implications. Care of the person includes encouraging them to express reactions and feelings to their visual loss. The visually impaired person may lose the ability to observe body language and the reading and writing components of communication. It is important for the individual to be able to interact with people who they encounter. Communication methods may also be taught to family members and significant others.

### Key aspects related to assisting the visually impaired person

- Encourage as much self-care as possible. The person who is experiencing recent visual impairment may need assistance until they adjust to their condition. A person who has been visually impaired for some time will probably have developed considerable self-reliance. The nurse should always consult the person when uncertain whether assistance is required.
- Address the person by name and identify yourself, visitors or others in the room. This avoids frightening the person and assists them in knowing who is in the room. It is also important to knock before entering and to inform them when you are about to leave the room.
- Speak to the person in the same manner as you would a fully sighted person. The nurse must suppress the urge to speak more loudly than usual, which people often do when conversing with a visually impaired person. There is no need to exclude words such as 'look' and 'see' from normal conversation.
- Any visual aids that the person uses should be kept in close proximity (Table 34.2). The person should have easy accessibility to the call bell if required.
- Encourage the person to maintain an interest in the outside environment through listening to the radio or television and discussing newspaper items.
- Provide full descriptions of people, places and things.
- Provide items that can compensate for diminished vision, such as bright non-glare lighting, large-print books, talking books, telephones with enlarged buttons and a clock with numbers and hands that can be felt.
- At mealtimes it may be necessary for the nurse to describe the position of foods on the plate (such as, peas are at 9 o'clock, potatoes at 12 o'clock, pumpkin at 3 o'clock and chicken at 6 o'clock).
- It is of particular importance to thoroughly explain any procedure or treatment before it is started. Whenever possible, if it will not affect sterility, the person should be allowed to feel any items used during a procedure.
- Provide contrasting colours; for example, non-white crockery and brightly coloured telephones, handles, borders or edges allow familiar objects to become more visible. Coloured tape, paint or nail polish can be used to colour-code appliance dials.
- Painting the edge of stairs with bright paint can help the person distinguish the edge of the step more clearly.
- Inform the person when they are approaching stairs or steps, remembering to let them know whether they are up or down.

**TABLE 34.2 | Aids for the visually impaired**

| Aid | Description |
|---|---|
| Magnifiers | Hand-held or standing magnifiers can be used to enlarge print, or for fine detail |
| Enlarged print | Large-print books, magazines and newspapers may be borrowed from the local library |
| Talking books | Tapes of books may be available on loan from agencies for the blind or from public libraries |
| Telephone aids | Special dials are available for telephones in both large print and braille |
| Braille | The braille system of writing and printing uses tangible points or dots, which the individual feels and 'reads' with the fingertips |
| Optical-to-tactile converters | Consist of devices that convert vision into tactile sensation, by reproducing the outline of a letter on a tactile screen |
| Canes | A variety of canes is available (e.g. a white or collapsible cane) which helps the individual to locate obstacles in the environment. Laser canes also locate objects and can identify changes in the region from as far away as 6 metres |
| Guide dogs | Trained dogs allow greater mobility and independence for the visually impaired person. The individual holds a U-shaped handle, which is attached to a harness on the dog. Communication between the two takes place through the movements of the harness. When a guide dog is working (i.e. when it is in harness) other people should not approach or pat the dog without the handler's permission, as the dog may become distracted |

*(Vision Australia 2015)*

- When walking with the person, the nurse should walk slightly ahead and let the person take their elbow. This technique ensures that the person senses the direction they are walking towards. The nurse should encourage the use of handrails while ambulating and warn the person of any hazards as they are approached.
- Cultural aspects of care should always be taken into account when caring for a person who has impaired vision.
- On discharge, review specific hazards in the home with the person and family. Assessment must be made of both indoor and outdoor living arrangements. The person's living quarters should not be altered after they have become familiar with placement of furniture.
- Inform the person and family that progress will be slow and that they will need to seek support from outside agencies. Encourage families to explore community resources available to persons with partial or total loss of vision, and the rehabilitation programs available to them. Some of these include: Association for the Blind; state and territory guide dog associations and Seeing Eye Dogs Australia; Australian Braille Authority; Vision Australia; Blind Welfare Australia; and Blind Citizens Australia. All coordinate services for the blind and visually impaired.

## Local eye care

Various nursing procedures involving the eye should be performed in accordance with the policies of the healthcare institution. General principles that should be followed in all ophthalmic procedures include:

- Explain what you are going to do
- Ensure that the person is sitting or lying with their head well supported
- Ensure that there is adequate lighting; lights should never be allowed to shine directly into the person's eyes
- Wash hands thoroughly before and after the procedure and wear disposable gloves to prevent cross-infection
- Use gentle unhurried movements and refrain from exerting any pressure on the eye
- Avoid all sudden movements
- Avoid touching the cornea with the fingers or equipment, to prevent corneal damage
- Use aseptic technique. When only one eye is infected or inflamed, the unaffected eye must receive attention first to prevent cross-infection
- Ensure that if an eye pad is to be applied, the eyelid is closed firmly to avoid corneal abrasion.

See Clinical Skill 34.1.

## Application of eye pads

A light eye pad may be applied to prevent further injury after trauma to the eye or to avoid eye damage after administration of a local anaesthetic. Before the eye pad is applied the individual is asked to close their eyelid firmly. The pad should be applied so that the eyelid cannot be opened. Pressure should not be applied, unless a medical officer has prescribed it. The

## CLINICAL SKILL 34.1 Application of eye pad

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile eye pad<br>Disposable gloves<br>Tape |

| **Skill activity** | **Rationale** |
|---|---|
| Validate the medical order in the individual's healthcare record | Ensures correct procedure is about to take place |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Ensure that the person is sitting or lying with their head well supported and there is adequate lighting | The person is relaxed and comfortable and therefore less likely to move during procedure and cause corneal damage |
| Place the equipment in a convenient location near the bedside<br>Raise the bed to the appropriate working position based on your height | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination |
| Before the eye pad is applied the person is asked to close their eyelid firmly | Ensures the eye is not directly in contact with the eye pad and prevents corneal damage |
| Use gentle unhurried movements and avoid all sudden movements | Prevents person from moving or flinching to prevent corneal damage |
| The pad should be applied so that the eyelid cannot be opened. Check medical orders as sometimes double padding is required | Ensures the eye is not directly in contact with the eye pad and prevents corneal damage |
| Pressure should not be applied, unless prescribed by a medical officer | Pressure can damage the eye |
| The eye pad is secured into position using hypoallergenic tape<br>Place the tape diagonally from forehead to cheek | Prevents exposure of the eye<br>Placing tape at an angle reduces the risk of pressure on the eye |
| Clean and dispose of waste equipment appropriately<br>Remove gloves. Perform hand hygiene | Prevents cross-infection |
| Lower the bed and assist the individual to reassume a comfortable position<br>Ask the individual to report any complications during and post procedure if able. Explain that their range of vision and depth perception may be altered | Promotes rest and relaxation, monitors for adverse effects<br>Provides anticipatory guidance so that they take more care when ambulating or feeding themselves |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team<br>Allows for the planning and implementation of care |

*(Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012; 2015; Batterbury et al 2009; Berman et al 2015; Tollefson et al 2016)*

eye pad is secured into position using hypoallergenic tape, placing the tape diagonally from forehead to cheek.

## Eye irrigation

Irrigation is a technique performed to flush secretions, chemicals or foreign bodies from the conjunctival sac. Chemical injuries to the eye require flushing of the conjunctival sac with copious amounts of solution. It may be necessary to cleanse the eyelids before irrigation; for example, if there is excessive discharge or crusting. A suggested technique for eye irrigation is outlined in Clinical Skill 34.2.

## Eye prostheses

Two types of eye prosthesis are contact lenses and artificial eyes.

*Contact lenses*: a contact lens is a small plastic disc that is positioned on the cornea and held in place by surface tension. A person who has a refractive error, for example astigmatism,

### CLINICAL SKILL 34.2 Eye irrigation

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Dressing pack or sterile gauze and kidney dish or other receptacle<br>Sterile eye irrigating solution<br>Gloves<br>Towel or absorbent mat |
| **Skill activity** | **Rationale** |
| Validate the medical order in the individual's healthcare record | Ensures correct procedure is about to take place |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Assist the person into a recumbent position, with the head tilted towards the affected side | Prevents the solution running either over the cheek into the other eye or out of the affected eye and down the side of the nose |
| Place the equipment in a convenient location near the bedside<br>Raise the bed to the appropriate working position based on your height | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination |
| Place a towel under the head on the affected side and across the neck. Place a kidney dish against the person's cheek and ask the individual to hold it in position | Prevents solution from flowing down the neck |
| Pour irrigating solution into the sterile receptacle or open the container of eye wash. Gently hold the eyelid open with one hand | A person will instinctively try to close the eye |
| Hold the fluid container 2.5 cm away from the eye | If the fluid container is held too high, fluid will flow at increased pressure, causing discomfort and possible damage to the eye |

*Continued*

| CLINICAL SKILL 34.2 Eye irrigation—cont'd | |
|---|---|
| Pour a little solution over the cheek first | Accustoms the person to the feel of the solution and prevents person moving during procedure |
| Direct the flow of solution from the nasal corner outwards | Because the head is tilted, the stream of irrigating solution will flow over the eyeball and prevent contamination of the other eye |
| Avoid directing the stream forcefully onto the eyeball, and avoid touching the eye's structures | Prevents discomfort and damage to the eye |
| Ask the person to look up and down and to either side while irrigating | Ensures that the whole area is washed |
| When the eye has been thoroughly irrigated, ask the person to close the eyes, and use a new gauze swab to dry the lids | Promotes comfort |
| Clean and dispose of waste equipment appropriately<br>Remove gloves. Perform hand hygiene | Prevents cross-infection |
| Lower the bed and assist the individual to reassume a comfortable position<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects<br>Provides anticipatory guidance so that they take more care when ambulating or feeding themselves |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team<br>Allows for the planning and implementation of care |
| *(ACSQHC 2012; 2015; Batterbury et al 2009; Berman et al 2015; Tollefson et al 2016)* | |

may wear contact lenses in place of glasses. A variety of lenses are available including hard, soft, gas permeable, extended wear, daily wear, coloured and disposable. It is important to know that all lenses require care and must be removed periodically to prevent corneal damage and eye infection. Education is required regarding proper lens care; for example, daily wear lenses should be removed overnight for cleaning and disinfection. Only the recommended solutions should be used for cleaning, soaking and storing lenses. Wetting lenses with contact lens solution before insertion minimises discomfort. The hands should be washed and dried before insertion or removing lenses (Crisp et al 2013).

*Artificial eyes*: an artificial eye may be inserted after surgical removal of an eye. Persons with artificial eyes have had enucleation of an entire eyeball. An artificial eye may be removed from the socket, cleaned and replaced. Alternatively, the prosthesis may remain in the socket permanently. Most persons prefer to care for their own eyes but there may be times when assistance from the nurse is required. When a prosthesis is removed from the socket it is placed in warm normal saline for cleansing (Crisp et al 2013).

## Eye surgery

*Laser eye surgery* is commonly performed to correct refractive errors such as myopia, hyperopia and astigmatism. A laser is used to permanently change the shape of the cornea, and in most cases the need to use corrective lenses is reduced or eliminated. Several surgical procedures are now available:

- Laser in situ keratomileusis (LASIK)
- Photorefractive keratectomy (PRK)
- Laser epithelial keratomileusis (LASEK)
- Laser thermokeratoplasty (LTK) (Batterbury et al 2009).

These procedures reshape the cornea using laser technology to remove a thin layer of epithelial cells or to shrink and reshape the cornea. Candidates for laser vision-correction should be in good health and must have adequate corneal thickness to ensure that the risk of perforation does not occur.

Following surgery, persons may experience a temporary loss of contrast sharpness (images do not appear crisp as with corrective lenses), over- or under-correction of visual acuity, dry eyes or temporarily decreased night vision with halos, glare and starbursts (LeMone et al 2014).

*Corneal transplant*: once the cornea has become scarred and opaque, no treatment can restore clarity. The first successful corneal transplant was performed in 1906. Corneas are harvested from cadavers of uninfected adults who were under the age of 65 and who die as a result of acute trauma or illness. Corneal transplantation is usually an elective procedure, although emergency transplantation may be required in the case of perforation of the cornea (Brown et al 2015; LeMone et al 2014).

# THE EAR

The ear is specially adapted as the organ of hearing but it is also concerned with the sense of position, balance and equilibrium. Hearing is a special sense that allows individuals to experience the world in which we live by providing a pathway for sounds to reach the brain. Hearing is a complex mechanism in which the ears receive sound waves and convert them into nerve impulses. The nerve impulses are transmitted by the acoustic nerve to the brain where they are interpreted. The externally visible portion of each ear is located on the lateral surface of the head on each side. The remaining parts of each ear are embedded in the bone of the skull (Marieb 2015).

## Structure of the ears

Each ear can be divided into three areas: the external, the middle and the inner ear (Figure 34.7).

### The external ear

The external ear consists of the auricle (pinna) and the external auditory canal. The auricle consists of a piece of elastic cartilage with a number of associated ligaments and muscles, and has a small amount of adipose tissue in the earlobe. The skin of the auricle is covered with fine hairs and is continuous with the skin lining the external auditory canal. The external auditory canal is an S-shaped canal about 2.5 cm long. It extends from the auricle to the tympanic membrane (eardrum). The skin lining the canal contains glands that produce cerumen (wax) that protects the lining from damage and keeps dust particles away from the eardrum. The tympanic membrane lies between the external ear and the middle ear. It is a semi-transparent sheet consisting of three layers. The outermost layer consists of hairless skin, the middle layer is connective tissue and the innermost layer is continuous with the mucous membrane lining of the ear (Ballachanda 2013).

### The middle ear

The middle ear, or tympanic cavity, is a small chamber within the temporal bone. Three small bones, or ossicles, lying in the middle ear transmit sound from the tympanic membrane to the oval window. Because of their shapes, the bones are named the malleus (the mallet), the incus (the anvil) and the stapes (the stirrup). The malleus is attached to the tympanic membrane; the stapes is attached to the oval window; and the incus articulates with the other two ossicles. The three ossicles are attached to the wall of the middle ear by ligaments. The auditory tube (or eustachian tube) connects the middle ear with air from the nasopharynx. It is about 3–6 cm long and is lined with mucous membrane. Normally the tube is flattened and closed at the pharyngeal orifice, but swallowing or yawning opens it briefly (Patton & Thibodeau 2014).

### The inner ear

The inner ear (Figure 34.8) consists of a bony cavity within the temporal bone known as the osseous labyrinth. It is lined with periosteum and filled with a fluid called perilymph. The three divisions of the osseous labyrinth are the cochlea, the vestibule and the semicircular canals. The cochlea is a spiralling bony cavity, which resembles the shell of a snail. It houses the organ of Corti, the receptor organ of hearing. The vestibule lies between the cochlea and the semicircular canals. It contains structures responsible for maintaining equilibrium during movement of the head. The semicircular canals consist of three canals (in each ear), arranged at right angles to each

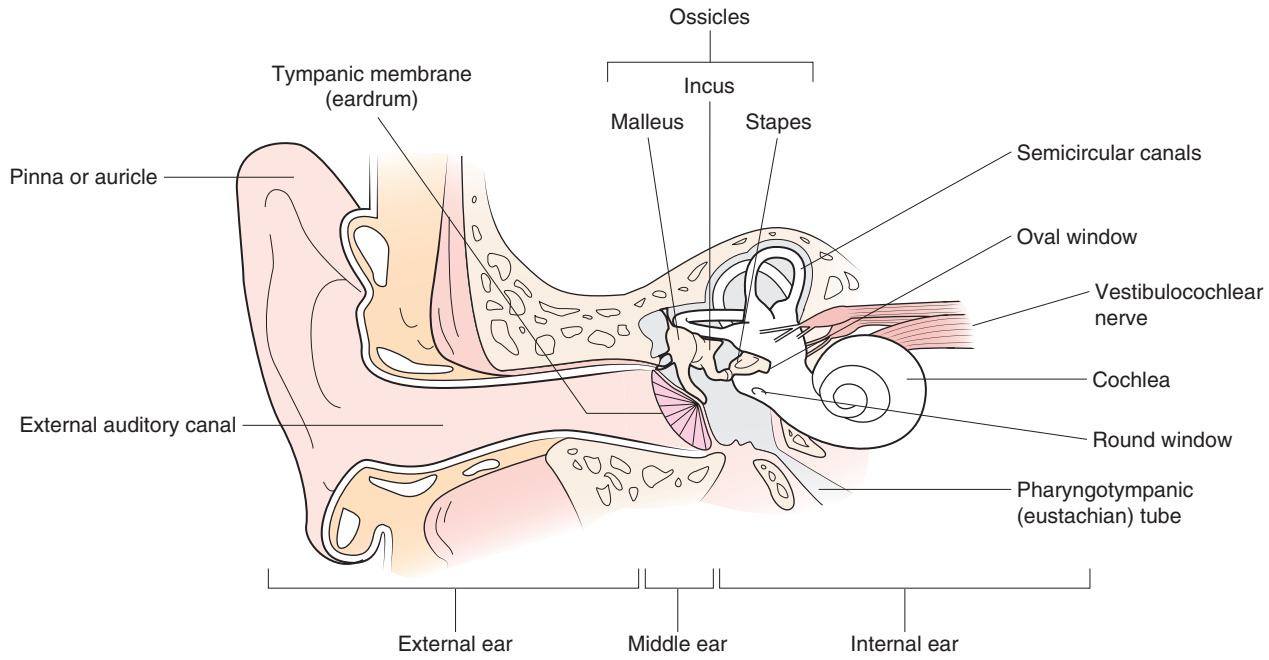

**Figure 34.7** The ear

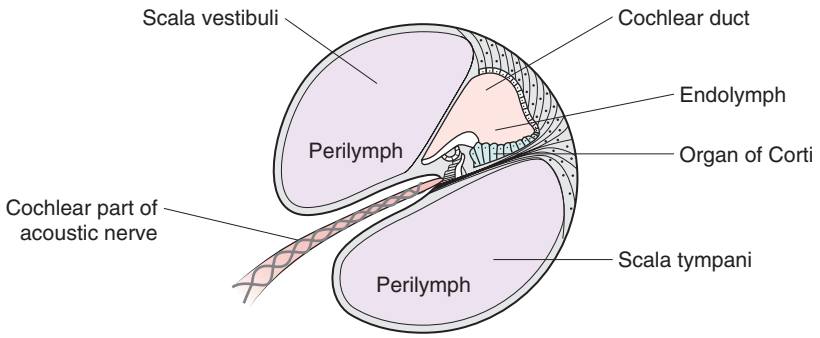

**Figure 34.8** A section of membranous cochlea showing the organ of Corti

other. They are filled with endolymph (the fluid inside the membranous labyrinth at the ear) and contain specialised nerve endings that are stimulated by the movement of the endolymph. The semicircular canals assist the body to adjust to changes of direction. The movement of fluid in this area can cause the person to experience a feeling of dizziness.

The membranous labyrinth is a membrane consisting of three layers, and lies within the osseous labyrinth. In the areas where it is not attached to the osseous labyrinth it is surrounded by perilymph. The fluid contained within the membranous labyrinth is known as endolymph. Part of the membranous labyrinth is concerned with hearing and part is concerned with the position of the head in space (Marieb 2015).

## The physiology of hearing

Hearing is a sense that enables sound to be perceived. Sound waves are collected and directed by the auricle into the external auditory canal, where they pass through and cause the tympanic membrane to vibrate. They then pass through the middle ear by vibration of the ossicles, and into the internal ear. From the internal ear sound waves are transmitted to the brain, via the acoustic nerve, for interpretation. Perception of sound involves interpretation of pitch and intensity. The entire process of hearing involves the following steps:

- Movement of air molecules causes a sound wave to form
- The sound wave travels through the air to the auricle, which directs it into the external auditory canal
- The sound wave enters the auditory canal and comes in contact with the tympanic membrane, causing it to vibrate
- The vibrations are transferred to the ossicles, which begin to vibrate, and the sound wave is transmitted across the middle-ear cavity to the oval window and into the fluid-filled internal ear
- The sound waves set the cochlear fluids into motion. The receptor cells are stimulated, and the sound waves are transmitted along the acoustic nerve to the temporal lobe of the brain for interpretation (Patton & Thibodeau 2014).

Two qualities of sound, pitch and intensity, are important in the interpretation of sound. Pitch is related to the frequency of the sound wave. A high-frequency sound stimulates the neurons supplying the cells near the base of the cochlea. Low-frequency sounds stimulate neurons nearer the apex of the cochlea. Intensity is related to the loudness of sound and is measured in decibels (dB). A loud sound causes the nerve endings to be stimulated at a greater rate than does a softer sound. The intensity of normal conversational speech is about 60 dB, and a decibel level of 160 can cause bursting of the tympanic membrane.

## Maintenance of equilibrium (balance)

Two structures within the internal ear, the semicircular canals and the vestibule, work together to help the individual maintain balance and equilibrium. Components of the semicircular canals alert the brain to rotational movement, and components of the vestibule alert the brain to gravitational movement. Movement of fluid in the canals gives a constant flow of information about body position and the speed and direction of any body movement. This information is used to coordinate movements and to maintain balance (Hendry et al 2012).

## Pathophysiology of the ear

Normal function of the ear can be altered by a variety of pathophysiological factors including those that are congenital, degenerative, infectious, obstructive, neoplastic or traumatic (Marieb 2015).

### Congenital factors

Congenital alteration, which may be either hereditary or acquired, include structural malformations that can lead to hearing loss or deafness, disorders resulting from maternal infection during pregnancy or trauma incurred during pregnancy or delivery or before maturity. Congenital disorders may be caused by a genetic defect or may result from prenatal trauma or toxicity. Some of the disorders affect the cosmetic appearance only, while others result in varying degrees of hearing loss. Congenital disorders include partial or total absence of the external ear (auricle), protruding ears, fused or absent ossicles and malformation of the cochlea (Patton & Thibodeau 2014).

## Degenerative factors

Degenerative changes in the bones and joints of the ossicles can result in conductive hearing loss, while narrowing of blood vessels to the inner ear can result in tinnitus, vertigo or hearing loss. Gradual sensorineural hearing loss can result from a decrease in the number of hair cells and nerve fibres in the auditory system as a consequence of the ageing process. **Presbycusis** is a slowly progressive bilateral hearing loss resulting from physiological changes of ageing. It results from a loss of hair cells in the organ of Corti and causes sensorineural hearing loss, usually of high-frequency tones. Manifestations include gradual progressive hearing loss, which may be accompanied by tinnitus and dizziness, depression or irritability (Brown et al 2015).

## Infectious factors

Microorganisms can cause external, middle or inner ear infections, all of which result in pain and varying degrees of conductive hearing loss. Otitis externa, which may be acute or chronic, is inflammation of the external ear canal and auricle; the most common causative organism is *Streptococcus pyogenes* although *Proteus vulgaris*, *Staphylococcus aureus*, *Candida albicans* and *Aspergillus niger* may be responsible for infection. Predisposing factors include swimming in contaminated water, abrasion of the ear canal from inserting sharp or small objects to clean the ear, exposure to irritants and constant use of earphones or ear plugs. Manifestations include otalgia which is exacerbated on chewing or opening the mouth, lymphadenopathy, pyrexia, regional cellulitis, offensive smelling discharge, pruritus and partial hearing loss.

Otitis media, which may be acute or chronic, is inflammation of the middle ear. Causative organisms include *Haemophilus influenzae*, pneumococci and beta-haemolytic streptococci. Predisposing factors include the wider, shorter and more horizontal pharyngotympanic tube in infants and children; anatomical abnormalities such as cleft palate; and respiratory tract infection. Manifestations include severe otalgia, pyrexia, hearing loss, dizziness, nausea and vomiting. If the tympanic membrane ruptures, there is often purulent discharge from the ear canal (Hendry et al 2012).

## Obstructive factors

Obstruction of the auditory system, which may result in conductive or sensorineural hearing loss, includes impacted cerumen, foreign bodies, oedema and neoplasms. An obstruction can impede the passage of sound waves causing an imbalance of pressure on either side of the tympanic membrane or it may disrupt the transmission of sound to the inner ear.

## Neoplastic factors

Neoplasms, which may be benign or malignant, can affect the external middle or inner ear. The effects of a neoplasm include pain, discharge, vertigo, tinnitus and hearing loss. An acoustic neuroma is a benign tumour arising from the eighth cranial nerve and occurring within the internal auditory canal. As the tumour grows the cochlear branch of the eighth cranial nerve becomes involved. Manifestations include tinnitus followed by an increasing high-frequency hearing loss. As the tumour increases in size, symptoms of other cranial nerve involvement occur, such as trigeminal pain and loss of taste in part of the tongue. Nystagmus and ataxia may occur (Brown et al 2015; LeMone et al 2014).

## Traumatic factors

Trauma to the external ear includes bruising, lacerations and frostbite. Trauma to the head can result in fractures of the temporal bone, dislocation of the ossicles, rupture of the tympanic membrane and damage to the auditory nerve. Trauma can lead to vertigo, tinnitus, nystagmus, pain, bleeding and hearing loss. Hearing loss can also result from sudden exposure to a loud explosive sound or from continued exposure to loud noise.

Abrasion: because of its vulnerable position, the external ear may sustain abrasion of the canal, burns or contusions of the pinna. Foreign bodies may be inserted into the canal and become lodged, or insects may fly into the ear, causing irritation.

Perforated eardrum: a perforated tympanic membrane may be caused by a variety of factors, such as the introduction of a sharp object to clean the canal, unskilled irrigation of the auditory canal, middle ear infection, trauma to the head or sudden exposure to loud noise. Most traumatic perforations heal spontaneously, but a perforated tympanic membrane results in scarring and renders the person susceptible to chronic ear infections and hearing loss. Manifestations include sudden severe pain inside the ear, loss of hearing, tinnitus and bleeding.

Barotrauma: barotrauma is injury caused by changes of air pressure to the wall of the pharyngotympanic tube and mucous membrane of the middle ear. It is caused by failure of the pharyngotympanic tube to open sufficiently, resulting in unequal pressure between the middle ear and the atmospheric pressure. It may occur during take off or landing in planes, or during deep-sea diving. Manifestations include severe pain, decreased hearing, tinnitus and vertigo.

Noise-induced hearing loss: this condition develops gradually as a result of continued exposure to environmental or industrial noise. Acoustic trauma is sudden hearing loss from brief exposure to a high-intensity sound at close range, such as gunshots. Manifestations of noise trauma include hearing loss, tinnitus and a feeling of fullness within the ear.

Ototoxicity: ototoxicity is a toxic reaction to medications or chemicals that can damage the auditory and/or vestibular system. Auditory damage may be permanent, whereas vestibular damage may be reversed after the drug therapy is discontinued. A variety of substances may result in ototoxic reactions, including diuretics, alcohol, lead, carbon monoxide, aspirin and antibiotics. Manifestations include bilateral hearing loss, tinnitus, vertigo and ataxia (Brown et al 2015).

## Major symptoms of ear disorders

The major manifestations of ear disorders are pain, discharge, tinnitus, vertigo, nystagmus and hearing loss. Table 34.3 is a representation of these manifestations.

### CRITICAL THINKING EXERCISE 34.3

A mother and 4-year-old child present at the clinic. The child has a temperature of 38°C, is crying and pulling at its left ear. The mother tells you the child has been like this all night. While at the clinic the child vomits and a purulent discharge emerges from the ear. What might these symptoms suggest is happening? What nursing management strategies would you suggest?

### Disorders of multiple causes

Otosclerosis is a disorder in which the spongy temporal bone becomes a dense sclerotic mass, eventually immobilising the stapedial footplate and causing a conductive hearing loss. Although no definite cause has been identified, heredity is a significant factor. Females have a higher incidence of the disorder than males. Manifestations are slowly progressive and include bilateral conductive hearing loss and mild tinnitus (Patton & Thibodeau 2014).

Ménière's disease is a disorder of the inner ear that results from over-production or decreased absorption of endolymph. The resulting dilation of the membranous labyrinth can progress to herniation and rupture. Manifestations are exacerbation and remissions of three symptoms: vertigo, tinnitus and sensorineural hearing loss. During an acute episode the person may experience nausea and vomiting, sweating, giddiness, nystagmus and ataxia (Marieb 2015).

### CRITICAL THINKING EXERCISE 34.4

Rebecca, a 42-year-old woman with Ménière's disease, is experiencing an increasing frequency of attacks of vertigo and tinnitus. Rebecca and her husband are booked on a holiday to England soon and are worried that she may not be able to fly. What do you think is probably happening to Rebecca? What may be some of the reasons for the increase in frequency of symptoms? What home management strategies would you suggest for Rebecca?

**TABLE 34.3 | Major manifestations of ear disorders**

| | |
|---|---|
| Pain | Earache (**otalgia**) is a common manifestation of many ear disorders. Middle ear pain associated with otitis media is often described as deep seated and throbbing, whereas the pain associated with otitis externa is often described as tenderness of the pinna only. Ear pain can also result from referred pain via various cranial or cervical nerves as occurs with tonsillitis |
| Discharge | Discharge form the ear, also known as otorrhoea, is generally associated with infections of the middle ear (otitis media). Purulent or haemopurulent discharge may drain from the middle ear through a perforation in the tympanic membrane. Otitis externa can sometimes produce a prolific discharge but is less likely than with otitis media |
| Hearing loss | Hearing loss is a common manifestation in ear disorders. There are two types of hearing loss:<br>Conductive—caused by blockage or damage in the outer ear, middle ear or both. Some of the causes of a conductive hearing loss include ear infections, otosclerosis, otitis media, barotrauma, damage to tympanic membrane or blockage of the ear canal by wax or foreign objects.<br>Sensorineural (perceptive or nerve)—caused by damage to, or a malfunction of, the cochlea (the sensory part) or the nerve (the neural part). It can be hereditary or genetic; it can also be caused by the ageing process, excessive noise exposure, diseases such as meningitis or Ménière's disease and viruses such as mumps or measles.<br>Some hearing loss is caused by a mixture of both above types, known as mixed hearing loss |
| Tinnitus | The term '**tinnitus**' is used to describe a noise in the inner ear when there is no actual external noise. The word 'tinnitus' means 'tinkling or ringing like a bell', and is of Latin origin; usually pronounced tinn-i-tus, the 'i' as in 'sit'.<br>It can be constant or intermittent, and may be described as ringing, buzzing, hissing or roaring noises. There are many possible causes of tinnitus, including trauma, obstruction, inflammation and malignancies. However, little research has been done in this area and there is no known cure |
| Vertigo | Vertigo is a sensation of spinning. People describe it as feeling as though their head is spinning or the room is going around. Causes can include trauma, malignancies, Ménière's disease and obstruction |
| Nystagmus | **Nystagmus** is the involuntary, rhythmic movement of the eyes. Movement may be horizontal, vertical, rotary or mixed. Nystagmus can be a sign of disorders of the inner ear but can also be present in some neurological disorders. Nystagmus can also be induced by introducing cold or warm water into the external auditory canal |

*(Crisp et al 2013; Brown et al 2015)*

## CASE STUDY 34.1

Georgia Murdoch is a 45-year-old mother of three who runs her own accounting business from home. She has been admitted with complaints of feeling that she is spinning or falling and has ringing and a feeling of fullness in her left ear. These symptoms have been getting worse over the past 2 weeks, and now she has difficulty getting up from a sitting position, and is worried about driving with her children in the car.

1. What do you think is happening to Georgia?
2. What are some of the nursing care considerations you need to take into account when caring for Georgia?

## Health promotion

Health promotion focuses on identifying persons with potential ear disorders (see Case Study 34.1). Persistent episodes of dizziness, ringing in the ears, balance problems or loss of hearing should be reported to a healthcare provider. The nurse is in a key position to educate persons about the ways in which hearing can be protected and preserved:

- Regular hearing examinations are important for the early detection of hearing problems, especially for children, whose ability to learn can be impaired by hearing defects
- Regular screening is also important for the person over age 65 because the ageing process is commonly accompanied by degenerative ear changes. Recommended preventative screening should be carried out for all ages as required
- Prevention of trauma to the ears includes education, such as the importance of never putting small or sharp objects into ears
- Excessive cleaning of the ear canal is contraindicated, as it removes the cerumen, which has a protective function
- Protection of the ears from contamination by water when swimming or diving is particularly important if the person has experienced ear infections
- Infections that could involve the ear (e.g. upper respiratory tract infections require adequate treatment)
- Protection of the ears from damage by noise: prolonged exposure to noise levels greater than 85–90 dB causes cochlear damage. People working in areas of high noise levels are required to wear protective devices such as earplugs or earmuffs. Exposure to loud volume from live music, audio equipment and headphones should be avoided
- Nurse assessment of the person's compliance with routine health screening
- Monitoring for vertigo, nystagmus, nausea, vomiting and hearing loss
- Instructing the person not to get up without assistance during episodes of vertigo due to increased falls risk
- Education to avoid sudden head movements or position changes
- Discussion of the effect of unilateral hearing loss on the ability to identify the direction of sounds (Crisp et al 2013).

## Diagnostic tests

Tests used to assist in the diagnosis of ear disorders assess auditory and vestibular function.

### Auditory tests

Otoscopic examination is the direct visualisation of the external auditory canal and the tympanic membrane through an otoscope (auroscope). Otoscopy is performed to detect foreign bodies or cerumen in the external canal, or to detect external and middle ear pathology. Tuning forks detect hearing loss and provide information as to the type of loss:

- The Weber test determines whether the individual lateralises the tone of the tuning fork to one ear
- The Rinne's test evaluates air and bone conduction in both ears
- The Schwabach test compares the individual's bone conduction response with that of the examiner, who is assumed to have normal hearing (LeMone et al 2014).

*Audiometry*: pure tone audiometry is the testing of each ear separately for air conduction via earphones, and for bone conduction via a vibrator placed on the mastoid bone. The faintest point at which the individual hears the tone is called the hearing threshold level. Comparison of air and bone thresholds can suggest a conductive, sensorineural or mixed-type hearing loss.

Speech audiometry tests the person's ability to understand and discriminate sounds. Two-syllable words are presented through earphones to measure how loud speech must be before it is heard.

Speech discrimination testing measures the person's ability to distinguish phonetic elements of speech and thus understand what is heard. The examiner presents one-syllable words through the ear phones.

Impedance audiometry evaluates middle ear function by measuring the flow of sound energy into the ear, and the resistance to that flow. The objective is to determine the resistance (impedance) of flexibility (compliance) of the tympanic membrane (Patton & Thibodeau 2014).

### Vestibular tests

*Electronystagmography* (ENG) evaluates vestibular function by measuring the effect of the semicircular canals on the ocular muscles. Electrodes are positioned at precise points on the face and eye, with movements in response to specific stimuli recorded on a graph.

*Caloric tests* compare the nystagmus produced by warm and cold stimulation in each ear. Each ear is irrigated with water to stimulate mild vertigo and nystagmus. No response indicates that the labyrinth is non-functional.

Other tests used to diagnose ear disorders include cultures of secretions to detect the source of an infection, and radiological examination of the temporal bone.

## Care of a person with an ear disorder

While the general care of the person with a disorder of the ear is directed towards helping them to meet their needs, the three main aspects of care are:

1. Maintaining a safe environment
2. Education
3. Providing any prescribed local ear care (Brown et al 2015; LeMone et al 2014).

### Maintaining a safe environment

Any hearing impairment renders the person susceptible to accidents and injury. Any environment can heighten or reduce sensory stimulation. The nurse must assess the person's environment in the healthcare setting as well as assisting the person and the family to identify hazards in the home environment, and recommend appropriate adaptations. Persons with vestibular disorders are at risk of losing their balance and falling. It is important to ensure that bathrooms have a non-skid surface in the shower and bath, grab bars are installed and that the nurse provides the family with education regarding supervision of the person when ambulant, to minimise the risk of falls (Crisp et al 2013).

### Education

The person who is experiencing hearing loss that is either temporary or permanent needs assistance to adjust to the physical and psychosocial implications. Communication is a key component of assisting the person with impaired hearing. Initially the person may withdraw by avoiding communication or socialisation with others to cope with the hearing loss. This can lead to social isolation and low self-esteem. The nurse should encourage the person to discuss feelings of fear and frustration with their family members (LeMone et al 2014).

Clinical Interest Box 34.7 provides an overview of hearing aid care and education.

### Key aspects related to assisting the hearing-impaired person

- Reduce background noise; attract the person's attention before speaking.
- Stand directly in front of the person or, if in a group setting, arrange semicircular seating. This enables the person to see facial expressions, body gestures and to read lips. Vision becomes a primary sense for the person who is hearing impaired. The nurse should avoid covering the mouth while speaking.
- Communication can be improved by employing non-verbal cues to help convey the meaning of your conversation; for example, facial expressions, hand gestures, pointing and writing.
- Allow the person time to insert, or adjust, any hearing aid before you speak.
- Speak clearly and more slowly than usual but avoid exaggerated movements or shouting. Shouting distorts sound and is painful to the wearer of a hearing aid.
- Rephrase your words if the person has not understood. It may be helpful to write out the message if you remain uncertain whether the person has understood.
- Encourage the hearing-impaired person who has a speech disorder to communicate verbally. If you do not understand their communication, do not pretend to

## CLINICAL INTEREST BOX 34.7 Hearing aid care

A hearing aid helps capture, amplify and funnel sound waves to the auditory nerve in a person with sensorineural hearing loss. Hearing aids are delicate and must be protected from heat, moisture and breakage. The manufacturer's guidelines for instructions specific to the person's hearing aid should be read by the person and/or family members. The aid is turned on to be certain it is working, then the ear mould is gently inserted into the ear canal. Once the mould has been inserted, the individual adjusts the volume. The tube, if fitted, is placed over the ear and attached to the battery device. Key aspects related to care of aids include:

- Ensuring that the ear mould and tubing are not blocked by wax or moisture. The hearing aid may be wiped with a soft tissue to remove any oils or waxes
- Keeping the aid dry and away from high temperatures (e.g. direct sunlight)
- Removing the aid before the person showers or washes their hair
- Switching off the aid when it is not in use
- Checking the battery and replacing it when necessary. Ensure that the battery is inserted correctly
- Checking that the hearing aid is switched on when in use and that the volume is adjusted
- Investigating the cause of any 'whistling', which can result in embarrassment and annoyance. Causes of whistling include a poorly fitting ear mould, ear mould incorrectly positioned, cracked or broken tubing and the volume turned up too high
- Notifying the audiologist or hearing-aid specialist if the aid is malfunctioning.

Research has resulted in the development of an implantable device to improve hearing—the cochlear implant. A cochlear implant is an electronic device that is surgically implanted. The device picks up environmental sounds and converts them to electrical impulses, which are relayed to an implant receiver. Direct electrical stimulation to the nerve fibres of cranial nerve VIII sometimes enables profoundly deaf persons to hear some sounds.

**TABLE 34.4 | Aids available to hearing-impaired persons**

| Aid | Description |
|---|---|
| Hearing aid | Device that receives speech and environmental sounds through a microphone, and amplifies sound. Various styles including those worn in the ear canal, behind the ear, on the arm of spectacles, and in the form of a transmitter that is attached to the clothing (body aid). Some styles may be used with an induction coil for use with television, telephone and radio |
| Modified telephone | Telephone fitted with volume control and induction coil |
| Radio and television | Used in conjunction with headphones, induction coils, infra-red and FM transmitters |
| Telephone typewriter | Device fitted to a telephone whereby a caller's message is typed and translated into a written message, which is either displayed on a screen or printout |
| Captioning devices | Added to a television set, these devices display captions or subtitles at the bottom of the screen. Not all television programs are coded for this service |
| Hearing dog | Dog trained to respond to specific sounds (e.g. door bell, telephone, a baby's cry) and to alert the hearing-impaired person to the source of the sound |

*www.deafness.org.au*

have done so. The person should be encouraged to repeat the sentence or to use other words or gestures to get the message across.

- Use items that are available from organisations such as the Deafness Foundation (www.deafness.org.au). Such organisations provide packaged kits to healthcare institutions, designed to assist hearing-impaired persons and staff. The kit generally includes adhesive stickers, discs, cards and information sheets.
- Other assistive devices may be required, such as sound lamps in which the light responds to sounds and telephones and alarm clocks with enhanced noise or flashing lights.
- Cultural aspects of care should always be taken into account when caring for the person who has impaired hearing.
- On discharge the nurse should encourage the person and their family to explore community resources available to people with partial or total loss of hearing, and rehabilitation programs that provide assistance in performing the activities of daily living (Crisp et al 2013).
- Table 34.4 provides examples of aids for hearing-impaired persons.

## Local ear care

Various nursing procedures involving the ear should be performed in accordance with the policies of the healthcare facility. The general principles should include:

- Explain the procedure to the person
- Ensure the person is sitting or lying with their head well supported
- Ensure adequate lighting
- Wash hands thoroughly before and after the procedure to prevent cross-infection
- Warm solutions and ear drops to body temperature, as hot or cold temperatures stimulate the inner ear, causing vertigo and sometimes nausea and vomiting (Berman et al 2015).

## Instillation of ear drops

Ear drops that may be prescribed include those that combat infection and those that soften wax. Ear drops are instilled only when they have been prescribed by a medical officer, and the nurse must follow the regulations and policies regarding the administration of medications. Key aspects regarding the use of otic medications are the same as those for using ophthalmic medications (see Chapter 24).

### DECISION-MAKING FRAMEWORK EXERCISE 34.1

Katie is an Enrolled Nurse working in an acute medical ward. The RN allocates her a patient who is prescribed ear drops four times a day. Katie is unsure if she is able to administer the ear drops. What steps must she work through to decide if she can administer the ear drops?

## Summary

The sense organs are those that contain receptors that pick up a stimulus from the environment and transmit impulses to the brain for interpretation. These unique organs are the tongue, eye, ear, nose and skin. With these organs taste, smell, touch, sight and sound are experienced.

The tongue contains taste buds that allow individuals to differentiate from sweet, salty and bitter tastes when substances are in solution. The information is transmitted to the brain via nerve impulses to be interpreted. The sensations of taste, sight and smell are closely related, and play an important part in stimulating appetite and the secretion of gastric juices.

One of the functions of the skin is the perception of touch, making it an organ of sensation. The sensation of touch allows individuals to be aware of pressure, heat, cold and pain—necessary to protect individuals from harm as well as to feel pleasure. The impulses that travel to the brain for interpretation enable individuals to distinguish if the intensity of the sensation is harmful.

Sight is the result of light rays reaching the retina in the eyes and the image being transmitted to the brain for interpretation of that image. This process requires several components that allow the right amount of light into the eye, the retina to be exposed to the light rays and the inner workings of the eye to be able to ensure the image is in focus and true to colour.

The ears enable individuals to hear sounds and interpret them into meaningful communication. The sense of hearing is closely linked with our ability to speak.

Sound waves enter the outer ear and travel to the tympanic membrane where nerve endings carry the resulting vibrations to the brain for interpretation. With the complex mechanisms required for hearing, individuals can interpret intensity of sound and pitch. Structures within the ear help to maintain balance.

The sense organs enable the individual to react and respond to their environment. Caring for a person with impaired sensory function requires the nurse to maintain a safe environment for the person to interact in and to be sensitive to the particular sensory loss being experienced.

## Review Questions

1. What does the term ageusia mean?
2. What are the three (3) structures of the middle layer of the eye?
3. What is the other term for myopia?
4. What are the three (3) classifications of cataracts?
5. What is the most common cause of blindness in developed countries?
6. What is Ménière's disease?
7. What is presbycusis?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER 35

# Nursing assessment and management of neurological health

*Anne MacLeod*

## KEY TERMS

absence seizure
aneurysm
aphasia
apraxia
ataxia
aura
cephalalgia
cerebrovascular accident (stroke)
chorea
decerebrate
decorticate
dysphasia
generalised seizure
hemiparesis
hemiplegia
hydrocephalus
neuralgia
neuritis
paraplegia
quadriplegia
spina bifida
status epilepticus
transient ischaemic attack (TIA)

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define the key terms
- Describe the structure of the nervous system
- Describe the position of each part of the nervous system
- Describe the functions of the nervous system
- State the pathophysiological influences and effects associated with disorders of the nervous system
- Describe the major manifestations of nervous system disorders
- Briefly describe the specific disorders of the nervous system outlined in this chapter
- Apply principles of neurological assessment
- Demonstrate accurate documentation of a neurological assessment
- Discuss the nursing management of an acute neurological presentation
- State the diagnostic tests that may be used to assess nervous system function
- Assist in planning and implementing nursing care for the individual with a nervous system disorder

## CHAPTER FOCUS

The nervous system is responsible for the coordination of all other systems. It provides a network for communication within the body, and between the body and its environment. The brain is informed of events occurring both within and outside the body by nerve impulses that originate at a large number of sensory receptors. The receptors, which may be nerve endings, single specialised cells or a group of cells forming a sense organ, convert the energy of a stimulus into impulses that pass to specific areas of the brain. An understanding of this complex and dynamic system underpins many aspects of individual care, as almost all medical conditions can affect the human nervous system in some way.

The workings of the human brain, and indeed the entire nervous system, have both fascinated and mystified scientists for centuries. The knowledge that has been uncovered has enabled healthcare professionals to make more accurate assessments of individuals, allowing implementation of safer and more effective treatments. While application of this knowledge has significantly improved the expected outcomes for many individuals affected by disorders of the nervous system, there is still much research to be carried out to fully explain the workings of this intricate system.

This chapter focuses on the function and structure of the neurological system, pathophysiological influences and effects of disorders of the nervous system, neurological assessment and the care of an individual with a nervous system disorder.

## LIVED EXPERIENCE

Since my marriage a year ago I had recently noticed my wedding ring was getting tight. I also found my shoes pinched me and I bought a larger size. I had had occasional headaches, but these started to increase in frequency and intensity. I also thought I might need to get eyeglasses as my vision seemed to be getting worse. It wasn't until we were showing friends our wedding photos when my husband said I looked a bit different to the photos. Looking in the mirror we could see subtle differences—my chin seemed bigger or longer, my nose looked a bit more prominent, and my forehead had developed a mild furrow across it. I decided to see my GP who sent me for a scan. It showed a pituitary tumour. Apparently this explained some of my symptoms. I was referred to an endocrinologist and a neurosurgeon. I was told some of my symptoms (acromegaly) might improve after surgery and we traced around my hand as a baseline. The GP ordered visual field tests. I went into hospital the day of the surgery and had fiducials (little greenish lifesaver-looking things) stuck to my head. I was taught to wipe my nose, not blow it post op, and to turn any sneeze into a cough by opening my mouth at the time. Apparently this is to protect the graft stuck up my nose. The operation was due to be done through my nostril. When I awoke I had a nasal bolster under my nose (to catch the drips), an IV and a urinary catheter and a lumbar drain in my back to drain small amounts of spinal fluid. The lumbar drain was removed later that day and the IDC was removed the next morning. The nurses asked me to keep a record of anything I had to drink, and I used a bottle for measuring urine. I didn't have issues but some people will pass a lot of urine post op. Two days after surgery they removed the packs from my nostril (they looked like tampons). I was discharged after 4 days. My hand is back to normal size! I haven't noticed any other changes. I see the endocrinologist as a follow up, and also the neurosurgeon in 6 weeks. I will not get glasses until I have another visual field test (my peripheral vision was diminished on my left side). I was lucky to catch this tumour before it caused more vision problems or hormone problems.

**Tanya, age 26**

# THE FUNCTION AND STRUCTURE OF THE NEUROLOGICAL SYSTEM

## Nervous tissue

### Neurons

Neurons 'nerve cells' (Figure 35.1) are the primary components of the nervous system. Functioning alone, or as units, neurons detect internal and external changes and initiate body responses needed to maintain homeostasis. Each neuron is composed of a cell body, with projections forming dendrites, and one long axon. The dendrites are short-branched fibres, which receive impulses and conduct them towards the cell body of a neuron. The axon, which may vary in length from miniscule to over a metre, conducts impulses away from the cell body of a neuron. A single neuron may have many dendrites. Each axon has a covering called a neurilemma, and most have a fatty sheath, the myelin sheath. The myelin sheath protects and insulates the axon and increases the transmission rate of nervous impulses. Neurons are supported by many types of cells that support, insulate and protect, called neuroglia or 'nerve glue'.

### Neuroglia

The neuroglia include many types of cells that support and protect the neurons. They play a role in regulating neuronal activity, and in providing neurons with nutrients. Neuroglia differ from neurons in that they are not capable of transmitting nerve impulses and never lose their ability to divide. The neuroglia in the central nervous system (CNS) are comprised of five types of cells: astrocytes, cells with small cell bodies

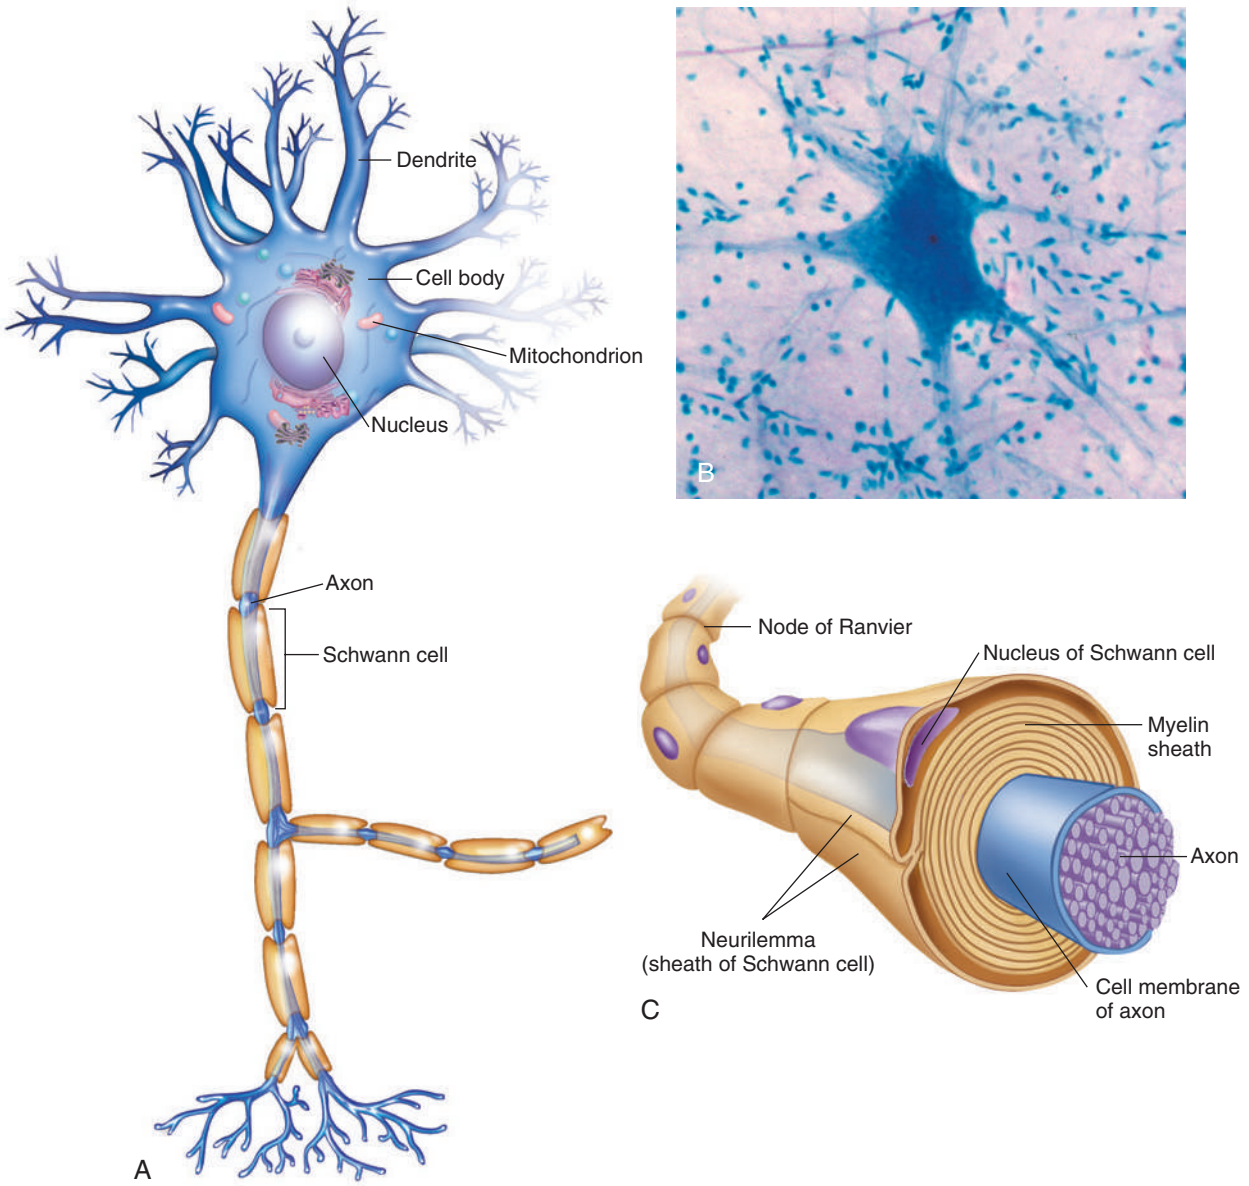

**Figure 35.1** A typical neuron A: Diagram of a typical neuron showing dendrites, a cell body and an axon B: Photomicrograph of a neuron C: Segment of a myelinated axon

*(Thibodeau & Patton 2012)*

and processes like dendrites, which protect the neurons from harmful substances that may be in the blood by forming a living barrier between the capillary blood supply and the neurons; oligodendrocytes in the CNS, which have few processes and produce the myelin sheath around the processes of the neurons; microglia which are phagocytes that dispose of debris; ependymal cells which line the cavities of the brain and spinal cord; and Schwann and satellite cells within the PNS. The Schwann cells protect, nourish and form myelin and the satellite cells protect and cushion.

## Functions of neurons

Neurons have two major functional properties: irritability and conductivity. Irritability is the ability to respond to a stimulus and convert it into a nerve impulse. Conductivity is the ability to transmit the impulse to other neurons, muscles or glands. An impulse is a complex electrical and chemical signal transmitted along a nerve pathway in response to a stimulus. The speed of transmission varies with the size of the nerve fibre, and may be as much as 120 metres per second.

A synapse is the space between the terminal axon of one neuron and the dendrites of another. By means of a chemical substance (neurotransmitter) released by the axons, impulses are transmitted through this space from one neuron to another. Examples of neurotransmitters are acetylcholine and noradrenaline. Many different types of stimuli (electrical, mechanical or chemical) can excite neurons so that they become active and generate an impulse. Most neurons are excited by the neurotransmitters released by other neurons, but other stimuli can excite neurons. For example, sound excites some of the neuronal receptors of the ear, and pressure excites some cutaneous receptors of the skin. Receptors, or sensory nerve terminals, act as transducers, converting the energy of a stimulus into impulses that pass to the brain.

The nervous system can be divided into two primary divisions: the central nervous system, consisting of the brain and spinal cord; and the peripheral nervous system, consisting of nerves that connect the central nervous system with the body tissues (Patton et al 2012; Thibodeau & Patton 2012).

## The central nervous system

The central nervous system is composed of nervous tissue, which is commonly described as grey and white matter. Examination of a section of the brain reveals that it is grey on the outside and white on the inside. Microscopic examination reveals that the grey matter is composed of neuron cell bodies responsible for processing information and white matter which is made up of myelinated fibres which allows communication to and from grey matter areas, and between the grey matter and the other parts of the body.

### The brain

The brain is a large organ weighing about 1.4 kg in the adult, held in position within the skull by membranes called the meninges. In most parts of the brain the outer portion, or cortex, consists of grey matter, while white matter forms the inner portion. The grey matter is convoluted to provide a greater surface area. The brain is divided into the:

- Cerebrum, comprising the left and right cerebral hemispheres
- Diencephalon, comprising the left and right thalamus and hypothalamus
- Brainstem, comprising the midbrain, pons and medulla oblongata—the stalk-like section that connects the brain to the spinal cord
- Cerebellum (Thibodeau & Patton 2012).

### The cerebrum

The cerebrum (Figure 35.2) is the largest part of the brain, filling the vault of the cranium from front to back. It is divided by fissures into the left and right hemispheres, and each hemisphere is further divided by fissures into four main lobes and the insula lobe. The insula lobe lies medial to the lateral sulcus and is thought to be involved in sensory and motor visceral functions as well as taste perception. The four main lobes are:

1. The frontal lobe, responsible for voluntary motor function, motivation, aggression, personality, sense of smell and mood
2. The parietal lobe, which receives and evaluates sensory information
3. The temporal lobe, which receives input for smell and hearing and has an important role in memory
4. The occipital lobe, responsible for reception and integration of visual input.

The left hemisphere of the brain controls the right side of the body and the right hemisphere controls the left side of the body. The hemispheres are connected by the corpus callosum which allows the cerebral hemispheres to communicate with each other.

The cerebrum is divided into several areas, some of which are sensory and some of which are motor areas. The sensory areas of each hemisphere receive and interpret sensations from the opposite side of the body, including touch, temperature, pain, pressure and an awareness of the position of the body in its environment. The motor areas of each hemisphere control all voluntary movement on the opposite side of the body. The centres of special sense are located in the various lobes, including the centres for hearing, speech, smell, taste and sight (Figure 35.3).

The functions of the cerebrum are therefore to receive and interpret impulses from the sensory organs, to initiate and control the movements of skeletal muscles and to perform the higher levels of mental activity such as thinking, reasoning, intelligence, learning and memory (Thibodeau & Patton 2012).

### The diencephalon

The diencephalon consists of three major structures: the thalamus, the hypothalamus and the pineal gland. It is located between the midbrain and cerebrum. The thalami are two oval masses of grey matter that form the lateral walls of the third ventricle. Each thalamus is subdivided into a number of nuclei. Most sensory pathways (except smell) synapse here, serving as the major relay station for sensory impulses. The thalamus plays an important role in the control of somatic motor activity and influences mood and strong emotions.

The hypothalamus lies beneath the thalamus and the pituitary gland is closely connected to it. The hypothalamus controls all the activities of the autonomic nervous system, which is described later in this chapter. The hypothalamus is important in controlling the endocrine system, as it regulates pituitary gland function.

The pineal gland is located posterior to the thalamus, receives sensory information about the strength of light seen by the eyes and varies the secretion of the hormone melatonin (Thibodeau & Patton 2012; Patton et al 2012).

### The brainstem

*The midbrain*. The midbrain is a short narrow segment connecting the cerebrum with the pons. It is composed primarily

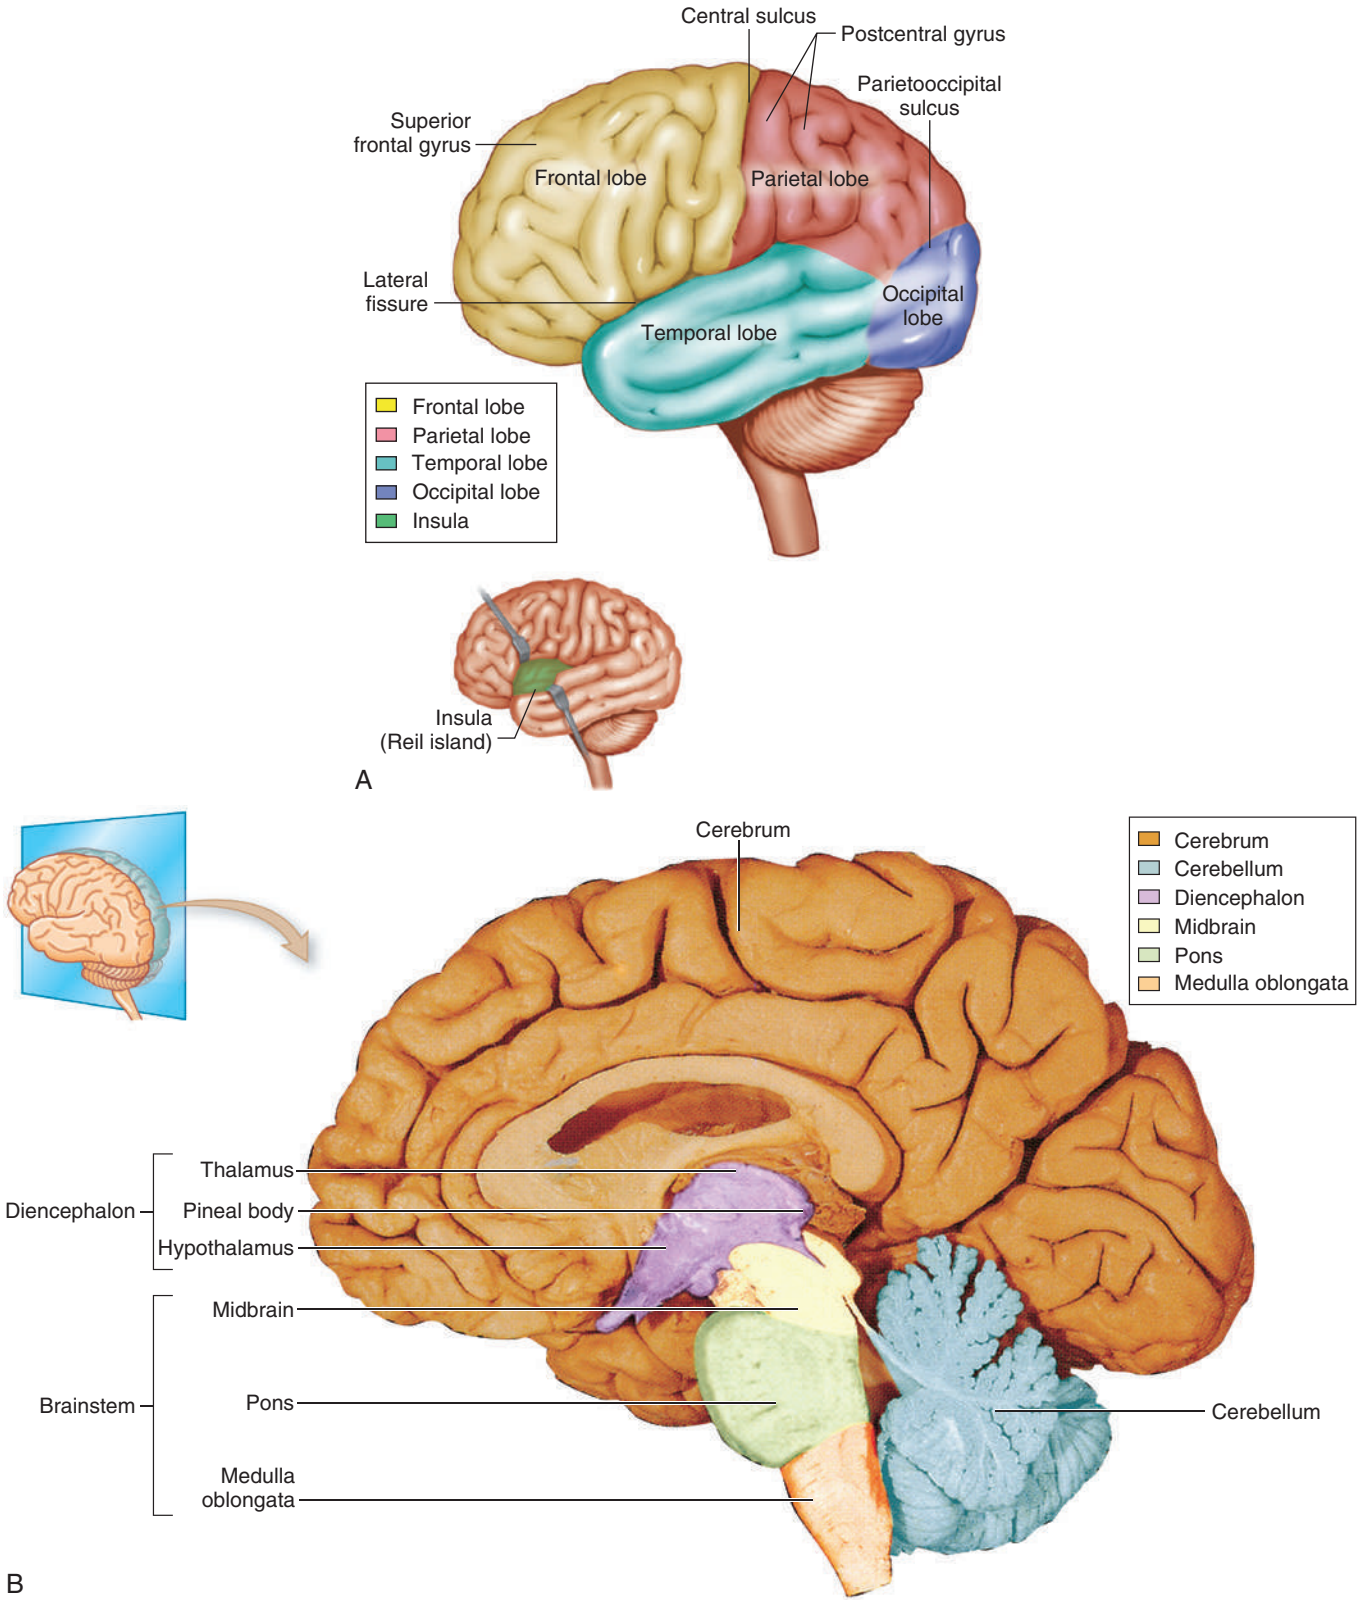

**Figure 35.2** A: Left hemisphere of cerebrum, lateral surface B: Divisions of the brain *(Thibodeau & Patton 2012)*

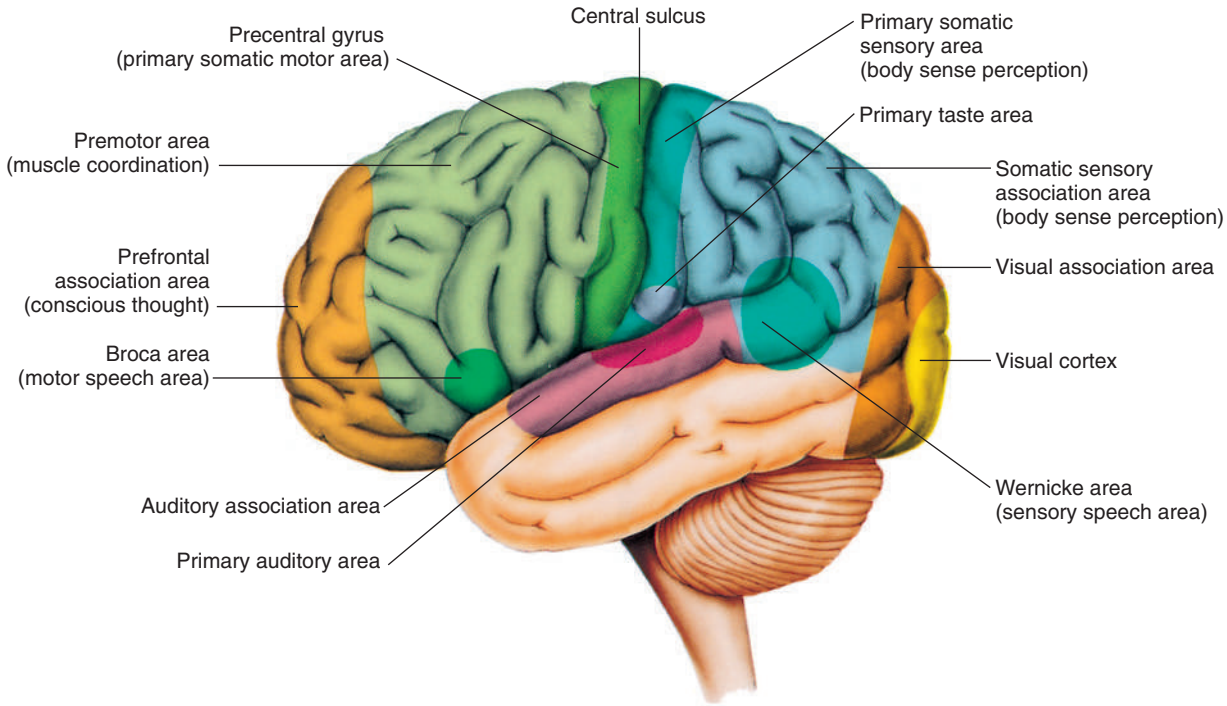

**Figure 35.3** Functional regions of the cerebral cortex
*(Patton et al 2012)*

of ascending and descending fibre tracts. Its functions are to provide a pathway for impulses passing between the cerebrum and spinal cord, and to receive stimuli that initiate eye and postural movements.

*The pons* lies just above the medulla oblongata. It contains two respiratory centres: the pneumotaxic centre and the apneustic centre. Its functions are to act as a relay station from the cerebrum to the cerebellum, and to modify the activity of the medullary respiratory centres through the pneumotaxic and apneustic centres.

*The medulla oblongata*. The medulla oblongata lies between the pons and the spinal cord. It provides the link between the brain and the spinal cord and contains the cardiac, respiratory, vasomotor and reflex centres. Its functions are:

- To provide a pathway where nerve fibres to and from the brain cross over to the opposite side
- To control heartbeat (through the cardiac centre)
- To control ventilation (through the respiratory centre)
- To control constriction and dilation of blood vessels (through the vasomotor centre)
- To initiate the reflex actions of swallowing, vomiting, coughing and sneezing (through the reflex centres).

## The cerebellum

The cerebellum lies behind the pons and medulla and below the occipital lobes of the cerebrum. Like the cerebrum, the cerebellum is divided into two hemispheres that have shallow convolutions in their surface of grey matter. Its functions are coordination of muscular activity and regulation of muscle tone, and maintenance of balance and posture.

## Blood supply to the brain

The carotid and the vertebral arteries supply blood to the brain. These arteries branch and join up again, forming a circle of arteries at the base of the brain called the circle of Willis. From here smaller cerebral arteries branch off to supply each region of the brain. Blood returns from the brain via the jugular veins to the superior vena cava.

The blood–brain barrier is a barrier that prevents or delays the entry of certain substances into brain tissue. The relatively low permeability of the capillaries supplying the brain means that some substances are either completely or partially prevented from gaining access to brain tissue. The blood–brain barrier thus acts as a protective mechanism, preventing substances such as bilirubin, which could disrupt brain function, from crossing the barrier. Water, oxygen, carbon dioxide and glucose cross the blood–brain barrier easily (Patton et al 2012).

## The spinal cord

The spinal cord is a cylindrical structure that lies within a canal inside the vertebral column. It extends from an opening on the underside of the skull (the foramen magnum) to the level of the first or second lumbar vertebra. Below this level the vertebral canal is occupied by nerves from the lumbar and

sacral segments of the cord; conus medullaris, the most distal bulbous part of the spinal cord which continues as the filum terminale: these constitute the cauda equina ('horse's tail'). The spinal cord, which is about 46 cm in length, consists of nervous tissue, with the white matter on the outside and the grey matter arranged roughly in an 'H' formation in the centre (Figures 35.4 and 35.5). The two anterior projections of grey matter are called the anterior horns, and the posterior projections are called the posterior horns. Sensory nerve fibres enter the posterior horns, and motor nerve fibres leave the anterior horns.

Leaving the spinal cord at intervals throughout its length are 31 pairs of spinal nerves. The functions of the spinal cord are:

- To receive sensory impulses from the tissues and convey them to the sensory areas of the brain via ascending (afferent) pathways
- To convey motor impulses from the brain to various parts of the body via descending (efferent) pathways
- To provide a pathway through which reflex actions take place.

A reflex action, or arc, is an automatic motor response to a sensory stimulus without conscious involvement (Figure 35.6). Most reflex actions are protective in nature and take place more quickly than voluntary actions. The structures involved in a reflex action are:

- A sensory organ (e.g. the skin) to receive the stimulus
- A sensory (afferent) nerve fibre to carry the impulse to the posterior horn of the spinal cord
- An association neuron in the spinal cord to receive the impulse and transmit it directly to the anterior horn
- A motor (efferent) neuron in the anterior horn to receive the impulse and transmit it to the motor organ
- A motor organ (e.g. a muscle) to receive and respond to the stimulus.

An example of a reflex action is when the hand comes into contact with a very hot object. The skin on the hand receives the stimulus of heat, and an impulse travels from the sensory nerve endings in the skin to the posterior horn of the spinal cord. From there, the impulse is transmitted to the anterior horn, then passed along the motor nerves to the muscles of the shoulder, arm and hand. As a result, the hand is pulled rapidly away from the source of heat before the brain has even processed the information (Patton et al 2012; Thibodeau & Patton 2012).

### The meninges

The meninges are the three membranes that cover the brain and the spinal cord. The individual membranes are:

1. The dura mater (meaning 'hard mother') is the tough outermost layer. It consists of two layers of fibrous connective tissue, with one layer forming the periosteum covering the inner surface of the skull bones, and the other layer covering the brain and spinal cord
2. The arachnoid mater (meaning 'mother like a spider's web') is the middle layer. The name refers to the fact that it is so thin that, when viewed under a microscope, it resembles a spider's web
3. The pia mater (meaning 'gentle mother') is the delicate innermost layer. It adheres closely to the surface of the brain and spinal cord, dipping down into the convolutions and fissures. The pia mater is richly supplied with blood vessels that carry blood to the brain and spinal cord.

The subarachnoid space is the space between the arachnoid mater and pia mater, filled with cerebrospinal fluid in circulation. The functions of the meninges are to form a protective covering against physical injury around the brain and spinal cord, and to help secure the brain to the cranial vault (Thibodeau & Patton 2012; Patton et al 2012).

### Cerebrospinal fluid

Cerebrospinal fluid (CSF) is a clear watery fluid with a composition similar to plasma. It contains substances including water, glucose, sodium, chloride, potassium, protein and waste products such as urea. The CSF is formed from the blood and is produced by a combination of filtration and active secretory processes by the choroid plexus in the ventricles of the brain. CSF circulates in the subarachnoid space surrounding the brain and spinal cord. The total volume of the CSF is about 140 mL. The fluid is formed continuously in the ventricles at a rate of about 500 mL/day, and is reabsorbed into the blood at about the same rate. The functions of CSF are to:

- Form a protective cushion around the brain and spinal cord
- Maintain normal pressure around the brain and spinal cord
- Provide a medium for the exchange of nutrients and waste products between the bloodstream and the nervous tissue (Patton et al 2012).

## The peripheral nervous system

The peripheral nervous system (PNS) consists of the 12 pairs of cranial nerves, and 31 pairs of spinal nerves that leave the spinal cord. The peripheral nerves may be sensory, motor or mixed. Sensory (afferent) nerves carry impulses to the brain and spinal cord. Motor (efferent) nerves carry impulses from the brain and spinal cord to the muscles, organs and tissues. Mixed nerves are composed of both sensory and motor fibres and transmit impulses in both directions. The motor peripheral nervous system has two functional divisions:

- The somatic nervous system, which allows us to consciously, or voluntarily, control our skeletal muscles. This division is often called the voluntary motor system but it also includes involuntary reflexes
- The autonomic nervous system, which regulates events that are automatic, or involuntary, such as the activity of smooth and cardiac muscle and glands. The autonomic nervous system itself has two parts: the sympathetic and parasympathetic nervous systems (described further below) (Marieb 2015; Patton et al 2012).

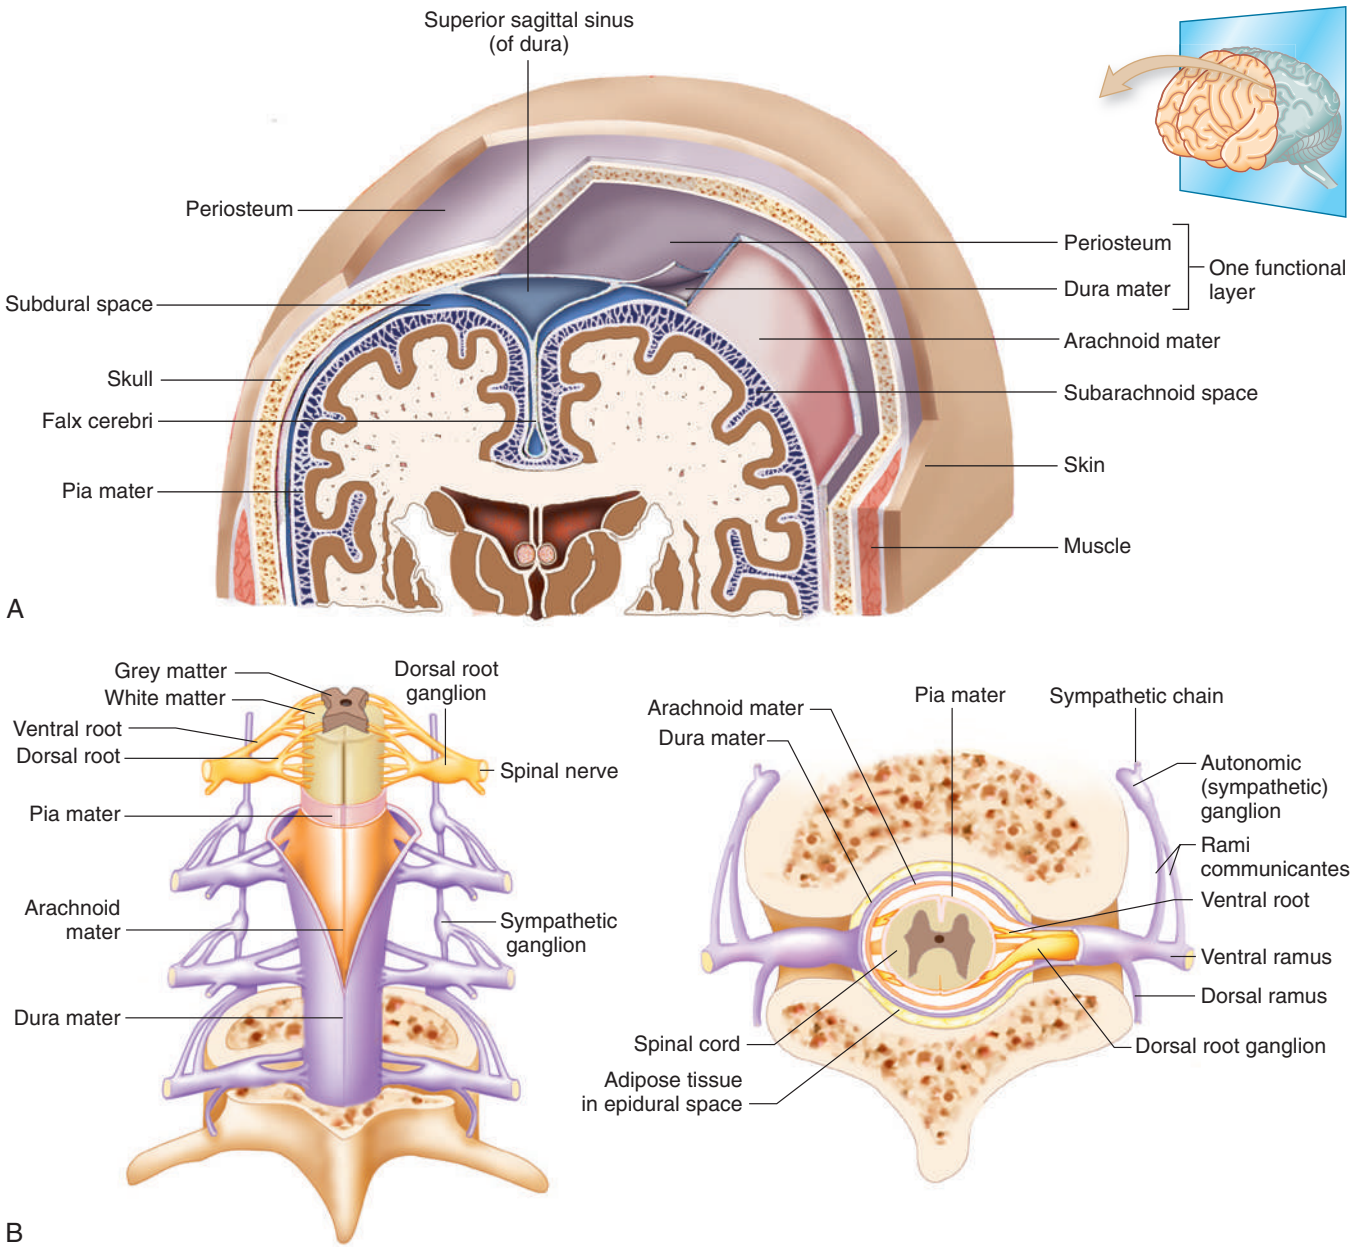

**Figure 35.4** A: Coverings of the brain B: Coverings of the spinal cord *(Patton et al 2012)*

## The cranial nerves

Twelve pairs of cranial nerves (CN) leave the brainstem. The numbers (Roman numerals are the convention), names and functions of the cranial nerves are:

I. Olfactory nerve: sensory—the nerve of smell
II. Optic nerve: sensory—the nerve of sight
III. Oculomotor nerve: motor—supplies the muscle of the eye
IV. Trochlear nerve: motor—supplies one of the eye muscles
V. Trigeminal nerve: mixed—sensory fibres receive stimuli from most of the skin of the head and face, the membranes of the nose and mouth, the orbits, the upper and lower jaws and teeth; motor fibres supply the muscles of mastication
VI. Abducent nerve: motor—supplies one of the eye muscles
VII. Facial nerve: mixed—sensory fibres convey the sensation of taste from the anterior portion of the tongue; motor fibres supply the muscles of facial expressions

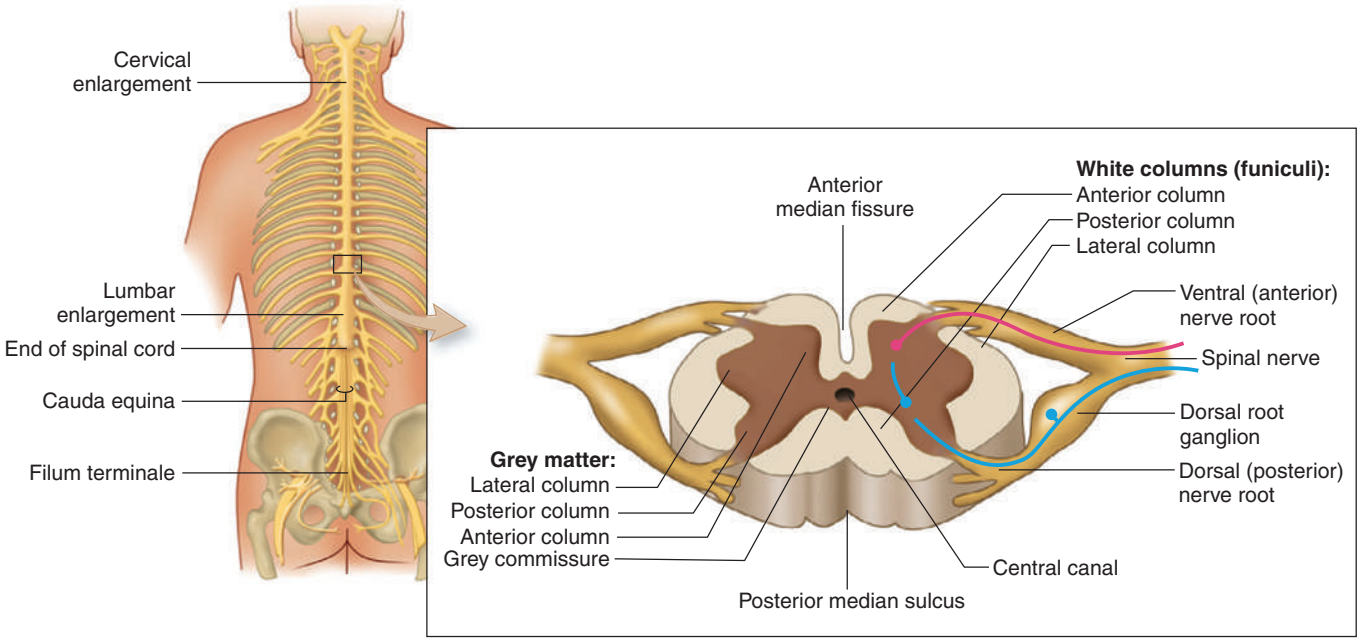

**Figure 35.5** Spinal cord
*(Patton et al 2012)*

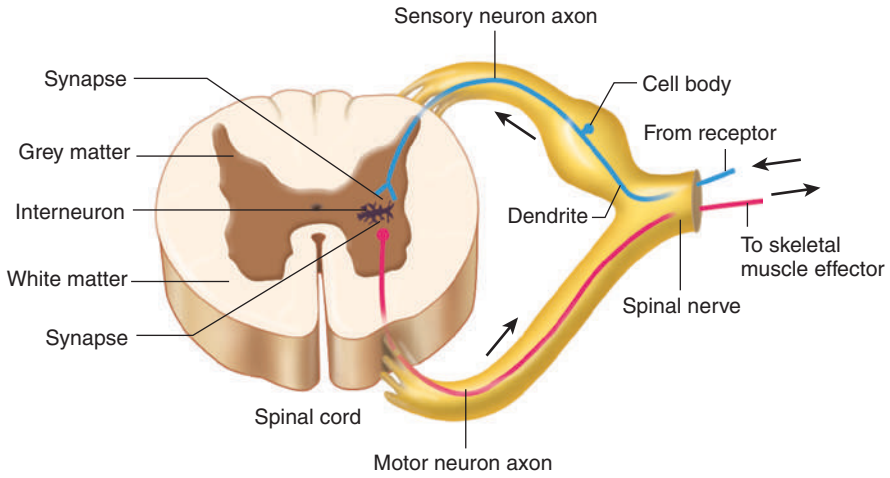

**Figure 35.6** A reflex arc
*(Patton et al 2012)*

VIII. Auditory nerve: sensory—the nerve of hearing and balance
IX. Glossopharyngeal nerve: mixed—sensory fibres convey taste sensations from the posterior part of the tongue; motor fibres supply the pharynx
X. Vagus nerve: mixed—controls secretion and movement of the internal organs (e.g. oesophagus, larynx, trachea, heart, stomach, intestines, pancreas, spleen, kidneys and blood vessels)
XI. Accessory nerve: motor—supplies the muscles of the neck, and also the pharynx and larynx
XII. Hypoglossal nerve: motor—supplies the tongue muscles (Marieb 2015; Patton et al 2012).

## The spinal nerves

The spinal nerves project out of the vertebral canal, one pair emerging below each vertebra, and one pair emerging between the cranium and the first cervical vertebra. The spinal nerves

are mixed nerves, containing both sensory and motor fibres. They allow for sensation and movement in peripheral parts of the body not supplied by the cranial nerves, such as skin, muscles, bones and joints of the trunk and limbs. The spinal nerves are arranged in groups according to their region of origin in the cord. There are:

- Eight pairs of cervical nerves (C1–C8)
- Twelve pairs of thoracic nerves (T1–T12)
- Five pairs of lumbar nerves (L1–L5)
- Five pairs of sacral nerves (S1–S5)
- One pair of coccygeal nerves.

In some regions the nerves divide immediately after leaving the cord. These then branch and unite with each other to form what is called a plexus (meaning braid). The major plexuses are:

- The cervical plexus, which supplies the muscles of the neck and shoulders, and also gives rise to the phrenic nerves that supply the diaphragm
- The brachial plexus, which gives rise to the radial, median and ulna nerves, which supply the arm
- The lumbar plexus, which gives rise to the femoral nerve, which supplies the thigh muscles
- The sacral plexus, from which the sciatic nerve arises.

The sciatic nerve is the largest nerve in the body, running over the hip posteriorly down the back of the thigh to the knee where it divides into the peroneal nerve and tibial nerve (Marieb 2015; Patton et al 2012).

## The autonomic nervous system

The autonomic nervous system is the division of the peripheral nervous system concerned with involuntary activity of the body. It supplies nerves to all the structures in the body that are not under conscious control. The autonomic nervous system consists of two divisions: the sympathetic and the parasympathetic nervous systems.

### The sympathetic nervous system

The sympathetic nervous system arises from grey matter in the spinal cord from T1 through to L2. Sympathetic nerves then synapse in a chain of ganglia that lies on either side of the vertebral column, before reaching organs or tissues. A ganglion (plural ganglia) is a knot-like mass of cell bodies. Plexuses are formed by fibres from these ganglia; for example, the solar plexus lying behind the stomach and supplying the abdominal organs, and the cardiac plexus supplying the heart and lungs (Marieb 2015).

### The parasympathetic nervous system

The parasympathetic nervous system consists of cranial nerves III, VII, IX and X and nerves that emerge from the sacral region of the spinal cord. The vagus nerve (cranial nerve X) is the largest autonomic nerve.

***Vasovagal syncope*** When the vagus nerve is overstimulated the body's blood vessels dilate causing the heart rate to slow and lowering the BP, which may cause sweating and a loss of consciousness. There are many causes for vasovagal syncope, including nausea, gastrointestinal cramping, straining during a bowel movement, the sight of blood, standing for too long or emotional or physical stressors that over-stimulate the vagus nerve (Mayo Clinic 2015).

### Functions of the autonomic nervous system

The functions of the autonomic nervous system are to control the movements of internal organs and the secretions of glands. The system provides dual control: the activity of an organ is stimulated by one set of nerves, and inhibited by the other set of nerves. This dual control achieves smooth rhythmic action of involuntary muscles and internal organs, maintaining a balance between activity and rest.

The sympathetic nerves are called adrenergic nerve fibres and release the neurotransmitter noradrenaline. These nerves can be affected by strong emotions such as anger, fear or excitement, and have a stimulating effect on most organs. The effect resembles that produced by adrenaline, a hormone secreted by the adrenal glands. This effect is called the 'fright, fight or flight' effect, in which the body responds to a fright either by preparing to fight or by running away. The response of the body includes:

- Dilation of the pupils of the eyes
- Increased force and rate of heartbeat, increasing circulation
- Increased blood pressure and constriction of arterioles in the skin and abdominal organs to divert blood to all skeletal muscles, heart, lungs and brain
- Dilation of the bronchi to allow more oxygen to enter
- Slowing of digestion so that the digestive organs can receive a reduced blood supply, enabling blood to be diverted to vital structures
- Increased production of sweat by sweat glands
- A rise in blood sugar level, as the liver is stimulated to release more glucose for increased energy needs.

The parasympathetic nerves are called cholinergic fibres and release the neurotransmitter acetylcholine. These nerves tend to slow down body processes, so that the end result of the antagonistic action of each division of the autonomic nervous system is a balance between acceleration and retardation. After the 'fright' or stressful situation is over, the parasympathetic nervous system returns things to normal. The digestive organs receive more blood, the glands increase their secretions, the heartbeat is decreased and the blood pressure falls. The effects of sympathetic and parasympathetic stimulation on various body organs are compared in Table 35.1 (Marieb 2015; LeMone et al 2014; Patton et al 2012).

# PATHOPHYSIOLOGICAL INFLUENCES AND EFFECTS OF DISORDERS OF THE NERVOUS SYSTEM

The pathophysiological changes that can disrupt normal function of part or all of the nervous system can be due to congenital or developmental disorders, infectious or inflammatory conditions, trauma, neoplasia, degenerative conditions and metabolic or endocrine disorders. Any pathophysiological

**TABLE 35.1 | Effects of sympathetic and parasympathetic stimulation**

| Organ | Sympathetic stimulation | Parasympathetic stimulation |
|---|---|---|
| Heart | Increases rate/strength of heartbeat<br>Dilates coronary arteries to increase blood supply to the heart muscle | Decreases rate/strength of heartbeat<br>Constricts coronary arteries to decrease supply of blood to the heart muscle |
| Bronchi | Dilates bronchi, allowing more air to enter the lungs | Constricts bronchi, limiting air intake |
| Digestive system | Decreases activity of the system and constricts digestive system sphincters<br>Inhibits production of saliva | Increases peristalsis and relaxes sphincters<br>Stimulates production of saliva |
| Urinary bladder | Relaxes bladder wall. Contracts internal sphincter muscle | Contracts bladder wall. Relaxes internal sphincter muscle |
| Eye | Dilates the pupil. Retracts the eyelids | Constricts the pupil. Closes the eyelids |
| Skin | Stimulates perspiration<br>Stimulates smooth muscles attached to hair follicles, producing 'goose bumps' | No effect on sweat glands<br>No effect on muscles/hair follicles |

*(Marieb 2015; Thibodeau & Patton 2012; Patton et al 2012)*

change is capable of causing various types and degrees of dysfunction.

## Aetiology of nervous system disorders

### Congenital disorders

The central nervous system of the developing fetus is very vulnerable to damage. Factors that may cause nervous system damage include the passage of microorganisms and drugs across the placental barrier into the fetal circulation. Other factors that may cause nervous system defects and result in physical and intellectual deterioration include chromosomal abnormalities, metabolic disorders, cranial malformations and structural abnormalities. The central nervous system may also be damaged during the birth process; for example, by cerebral anoxia or cerebral haemorrhage (National Institute of Neurological Disorders and Stroke ndb).

### Inflammatory and infectious conditions

Bacterial or viral infective processes affecting the central nervous system may result in the destruction of nervous tissue through the action of toxins released by the living microorganisms and from the material released from dead microorganisms, which stimulates the inflammatory process. Infection and inflammation of nervous tissue may result in altered behaviour, altered consciousness and sensory or motor deficits. Brain and spinal cord infections can cause dangerous inflammation with a wide range of symptoms, including raised temperature, headache, seizures, change in individual behaviour or confusion, brain damage, stroke or even death. Infection of the meninges is called meningitis and inflammation of the brain is called encephalitis. Myelitis refers to inflammation of the spinal cord. When both the brain and the spinal cord are involved, the condition is called encephalomyelitis (National Institute of Neurological Disorders and Stroke nde).

### Trauma

Trauma to the nervous system may result from elements within the system or from external forces. Trauma occurring from elements within the nervous system includes: bleeding from an **aneurysm** or ruptured intracranial vessel; transient interruption of the cerebral blood flow, causing ischaemia; and occlusion of a cerebral blood vessel by a thrombus or embolus. The most common causative factors in these conditions are hypertension and atherosclerosis.

Trauma from external forces may be caused by a direct or an indirect injury. A direct acceleration brain injury occurs when the head is struck by a moving object, and a direct deceleration injury occurs when the head in motion strikes a stationary object. In an indirect brain injury, the traumatic force is transmitted to the head through an impact to another part of the body, such as the neck or buttocks.

In open head trauma, a penetrating injury damages the integrity of the skull and/or meninges and brain. Infection may occur, as the injury allows the entry of microorganisms. A closed head injury is non-penetrating, with generally no disruption to the integrity of the cerebral meninges. Closed head injuries can result in jarring, bruising or tearing of brain tissue, which can cause haemorrhage, cranial nerve damage and cerebral oedema. An important event in closed head injury is known as coup and contrecoup. The coup injury is cerebral bruising resulting from impact to the skull, and contrecoup refers to the rebound effect of the injury, the movement of the brain opposite to the site of impact.

The nervous system response to trauma, which may cause more damage than the actual injury, results in oedema, bleeding and increased intracranial pressure. These factors destroy nervous tissue by compression or restriction of the circulation.

The spinal cord may be damaged as a result of a crushing or penetrating injury, dislocation of the spinal column, prolapsed intravertebral discs or neoplasia. In addition to tearing of, and pressure on, the spinal cord tissues, damage may be caused by haemorrhage, oedema or disruption of the blood supply to the spinal cord.

Damage to the peripheral nerves may result in loss of sensory and/or motor function (LeMone et al 2014).

### Neoplasia

Tumours of the nervous system, which may be either benign or malignant, cause symptoms related to pressure, destruction of nervous tissue, oedema and disruption of the blood supply. The neurological manifestations of a tumour affecting the nervous system depend on the location of the tumour and on its rate of growth. Examples of neoplasia include astrocytomas which arise from astrocytes and gliomas which arise from glial cells.

### Degenerative conditions

The causes of degenerative disorders of the nervous system are varied and involve atrophy of neurons and nerve fibres. The course of a degenerative disorder is generally gradual and progressive over many years. The effects of degenerative disorders include: progressive muscular atrophy; impaired speech, chewing, swallowing and breathing; deterioration of intellectual capacity; impaired motor function; and dementia. Examples of degenerative conditions include Parkinson's disease, motor neuron disease and Alzheimer's.

### Metabolic and endocrine disorders

Nervous system dysfunction may result from the effects of certain metabolic and endocrine disorders. Some nutritional deficiencies may affect nerve cells, resulting in their damage or death. For example, degeneration of the posterior and lateral columns of the spinal cord may occur from the vitamin B12 deficiency of pernicious anaemia. Disorders of cortical function, leading to confusion or coma, may result from a deficiency of thiamine (vitamin B1).

Specific endocrine disorders such as hypothyroidism result in decreased metabolic rate, and hypothermia can develop. If the body temperature falls below 30°C, unconsciousness will result. Myxoedema coma (hypothyroid state) is characterised by exaggeration of the signs and symptoms of hypothyroidism, with neurological impairment leading to loss of consciousness (LeMone et al 2014).

## Major manifestations of nervous system disorders

The manifestations of a nervous system disorder will vary depending on the type and severity of the disorder.

### Headaches (cephalalgia)

Headaches, or **cephalalgia**, are common in a variety of disorders and situations ranging from functional disturbances of blood vessels to tension and stress. In neurological disorders, headaches are one of the most common symptoms. Headaches can result from compression, traction, displacement or inflammation of the cranial periosteum, the dura mater, cerebral arteries or branches of the cranial nerves. Headaches may also occur as a result of tension within extracranial structures such as muscles, air sinuses and blood vessels. Headaches are commonly classified as vascular, tension or traction–inflammatory.

*Vascular headaches* include migraine, cluster headaches, hypertension headaches and headaches resulting from temporal arteritis. Although the mechanisms of migraine are not completely understood, migraine appears to result from an inherited predisposition and seems to be precipitated by trigger factors such as stress, abrupt falls in oestrogen levels, low blood glucose levels and dietary intake. One theory is that migraine results from spasm of intracranial blood vessels and dilation of extracranial blood vessels. The classic characteristics of migraine headache include throbbing and a tendency for the attacks to be unilateral. Some attacks are preceded by a variety of visual disturbances, such as loss of half of the visual field or flashing lights across the visual fields. Some individuals experience vertigo, nausea and vomiting.

Cluster headaches are a rapid succession of attacks over several days, followed by remission. Previously thought to be caused by histamine sensitisation, cluster headaches are now considered to have a vascular cause. Headaches associated with severe hypertension may be intense and similar to those caused by intracranial lesions. Temporal arteritis causes severe, throbbing headaches in the region of the temporal artery and is sometimes accompanied by visual loss.

*Tension headaches* are caused by prolonged contraction (tension) of the neck, head or facial muscles. Tension headaches are frequently associated with psychological factors such as anxiety or depression. The pain tends to be bilateral and, unlike vascular headaches, is not throbbing in character.

*Traction–inflammatory headaches*: headaches of this type are related to increased intracranial pressure, which causes irritation of, and traction on, blood vessels and the dura mater within the skull. Inflammation of the meninges (meningitis) can also result in severe headache. Headaches of intracranial origin related to increased intracranial pressure vary from mild to excruciating depending on the location and cause, such as a tumour, lesion or cerebral oedema (Brown et al 2015; National Institute of Neurological Disorders and Stroke ndd).

### Sensory changes

Sensory changes, which can result from disorders of the brain, spinal cord or peripheral nerves, include alterations in the sense of touch, pain, temperature sensitivity and the loss of a

sense of position. The loss of these sensations may be partial or complete. Common sensory disturbances include neuritis and neuralgia. **Neuritis**, characterised by pain and tenderness along the path of a nerve, can progress to complete loss of sensory and motor function. **Neuralgia** is characterised by severe stabbing pain, and can be caused by a variety of disorders affecting the nervous system. Other sensory changes that may accompany nervous system disorders include a loss of taste or smell, visual changes and hearing loss (LeMone et al 2014).

### Motor changes

Alterations in motor function include localised or generalised weakness, with difficulty in moving normally. Muscle tone may be abnormally increased or decreased. A pronounced increase in tone is referred to as rigidity. Spasticity of muscles is an increased resistance to passive stretch, with rapid flexion of a joint. Abnormal movements include:

- Twitching: localised spasmodic contraction of a single muscle group
- Tremor: rhythmic quivering movements resulting from involuntary alternating contraction and relaxation of opposing groups of muscles
- Myoclonus: spasm of a muscle or a group of muscles
- Dystonia: intense irregular muscle spasms
- Athetosis: slow, writhing involuntary movements of the extremities
- **Chorea**: involuntary, purposeless, rapid jerky movements
- Dyskinesia: involuntary twitching of the limbs or facial muscles.

Symptoms of **ataxia**, a condition characterised by impaired ability to coordinate movement, may be caused by a lesion in the spinal cord or cerebellum. Dizziness or vertigo, when the individual is unable to maintain normal balance in a standing or seated position, may also be related to a disorder of the nervous system. Unusual gait or stance may result from motor or sensory deficits caused by a disorder of the nervous system, such as Parkinson's disease. Paralysis, a symptom of motor disturbances, can occur in varying degrees with many nervous system disorders. Upper motor neuron lesions, in which the reflex area remains intact, generally cause spastic paralysis. Flaccid paralysis generally occurs in lower motor neuron lesions, which disrupt the reflex area (LeMone et al 2014).

### Reflex changes

Reflex changes can provide evidence of damage to the nervous system. The absences of normal reflexes, or the presence of abnormal reflexes, generally indicate nervous system dysfunction. Reflexes are classed as either superficial (cutaneous) or deep tendon (muscle stretch). Superficial reflexes are elicited when a stimulus is applied to the skin surface or to mucous membrane. Deep tendon reflexes are elicited when a stimulus is applied to a tendon, bone or joint (Patton et al 2012).

### Altered awareness, personality or level of consciousness

A neurological disorder that results in altered brain structure may cause impairment of a person's cognitive functions. They may experience difficulty in being able to think, remember, reason or understand. The person may also be confused in that orientation to time, place and person is impaired. Signs of reduced alertness or responsiveness may also be shown. Brain damage, for example as a result of a head injury, can cause a confused state characterised by fluctuating disorientation and incoherence.

Cerebral impairment may also cause mood changes and/or inappropriate emotional responses. Diffuse brain damage such as that caused by a large cerebral infarction may result in emotional instability or lability (a tendency to show alternating states of happiness and sadness that seem to be inappropriate). The person may also show signs of emotional flatness or apathy, demonstrated by a reactive absence of emotions. Alternatively, the individual may become euphoric.

Damage to the brain can also result in altered states of consciousness, ranging from drowsiness and difficulty in being aroused by normal stimuli, to coma. More information on assessment of level of consciousness is provided later in this chapter (Brown et al 2015).

### Seizures

Seizures, which are paroxysmal events associated with sudden abnormal discharges of electrical energy in the neurons of the brain, may be secondary to central nervous system disease. Seizure disorders are described later in this chapter.

## ASSESSING NEUROLOGICAL STATUS

Assessment is of prime importance in the care of an individual with a neurological disorder. The nurse must recognise changes that indicate a change in condition, as changes can occur rapidly and dramatically or develop over a period of days or weeks.

### Intracranial pressure

Intracranial pressure (ICP) is the pressure exerted by the CSF within the ventricles of the brain. However, it is more accurate to think in terms of intracranial 'pressures' rather than a single pressure, as the rigid skull is filled with brain tissue, intravascular blood and CSF. If any one of these three components increases in volume without a reciprocal change in volume of the other two, intracranial pressure will rise. Increased intracranial pressure affects the cerebral perfusion pressure, causing hypoxia, ischaemia, irreversible neurological damage and even death. Unless increased intracranial pressure is treated, the outcome will be herniation of a portion of the cerebrum through the tentorium, with pressure being exerted on the brainstem. The brainstem will then herniate through the foramen magnum, the only opening in the closed cranial vault.

Common causes of increased intracranial pressure include: space-occupying masses such as tumours, haematomas, abscesses or cerebral oedema; conditions that increase cerebral blood volume; and conditions that increase CSF. It is very important to identify early signs of increased intracranial pressure so that actions can be implemented to prevent or minimise irreversible brain damage. The manifestations of increased intracranial pressure include:

- Early signs and symptoms: deterioration in the level of consciousness (confusion, restlessness, lethargy), pupillary dysfunction, motor weakness such as **hemiparesis** and possible headaches
- Later signs and symptoms: continued deterioration in the level of consciousness (coma), possible vomiting, hemiplegia, decortication, decerebration, increasing systolic blood pressure, bradycardia and decreasing or irregular ventilations (Crisp et al 2013).

## Neurological assessment

Neurological assessment includes checking the level of consciousness, the pupils, motor function, sensory function and the vital signs. The frequency with which assessment is performed and documented depends on the individual's condition and on the healthcare institution's policy (see Clinical Skill 35.1).

### Level of consciousness

The level of consciousness is a most important factor in neurological assessment, providing valid information about changes in neurological status. Change can occur slowly over the course of many days, or it can occur rapidly in a few minutes or hours. The rapidity of change is an indicator of the severity of the neurological problem. The individual's level of consciousness is evaluated by providing stimuli and observing the response. Sound and pain are the major stimuli used. Speaking to the individual is the most common method of applying an auditory stimulus, while painful stimuli are reserved for the individual with obviously decreased levels of consciousness. When spoken to, a fully conscious individual should reply with an appropriate verbal response. A person with a decreased level of consciousness may respond in a puzzled way or may not respond at all, showing no response even when someone speaks directly into their ear (Crisp et al 2013; Agency for Clinical Innovation 2013; Rebeiro et al 2013).

### Painful tactile stimuli

Painful tactile stimuli may be necessary to arouse the semicomatose individual. Painful stimuli can be provided by exerting firm digital pressure on the nail beds, the Achilles tendon or the gastrocnemius muscle. Response to painful stimuli can be classified into:

- Purposeful, when the individual winces, pushes the assessor away or withdraws the affected body part
- Non-purposeful, when the individual moves the stimulated body part only slightly, or when the application of painful stimuli causes an extensor response (a contraction of muscles) only
- Unresponsive: when the individual shows no sign of reacting to painful stimuli.

The Glasgow Coma Scale (GCS) (Table 35.2) was originally designed to assess the level of consciousness in people with head injuries but is now used in a variety of settings. It has gained increasing acceptance as an accurate and effective means of evaluating levels of consciousness. Using the GCS, a score of 15 reflects a fully alert, well-oriented person, while a score of 8 or less is considered to indicate coma. The lowest possible score of 3 is indicative of brain death. The GCS is standardised worldwide (Agency for Clinical Innovation 2013; Rebeiro et al 2013).

### Evaluation of the pupils

Evaluating the pupils provides vital information about the brain and raised intracranial pressure. The findings in one pupil are compared with the findings in the other, and the differences between the two pupils are documented. The pupils are assessed for size, shape and reaction to light. Normally the pupils are equal in size (average diameter of 3.5 mm), round and they constrict briskly when light is shone into the eye. A pupil gauge may be used to estimate the size of each pupil. Abnormal responses of a pupil to light may be described as sluggish, non-reactive or fixed. Generally, any change in a pupil's size, shape or reaction is indicative of an intracranial change.

### Assessment of motor function

Assessment of motor function usually focuses on the arms and legs, and the identification of significant changes is important for denoting improvement, stabilisation or deterioration in the individual's condition. The techniques used to evaluate motor function depend on the individual's level of consciousness. In the conscious individual, the assessment can be made by observing motor responses to directions; for example, by asking the individual to squeeze the assessor's hands. If the individual is unconscious or is unable to provide accurate responses, the assessor must rely on observational skills to evaluate motor function.

### Assessment of sensory function

Assessment of sensory function is described earlier in this chapter.

### Assessment of the vital signs

Assessing the vital signs (see also Chapter 20) provides data concerning vital functions of the body. The individual's temperature, pulse, ventilations and blood pressure are monitored and documented at a frequency that depends on their condition. Data from neurological assessments are documented according to the healthcare institution's policy. Many institutions use a special neurological assessment chart. If clinical deterioration is recognised the response to be implemented is in accordance with the health service organisation

*Text continued on page 1011*

## CLINICAL SKILL 35.1 Performing a neurological assessment

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sphygmomanometer, BP cuff, stethoscope<br>Thermometer<br>Watch with a second hand<br>Penlight and pupil gauge<br>Neurological observations sheet (must include Glasgow Coma Scale (GCS)) |
| **Skill activity** | **Rationale** |
| Determine the need for neurological assessment and validate the medical orders in the individual's record | Ensures correct procedure is about to take place<br>Physical signs and symptoms such as confusion, drowsiness and limb weakness may indicate alterations in neurological function |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Critically think through the assessment data and problem solving—provide privacy, comfort measures, pain relief, neurological history (e.g. stroke, seizure, paralysis, confusion) | Evaluate each aspect and its relationship to other data to help identify specific problems and modifications of the procedure that may be needed for the individual |
| Place the equipment in a convenient location near the bedside<br>Raise the bed to the appropriate working position based on your height<br>Position the individual | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination |
| **Eyes opening (E)**<br>Assess arousal or wakefulness:<br>• Assess for eye opening by observing the individual as you approach him/her—if he/she opens eyes spontaneously (spontaneous, score 4)<br>• If the individual's eyes remain closed speak in a clear strong voice by calling the individual by name to elicit a response. If eyes open (to speech, score 3)<br>• If there is no response to speech exert a painful stimulus (e.g. trapezium squeeze/supra-orbital pressure or sternal rub—used as a last measure)<br>• If eyes open (to pain, score 2)<br>• If there is no eye opening following the application of painful stimulus (none, score 1)<br>• Record (C) if the eye is closed due to trauma or swelling<br>Note: Record the best response only in this chart section | Altered level of consciousness is a key indicator to brain function<br>The GCS assesses the individual's level of consciousness<br>A fully conscious individual responds to questions spontaneously<br>As level of consciousness decreases individual may show irritability, a shortened attention span or an unwillingness to cooperate<br>Watch the individual for any response<br>If no response is gained the individual is spoken to at first quietly then more loudly<br>Response is opening the eyes<br>If there is no auditory response gentle touch is used then use a central painful stimulus<br>If the individual has periorbital oedema due to trauma or surgery a 'c' for closed can be documented next to 'None' (1) column |

## CLINICAL SKILL 35.1 Performing a neurological assessment—cont'd

| | |
|---|---|
| **Assess verbal response (V)**<br>Examine appropriateness of speech and awareness:<br>• Obtain the individual's attention and allow time for the individual to respond<br>• Ask questions to assess orientation to person, place and time (e.g. ask the individual to tell you their full name, what the month or year is, and where they are). If correct answers are elicited to all 3 questions (orientated, score 5)<br>• If the individual talks but is confused to either of the above three questions (confused, score 4)<br>• Record as 'X' if culturally and linguistically diverse<br>• If the individual uses words or phrases that make little or no sense (inappropriate words, score 3)<br>• If the individual makes unintelligible sounds, moaning or groaning (incomprehensible sounds, score 2)<br>• If the individual makes no attempt to speak and no sounds are made, in response to the painful stimulus (none, score 1)<br>• Record as 'T' if unable to speak due to tracheostomy or ETT<br>Note: Record the best response only in this chart section | When spoken to, a fully conscious individual should reply with an appropriate verbal response. A person with a decreased level of consciousness may respond in a puzzled way or may not respond at all, showing no response even when someone speaks directly into their ear<br>The individual who is able to respond is asked a series of simple questions (e.g. identify themself, what month, season or year it is)<br>Impaired hearing may affect response<br>If the individual is not orientated to person, place or time, ascertain their best verbal response<br>Scores on the GCS are confused, inappropriate words, incomprehensible sounds and no response |
| **Assess best motor response (M)**<br>Assess overall awareness and ability to respond to external stimuli by recording best arm response:<br>• Ask the individual to perform a simple motor task (e.g. 'raise your arm' or 'squeeze and let go of my hands'). If the individual follows the command even weakly (obeys commands score 6)<br>• If the individual does not respond to verbal commands apply a central painful stimulus (e.g. trapezium squeeze/ supra-orbital pressure or sternal rub—used as a last measure) to determine the best arm response<br>• If the individual demonstrates purposeful movement to locate and remove the source of painful stimulus by bringing the hand up to at least nipple line it is recorded as localising (localise to pain, score 5)<br>• If the individual's hand or body moves away from the source of pain it is recorded as withdraws (withdraws, score 4)<br>• The individual may respond by flexing an arm demonstrating abnormal posturing (decorticate) (flexion to pain, score 3)<br>• The individual may respond by extending an elbow and internally rotating wrist (decerebrate posturing). This response is recorded as abnormal extension (extension to pain, score 2)<br>• If there is no response to the painful stimulus (none, score 1)<br>Note: Record the best response only in this chart section | Assessment of motor function usually focuses on the arms and legs, and the identification of significant changes is important for denoting improvement, stabilisation or deterioration in the individual's condition. As neurological function deteriorates motor responses are reduced<br>If eyes are closed due to trauma and the individual is aphasic, motor response indicates the level of consciousness<br>If nil response to verbal command, progress to use painful stimulus<br>Record the best movement response<br>Be careful not to misinterpret a grasp reflex. If you ask the individual to squeeze your hands, also ask them to release your hands as stimulation of pain can stimulate a grasp reflex in the severely head injured person<br>An individual with serious neurological impairment exhibits abnormal posturing in response to pain<br>Compare the right and left sides and upper and lower extremities |
| GCS is out of 15 and recorded on neurological observation chart<br>Overall score or change in score determines need to report to Registered Nurse and medical officer. Refer to facility/organisation policy regarding clinical review/ rapid response criteria | The GCS allows the evaluation of an individual's neurological status<br>The higher the score the more normal the level of neurological functioning |

*Continued*

## CLINICAL SKILL 35.1 Performing a neurological assessment—cont'd

| | |
|---|---|
| **Assess pupillary activity**<br>• Note the size (mm), shape and equality of both the pupils in normal lighting<br>• Shine a pen torch light, moving from the outer aspect of the eye to the pupil. Observe the reaction of the pupil<br>• Test each eye separately and record reaction:<br>Yes '+'<br>No '–'<br>Closed 'C'<br>Sluggish 'SL'<br>Pupillary response should be brisk constriction to light<br>Pupils are assessed for equality (are both pupils the same size?)<br>Report to Registered Nurse and medical officer if pupils become unequal or if one becomes more sluggish than the other | Evaluating the pupils provides vital information about the brain and raised intracranial pressure<br>Pupil size (1–8 mm) is determined using the pupil gauge before the light reflex is used<br>Pupil shape is determined as round, oval or drawn to indicate abnormality<br>Pupil reactivity to light is assessed by bringing the penlight from the lateral side of the individual's head towards the nose. Observe for pupil constriction (direct response) and repeat with the other eye<br>Document a lack of consensual reaction (opposite pupil fails to constrict when light is shone in eye) in healthcare record<br>Do not confuse a prosthetic eye with a fixed pupil. There will be no response from a blind eye.<br>If pupils are not the same size 'unequal' differences are noted between the right and left sections of the chart |
| **Assess limb strength**<br>Testing limb strength gives an indication of the part of the brain that is affected as opposed to testing LOC<br>Bilateral upper limb muscle strength:<br>• Instruct individual to move arms, lift limb against gravity, move limb against your resistance<br>• Ask the individual to squeeze both the assessor's hands followed by asking the individual to:<br>> pull your hands towards them against resistance<br>> ask the individual to push your hands away against resistance (normal power)<br>• Active movement of body part against gravity with some resistance (mild weakness)<br>• Active movement of body part against gravity (severe weakness)<br>• Active movement of body part when effect of gravity is removed (spastic flexion)<br>• Only a trace or flicker of movement is seen or felt in the muscle (extension)<br>• No detectable muscle contraction (no response)<br>Bilateral lower limb muscle strength<br>• Instruct individual to move legs laterally on bed; lift limb against gravity; move limb against your resistance<br>Note: Record the response for each limb separately in this section of the chart as per upper limb muscle assessment:<br>• (normal power)<br>• (mild weakness)<br>• (severe weakness)<br>• (extension)<br>• (no response) | Assessment of limb strength usually focuses on the arms and legs, and the identification of significant changes is important for denoting improvement, stabilisation or deterioration in the individual's condition. The techniques used to evaluate limb strength depend on the individual's level of consciousness<br>Each extremity is assessed unless contraindicated<br>The individual is given clear commands such as 'squeeze my hands' 'push against my hands'. Compare both sides. Record right (R) and left (L) separately if there is a difference between the two sides<br>Response is recorded as normal, mild weakness, severe weakness, flexion, extension or no response |

| CLINICAL SKILL 35.1 Performing a neurological assessment—cont'd | |
|---|---|
| **Assess vital signs**<br>Initially vital signs are monitored every 15 minutes until stable then hourly or as per organisational/facility guidelines | Vital sign changes are late changes in brain deterioration<br>A drop in level of consciousness is the earliest sign of neurological deterioration<br>Change in vital signs can indicate a worsening neurological condition, and therefore vital signs are always recorded at the same time as other neurological observations<br>Change in vital signs may also provide clues as to other medical problems in an unconscious individual who cannot tell staff what symptoms they are experiencing<br>Vital sign changes associated with raised intracranial pressure:<br>• Bradycardia<br>• Tachycardia (very late sign)<br>• Hypertension (typically, an elevated systolic blood pressure combined with a widening pulse pressure)<br>• Irregular respirations |
| Clean and dispose of waste equipment appropriately<br>Remove gloves. Perform hand hygiene | Prevents cross-infection |
| Lower the bed and assist the individual to reassume a comfortable position<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer<br>Report to medical officer immediately or initiate a clinical review/rapid response (depending on facility policy) if the GCS drops by 1–2 points (depending on facility/organisation policy) | Provides relevant information to other members of the healthcare team<br>Allows for the planning and implementation of care<br>The information gathered is documented on the GCS or neurological observation chart depending on which is used within the facility/organisation, where there are designated places for each of the observations<br>Any change in the individual's level of consciousness should be recorded in the individual's healthcare record<br>Documentation increases the communication between healthcare professionals and complies with legal requirements for reporting change |

policy and procedures (Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012).

## DIAGNOSTIC TESTS

Specific tests may be performed for diagnostic purposes or to aid in evaluation of an individual's condition.

### The neurological examination

The purpose of the neurological examination is to determine the presence or absence of disease in the nervous system by assessing cerebral, cranial nerve, motor, sensory and reflex function. Evaluation of cerebral function is performed by assessing the individual's general behaviour and cognitive functions, such as orientation to time and place, concentration, memory, vocabulary and abstract reasoning. Evaluation of the cranial nerves involves assessing:

- The olfactory nerve: the sense of smell is tested by obstructing one nostril while testing the other. A variety of substances is placed near the unobstructed nostril and the individual is asked to identify the odour of each
- The optic nerve: each eye is tested to assess visual acuity and visual fields. The fundus of each eye is assessed by ophthalmoscopic examination
- The oculomotor, trochlear and abducens nerves: these three nerves are generally tested together, as they supply the various muscles that rotate the eyeball. The ophthalmoscope is used during the assessment; the pupils are observed for size, shape and equality, and

**TABLE 35.2 | Levels of Consciousness: Glasgow Coma Scale**

| Faculty measured | Response | Score |
|---|---|---|
| Eye opening | Spontaneous | 4 |
| | To verbal command | 3 |
| | To pain | 2 |
| | No response | 1 |
| Motor response | To verbal command | 6 |
| | To localised pain | 5 |
| | Flexes and withdraws | 4 |
| | Flexes abnormally | 3 |
| | Extends abnormally | 2 |
| | No response | 1 |
| Verbal response | Oriented, converses | 5 |
| | Disoriented, converses | 4 |
| | Uses inappropriate words | 3 |
| | Makes incomprehensible sounds | 2 |
| | No response | 1 |

*(Berman et al 2015)*

movement of the eyes is evaluated by requesting the individual to follow a finger through the six cardinal areas of vision

- The trigeminal nerve: the sensory component of this nerve is tested with the individual's eyes closed. Test tubes of warm and cold water are brought into contact with the skin of the face to check temperature perception. Touching the face with a wisp of cotton checks perception of light touch. Pain perception is evaluated either by applying pressure or by touching areas of the face with the point of a pin. The motor component of the trigeminal nerve is evaluated by asking the individual to clench and unclench the teeth, and by observing their ability to open the mouth against resistance. The corneal reflex is assessed by lightly stroking the cornea with a wisp of cotton. If the corneal reflex is intact, the individual will automatically blink
- The facial nerve: the sensory component of this nerve is assessed by placing sweet, salty, sour and bitter substances on various areas of the tongue, and asking the individual to identify each taste. The motor component of the facial nerve is assessed by requesting the individual to perform specific facial movements such as smiling, closing the eyes, pursing the lips and wrinkling the forehead
- The acoustic nerve: generally, unless the individual has a history of vertigo, only the hearing branch of this nerve is assessed. A series of hearing tests is performed, and hearing in both ears is compared. For a more precise assessment of hearing acuity, a tuning fork is used
- The glossopharyngeal and vagus nerves: these nerves are usually tested together, as they are closely related both anatomically and functionally. A series of tests is performed to assess the gag and swallowing reflexes
- The spinal accessory nerve: this nerve is tested by evaluating the strength of the trapezius and sternocleidomastoid muscles; for example, by requesting the individual to shrug the shoulders against resistance and by asking them to turn their head to one side and push their chin against the assessor's hand
- The hypoglossal nerve: the strength and movement of the tongue muscles are evaluated by testing the individual's ability to protrude the tongue, and also by requesting them to push their tongue against a tongue depressor (Thibodeau & Patton 2012; Brown et al 2015).

**PROGRESS NOTE EXAMPLE 35.1**

| | |
|---|---|
| 23/03/2015 1500 hrs | Nursing: L3–4, L4–5 posterior lumbar interbody fusion on 21 March. Neuro: Mr Brown alert and orientated ×3, full power in left limbs, full power in right arm, mild weakness in right leg (pre-existing), cranial nerves II–XII intact, proprioception intact, normal sensation. Vitals: afebrile, Temp, pulse, resp rate, saturations and BP within SAGO chart limits. Pain score 6/10 this morning—given 5 mg Endone at 0830 with good effect. Pain score at 1000 was 3/10 on movement. Intake: Tolerating full ward diet and some free fluids. IV fluids discontinued this morning when IV antibiotics ceased. Output: IDC removed at 1000. For trial of void. Has not passed urine yet but no palpable bladder. Needs bladder scan at 1800. Bowels not opened yesterday or today. Will offer aperients this evening. Minimal drainage in Varivac drain—can be removed today. General: Needs assistance of one to get out of bed. Walked to shower with standby supervision. Showered self with minimal assistance to dry back and legs. Cleaned teeth. Pressure points intact. Wound dressing removed. Wound is clean and dry, no redness. Wound has been glued with Dermabond. Mr Brown taken for a walk by physio. TEDs in situ with non-slip socks. Family in attendance at time and shown how to help Mr Brown roll on to side to get out of bed. In better spirits today now he has visitors, and also having had a walk and a shower. To mobilise with supervision today. Mr Brown will be discharged in 3 days if bowels opened and mobilising safely.<br>***B. Hughes* (Hughes) EN** |

### Evaluation of motor function

Evaluating motor function involves assessing the individual's gait, posture, muscle strength and tone, balance and coordination. The assessor observes for abnormalities and compares the findings on both sides of the body for asymmetry.

### Evaluation of sensory function

Evaluating sensory function involves assessing the individual's ability to perceive various sensations with their eyes closed. Assessment includes testing of sensitivity to touch, pain, temperature, testing of joint motion and position and assessment of discriminative function and vibratory sensation.

### Evaluation of reflexes

Evaluation of reflexes involves testing the two types of reflex to assess the integrity of the motor and sensory systems.

***The superficial reflexes*** These include the upper abdominal, lower abdominal, gluteal and plantar reflexes. The abdominal and gluteal reflexes are evaluated by applying a stimulus to the skin surface; for example, stroking with a finger or pointed object and observing for muscle contraction. The plantar reflex is evaluated by stroking the sole of the foot, with one continuous movement from the heel to the toes. Normally, the big toe curls downwards in response to this stimulus. An abnormal response, Babinski's sign, when there is dorsiflexion of the big toe and fanning of the other toes, indicates upper motor neuron disease.

***The deep tendon reflexes*** These include the biceps, triceps, quadriceps and Achilles tendons. Deep tendon reflexes are elicited by using a percussion hammer and observing the response, as follows:

- The biceps reflex is tested with the arm partially flexed at the elbow and the palm down. When the hammer is applied to the biceps tendon, the elbow should flex
- The triceps reflex is tested with the arm partially flexed at the elbow and the palm directed towards the body. When the hammer is applied to the triceps tendon, the elbow should extend
- The quadriceps reflex is tested with the knee flexed. When the patellar tendon is struck with the hammer, the knee should extend
- The Achilles reflex is tested with the knee flexed. When the Achilles tendon is struck with the hammer, the foot should plantar flex (Brown et al 2015).

### Neurovascular assessment

Neurovascular assessment includes skin assessment (colour, temperature, oedema), palpation and assessment of pulses, sensation, motor function and pain.

Extremities should be palpated for swelling and assessed for pain, an appropriate colour, warmth, symmetry in shape and size, and capillary refill should be less than 2 seconds (immediate). Pulses should be strong and equal. For lower limbs, popliteal, posterior tibial and dorsalis pedis pulses should all be present and assessed for strength and equal amplitude. Assessment findings are used to support a diagnosis and determine or modify nursing care interventions (Berman et al 2015; Crisp et al 2013; LeMone et al 2014; The Royal Children's Hospital Melbourne 2015; The Sydney Children's Hospitals Network 2014).

See Clinical Skill 35.2.

## Radiographic examination

### X-ray

Plain x-ray films of the skull may be performed to detect fractures, to aid in the diagnosis of pituitary tumours or to detect congenital abnormalities. X-ray films of the spine may be performed to detect trauma to the vertebral column or to aid in the diagnosis of conditions that cause motor or sensory impairment.

### Computerised tomography scan

Computerised tomography (CT) is commonly used to diagnose intracranial and spinal cord lesions. It is usually non-invasive but a contrast dye is sometimes administered to visualise blood vessels or to define lesions. The individual lies on an x-ray table, with the head immobilised and face uncovered. The head is moved into the scanner, and a moveable frame revolves around it while x-ray films are taken. If a contrast agent is used the individual may feel warm and experience a transient headache, a salty taste and nausea.

### Myelogram

A myelogram involves fluoroscopy and radiography to evaluate the spinal cord and vertebral column after injection of a contrast medium via lumbar puncture into the subarachnoid space. The individual is positioned to allow the medium to flow through the subarachnoid space. A series of x-ray films are taken, after which the contrast medium may be either withdrawn or allowed to remain in the CSF. Water-soluble agents are allowed to remain, as they will eventually be excreted by the kidneys.

### Angiography

Cerebral angiography involves injecting a radio-opaque contrast medium into an artery for radiological visualisation of the intracranial and extracranial blood vessels. Common injection sites are the carotid or femoral arteries, with x-ray films taken at various intervals after injection of the medium. Cerebral angiography may be performed using either local or general anaesthetic. Digital subtraction angiography is a computer-assisted radiographic procedure for visualising extracranial and intracranial vessels and involves injection of a contrast medium through a catheter into the superior vena cava. Cerebral vessels are visualised on a screen, and pictures taken. Cerebral angiogram is used to diagnose aneurysms, arteriovenous malformations, thrombosis, vasospasm, tumours and haematomas.

### Magnetic resonance imaging (MRI)

An MRI is a non-invasive procedure in which the individual is placed in a strong magnetic field and is subjected to precise

computer-programmed bursts of radio pulse waves. The sharpness and detail of the images produced assist diagnosis by providing identification of abnormalities and can detect neurological disorders with structural changes; for example, stroke, tumour, infection and seizures. MRI is contraindicated in individuals with pacemakers, metallic aneurysm clips and some metallic prostheses.

### Magnetic resonance angiography (MRA)

MRA is used to detect vascular lesions by reconstructing vessels with blood flow. Contrast may be used.

### Positron emission tomography (PET) scanning

PET scanning is a non-invasive nuclear imaging technique used to detect biochemical and physiological abnormalities. The individual is injected with a nuclide that reacts with electrons and produces gamma-ray photons. A scanner detects the gamma rays and codes this data into a computer. Radioisotopes evaluate cellular metabolism, and may show a typical pattern for Alzheimer's disease, and can be used to differentiate tumour reoccurrence from radiation necrosis. The computer then reconstructs cross-sectional images of the tissues being examined.

### Single-photon emission computed tomography (SPECT)

A SPECT scan is similar to a PET scan and can be used to diagnose strokes, brain tumours and seizure disorders.

### Carotid duplex study

Identifies carotid artery disease by using sound waves produced by blood flow to produce an image.

## Electroencephalography (EEG)

An electroencephalogram (EEG) is a recording of the electrical activity of the brain (brainwaves). Surface electrodes are attached to the scalp with a paste and transmit the brain's electrical impulses to a machine that records them as brainwaves on strips of paper. Brainwaves are recorded while the individual is at rest, after hyperventilation, with photic stimulation, after a sensory stimulus and during sleep (see Clinical Interest Box 35.1) (Patton et al 2012).

## Evoked potentials

Evoked potentials are used to measure nerve conduction and diagnose and evaluate neuromuscular disease and nerve damage.

## CLINICAL SKILL 35.2 Neurovascular assessment

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Neurovascular assessment chart |
| **Skill activity** | **Rationale** |
| Validate the medical order in the individual's record | Ensures correct procedure is about to take place |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Critically think through the assessment data and problem solving (e.g. provide privacy, comfort measures, pain relief) | Evaluate each aspect and its relationship to other data to help identify specific problems and modifications of the procedure that may be needed for the individual |
| Place the equipment in a convenient location near the bedside<br>Raise the bed to the appropriate working position based on your height<br>Position the individual | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |

## CLINICAL SKILL 35.2 Neurovascular assessment—cont'd

| | |
|---|---|
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination |
| **Assess the limb distal to the surgery/injury**<br>Compare affected limb with unaffected limb assessing both limbs for (document affected limb only):<br>• Colour<br>> Visually check colour, document as pink, pale/white or cyanotic, dusky, cyanotic, mottle or purple/black<br>• Temperature<br>> Check temperature with superficial touch, document as warm, cool or hot<br>• Pulses<br>> Palpate for presence of peripheral pulses distal to injury<br>> Document pulses as strong, weak, absent<br>• Sensation<br>> Touch and assess visual limb surfaces for presence and type of sensation. Document as normal, decreased sensation, loss of sensation, numbness, tingling or pins and needles<br>• Motor function<br>> Active movement or passive movement<br>• Pain<br>> Assess pain on movement of limb (document pain score 0 (no pain), 10 (worst pain))<br>• Swelling and ooze<br>> Visually check for swelling and ooze<br>> Document swelling as nil, small, moderate | Obtains a baseline prior to surgery<br>Assesses the vasculature and nerve supply to a traumatised limb<br>Monitors limb status so that permanent damage or complications are avoided by identifying indicators of problems early and intervening<br>Limb assessed as normal if limb pink in colour, warm to touch, capillary refill of 1–2 seconds, swelling full, strong pulse, normal sensation<br>Limb assessed as inadequate arterial supply if pale/white or cyanotic in colour, cool to touch, capillary refill >2 seconds, swelling hollow or prune like<br>Limb assessed as inadequate venous return if limb dusky, cyanotic, mottled or purple/black in colour, hot to touch, immediate capillary refill, swelling distended or tense, tissues feel hard<br>Capillary refill assessment is evaluated by pressing firmly down on the nail bed of fingers or toes for 5 seconds. The nail bed will blanch and the colour should return within 2 seconds once pressure is released<br>If pulses are not palpable due to plaster casts, assess closely above parameters<br>Individuals may report changes in sensation if neurovascular compromise is present or may be a result of a nerve block or epidural (this should be documented on the neurovascular chart)<br>Individual assessed as having active movement if able to voluntarily extend and flex an extremity or digit<br>Individual assessed as having passive movement if assessor is able to extend and flex an extremity or digit<br>If pulse is not present, document and notify medical officer, observe colour, capillary refill and temperature.<br>Immediately report to medical team if there is any deterioration in neurovascular assessment |
| Clean and dispose waste/equipment appropriately<br>Remove gloves. Perform hand hygiene | Prevents cross-infection |
| Lower the bed and assist the individual to reassume a comfortable position.<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Report and document all relevant information correctly in the healthcare record<br>Communicate abnormal findings to the Registered Nurse/medical officer | Provides relevant information to other members of the healthcare team<br>Allows for the planning and implementation of care<br>Information gathered is documented on the neurovascular assessment chart at a frequency as determined by medical officer and facility/organisation policy<br>Any change in the individual's neurovascular assessment should be recorded in the individual's progress notes and medical staff must be informed<br>Documentation increases the communication between healthcare professionals and complies with legal requirements for reporting change |

*(Berman et al 2015; Crisp & Taylor 2013; Dempsey et al 2014; LeMone et al 2014)*

## CLINICAL INTEREST BOX 35.1 Care of the individual undergoing an EEG

### Individual preparation

Explain the procedure to the individual, emphasising the importance of cooperation

Withhold fluids, foods and medications (as prescribed) that may stimulate or depress brainwaves. These include anticonvulsants, tranquillisers, depressants and caffeine-containing foods (e.g. coffee, tea, colas and chocolate). Medications are usually withheld for 24–48 hours before the test

Help the individual to wash their hair before the test

### Individual and family teaching

The test takes about an hour

The test is painless and will be performed while the individual sits in a comfortable chair or lies on a stretcher

The electrodes are applied to the scalp with a thick paste

During the test the individual will first be asked to breathe in and out deeply for a few minutes, then to close their eyes while a light is flashed on them and, finally, to lie quietly with eyes closed

After the test, the nurse will help the individual wash the paste out of their hair

*(LeMone et al 2014)*

## Electromyogram (EMG)

EMG is used to diagnose neuromuscular diseases by inserting needle electrodes into the muscle to be examined. Recordings measure the electrical activity of skeletal muscles at rest and during contraction.

## Lumbar puncture (LP)

A lumbar puncture may be performed to obtain a sample of CSF for either diagnostic or therapeutic purposes. The diagnostic indications include:

- Measurement of CSF pressure
- Examination of CSF for the presence of blood or microorganisms
- Injection of air, oxygen or radio-opaque material to visualise parts of the central nervous system radiologically
- Evaluation for signs of blockage of CSF flow.

Therapeutic indications include introduction of spinal anaesthesia for surgery, and intrathecal injection of medications.

For the procedure the individual assumes a lateral position, with their back curled and their knees flexed as close to their chest as possible. The head should be bent forwards so that the chin touches their chest (Figure 35.7). After preparation of the site, the medical officer inserts a spinal needle with a stylus (a fine probe) between L3 and L4 or L4 and L5 into the subarachnoid space and fluid is aspirated. If the lumbar puncture is being performed for diagnostic purposes, a manometer may be attached to the needle to measure CSF pressure. Samples of CSF are then collected for visual and laboratory examination. When the procedure is completed, the needle is withdrawn and an adhesive dressing applied over the puncture site (Thibodeau & Patton 2012).

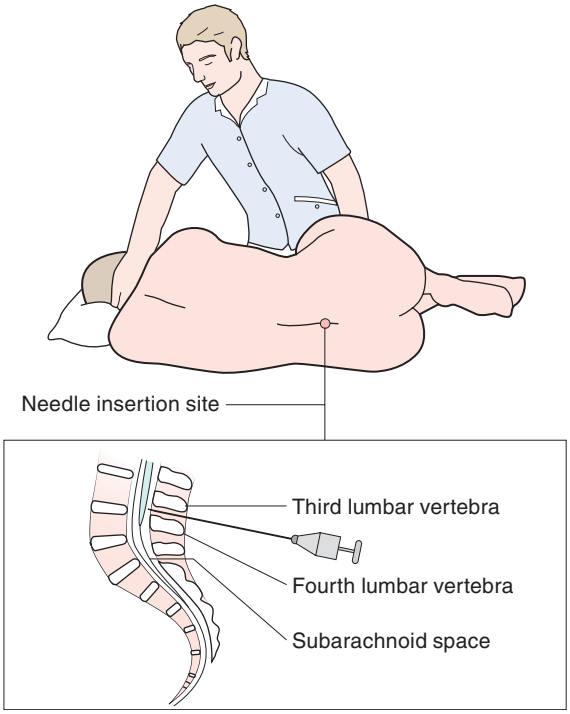

**Figure 35.7** Lumbar puncture, showing the position of the individual and the insertion site

## Further investigations

### Nerve conduction studies

These studies involve application of an electrical stimulus to peripheral nerves and measurement of their response by means of an oscilloscope (Brown et al 2015; Marieb 2015; Berman et al 2015).

# SPECIFIC DISORDERS OF THE NERVOUS SYSTEM

Disorders of the nervous system may be congenital or genetic, due to multiple causes, degenerative, infectious or inflammatory, immunological, neoplastic, obstructive or traumatic.

## Congenital disorders

Structural congenital abnormalities include anencephaly, spinal cord defects and hydrocephalus.

### Anencephaly

Anencephaly is the failure of normal development of the brain (cerebral hemispheres and cerebellum) and scalp. The

precise cause is unknown, and babies with the disorder do not live.

### Spinal cord defects

These include spina bifida, meningocele and myelomeningocele. These conditions are the result of incomplete closure of the neural tube during the first 3 months of embryonic development. Causes are thought to include maternal exposure to viruses, radiation and other environmental factors.

In severe forms, **spina bifida** involves incomplete closure of one or more of the vertebrae, causing protrusion of the spinal contents in an external sac. In spina bifida with meningocele, the sac contains meninges and CSF. In spina bifida with myelomeningocele the sac contains meninges, CSF and a portion of the spinal cord or nerve roots. Manifestations of congenital spinal cord defects vary and include a depression, dimple or tuft of hair on the skin over the spinal defect. The more severe defects cause neurological dysfunction such as paralysis of the legs, bowel and bladder incontinence and hydrocephalus (Better Health Channel 2015).

### Hydrocephalus

**Hydrocephalus** is an excessive accumulation of CSF within the ventricles of the brain. It may result from an obstruction in CSF flow or from faulty absorption of CSF. The condition can also occur as a result of cerebral injury or disease. In infants, the obvious manifestation of hydrocephalus is abnormal enlargement of the head. Other characteristics include distended scalp veins, thin and fragile scalp skin, downward displacement of the eyes, a shrill high-pitched cry, irritability and abnormal muscle tone of the legs.

A treatment for hydrocephalus is the insertion of a shunt which allows excess cerebrospinal fluid to drain to another area of the body. Typical shunt types are: a ventriculoperitoneal (VP) shunt, which moves fluid from the ventricles of the brain to the abdominal cavity; a ventriculoatrial (VA) shunt, which moves fluid from the ventricles of the brain to a chamber of the heart; and a lumboperitoneal (LP) shunt, which moves fluid from the lower back to the abdominal cavity. Each shunt has a valve attached. The two most common valves are fixed pressure valves, which are regulated by a predetermined pressure setting, and adjustable pressure valves, which can be adjusted non-invasively by a special magnetic tool (Medtronic 2015).

## Genetic disorders

Hereditary genetic defects include muscular dystrophy, Huntington's chorea and neurofibromatosis.

### Muscular dystrophy

Muscular dystrophy is a group of congenital disorders characterised by progressive wasting and weakness of muscles. There are many different forms and sources of muscular dystrophy, with all of the conditions causing muscle weakness which has a profound effect on the individual's life. Each neuromuscular condition has a characteristic pattern of muscle weakness. It may affect only the muscles around the eyes, throat or legs; however, the severest form may affect all the muscles of the body including the heart. There is no specific treatment. Duchenne's muscular dystrophy is the most common type. It begins to manifest between the ages of 3 and 5 years and is the most severe form. Initially it affects the leg and pelvic muscles but there is progressive involvement of all voluntary muscles. Later in the disease, progressive weakening of cardiac and respiratory muscles results in heart or respiratory failure. Early manifestations of Duchenne's muscular dystrophy include a waddling gait, lordosis (increased curvature of the lumbar spine) and marked difficulty rising from a supine to a standing position. As the disease progresses, facial, oropharyngeal and respiratory muscles become involved (Muscular Dystrophy Foundation 2014; Muscular Dystrophy Australia 2015).

### Huntington's chorea

Huntington's chorea is a disorder in which degeneration of the cerebral cortex and basal ganglia causes chronic progressive choreiform movements and mental deterioration. Onset is generally in early middle age, and the individual gradually develops progressively severe choreiform movements and dementia. The movements usually begin slowly, with facial grimacing and jerking arm actions. Over time, the movements become frequent, erratic and violent, affecting the trunk and lower limbs and making speech, swallowing, walking and other basic tasks more difficult. Dementia may be mild at first but eventually severely disrupts the person as the intellectual and emotional symptoms become more advanced (Huntington's NSW 2015).

### Neurofibromatosis

Neurofibromatosis can affect anyone and is one of the most common congenital abnormalities. The condition is usually classified according to which parts of the nervous system are affected. There are three types of neurofibromas: type 1 (NF 1), type 2 (NF 2) and Schwannomatosis. All are characterised by the growth of benign tumours which can grow anywhere there are nerve cells. In NF 1, multiple cutaneous and subcutaneous nodules of varying size occur. Subcutaneous nodules may attach to the peripheral portion of the nerve, causing pain or pressure and, rarely, sensory loss in the distribution of the affected nerve. Neuromas, which are an overgrowth of subcutaneous tissue, may reach enormous sizes and commonly affect the face, scalp, neck and chest. Neurological symptoms may appear if the tumours cause pressure on the brain or spinal cord as occurs in NF 2 (Neurofibromatosis Australia nd).

## Disorders of multiple cause

### Cerebral palsy

Cerebral palsy comprises a group of neuromotor disorders resulting from prenatal, perinatal or postnatal cerebral hypoxia

or damage. The incidence of cerebral palsy is highest in premature infants or in infants who have experienced a difficult birth resulting in cerebral damage. Causative factors include: chromosomal abnormalities; prenatal factors such as maternal infections, exposure to harmful chemicals or malnutrition; perinatal factors such as premature birth or instrumental delivery causing cerebral anoxia; and postnatal factors such as trauma, infection or malnutrition causing cerebral damage.

The manifestations of cerebral palsy range from mild muscle incoordination to severe spasticity. The spastic form of the disorder is characterised by rapid alternating muscle contraction and relaxation, muscle weakness and underdevelopment and muscle contraction in response to manipulation. The athetoid form of cerebral palsy is characterised by grimacing, writhing and jerking involuntary movements, which become more severe during stress. Ataxic cerebral palsy is characterised by disturbed balance, incoordination, muscle weakness and tremor. In addition to the range of motor deficits, the individual may experience sensory deficits such as speech, visual or hearing impairment. Intellectual disability accompanies cerebral palsy in about 40% of cases (Cerebral Palsy Australia 2015; Cerebral Palsy Alliance 2015).

## Cerebral aneurysm

A cerebral aneurysm is an abnormality (weak spot) of the wall of a cerebral artery that results in a localised dilation. As the aneurysm becomes larger the wall of the artery becomes weaker and can rupture. If the aneurysm ruptures, blood enters the subarachnoid space or cerebral tissue. Causative factors include congenital defects in the arterial walls, sclerotic changes in blood vessels, hypertension and cerebral trauma. Manifestations of a cerebral aneurysm do not generally appear until the aneurysm ruptures. The most common symptom of rupture is the sudden onset of a severe headache, which may be accompanied by nausea and vomiting, motor deficits, visual disturbances and loss of consciousness. A cerebral aneurysm may be detected before it ruptures if the individual shows signs of oculomotor nerve compression, eyelid ptosis and a pupil that is sluggish or non-reactive (Stroke Foundation 2015a).

## Transient ischaemic attacks

**Transient ischaemic attacks** (TIAs) result in a loss of function to a particular part of the body due to a sudden lack of blood flow to a part of the brain. The attacks, which may last from seconds to hours, are generally considered to be warning signs of an impending thrombotic cerebrovascular accident (stroke). The characteristics of a TIA, which may be caused by micro-emboli or arteriole spasm, are various symptoms of neurological dysfunction followed by a return of normal function. Symptoms include visual disturbances, double or blurred vision, short-term blindness, speech disturbances, slurred or thick speech, swallowing difficulty, staggering or uncoordinated gait, unilateral weakness or numbness, facial numbness or weakness, vertigo and loss of balance, nausea and vomiting. The difference between a TIA and an ischaemic stroke is that the symptoms of a TIA will completely disappear within 24 hours (Brain Foundation 2015).

## Trigeminal neuralgia

Trigeminal neuralgia is a painful disorder of one or more branches of the trigeminal nerve that produces paroxysmal attacks of excruciating facial pain. While the cause is often unknown, the disorder may be associated with other neurological conditions such as aneurysms, cerebral tumours or multiple sclerosis. The individual experiences excruciating burning pain, which generally occurs suddenly in response to a stimulus, such as a draught of cold air, drinking hot or cold fluids, brushing the teeth or speaking or laughing. The frequency of attacks varies from many times a day to several times a month or year.

## Intellectual disability

Intellectual disability is a syndrome of incomplete intellectual development associated with impaired learning and social adjustment. The causes include:

- Prenatal factors such as metabolic disorders, chromosomal abnormalities, cranial malformation, maternal infections, malnutrition or anoxia
- Perinatal factors such as prematurity, anoxia or intracranial haemorrhage
- Postnatal factors such as cerebral injury, central nervous system infections, anoxia, neoplasms, degenerative diseases, cerebral haemorrhage, nutritional deficiencies and emotional deprivation.

Manifestations include poor motor development, impaired concepts of space and time, learning difficulties, inappropriate behaviour and difficulty with social interactions.

## Peripheral neuritis

Peripheral neuritis (polyneuritis) is the degeneration of peripheral nerves, resulting in muscle weakness and atrophy, sensory loss and decreased or absent tendon reflexes. Causes include chronic intoxication (alcohol, arsenic, lead), metabolic and inflammatory disorders (diabetes mellitus, rheumatoid arthritis), nutrient deficiencies (thiamine) and infectious diseases (meningitis or Guillain–Barré syndrome). Manifestations usually develop slowly, beginning with leg pains and numbness or tingling in the feet and hands. As the disease progresses the individual experiences flaccid paralysis, muscle wasting, pain of varying intensity and loss of reflexes in the legs and arms. Footdrop, ataxic gait and inability to walk will eventually occur.

## Guillain–Barré syndrome

Guillain–Barré Syndrome (GBS) is an acute inflammatory disorder which causes the body's immune system to attack part of the peripheral nervous system, causing what is known as an autoimmune disorder. It is characterised by rapid and progressive neuromuscular paralysis with the first symptoms including decreased function, varying degrees of weakness or tingling sensation, and decreased reflexes distally in the lower

limbs which often spreads proximally to include the upper body. In some cases these symptoms can increase until the muscles are almost totally paralysed, resulting in a life-threatening situation requiring mechanical ventilation due to respiratory dysfunction.

The National Institute of Neurological Disorders and Stroke (ndc) states that most individuals will have good recovery from Guillain–Barré syndrome (GBS), although some may continue to have some residual weakness after 3 years.

While there is no known cause of GBS most individuals who are diagnosed with this condition have a 1–3 week previous history of upper respiratory or gastrointestinal viral infection. Occasionally, surgery may also trigger the syndrome. The disease progression may occur over the course of hours or days, or it may take up to 3 to 4 weeks. It is confirmed with a lumbar puncture, electromyography and nerve conduction studies.

In GBS the antiganglioside antibodies attack Schwann cells of the myelin sheath, causing demyelination of the peripheral nerves, which in turn halts nerve conduction. There is no known cure for GBS; however, plasmapheresis (also known as plasma exchange) and high-dose immunoglobulin therapy may be used to treat the complications of the disease. Plasmapheresis causes the Schwann cells to re-myelinate, which in turn reduces the severity and duration of the Guillain–Barré episode and in most cases individuals can expect a full recovery.

When caring for the individual with GBS the nurse should assess airway and breathing, refer to speech pathology, maintain the individual as nil by mouth until otherwise ordered, ensure adequate analgesia, perform pressure area care and take steps to reassure the individual (National Institute of Neurological Disorders and Stroke ndc).

***What is the prognosis?*** Guillain–Barré syndrome can be a devastating disorder because of its sudden and unexpected onset. Most people reach the stage of greatest weakness within the first 2 weeks after symptoms appear, and by the third week of the illness 90% of all individuals are at their weakest. The recovery period may be as little as a few weeks or as long as a few years. About 30% of those with Guillain–Barré still have a residual weakness after 3 years. About 3% may suffer a relapse of muscle weakness and tingling sensations many years after the initial attack (National Institute of Neurological Disorders and Stroke ndc).

### Bell's palsy

Bell's palsy is a disorder of the seventh cranial nerve that produces unilateral facial weakness or paralysis. An inflammatory reaction occurs in or around cranial nerve VII, resulting in nerve compression and the onset of flaccid facial paralysis. Factors responsible for the inflammatory reaction include infection, prolonged exposure to cold temperature and local trauma. The seventh cranial nerve can also be affected by other conditions such as a cerebral tumour, meningitis or a middle-ear infection. Manifestations are unilateral facial weakness, which is sometimes associated with pain around the angle of the jaw or behind the ear. On the affected side the mouth droops and the individual is unable to wrinkle the forehead, close the eyelid or smile. There may be excessive watering from the affected eye and drooling of saliva from the affected side of the mouth (National Institute of Neurological Disorders and Stroke nda; Brown et al 2015).

## Seizure disorders

Seizure disorders may be primary and idiopathic, or secondary and symptomatic of a central nervous system disorder. The most common type of seizure disorder is epilepsy. **Seizures** may be focal (partial) or **generalised**. Focal seizures generally affect a specific body part, and the symptoms of an attack depend on the location of the cerebral focus. For example, the focal motor seizure occurs from a lesion in the motor cortex. Typically it causes stiffening or jerking in one extremity that is accompanied by numbness or tingling.

**Absence seizures** only last a few seconds. They generally begin with a brief change in the level of consciousness, which is indicated by a blank stare, eyelid fluttering or head nodding or a pause in conversation. The individual generally retains posture and returns to pre-seizure activity without difficulty. This type of epilepsy usually occurs in childhood and may continue into early adolescence. Some partial seizures may progress to become **generalised seizures**. These are termed secondary generalised seizures.

Although seizures may result from a nervous system disorder, they may be caused by many other factors and are often idiopathic. The common classification of seizures is given in Table 35.3.

The most common generalised seizure is referred to as a tonic–clonic. This type of seizure usually consists of three phases:

1. Aura. The aura (which is not always experienced) is a warning of an impending seizure. An **aura** is a sensation (e.g. a specific taste or smell) experienced by the individual immediately before a seizure. The seizure commonly begins with a loud cry, which is caused by air being forced out through the vocal cords that are in spasm
2. Tonic–clonic phase. The individual then loses consciousness and may fall. The muscles become rigid, then alternate between episodes of muscle spasm and relaxation (tonus and clonus), resulting in jerky spasmodic body movements. Tongue biting, incontinence of urine, laboured breathing, apnoea and cyanosis may occur
3. Post-convulsive phase. The seizure generally stops within 2–5 minutes, when abnormal electrical conduction in the brain ceases. The individual regains consciousness but may be dazed and confused or fall asleep. Automatisms are more commonly associated with complex partial seizures.

**TABLE 35.3 | Common classification of seizures**

| | |
|---|---|
| Focal (partial) seizures | About 60% of people with epilepsy have focal (partial) seizures. These seizures can often be subtle or unusual, and may go unnoticed or be mistaken for anything from intoxication to daydreaming. Seizure activity starts in one area of the brain and may spread to other regions of the brain.<br>Types of focal (partial) seizures are:<br>• Focal seizure—awareness retained (formerly simple partial seizures)<br>• Focal dyscognitive seizures—awareness altered (formerly complex partial seizures)<br>• Focal seizures evolving to a bilateral convulsive seizure (formerly secondarily generalised tonic–clonic*) |
| Generalised seizures | Generalised seizures are the result of abnormal activity in both hemispheres of the brain simultaneously. Because of this, consciousness is lost at the onset of the seizure. There are many types of generalised seizures:<br>• Absence<br>> Typical<br>> Atypical absence<br>> Absence with special features<br>– Myoclonic absence<br>– Eyelid myoclonia<br>• Tonic–clonic<br>• Clonic<br>• Tonic<br>• Atonic<br>• Myoclonic<br>> Myoclonic atonic<br>> Myoclonic tonic |
| Unknown | This a grouping of seizures that cannot be diagnosed as either focal or generalised seizures and are thus grouped as unknown.<br>• Epileptic spasm<br>• Other |

*Note: Sometimes a seizure starts as a focal (partial) seizure and then becomes a generalised seizure—almost always a tonic–clonic seizure.
Most people will only have one or two seizure type(s), which may vary in severity. A person with severe epilepsy or significant damage to the brain may experience several different seizure types.
*(LeMone et al 2014; Berman et al 2015; Epilepsy Action Australia nd; Epilepsy Foundation 2015)*

**Status epilepticus** is a condition in which the individual experiences continuous seizures without regaining consciousness in between. It is generally accompanied by respiratory distress.

Table 35.4 provides an assessment and rationale for a nursing assessment before, during and after a seizure (LeMone et al 2011). Clinical Interest Box 35.2 provides an outline of teaching for home care of individuals in relation to seizures (LeMone et al 2014; Berman et al 2015; Epilepsy Action Australia nd; Epilepsy Foundation 2015).

## Degenerative disorders

### Parkinson's disease

Parkinson's disease is a degenerative process of nerve cells in the basal ganglia and substantia nigra. The substantia nigra is an area in the basal ganglia considered necessary for motor control. Although the precise cause of the disorder is unknown, research has demonstrated that a dopamine deficiency prevents affected brain cells from functioning normally. Dopamine is a neurotransmitter that plays a role in the transmission of nerve impulses between synapses. Factors implicated in the development of Parkinson's disease include cerebral atherosclerosis and long-term therapy with drugs such as haloperidol and phenothiazine (Parkinson's Australia 2015; Thibodeau & Patton 2012). Manifestations of Parkinson's disease are related to disturbances of movement: tremor, muscle rigidity and dyskinesia. The most common initial symptom is tremor; for example, 'pill-rolling' movements of the fingers, and to-and-fro head tremors. Tremors are aggravated by fatigue and stress, and decrease when the individual performs a purposeful activity or is asleep. The person experiences difficulty in initiating voluntary movement and loss of posture control, so that walking is with the body bent forwards. The gait consists of short shuffling steps that are slowly initiated. Facial expression becomes mask-like, and the voice is commonly high-pitched and monotone. The person's intelligence is not affected.

## TABLE 35.4 | Nursing assessments before, during and after a seizure

| Assessment | Rationale |
|---|---|
| What was the client's level of consciousness? If consciousness was lost, at what point? | Indicates area of brain involved and type of seizure. |
| What was the client doing just before the attack? | May suggest precipitating factors. |
| In what part of the body did the seizure start? | May indicate the site of seizure activity in the brain tissue; for example, if jerking movements were first observed in right hand, the seizure focus may be in left motor cortex. |
| Was there an epileptic cry? | Usually indicates the tonic stage of a generalised tonic–clonic seizure. |
| Were any automatisms such as eyelid fluttering, chewing, lip smacking or swallowing observed? | Often seen in complex, partial and absence seizures. |
| How long did movements last? Did the location or character change (tonic to clonic)? Did movements involve both sides of the body or just one? | Indicates areas in which focal activity originated. |
| Did the head and/or eyes turn to one side and, if so, which side? | Helps localise the focus of the seizure. During the seizure, the head and eyes typically will turn away from the side of the epileptogenic focus. |
| Were there changes in pupillary reactions? | Indicates involvement of the autonomic nervous system. |
| If the client fell, was the head hit? | Skull x-ray studies may be needed to rule out subdural haematoma or fracture. |
| Was there foaming or frothing from the mouth? | Usually indicates a tonic–clonic seizure. |

*(LeMone et al 2011)*

## CLINICAL INTEREST BOX 35.2 Health education for home care of individuals affected by generalised seizures

Teaching must be planned around a systematic assessment of the needs of both the individual and their significant others. Significant others need to be included so that they can learn seizure management, care and observations. The importance of safety and maintenance of a patent airway should be stressed. The following recommendations assist the individual and significant others to adjust:

- Correct misconceptions, fears and myths about epilepsy
- Encourage both the individual and their significant others to express their feelings
- Provide the name and location of community and national resources; for example, the Epilepsy Foundation of Victoria (www.epinet.org.au). Facilitate socialisation with others facing the same issues
- Stress the importance of follow-up care and keeping medical appointments
- Refer the individual to employment or vocational counselling as needed
- Review any state and local laws that apply to people with seizure disorders. Usually a driver's licence can be reinstated after a 2-year seizure-free period and a letter from a medical officer
- Stress the importance of wearing a medical alert bracelet and carrying a medical alert card at all times
- Emphasise the importance of aura identification and plan action to take
- Emphasise the importance of taking anticonvulsant medication as prescribed, even when seizures no longer occur
- Avoid physical and emotional stress
- Help individuals develop a positive focus on life
- In general, alcohol should be avoided and caffeine limited
- Discuss factors that may trigger a seizure (fatigue, abrupt stopping of medication, flashing video games)

*(LeMone et al 2014)*

### CRITICAL THINKING EXERCISE 35.1

Mrs T, 55, has recently been diagnosed with early-stage Parkinson's disease. Mr T is quite concerned about the progression of the disease—whether Mrs T can be left alone for several hours at a time while Mr T goes to work and what medications she will be required to take. How would you respond to his concerns? How can they find more information about Parkinson's disease?

### CRITICAL THINKING EXERCISE 35.2

An individual arrives for surgery for implantation of a deep brain stimulator. On examination you notice he has a mask-like face, pill-rolling movements in his hands when at rest, a shuffling gait and bradykinesia. What condition do you think he has? What is important about his medication management? What is 'on and off' in relation to this individual?

### Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis, which is the most common form of motor neuron disease (MND), is a progressive degenerative condition that is generally fatal within 3–10 years after onset. The disease affects the upper and lower motor neurons of the central nervous system, resulting in progressive muscular atrophy, progressive bulbar palsy and upper motor neuron deficits. While the cause is unknown, the disease is thought to result from viral, metabolic, toxic, infectious and immunological factors. Manifestations include skeletal muscle weakness and atrophy and impaired speech, chewing, swallowing and breathing. The cause of death is commonly respiratory muscle weakness and bulbar palsy causing respiratory failure (LeMone et al 2014; MND Australia 2013a; 2013b).

### Alzheimer's disease

Alzheimer's disease is a progressive degenerative disorder that causes cerebral atrophy and dementia. Although the precise cause is unknown, several theories propose that the disorder may result from a genetic factor, immunological dysfunction, a toxin or a virus. People with Alzheimer's disease have low levels of acetylcholine in their brain which is an important neurotransmitter for memory.

Alzheimer's disease, which affects an estimated 343 000 Australians, is characterised by memory loss and the eventual inability to self-care. Some medications to alleviate the symptoms have been developed, but presently there is no known treatment for the disease (Alzheimer's Australia nda; ndb).

Manifestations of the disease generally occur in three stages:

1. Memory loss, decline in judgment and logic, disorientation, global aphasia, irritability, mood swings and agitation
2. Neglect of hygiene, inability to carry out deliberate voluntary movements (**apraxia**), inability to recognise the nature or use of objects (agnosia), repetition of a motor or verbal action (perseveration) and seizures
3. Marked dementia, unresponsiveness, aphasia and apraxia.

Delirium is a common mental disorder affecting older adults. The acute condition is often misdiagnosed as a form of dementia and the underlying cause is therefore missed. The characteristics of delirium are listed in Clinical Interest Box 35.3. A history of the individual's behaviour before delirium developed is essential in early recognition of the condition (LeMone et al 2014).

### CLINICAL INTEREST BOX 35.3 Clinical criteria for delirium

- Delirium is an acute disturbance of consciousness that is accompanied by a change in cognition. It cannot be accounted for by a pre-existing or evolving dementia. Delirium develops over a short period of time, usually hours to days, and tends to fluctuate during the course of the day. It is usually a direct physiological consequence of a general medical condition.
- There is reduced clarity of awareness of the environment
- Ability to focus, sustain or shift attention is impaired
- Person is easily distracted by irrelevant stimuli
- There is an accompanying change in cognition (memory impairment, disorientation or language disturbance)
- Recent memory is most commonly affected
- Disorientation is usually shown, with a person disoriented to time or place
- Language disturbance may involve impaired ability to name objects or ability to write; speech may be rambling
- Perceptual disturbances may include misinterpretations, illusions or hallucinations

*(Crisp et al 2013; Australian Government Department of Health and Ageing 2011)*

## Immunological disorders

### Multiple sclerosis

Multiple sclerosis is a disorder characterised by progressive demyelination of nerve fibres in the spinal cord and brain. Patches of demyelination throughout the central nervous system result in varied neurological dysfunction. The cause is unknown, but the disease is thought to result from viral or immunological factors. Manifestations vary depending on the areas of the central nervous system that are affected. Some individuals experience mild exacerbations, with long remission periods, while others have frequent relapses, with increasing residual deficits. The most common initial symptoms are

## CLINICAL INTEREST BOX 35.4 Health education checklist—the individual with multiple sclerosis

In formulating a teaching plan it is important that the individual's significant others are included. The following aspects may be considered:

- Facilitate access to the Multiple Sclerosis Society of Australia (www.msaustralia.org.au)
- Ensure that the individual understands the clinical course of multiple sclerosis. Dispel any myths
- Identify strategies to manage symptoms such as dysphagia or altered cognitive responses
- Plan strategies for preventing complications such as pressure ulcers or depression
- Identify coping strategies
- Identify strategies for minimising fatigue
- Explain how to prevent injury
- Discuss ways to adapt to sexual dysfunction
- Develop strategies to control bowel and bladder function
- Explain benefits of continued physical activity and exercise
- Identify ways to minimise immobility and spasticity
- Describe the medication regimen and possible adverse effects.

fatigue, motor weakness and visual disturbances. Other characteristic changes include numbness and tingling sensations, intention tremor, gait ataxia, paralysis, urinary disturbances and emotional lability. Clinical Interest Box 35.4 provides a teaching plan for the individual as well as their significant others (Brown et al 2015; Multiple Sclerosis Society of Australia 2015; Thibodeau & Patton 2012).

### Myasthenia gravis

Myasthenia gravis is a chronic neuromuscular disorder that affects voluntary muscles and is characterised by fluctuating muscle weakness that is exacerbated by exercise. The disease is considered to be autoimmune in origin, resulting in an acetylcholine-receptor deficiency. The thymus gland is also thought to be involved in the disease because the gland is abnormal and remains active after puberty in individuals with myasthenia gravis.

Manifestations include progressive weakness of certain voluntary muscles, with some improvement in muscle function after rest. The eye muscles are most commonly affected, with drooping of the eyelids (ptosis) and double vision (diplopia). Other affected muscles include those involved with facial expression, speech, chewing and swallowing. The individual may experience problems with saliva, nasal regurgitation and choking. The shoulder and neck muscles may be affected so that the head tends to fall forwards. Weakened respiratory muscles make breathing difficult and predispose the person to respiratory tract infections (LeMone et al 2014: National Institute of Neurological Disorders and Stroke ndf).

## Infectious and inflammatory conditions

### Meningitis

Meningitis is inflammation of the meninges and can be caused by viruses, bacteria or fungi. The inflammation may involve one or all three layers of the meninges. Meningitis often begins when the causative organism enters the subarachnoid space, then the infection spreads because of the open communication over the brain's convexity. The accumulation of exudate from the inflammatory process over the convexities or in the ventricles can obstruct the flow of CSF. Aseptic meningitis is thought to occur from meningeal irritation resulting from encephalitis, leukaemia, lymphoma or the presence of blood in the subarachnoid space. The major manifestations of meningitis are severe headaches, pyrexia, irritability, neck rigidity, photophobia and pain in the back and limbs. Other manifestations are alterations in mental status, altered levels of consciousness and restlessness. Vomiting may occur, and cranial nerve involvement causes visual disturbances, pupil abnormalities, strabismus and vertigo. There may be generalised seizures due to cerebral oedema (Patton et al 2012).

### Encephalitis

Encephalitis is inflammation of the brain tissue caused by viruses, bacteria, fungi or protozoans. Endemic encephalitis begins in a non-human host or reservoir from which the virus is transmitted to humans, for example, through mosquito bites. After the pathogen gains access to the central nervous system via the bloodstream or along nerves, the white matter and meninges develop non-suppurative inflammation, and diffuse cerebral oedema results. Initial manifestations are headaches, pyrexia, vomiting, malaise and muscular aches and pains. These are often followed by alterations in the level of consciousness, confusion, motor and sensory deficits, hyperirritability and meningeal signs (National Institute of Neurological Disorders and Stroke nde).

### Brain abscess

A brain abscess is a collection of pus, usually occurring in the temporal lobes or the cerebellum. A brain abscess is accompanied by cerebral oedema and congestion. Most brain abscesses develop secondary to a primary source of infection such as mastoiditis or otitis media; or they may develop from a septic focus in the respiratory tract or, less often, from a pelvic or cardiac source. A small percentage result from a penetrating head wound such as a gunshot injury.

Manifestations include headache, pyrexia, vomiting, alterations in the level of consciousness, and local or generalised seizures. Other features differ according to the site of the abscess and include motor, sensory and speech disturbances (Brown et al 2015).

### Myelitis

Myelitis is the term that applies to a group of infective and non-infective processes that affect the spinal cord. Myelitis can be due to viruses, occur secondary to meningeal inflammation or be of unknown aetiology. The most common viral

diseases causing myelitis are poliomyelitis and herpes zoster. Manifestations include a sudden onset of motor paresis, accompanied by other neurological deficits such as loss of sensory and sphincter functions.

### Herpes zoster

Herpes zoster is a viral disorder that causes inflammation of the posterior root ganglia. The condition develops from reactivation of the varicella virus, the virus responsible for chickenpox. There is also evidence of a relationship between herpes zoster and certain systemic infections, neoplasms and immunosuppressive therapy. Manifestations include mild to severe neuralgic pain in the affected nerve root distribution. The pain, which may be burning, tingling, dull or sharp, may occur with or be followed by skin reddening and eruption of vesicles. The vesicles become pustules and develop a crust within 1–2 weeks. If infection or ulceration accompanies the vesicles, permanent scarring may result.

Occasionally, herpes zoster involves the cranial nerves, especially the trigeminal or oculomotor nerve. Trigeminal involvement causes eye pain and, possibly, corneal damage and impaired vision. Oculomotor involvement may result in conjunctivitis or ptosis. Rarely, herpes zoster leads to generalised central nervous system infection. Post-herpetic neuralgia can persist for months or years, and the skin may remain hypersensitive to touch (LeMone et al 2014).

### Poliomyelitis

Poliomyelitis is an acute infectious disease caused by one of the three poliomyelitis viruses, which generally enter the body through the mouth or nose, multiply in the bloodstream and travel to the central nervous system. The viruses are then spread along neural pathways and destroy cells in the anterior horns of the spinal cord. The brainstem may also be damaged. The incidence of acute anterior poliomyelitis has decreased dramatically in the western world since the introduction of vaccination in 1955.

The virus may cause only a minor illness, or there may be signs and symptoms of viral meningitis and paralysis. The extent of paralysis depends on the location of the affected neurons. The initial manifestations of paralytic poliomyelitis include pyrexia, headaches, vomiting, irritability and pains in the neck, back, arms and legs. About 5–7 days after onset, the individual experiences weakness of various muscles, paraesthesia, hypersensitivity to touch and resistance to neck flexion. If the disease affects the brainstem, the muscles involved in swallowing, chewing and ventilation are affected (LeMone et al 2014).

## Neoplastic and obstructive disorders

Tumours of the nervous system may be benign or malignant, and primary or metastatic. Tumours may arise in the brain tissue, the meninges, the skull, in the peripheral and cranial nerves or in the spinal cord. Brain tissue (cerebral) tumours include astrocytomas and glioblastomas. Meningiomas usually arise from the arachnoid layer of the meninges and do not invade the brain. Skull tumours, which are rare, may be either osteomas (benign) or sarcomas (malignant). Peripheral and cranial nerve tumours include acoustic neuromas, schwannomas and neuroblastomas. Spinal cord tumours may be either extradural or intradural.

Manifestations of nervous system tumours are related to invasion or compression of surrounding neural structures. Brain tumours may produce symptoms as a consequence of increased intracranial pressure; for example, from cerebral oedema. The neurological manifestations of a brain tumour depend on the location of the tumour and its rate of growth. The clinical features associated with a brain tumour include headaches, vomiting, papilloedema (swelling of the optic disc and distension of the retinal vessels), personality or behavioural changes, seizures, visual or hearing defects, dizziness, ataxia and hemiparesis. Manifestations of spinal cord tumours are related to spinal cord compression and include pain, paraplegia or quadriplegia, which may be slowly progressive or acute (Brown et al 2015; Cancer Council Australia 2015).

**CRITICAL THINKING EXERCISE 35.3**

Mrs Smith is transferred to your care a couple of days postoperatively after resection of an occipital tumour and occipital lobectomy. What symptoms may she have? What difficulties may she face for the immediate post op period? What assessments will she need? What discharge information will she need?

## Traumatic disorders

Despite being well protected by bone, meninges and CSF, the brain and spinal cord are frequently injured. Serious cerebral or spinal cord damage can result from a variety of factors such as motor vehicle accidents, sports accidents and penetrating injuries such as gunshot wounds. Acquired brain injury (ABI) or cerebral injury may be classified as concussion, contusion, laceration, haematomas and tentorial herniation. Traumatic brain injury (TBI) is a type of acquired brain injury caused by a blow to the head or contrecoup injury, usually with some loss of consciousness. As a result the brain may be torn, stretched, penetrated, bruised or become swollen (Brain Injury Australia 2015). See Case Study 35.1.

### Concussion

Concussion results from a blow to the head and is characterised by a loss of consciousness for less than 5 minutes and memory loss of events preceding and following the injury. Other features include headaches, confusion, dizziness, visual disturbances, vomiting and irritability.

### Contusion

Contusion is bruising of the brain that disrupts normal nerve function in the bruised area and which may be associated with haemorrhage or oedema. Manifestations include drowsiness, confusion, behavioural changes, loss of consciousness, hemiparesis, unequal pupil response and decorticate

## CASE STUDY 35.1

Gary is a 45-year-old male. He presented to the emergency department after a fall from a first-floor window last night. He had been out drinking at a work function and had forgotten his house keys. His wife called an ambulance this morning as Gary was very agitated and appeared to have a weakness in his left arm and leg. She also noticed some blood loss on the pillow from a gash on Gary's head.

1. How will you assess and manage Gary?
2. How specifically will you ask the questions to establish a Glasgow Coma Scale score for Gary?
3. What clinical risks does Gary present?

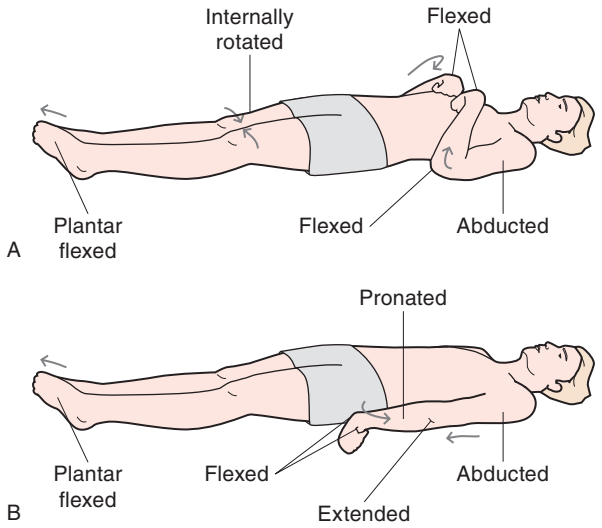

**Figure 35.8** Decorticate and decerebrate posturing A: Decorticate rigidity B: Decerebrate rigidity *(LeMone et al 2014)*

or decerebrate posturing. With **decorticate** posturing the individual demonstrates hyperflexion of the upper extremities and hyperextension of the lower extremities (Figure 35.8A). With **decerebrate** posturing, both the upper and the lower extremities are hyperextended (Figure 35.8B).

The Westmead Post-traumatic Amnesia Scale (WPTAS) is used to measure the period of post-traumatic amnesia following a closed head injury caused by either oedema or haemorrhage. The scale consists of seven orientation questions and five memory items which are designed to objectively measure the period of post-traumatic amnesia (PTA). An individual is said to be out of PTA if a perfect score is obtained for all questions 3 days in a row. Once the duration of PTA is determined the severity of injury can be classified according to the time the individual was in PTA (Department of Psychology, Macquarie University nd; Scope 2015; Synapse Reconnecting Lives 2015).

## CRITICAL THINKING EXERCISE 35.4

A 23-year-old man has been brought into the emergency department after a fall from a ladder. It was reported by his friend that he was unconscious for about 10 minutes. On presentation to ED he is alert and orientated. What type of injury is he most likely to have sustained? What discharge instructions would you give this individual's family? How would you modify these instructions if this individual lives alone?

### Laceration

Laceration is tearing of the brain tissue, followed by intracerebral bleeding. Manifestations include prolonged unconsciousness, immediate neurological deficits and deterioration of the individual's condition.

### Haematomas

Haematomas are collections of coagulated blood and, in the brain, may be epidural, subdural or intracerebral. An epidural haematoma results from haemorrhage in the epidural space between the skull and the dura mater. A subdural haematoma results from an accumulation of blood in the subdural space, between the arachnoid and dura mater. An intracerebral haematoma is a collection of blood within the brain tissue.

Manifestations of cerebral haematomas vary according to the location and whether the haematoma develops rapidly or slowly. Typically an epidural haematoma causes immediate loss of consciousness, followed by a lucid interval that eventually gives way to a rapidly progressive decrease in the level of consciousness. Accompanying features include hemiparesis, severe headaches, unilateral pupil dilation and signs of increased intracranial pressure (decreasing pulse and ventilation rate, increasing systolic blood pressure). Manifestations of a subdural haematoma may not occur until days after the injury. Common features include headaches, drowsiness, confusion, slow responses and seizures. Pupillary changes and motor deficits commonly occur. Manifestations of intracerebral haematoma include neck rigidity, photophobia, nausea and vomiting, dizziness, decreased ventilation rate and seizures (LeMone at al 2014).

### Cerebral herniation

Increased pressure in the cranial cavity can cause damage to the brain through hypoxia, ischaemia and infarction. Unrelieved or untreated raised pressure results in cerebral herniation. When pressure builds up in one area of the brain, brain tissue will begin to move into an area of lower pressure.

Tentorial herniation occurs when part of the temporal lobe herniates through the tentorial hiatus. Typical signs of this form of herniation are pupil dilation and hemiplegia.

Tonsillar herniation or 'coning' occurs when part of the cerebellum and/or brainstem herniates through the foramen magnum. Typical signs of this type of herniation are neck rigidity, dysfunction of the cardiac and respiratory drive and abnormal posturing. Irreversible brain damage and death can occur rapidly (LeMone et al 2014).

### CRITICAL THINKING EXERCISE 35.5

Mr P is a 42-year-old police constable. He has been troubled by recurrent atrial fibrillation, and treated with an anticoagulant. Mr P was on a ladder cleaning the gutters of his house when he fell and hit his head. Although shaken, he felt well after a short rest. However, over the next few days, Mrs P began noticing several behavioural changes in her husband. He seemed vague and forgetful at times. Finally, when she found him urinating in the sink, Mrs P sought medical assistance. An MRI showed a subdural haematoma. Mr P was booked in for evacuation of the clot via burr holes. Following surgery Mr P was alert and orientated. Before surgery, the nurse taking care of Mr P made the following nursing diagnoses:

- Risk for injury related to confusion secondary to increased intracranial haemorrhage
- Self-care deficit: bathing/hygiene related to decreased level of consciousness
- Sleep pattern disturbance related to frequent assessments and loss of sleep.

Describe the nursing interventions, with rationales, that may be planned in response to the issues identified above.

### Spinal cord damage

Spinal cord damage may occur from traumatic injuries as a result of motor vehicle or sports accidents, gunshot or stab wounds or falls from high places. Fractures and dislocations can occur anywhere along the spinal column and, if the spinal cord is injured, may result in temporary or permanent damage.

### Peripheral nerve damage

Peripheral nerve damage can result from pressure, compression, constriction or traction on a nerve, or as a consequence of skeletal fractures, lacerations or penetrating wounds. Nerve damage can also result from an injection of a toxic or metabolic substance into the nerve. The peripheral nerves most commonly injured are the radial, axillary and ulnar nerves and the brachial plexus. Manifestations include loss of motor function, loss of sensation and muscle atrophy. Depending on which nerve is damaged, there may be foot drop, wrist drop, limited range of motion or paralysis.

## CARE OF THE INDIVIDUAL WITH A NERVOUS SYSTEM DISORDER

Although specific nursing actions and medical management vary depending on the disorder, the main aims of care are to:

- Promote a clear airway
- Maintain fluid and nutritional status
- Prevent and manage alterations in elimination
- Promote effective communication
- Promote safety
- Promote mobility
- Prevent complications of immobility
- Provide psychological support
- Assess neurological status
- Provide a suitable environment
- Provide pre- and post-diagnostic test care
- Promote rehabilitation and independence.

Each individual presents specific nursing problems for which an individualised nursing care plan must be developed, implemented and evaluated.

### Promoting a clear airway

Disorders of the nervous system may affect the individual's ability to breathe normally, to cough effectively or to prevent the tongue from obstructing the airway. Altered levels of consciousness, decreased motor function or disrupted cranial nerve function may impair the individual's ability to maintain a clear airway. To ensure a patent airway the individual's nose, mouth and respiratory tract must be clear, allowing adequate oxygen and carbon dioxide exchange.

With a conscious individual:

- The individual should be assisted into a position that will promote effective breathing. A sitting or upright position provides better lung expansion, which improves breathing and lessens the risk of respiratory tract infection
- The individual is instructed to take deep breaths hourly and to cough and expectorate mucus frequently. Chest physiotherapy (e.g. percussion) may be necessary to help mobilise secretions
- If the individual's ability to chew and swallow is impaired, care must be taken when food, fluids or oral medications are being consumed
- Suction equipment should be readily available if the individual is at risk of choking or unable to expectorate secretions effectively
- Active or passive range-of-motion (ROM) exercises and 2–4-hourly position changes help to mobilise respiratory tract secretions
- An adequate fluid input is provided to keep respiratory tract secretions moist.

With an unconscious individual:

- The individual should be nursed in a lateral recumbent position to promote drainage of secretions and to prevent the tongue from obstructing the airway. Positioning on alternate sides 2-hourly should be carried out to prevent pooling of secretions in the lungs
- Oronasopharyngeal suction should be performed to keep the upper airway free of accumulated secretions. Mouth and nasal care should be performed 2–4-hourly for the same purpose (information on oronasopharyngeal suctioning is provided in Chapter 25)
- Chest percussion and postural drainage may be prescribed to help remove retained secretions, particularly if the cough reflex is impaired
- The individual may require mechanical assistance for adequate ventilation. A tracheostomy or endotracheal tube may be inserted and mechanical ventilation

provided (information on tracheostomy care and mechanical ventilation is provided in Chapter 25)
- Eye care is essential for the unconscious individual. If the individual's corneal reflex is absent, keep the eyes moist with artificial tears and protect the eye with a protective shield. These should be ordered by a medical officer.

## Maintaining nutritional and fluid status

An individual with a neurological disorder may have deficits that interfere with an adequate intake of food and fluid, such as:
- Altered level of consciousness
- Altered mental status
- Diminished or absent swallowing or gag reflex
- Inability to feed themself; for example, if there is paralysis of the arm(s)
- Fear of choking
- Paralysis of the muscles of mastication and/or the tongue
- Loss of appetite due to altered sensory function; for example, sight, smell, taste.

Information on assisting the individual to meet nutritional and fluid needs is provided in Chapters 26 and 30. Specific nursing activities to assist the individual with a nervous system disorder include:
- Providing appropriate devices to facilitate the cutting and eating of food
- Ensuring that suction equipment is readily available should it be needed; for example, if the individual's swallowing or gag reflexes are impaired
- Assisting the individual who is unable to feed themself
- Placing the food into the unaffected side of the mouth if the individual has any facial weakness. If able to feed themself the individual should be advised to feed in this manner
- Preparing food for the individual who has motor deficits; for example, cutting meat, spreading butter, pouring fluids
- Redirecting the individual's attention to eating if they become distracted or are unable to concentrate at mealtimes
- Assisting with the care of the individual who is being provided with nutrition and fluids by alternative methods; for example, tube feeding or total parenteral nutrition
- Keeping a record of fluid input and output if the individual has difficulty in feeding themself or swallowing, or if they are receiving dehydrating medications or intravenous solutions to reduce or prevent increased intracranial pressure.

## Preventing and managing alterations in elimination

Many disorders affecting the nervous system can result in constipation, retention of urine or incontinence. Factors that contribute to altered patterns of elimination include loss of sphincter control, diminished awareness of the need to empty the bladder or bowel, altered levels of consciousness and impaired mental status, with resulting incontinence (LeMone et al 2014). (Information on the prevention and management of constipation, retention of urine and incontinence is provided in Chapters 31 and 32.)

## Promoting effective communication

Disorders of the nervous system may affect the ability of individuals to express themselves verbally or non-verbally, and the ability to understand the spoken or written word. (General information on communication can be found in Chapter 8.) The ability to communicate may be impaired by factors that include:
- Damage to the speech centres in the brain
- Damage to the temporal lobes, which hinders the perception and interpretation of stimuli
- Damage to the cranial nerves responsible for movement of the lips, tongue, pharynx and larynx
- Limited motor function that hinders non-verbal communication actions (e.g. facial expressions and gestures)
- Visual or hearing deficits
- Altered levels of consciousness or mental status.

The two major terms used to describe communication deficits are **dysphasia** (difficulty in communicating), and **aphasia** (loss of the ability to communicate) (Brown et al 2015; Berman et al 2015).

### Aphasia

Aphasia is subdivided into three major classifications.
1. Expressive aphasia (Broca's aphasia): inability to express oneself verbally or in writing. The degree of difficulty can range from mild hesitancy in flow of speech to limitation of expression to 'yes' and 'no'. The ability to understand the spoken and written word remains intact
2. Receptive aphasia (Wernicke's aphasia): inability to understand the spoken word. Although the individual hears the sounds of speech, comprehension of speech is impaired. The individual can speak but makes many errors when using words and is often unaware of the imperfect messages. The ability to comprehend the written word is also impaired
3. Global aphasia: a combination of both expressive and receptive aphasia. The individual neither understands what they hear or read, nor can they convey their thoughts in speech or writing.

The loss or impairment of the ability to communicate is devastating and frustrating to the individual and to their significant others, often resulting in fear and depression. Although the speech therapist will be the key person in the treatment of an individual with a communication problem, the nurse must be aware of prescribed therapy so that it can be continued when the speech therapist is not with the individual. The nurse should assume a calm, reassuring and supportive manner that conveys a sense of acceptance of the

**TABLE 35.5 | Assisting the aphasic individual**

| Expressive aphasia | Receptive aphasia |
|---|---|
| Stimulate conversation and ask open-ended questions | Speak slowly and distinctly, using a common vocabulary and simple sentences |
| Allow the individual time to find the words to express themself | Stand within the individual's line of vision, so that lip movements can be observed |
| Be supportive and accepting as the individual deals with the frustration of finding the right words | Use simple gestures as an added cue |
| Accept self-expression (e.g. pointing or gestures) | Repeat or rephrase any instructions if they are not understood |
| Provide charts or books with pictures of common objects so that the individual can point when they cannot say the word | Speak in a normal voice |
| Reassure the individual that speech skills can be relearned, given time | Divide any tasks into small units, working with the individual to accomplish the task |
| Give praise for achievements and progress | Use pointing and touch to express ideas<br>Eliminate background distractions<br>Give praise for achievements and progress |

*(Brown et al 2015).*

individual's behaviour. Table 35.5 provides guidelines that can be used when working with an individual with aphasia.

Communication with the unconscious individual is very important because, although the individual appears to be completely unaware of their environment, it is impossible to determine their awareness of any stimulus. Many individuals have recovered from unconsciousness and given accurate details of events or conversations that took place in their presence while they were unconscious. Therefore the nurse should assume that some stimuli will penetrate the complexities of unconsciousness. Stimuli can be provided by talking to the individual, by touch and by playing a radio or CDs. The individual should be told what the nurse will be doing—orient the individual to time, place and person and describe the surroundings. Coma arousal is a technique whereby the unconscious individual is continuously exposed to a variety of stimuli, such as sounds, touch and smells in an attempt to increase the level of consciousness (Berman et al 2015; Crisp et al 2013).

## Promoting safety

The individual with a nervous system disorder is often susceptible to injury because of factors such as impaired consciousness or awareness, reduced mobility, impaired motor and sensory functions and reflexes. The individual is most at risk of skin breakdown, physical injuries or infection.

## Maintaining skin integrity

The nurse should assess the individual for potential skin problems and implement nursing measures in accordance with the National Safety and Quality Health Service Standard 'Preventing and managing pressure injuries'. This Standard describes the systems and strategies that prevent individuals from developing pressure injuries and the best practice management if a pressure injury occurs (ACSQHC 2012). Nursing measures to prevent skin breakdown from pressure, extremes of temperature and physical trauma is as follows:

- The skin is kept clean and dried to prevent irritation and possible breakdown. Very dry skin should be lubricated with a suitable oil or cream to prevent cracking and breakdown
- A protective cream or lotion may be applied to the genital area and buttocks if the individual is incontinent. Wet or soiled linen must be replaced immediately
- The individual's position is changed every 2–4 hours to protect the skin from irritation and prolonged pressure. Pressure-relieving aids may be used
- The skin is assessed every 2 hours for colour, temperature, dryness and the signs of impaired circulation. Any signs of skin breakdown are reported immediately so that appropriate actions can be implemented to prevent further deterioration
- Precautions must be taken to avoid injury to the skin by hot, cold, sharp or rough objects. The individual is always moved correctly and gently to avoid damage to the skin (Berman et al 2015).

## Preventing physical injuries

An individual who has impaired motor, sensory or intellectual function must be protected from accidents and injuries in accordance with the National Safety and Quality Health Service Standard 'Preventing falls and harm from falls'. This Standard describes the methods and strategies to reduce the incidence of individual falls and the best practice management if a fall should occur (ACSQHC 2012). Protective strategies include:

- Maintaining the bed in a low position when not providing direct care at the bedside
- Using alarms that are triggered when the individual attempts unsafe activities (e.g. standing from chair unaccompanied)

- Accompanying the individual when ambulating if they are unsteady or disoriented
- Providing walking aids and handrails as a means of support and to promote greater safety
- Providing an uncluttered environment and adequate lighting
- Placing the individual's requirements, including the call bell, within reach
- Supervising individuals who are at risk of falling while performing the activities of daily living.

## Preventing infection

An individual with a nervous system disorder that impairs mobility, motor function or level of consciousness is prone to infection. When a person is ill, the body's natural defence mechanisms are stressed and therefore less able than usual to resist the invasion of pathogenic microorganisms. The two most common types of infection that may occur are urinary tract infection due to urinary stasis or catheterisation, and respiratory tract infection resulting from inadequate lung expansion, pooling of secretions in the lungs, the presence of an artificial airway or mechanical ventilation.

The National Safety and Quality Health Service Standard 'Preventing and controlling healthcare associated infections', describes the systems and strategies to prevent individuals within the healthcare system acquiring infections such as a urinary tract infections (ACSQHC 2012). Strategies to prevent a urinary tract infection include ensuring that:

- The individual receives an adequate fluid input
- Whenever possible, an external urinary drainage device or intermittent catheterisation is used rather than an indwelling catheter
- If an indwelling catheter is unavoidable, measures to prevent cross-infection are implemented. These measures include maintaining a sterile closed drainage system, performing meatal and perineal care, maintaining dependent drainage, maintaining strict aseptic care and using correct handwashing technique, which is the most effective way of preventing cross-infection. (Further information on maintaining an indwelling catheter is provided in Chapter 31.)

Measures to prevent a respiratory tract infection include ensuring that:

- When possible, the individual is nursed in a sitting or upright position to promote maximal lung expansion
- The individual performs 4-hourly deep breathing and coughing exercises
- If necessary, suction is used to remove oral and nasopharyngeal secretions
- Aseptic techniques are implemented when caring for an artificial airway.

## Promoting mobility and preventing the complications of immobility

Many nervous system disorders impair physical mobility through motor deficits, cerebellar dysfunction, alterations in sensory perception and changes in conscious or mental status. Prolonged lack of physical exercise and movement can lead to many complications, including pulmonary stasis, urinary stasis, venous stasis, decubitus ulcers, constipation and contractures. Impaired mobility varies from reductions in range of motion, or unsteady gait, to total immobility. Maintaining muscle tone and preventing orthopaedic disabilities are of prime importance when caring for an individual with impaired mobility.

To prevent functional loss:

- Active or passive range-of-motion exercises should be performed every 4 hours
- The individual should be repositioned every 2 hours to maintain correct body alignment. Weak or paralysed body parts must be carefully positioned to prevent deformity. Limb splints are often used to maintain joints in normal anatomical position. These must be checked regularly to detect any areas of pressure
- Specific exercises, such as lifting hand weights, may be prescribed to strengthen a weakened limb
- As soon as the individual's condition permits, balancing and sitting exercises are implemented. If the individual has been immobile for a prolonged period it is necessary to progress slowly to prevent orthostatic hypotension
- Once the individual is able to balance and sit, transfer activities are started; for example, from bed to chair
- When the individual is able to stand and balance in an upright position, ambulation is started
- For the individual who is unable to ambulate, wheelchair mobility may be achieved.

The individual's age, severity of illness, other neurological deficits, chronic conditions or complications contribute to progress. The individual's attitude and motivation are also important factors in regaining mobility. Frequent assessment provides evaluation of the individual's needs so that rehabilitation can progress towards the greatest level of independence. More information on preventing the complications of immobility is provided in Chapter 28.

## Providing psychological support

Many individuals who have a nervous system disorder will suffer neurological deficits resulting in loss of independence, mobility, sensory function or speech. As a result, the individual's body image and self-concept may be greatly altered and they may experience emotional lability, depression, anxiety, frustration or hostility. The individual may undergo personality changes, which may be functional or organic in origin. They may require a lengthy period to regain what were once automatically performed skills involved in the activities of daily living, or they may have to come to terms with the realisation that some skills may never be regained. The emotional shock to an individual who experiences paralysis can be devastating. The nurse has an important role in providing emotional and psychological support for the individual and their significant others. Some of the key aspects related to supporting the individual are as follows:

- During the period of dependence, it is important that dignity is preserved. Sensitivity is needed when dealing with any problems associated with loss of control (e.g. incontinence or loss of social restraint)
- Positive feedback should be provided for accomplishments no matter how minor they may appear
- Adequate information about the disease process and its management should be provided, and the individual should be encouraged to participate in decision making regarding care
- Individual needs should be anticipated to decrease frustration. As much self-care as practicable should be allowed, as a return to independence is the ultimate goal of care. The individual's significant others should be allowed to be involved in care, if they so wish
- The individual and their significant others should be encouraged to express their feelings and anxieties. If the individual is experiencing a communication problem, appropriate methods of communicating should be developed. Time, patience and understanding are necessary to allow them to come to terms with the effects and implications of the disease
- The individual should be encouraged to participate in activities of interest that will help to promote a feeling of self-worth. The occupational therapist and physiotherapist generally assist the individual to find activities that interest them and that will also provide exercise for weak or paralysed muscles.

### Providing a suitable environment

The immediate physical environment should be adapted to meet the individual's specific needs. Items should be arranged to promote safety; for example, adequate lighting, the call bell within easy reach and the bed adjusted to a suitable height. If the person is experiencing sensory deprivation (a lack of sensory input from the environment), the nurse can provide multisensory stimuli. Sensory input can be provided by talking to the person, playing a radio or recordings of the voices of the individual's significant others, by touch and by reality orientation. Reality orientation is a process of making the individual aware of their environment, for example, the date, time, people, place and objects.

Conversely, the individual may experience sensory overload, particularly if critically ill and the condition requires the use of equipment such as mechanical ventilation or a cardiac monitor, or if they are receiving the constant stimuli of nursing care. Sensory overload occurs when sustained multisensory experiences are perceived as confusing or irritating by the individual. The manifestations of sensory overload are confusion, disorientation, restlessness, agitation, panic and possible hallucinations. Every effort should be made to control and moderate the intensity of stimuli; for example, reducing tactile and environmental stimuli.

When the individual is to be discharged from hospital, the physical home environment should be evaluated and the delivery of any necessary equipment arranged so that the activities of daily living can be accomplished and independence maintained. The physiotherapist and occupational therapist arrange for the home use of ambulatory equipment and identify special needs and alterations in the individual's environment that could be beneficial to support their independence.

### Providing diagnostic test care

Preparation of the individual for, and care after, diagnostic tests is part of the nurse's role (see Chapter 19). The nurse must refer to the healthcare institution's policy manual for information about preparation of the individual for specific diagnostic tests. Preparation includes a general explanation of the procedure to reinforce the information provided to the individual by the medical officer. Other preparation may include dietary or fluid restrictions, administration of prescribed medications, assisting the individual into a specific position, skin preparation and measurement of baseline vital and neurological signs.

Post-procedural care may include assessing vital and neurological signs, measuring and recording fluid input and output, administering prescribed medications and assessing the individual for signs and symptoms such as headaches, back pain, neck rigidity, nausea or vomiting, elevated temperature or voiding difficulty.

### Promoting rehabilitation and independence

Rehabilitation is an integral part of care and is a dynamic process in which the individual is assisted to achieve optimal potential. Throughout the individual's illness, all care is directed towards the maintenance of optimal function and prevention of complications to promote as much independence as possible. Rehabilitation of an individual with a nervous system disorder includes helping with relearning the activities of daily living, management of neuromuscular and impaired perception and communication deficits, bladder and bowel retraining and educating the individual and their significant others in preparation for discharge from hospital (Brown et al 2015). (Information on rehabilitation is provided in Chapter 40.)

## CARE OF THE UNCONSCIOUS INDIVIDUAL

Consciousness is defined as a state of awareness of self and the surroundings. Consciousness implies an ability to perceive sensory stimuli and to respond appropriately to them. Unconsciousness is defined as an abnormal state in which the individual is unresponsive to sensory stimuli. There are degrees of unconsciousness that vary in length and severity, ranging from a brief episode of unconsciousness in the form of fainting to a prolonged and deep coma.

### Causes of impaired consciousness

Impaired consciousness arises from widespread damage to both cerebral hemispheres or from disruption of the reticular

activating system in the upper brainstem. Loss of consciousness may result from a cerebral tumour, abscess, haemorrhage, haematoma, laceration, bruising or ischaemia, or from metabolic processes that depress or interrupt the function of both cerebral hemispheres; for example, hypoxia, hypoglycaemia or toxic agents.

### Outcome of unconsciousness

The ultimate outcome of unconsciousness varies from full recovery of brain function, through a wide range of disabilities, to irreversible coma and death. The development of sophisticated monitoring techniques and life-support systems has increased the survival rate for comatose individuals with severe brain damage. A small percentage of individuals emerge from deep coma to a state of wakefulness without awareness, never regaining any recognisable mental function.

Irreversible coma or persistent vegetative state is used to describe a chronic condition occurring after severe cerebral damage. It is characterised by intact autonomic functions, generally intact reflexes, presence of a sleep–wakefulness cycle, spontaneous eye opening to verbal stimuli, no localising motor responses to verbal stimuli and no intact cognitive functions or awareness of self or of the environment (LeMone et al 2014).

### Brain death

Brain death is a state of irreversible brain damage characterised by absence of cognitive functions and awareness of self and the environment, inability to maintain vital functions and the absence of isoelectric activity on EEG. In brain death (or brainstem death) the higher cortical functions cease, consciousness and awareness are lost, as is voluntary control of movement and all brainstem function. Some functions are not completely dependent on the integrity of the brainstem; for example, heart rate continues, though this is usually for a limited time as the individual requires ventilatory support. If brainstem function can be shown to have ceased, then there is no prospect of recovery. The basic criteria for diagnosing brain death usually include:

- No pupillary response
- No corneal response
- No vestibulo-ocular reflex
- No motor response in cranial nerve distribution
- No gag or tracheal response
- No respiratory response to hypercapnia
- Apnoea
- Irreversible coma
- Absence of brainstem reflexes
- Isoelectric electroencephalogram (ECG)
- No spontaneous movements.

Before considering a brain death diagnosis there is a need to exclude that brain dysfunction is the result of structural or metabolic disease, rather than the result of depressant drugs, alcohol, poisoning or hypothermia (Australian Government Organ and Tissue Authority 2014; LeMone et al 2014).

Brain death is a controversial legal, ethical and medical dilemma, but it is considered ethical and legal to terminate life support in individuals diagnosed as brain dead.

## Management of an unconscious individual

When an individual is unconscious a high standard of care must be provided, with the objectives of maintaining and restoring body function and preventing complications. Medical management involves establishing a patent airway and providing adequate ventilation, controlling intracranial pressure and establishing the cause of unconsciousness and, if possible, reversing it. Nursing care of the unconscious individual requires the following practices.

### Maintaining a patent airway

With the absence of cough and swallowing reflexes, secretions accumulate in the posterior pharynx and upper trachea. An oral artificial airway may be sufficient to maintain patency, or tracheostomy or endotracheal intubation and mechanical ventilation may be necessary. To prevent airway obstruction:

- The individual is positioned on alternate sides every 2–4 hours to prevent secretions accumulating in the airways on one side. The neck should be maintained in a neutral position
- Dentures and partial plates are removed
- Nasal and oral care is provided to keep the upper airway free of accumulated secretions and debris
- Oronasopharyngeal suction equipment may be necessary to aspirate secretions
- Chest percussion and postural drainage may be prescribed to assist in the removal of tenacious secretions.

### Monitoring neurological function

The individual's neurological signs are monitored at intervals determined by their condition. The results are documented and compared with previous assessments. Information on assessment of neurological function is provided earlier in this chapter.

### Positioning

The individual is generally nursed in a lateral position with a small pillow placed under the head and neck to maintain the head in a neutral position. The upper arm is positioned on a pillow to maintain the shoulder in alignment, and the upper leg is supported on a pillow to maintain alignment of the hip. The individual's position is changed so that they lie on alternate sides every 2–4 hours. If hemiplegia is present the individual may be positioned on the affected side for brief periods, but care must be taken to prevent injury to soft tissue and nerves, oedema or disruption of the blood supply. Because vasomotor tone is decreased in the affected areas, such adverse effects can develop rapidly from improper positioning. If the correct position is maintained, secretions are able to drain from the individual's mouth, the tongue is less likely to obstruct the airway and postural deformities can be prevented.

### Meeting hygiene needs

*Care of the skin* involves keeping it clean and dry and protected from damage. Areas of the skin, particularly over the

bony prominences, should be assessed regularly for the signs of impaired blood circulation and irritation that contribute to the formation of decubitus ulcers. Dry skin may be lubricated with a suitable cream or lotion to prevent cracking and breakdown, and a water-repellent substance may be used to protect the skin against excreta or perspiration. The male should receive a facial shave as part of his daily hygiene care; the individual's nails are kept short and clean; and the hair is brushed, combed and washed as necessary.

*Care of the mouth* involves cleansing all areas at 2–4-hourly intervals to prevent a build-up of plaque, development of caries and development of a focus of infection. To prevent aspiration of fluid while oral hygiene is being performed, the individual's head is turned to one side and suction equipment made available throughout the procedure. The lips are lubricated with a suitable water-based substance.

*Care of the nose* involves cleansing the nostrils to keep them free of dried mucus. Cottonwool-tipped applicators and saline solution may be used to remove mucus and dried crusts, and a thin coating of cream may be applied to the rim of the nostrils.

*Care of the eyes* involves swabbing the eyes with moistened cotton wool to remove secretions, the instillation of artificial tears (or antibiotic eye drops if prescribed) and protecting the eyes from corneal abrasions. If the eyelids do not close fully, the use of eye shields or pads may be necessary to protect the corneas. (See Chapter 34 for more information on care of the eye.)

## Meeting nutritional and fluid needs

The nutritional and fluid needs of the individual must be regularly assessed and met to maintain body function, support tissue repair and combat infection. The dietitian prescribes a nutritional program based on consideration of the individual's energy needs, requirements for tissue repair, loss of fluid and basic life functions. Methods of administering nutritional and fluid support to the unconscious individual include total parenteral nutrition, and enteral feedings administered via a nasogastric, nasojejunal or gastrostomy tube. Parenteral nutrition is only used if there is a long-term gut absorption problem, as the aim is to normalise gut function as soon as possible. Fluid input may be restricted to a specific amount of fluid in a 24-hour period. The purpose of fluid restriction is to control increased intracranial pressure by keeping the individual slightly under-hydrated. As fluid input is correlated with output, an accurate input and output record must be maintained. (See Chapter 30 for more information on nutrition.)

## Meeting elimination needs

Because an unconscious individual is incontinent, an external urinary drainage appliance or an indwelling catheter (IDC) may be used to manage urinary drainage. Both methods are used to keep the skin dry, as urinary incontinence can quickly lead to skin breakdown. Urinary drainage devices also enable accurate calculation of urinary output. Long-term IDC is avoided whenever possible due to risk of infection. Frequent checks and meticulous skin care is preferable. (Information on care of the individual with a urinary drainage device is provided in Chapter 31.)

Constipation and faecal impaction are common complications in an unconscious individual because immobility and lack of a normal diet inhibit peristalsis. A program is established whereby aperients and rectal suppositories are administered to promote regular bowel evacuation. The frequency of bowel actions and the amount and nature of the faeces are documented (see Chapter 32).

### CLINICAL INTEREST BOX 35.5 Altered consciousness and taking temperature

Temperature should never be taken orally in individuals with altered conscious state. For an oral temperature reading to be taken safely and accurately, the individual must be able to close their lips completely and understand the importance of not biting the thermometer. Measure temperature via the tympanic or axillary routes; of these, tympanic is more accurate and therefore preferred.

## Promoting safety

Providing and maintaining a safe environment is of prime importance because an unconscious individual is unable to perceive or react to safety hazards. Clinical Interest Box 35.5 suggests alternative routes for measuring temperature when an individual is in a state of altered consciousness.

## Preventing complications

Because the unconscious individual is not mobile, they are at risk of developing any of the complications associated with immobility (muscle contractures, decubitus ulcers or venous, pulmonary or urinary stasis). (Information on preventing these complications is provided in Chapter 28.)

## Providing sensory stimulation

The extent to which an unconscious individual may be aware of what is happening to and around them cannot usually be determined; the nurse should therefore assume that the brain is receiving some sensory input. When the duration of coma extends into weeks or months, it may seem meaningless to keep explaining each activity to an individual who gives no sign of comprehension. However, on regaining consciousness some individuals have been able to describe accurately events that happened to and around them while they were unconscious. Although they were unable to communicate their feelings they were able to discriminate between the gentle caring manner of some people and the inattentive ways of others. Some individuals have reported that they longed for someone to talk to them rather than about them.

The nurse should therefore act as though the individual is conscious and demonstrate respect for them as a person.

All activities should be explained to them, privacy during procedures should be ensured and they should be treated with dignity. Family members and friends should be encouraged to talk to and touch the unconscious individual. They should be encouraged to perform certain activities for the individual, such as combing the hair or applying skin lotion. Other sensory stimuli can be provided by playing a radio or music, or by placing perfumed flowers in the room.

Recovery from unconsciousness is a gradual process that tends to vary with each individual. Rehabilitation after a prolonged period of unconsciousness includes protecting the individual from orthostatic hypotension. When able to tolerate a vertical position, an ambulation program is developed, unless neurological deficits make it infeasible (Crisp et al 2013; Berman et al 2015; LeMone et al 2014). (Information on rehabilitation nursing is provided in Chapter 40.)

### Management of the individual with impaired motor function

Disturbance of motor function is common among individuals who experience disorders of the brain, spinal cord or peripheral nerves, such as cerebral haemorrhage, spinal cord injury or peripheral neuritis. While this chapter addresses the care of an individual who has experienced a stroke or a spinal cord injury, the principles of care can be applied to individuals who experience impaired motor function from other causes. Some terms relating to impaired motor function are:

- Paresis: incomplete paralysis or muscle weakness
- Paralysis: loss or impairment of the ability to move part(s) of the body. Paralysis may be complete or incomplete, spastic or flaccid, symmetric or asymmetric, temporary or permanent
- **Hemiplegia**: unilateral paralysis, or paralysis of one side of the body. Because nerves cross in the pyramidal tract before descending to the spinal cord, damage to one side of the brain causes hemiplegia on the opposite side of the body
- **Paraplegia**: paralysis of the lower limbs and, sometimes, paralysis of the lower trunk and sphincters. Paralysis may be complete or incomplete, spastic or flaccid, temporary or permanent
- **Quadriplegia** (tetraplegia): paralysis of the arms and legs and of the body below the level of injury to the spinal cord (Brown et al 2015).

## Stroke

A stroke, also known as a **cerebrovascular accident (stroke)** or brain attack, is one of the leading causes of death in the western world, and each year many thousands of individuals survive a stroke but are left with permanent disabilities. A stroke is a sudden impairment of cerebral circulation, which causes cerebral infarction. The two types of stroke are ischaemic and haemorrhagic. In an ischaemic stoke, cerebral blood flow is suddenly impaired by a thrombus or embolus. In a haemorrhagic stroke, the rupture of a cerebral blood vessel causes bleeding into the subarachnoid space or brain tissue.

Manifestations of a stroke vary depending on the artery involved, and consequently the area of brain it supplies, and the severity of damage to cerebral tissue.

Table 35.6 lists the clinical features resulting from specific cerebral artery occlusion or rupture. If the stroke occurs in the left hemisphere, it produces symptoms on the right side of the body. If it occurs in the right hemisphere, the left side of the body is affected.

A thrombotic stroke, the most common type, is associated with atherosclerosis, which causes narrowing of the lumen of arteries. A thrombus forms in one of the cerebral arteries, occluding the vessel and resulting in cerebral ischaemia. An embolic stroke occurs when an embolus, which may be part of a thrombus, fat or other substance, is carried to the brain and occludes a cerebral blood vessel. A haemorrhagic stroke, which is often associated with hypertension, occurs when a cerebral blood vessel ruptures, spilling blood into the brain tissue. Rupture of an artery may result from a degenerative change in the arterial wall, or from an anatomical defect such as an aneurysm (Brain Foundation 2015; Stroke Foundation 2015a; 2015b). See Case Study 35.2.

### Risk factors

Educational programs have been developed to inform the general public about stroke and prevention. Many factors have been identified as predisposing a person to a stroke and, by increasing public awareness, those at risk can seek medical

### CASE STUDY 35.2

Mr Ken Nyugen is a 56-year-old male who has been admitted to the acute medical ward with an ischaemic stroke. He initially presented by ambulance after being found slumped in a chair at home by his daughter. On initial presentation to the emergency department the following assessment data was obtained:

GCS 11/15 (E4 V2 M5)
PEARL 4
RR 20
BP 210/100
HR 50 regular (12 lead ECG RBBB—old)
$SpO_2$ 92% RA—coarse crackles right lower lobe
T 37.5
Right hemiplegia
Aphasia
Dysphagia
Incontinence

1. Detail how you would perform your physical assessment of the individual.
2. What risk factors does Mr Nguyen have in relation to his stroke and how do the risk factors contribute to stroke?
3. What are some indications of dysphagia?
4. What is your management plan for Mr Nguyen? What medical interventions will be required?

## TABLE 35.6 | Manifestations of cerebrovascular accidents according to vessel involved

| Vessel | Manifestations |
|---|---|
| Middle cerebral artery (MCA) | Hemiparesis or hemiplegia (contralateral to lesion)<br>Aphasia (if left hemisphere lesion)<br>Sensory impairment (same side as hemiplegia)<br>Homonymous hemianopia<br>Deterioration in conscious level from confusion to coma<br>Headaches<br>Inability to turn eyes towards the affected side<br>Denial or lack of recognition of a paralysed extremity (if right hemisphere lesion)<br>Possible Cheyne–Stokes breathing |
| Anterior cerebral artery (ACA) | Hemiparesis or hemiplegia of leg and foot (contralateral to lesion)<br>Paresis of the arm on the side of hemiplegia<br>Gait dysfunction<br>Expressive aphasia<br>Mental status impairments:<br>• Confusion<br>• Perseveration<br>• Apathy<br>• Amnesia<br>• Short attention span<br>• Slowness<br>Deviation of eyes and head towards the affected side<br>Urinary incontinence |
| Posterior cerebral artery (PCA) | Peripheral signs:<br>• Homonymous hemianopia<br>• Memory deficits<br>• Dyslexia<br>• Several visual defects<br>• Perseveration<br>Central signs:<br>• Hemiplegia or hemiparesis<br>• Pupillary dysfunction<br>• Intention tremor<br>• Diffuse sensory loss<br>• Nystagmus |
| Internal carotid artery (ICA) (may show any or all of the signs associated with middle cerebral artery and anterior cerebral artery disease) | Hemiparesis with facial asymmetry (contralateral to lesion)<br>Paraesthesia on same side as hemiparesis<br>Hemianopia<br>Repeated attacks of visual blurring or blindness in the ipsilateral eye<br>Dysphasia (intermittent) if dominant hemisphere involved |
| Posterior inferior cerebellar artery (PICA) | Dysphagia<br>Dysarthria<br>Loss of sensation on ipsilateral side of the face<br>Loss of sensation on contralateral side of the body<br>Horizontal nystagmus<br>Ataxia<br>Vertigo<br>Nausea and vomiting<br>Ipsilateral Horner's syndrome (miotic pupils, ptosis and facial anhidrosis (inadequate perspiration))<br>Paralysis of larynx and soft palate |
| Anterior inferior cerebellar artery (AICA) | Horizontal nystagmus<br>Sensory impairment<br>Deafness and tinnitus<br>Nausea and vomiting<br>Facial paralysis<br>Horner's syndrome<br>Ataxia |
| Vertebral–basilar system (may show any of the signs of the PCA, PICA or AICA occlusion) | • Dysarthria<br>• Dysphagia<br>• Vertigo<br>• Nausea<br>• Syncope<br>• Memory loss, disorientation<br>• Ataxic gait<br>• Double vision<br>• Tinnitus<br>• Nystagmus<br>• Facial paresis<br>• Drop attacks |

*(Brown et al 2015; American Nurse Today 2015)*

advice to have any pre-existing conditions managed, thus reducing the risk of stroke. Risk factors include:

- A history of transient ischaemic attacks (TIAs)
- Atherosclerosis
- Hypertension
- Family history of stroke
- Heart disease
- Diabetes mellitus
- Smoking

Alcohol

- Sedentary work with little exercise
- Obesity
- Elevated cholesterol and triglyceride levels (Brain Foundation 2015).

### Manifestations of a stroke

In all cases of stroke, areas of the brain are deprived of an adequate oxygen supply. If the blood supply is impaired for an extended period, the involved cerebral tissue may become necrotic, resulting in permanent neurological deficits. In instances of ischaemia, temporary neurological impairment may result. The particular type and degree of neurological deficits depend on the area of the brain involved (see Table 35.6). Table 35.7 lists a comparison of manifestations associated with right- and left-sided hemiplegia.

## Care of the individual who has had a stroke

Medical management involves control of cerebral oedema and subsequent increased intracranial pressure, surgical intervention if indicated and drug therapy; for example, thrombolytic medication such as tissue plasminogen activator (TPA) may be given to individuals experiencing a non-haemorrhagic stroke. Nursing care of the individual involves:

- Managing the acute phase
- Meeting basic needs
- Preventing complications
- Providing psychological support
- Promoting rehabilitation.

**TABLE 35.7 | Manifestations of stroke**

| Left-sided stroke | Right-sided stroke |
|---|---|
| Right-sided hemiplegia (left stroke) | Left-sided hemiplegia (right stroke) |
| Aphasia—expressive, receptive or global | Spatial–perceptual deficits |
| Intellectual impairment | Tends to be distractible; impulsive behaviour |
| Slow behaviour | Appears to be unaware of deficits; poor judgment |
| Defects in right visual fields | Defects in left visual fields |

*(Brown et al 2015)*

### Care during the acute phase

The acute phase begins when the individual is admitted, and continues until their condition is stable. Nursing care is directed towards maintaining a patent airway and monitoring vital and neurological signs.

*Maintaining a patent airway*. This involves positioning the individual on their side, administering oxygen as prescribed and suctioning secretions from the airway. Care must be taken when performing oronasopharyngeal suction, as suction applied for longer than 15 seconds at a time may increase intracranial pressure.

*Recording fluid input and output*. This information should be kept to monitor kidney function and to evaluate fluid and electrolyte balance.

*Vital and neurological signs*. These signs should be assessed frequently, for example every 15–30 minutes, to detect changes in the individual's condition. Information on neurological assessment is provided earlier in this chapter. If the individual is unconscious, the principles of care described previously should be incorporated.

### Care after the acute phase

Detailed information about the nursing measures necessary to meet the individual's basic needs for hygiene, safety, elimination, nutrition and fluids, psychological support, mobility and rehabilitation are provided elsewhere in this text. Clinical Interest Box 35.6 provides some suggestions that can facilitate self-care after stroke.

The main aims of care for an individual who has experienced a stroke are to:

- Assist in meeting hygiene needs
- Monitor vital and neurological signs
- Maintain muscle tone and prevent contractures
- Prevent skin breakdown
- Prevent venous stasis (thrombus and embolus formation)
- Prevent and manage alterations in elimination (e.g. incontinence, retention of urine, constipation)
- Maintain nutritional and fluid status
- Establish an adequate means of communication
- Promote reorientation of a confused individual
- Enhance self-concept and body image
- Institute a rehabilitation program aimed at achieving an optimal level of independence (Stroke Recovery Association NSW 2014a; Brown et al 2015).

### Rehabilitation

Rehabilitation of the individual begins on admission to hospital and continues for as long as necessary including after discharge home. In some healthcare institutions the individual may be transferred to a rehabilitation unit after the acute phase of their illness. The focus of rehabilitation is directed at helping the individual to relearn lost skills and to become as independent as possible. The individual and their significant others are made aware of the plan and goals of the rehabilitative phase, and their active participation is encouraged. Recovery from a stroke is a slow process; therefore the

## CLINICAL INTEREST BOX 35.6 Devices to facilitate self-care after stroke

The following list identifies useful items that may assist neurologically impaired individuals to perform self-care more easily and safely after a stroke or other disorders.

**Eating devices**

- Plate guards to prevent food from being pushed off plate
- Wide grip utensils to accommodate weak grasp
- Non-skid mats to stabilise plates

**Mobility aids**

- Canes, walkers, wheelchairs
- Transfer devices such as slide boards and belts

**Bathing and grooming devices**

- Shower and bath chairs
- Electric razors with head at 90 degrees to handle
- Grab bars, non-skid mats, hand-held shower heads
- Long-handled bath sponge

**Dressing aids**

- Velcro closures
- Elastic shoe laces
- Long-handled shoe horn

**Toileting aids**

- Raised toilet seat
- Grab bars next to toilet

*(Independent Living Centre NSW 2015)*

nurse must provide support and positive feedback so that the individual does not become discouraged. Rehabilitation of the individual includes:

- Encouraging participation in their own care as much as possible
- Teaching them to perform the activities of daily living with regard to ways of compensating for any disabilities
- Teaching and assisting with performance of transfer activities (e.g. bed to chair)
- Assisting in the regaining of any lost communication skills
- Encouraging expression of feelings, to decrease anxiety and to allow for correction of any misunderstood information
- Developing a bladder and bowel retraining program (if necessary) (Stroke Recovery Association NSW 2014c).

More information on rehabilitation nursing is provided in Chapter 40.

### Planning for discharge

Discharge planning is directed at facilitating the transition from the healthcare institution to the home environment. Discharge planning involves assessing the individual and the family, identifying specific needs, planning to implement ways of meeting those needs and evaluating the discharge process and the results. After the individual is discharged home, they and the family must have contact with support services, such as the district nurse, whom they can rely on for continued help and support (Stroke Foundation 2015a; 2015b; Stroke Recovery Association NSW 2014b).

## Spinal cord injury

Injuries involving the spinal cord result most often from motor vehicle accidents, falls, sporting and industrial accidents and firearm or stab wounds. Injuries to the vertebral column and spinal cord result from forces applied directly or indirectly to the head, neck or trunk. Apart from direct tearing of the spinal cord, the main damage is caused by haemorrhage, oedema and disruption of the blood supply to the cord. Additional compression can result if bony fragments or disc material press on the spinal cord.

Manifestations of spinal cord damage depend on the degree and site of the injury. Complete spinal cord transection causes a total loss of motor and sensory function below the level of injury. With cervical cord transection there is paralysis of all four extremities (quadriplegia/tetraplegia). There are varying degrees of arm and ventilatory paralysis, depending on the injury level. With thoracic cord transection, down to the level of the second lumbar vertebra, there is paralysis of the lower extremities (paraplegia). There is often some loss of intercostal muscle function and loss of bladder and bowel function. With transection in the region of lumbar vertebrae there is loss of a combination of sensory, motor, bowel and bladder function.

Complete cord transection results in immediate flaccid paralysis, loss of sensation and loss of reflexes below the level of injury. As paralysis subsides, reflexes usually return and flaccidity changes to involuntary spastic movements. Recovery of any motor or sensory function is rare when there has been complete paralysis of these functions for several days. With incomplete spinal cord injuries, degrees of motor and sensory deficit below the level of damage vary. The individual may experience temporary paralysis, with function returning when any oedema subsides (Spinal Cord Injuries Australia nd; LeMone et al 2014).

Damage to the spinal cord and nerve roots results from:

- Compression by displaced bone or ligaments, extruded disc or haematoma formation
- Excessive stretching, crushing, shearing or severance of neural tissue
- Swelling in response to bruising or compression
- Impaired capillary circulation and venous return.

There are four possible vectors (forces) that can be applied to the spinal column to cause injury:

1. Flexion: excessive flexion (hyperflexion) tends to produce compression of the vertebral bodies, with disruption of the posterior ligaments and the intervertebral discs. Hyperflexion injuries are caused by hyperflexion of the head and neck, as in sudden deceleration of a vehicle

2. Extension: excessive extension (hyperextension) usually causes fractures of the posterior elements of the vertebral column and disruption of the anterior ligaments. Hyperextension injuries are caused by hyperextension of the head and neck, as may occur in a rear-end vehicular accident
3. Rotation (lateral flexion): excessive rotation is most likely to produce rupture of the ligaments, fracture and fracture dislocation of the vertebral facets. Rotational injuries are caused by extreme lateral flexion or rotation of the head and neck
4. Compression: compression can result in fractures of the vertebral body and arch, and rupture of the supporting ligaments. Compression injuries are caused by vertical pressure as occurs when a person falls from a height and lands on their feet or buttocks (Spinal Hub 2015a).

### Classification of spinal cord injuries

Spinal cord injuries can be classified by the type of injury and by syndromes:

- Concussion: severe shaking of the spinal cord that causes temporary loss of function lasting about 24–48 hours
- Contusion: bruising of the spinal cord, which includes bleeding into the cord
- Laceration: an actual tear in the spinal cord
- Transection: severing of the cord—may be complete or incomplete
- Haemorrhage: bleeding into or around the cord. Escaped blood is an irritant to the delicate tissue
- Anterior cord syndrome: due to injury of the anterior part of the spinal cord and associated with flexion injuries and fracture dislocations of the vertebrae. Manifestations include loss of pain and temperature sensation and motor function below the level of the injury. The sensations of light touch, position and vibration remain intact
- Posterior cord syndrome: a rare syndrome in which the senses of position and vibration are involved
- Central cord syndrome: due to injury and/or oedema to the central cord in the cervical region (e.g. as a result of hyperextension injuries). Manifestations include a greater loss of motor function in the upper limbs (rather than the lower), bladder dysfunction and varying degrees of sensory impairment
- Brown-Séquard syndrome: results from open penetrating wounds that produce transverse hemisection of the cord. Manifestations include loss of pain and temperature sensation on the side opposite the injury, and loss of motor function, light touch, position and vibratory sensation on the side of the injury (Brown et al 2015).

### Manifestations of spinal cord injury

Generally, the degree of damage to the spinal cord at any level is described as incomplete or complete transection. Incomplete transection of the cord produces loss or impairment of sensation and motor function that reflects the specific nerve tracts that have been damaged. Complete transection of the cord results in permanent loss of voluntary movement, sensation, reflex and autonomic function below the level of injury.

### Spinal shock

Spinal shock is an immediate response to an acute spinal cord injury and is the temporary suppression of reflexes controlled by the segments below the level of injury. After a period that may vary from hours to months, the spinal neurons gradually regain their excitability. Subsequent return of some function results from decompression of the cord as oedema resolves (Spinal Hub 2015b; Brown et al 2015).

### Functional loss from spinal cord injury

The different functions and dysfunctions associated with spinal cord injuries at specific levels are listed in Table 35.8. The effects of spinal cord injury on sexual response vary depending on the level and degree of injury. Sexual function is controlled by spinal levels S2, S3 and S4. Knowledge of the physiology of alterations in sexual response after spinal cord injury is incomplete, and significant individual differences exist. People with complete loss of sensation in the genitalia may still experience orgasm in response to sensations produced by stimulation of other areas of the body in which sensation is intact. Sexual pleasure can also be increased by psychological stimuli, such as memory, sight, sound and odour. Physical stimulation of the genitalia may produce reflex erection of the penis and vaginal lubrication, even though there is no sensory awareness of stimulation (LeMone et al 2014).

## Care of the individual with spinal cord injury

Management of the individual at the scene of the accident is critical to the ultimate neurological outcome. The basic objectives of first aid management at the scene are to:

- Prevent death from asphyxia
- Prevent further spinal cord damage from torsion, flexion or extension of the unstable spine
- Transport the individual rapidly and safely to an appropriate facility
- Subsequent management of the individual involves emergency department care, early management, post-acute and long-term management.

### Initial management

On arrival of the individual in the accident and emergency department, the medical officer assesses the individual, and x-rays are taken to determine the extent of the injuries. The medical officer develops a plan of care that may include immediate surgery or a non-surgical approach with traction and immobilisation and insertion of a nasogastric tube, indwelling urinary catheter and intravenous infusion. Generally, glucocorticoid steroids are prescribed to reduce cord swelling.

**TABLE 35.8 | Spinal cord injury—functional loss**

| Level of injury | Motor function | Sensory function | Bladder/bowel function | Ventilatory function |
|---|---|---|---|---|
| C1–C4 | Loss of all function from the neck down | Loss of sensation from the neck down | No bladder or bowel control | Loss of independent ventilatory function |
| C5 | Loss of all function below the upper shoulders | Loss of sensation below the clavicles | No bladder or bowel control | Phrenic nerve is intact but the intercostal muscles are non-functional |
| C6 | Loss of all function below the upper arms | Loss of sensation below the clavicles, but some arm and thumb sensation | No bladder or bowel control | Phrenic nerve is intact but the intercostal muscles are non-functional |
| C7 | Incomplete quadriplegia. Loss of motor control to parts of the arms and hands | Loss of sensation below the clavicles but some arm and hand sensation | No bladder or bowel control | Phrenic nerve is intact but the intercostal muscles are non-functional |
| C8 | Incomplete quadriplegia Loss of motor control to parts of the arms and hands | Loss of sensation below the chest and part of the hands | No bladder or bowel control | Phrenic nerve is intact but the intercostal muscles are non-functional |
| T1–T6 | Loss of function below the mid-chest | Loss of sensation from the mid-chest down | No bladder or bowel control | Independent phrenic nerve function; some intercostal muscle impairment |
| T6–T12 | Loss of function below the waist | Loss of sensation below the waist | No bladder or bowel control | No interference to ventilatory function |
| L1–L2 | Loss of most control of the pelvis and legs | Loss of sensation to the lower abdomen and legs | No bladder or bowel control | No interference to ventilatory function |
| L3–L4 | Loss of control of part of the lower legs and feet | Loss of sensation to part of the lower legs and feet | No bladder or bowel control | No interference to ventilatory function |
| L5–S5 | Loss of control of parts of the hips, knees, ankles and feet | Loss of sensation to parts of the lower limbs and perineum | May or may not be loss of bladder and/or bowel control | No interference to ventilatory function |

*(eMedicine Health 2015; Brown et al 2015)*

### Early management

After initial assessment and stabilisation of the individual, they are admitted to the intensive care or spinal unit. An individual with less severe injuries may be admitted to a general ward. Medical management will depend on the type of spinal cord injury and any associated injuries. Treatment may be surgical, non-surgical or a combination of both approaches. Surgical management may take the form of decompression laminectomy, fusion of vertebrae, open or closed reduction of fractures or dislocations or the insertion of rods. Non-surgical management involves immobilisation of the spine (Figure 35.9) using skeletal tongs with traction, halo traction, a cervical collar or a device designed to maintain thoracic or lumbar alignment, such as a fibreglass body jacket.

## Nursing care of the individual with a spinal cord injury

Nursing management will vary according to the individual's injury and whether a surgical or non-surgical approach is selected. However, the major aspects of care are directed towards maintaining respiratory function, immobilisation and alignment of the spine, preventing complications, meeting basic needs, providing psychological support and rehabilitation.

### Respiratory care

An individual with a spinal cord injury can develop varying degrees of respiratory difficulty, depending on the level of spinal injury. The individual will require a plan of care

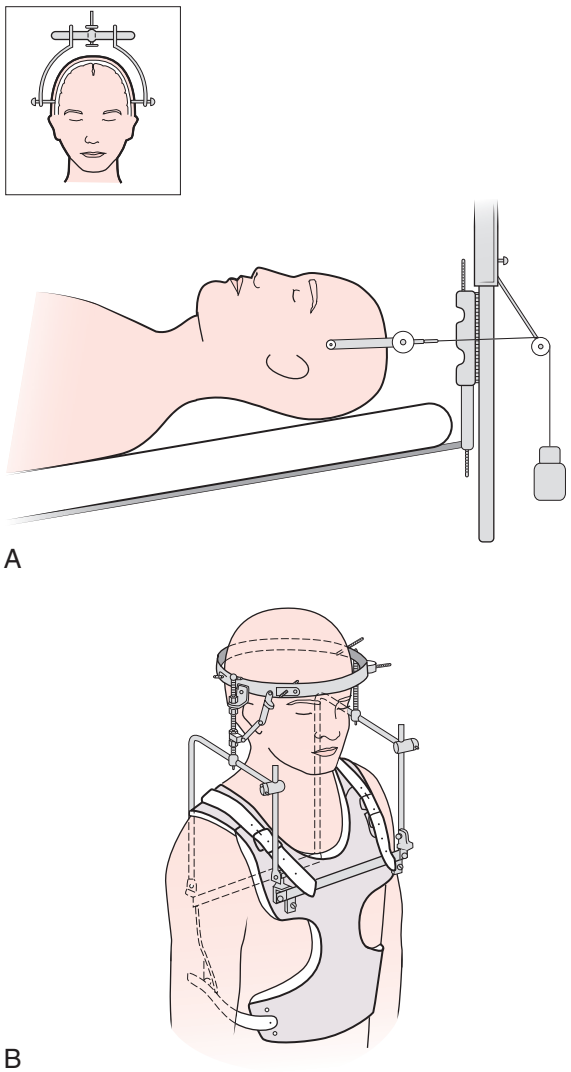

**Figure 35.9** Immobilisation of the spine

A: Cervical traction with tongs. The inset shows the position of the tongs on the bone structure of the skull B: Halo traction and vest

directed at preventing pulmonary complications. Intubation and mechanical ventilation will be required if there is impairment of respiratory muscle function. The program of care includes:

- Regular assessment for indications of inadequate ventilation
- Chest physiotherapy at least every 4 hours
- Maintenance of a patent airway
- Use of an incentive spirometer to promote lung expansion.

## Immobilisation and alignment of the spine

After alignment of the spine has been achieved, immobilisation serves to maintain alignment and promotes healing at the site of injury. For most thoracic, lumbar or sacral injuries the individual remains confined to bed, with the back positioned and supported to achieve hyperextension of the spine at the site of injury. A bed with a firm mattress and steel base and correctly positioned pillows are necessary to maintain the prescribed posture.

## Skeletal traction

When the injury involves dislocation or fracture-dislocation of the cervical or high thoracic spine, skeletal traction is commonly used to accomplish alignment and immobilisation (see Figure 35.9). Skeletal traction may be achieved by means of cervical tongs, such as Crutchfield tongs, or by the halo device. The halo device may also be incorporated with the use of a body vest or jacket to stabilise the spine, thereby allowing the individual to be ambulatory. When skeletal traction is used, the individual may be nursed on a firm mattress and fracture board, or on a special bed such as a Stryker frame.

After skeletal traction has been established, pain is decreased and the individual's comfort is enhanced. Turning can be carried out using a special technique (as described in Chapter 23) to allow for skin care and a change of position. Management of the individual in cervical skeletal traction includes:

- Checking the traction equipment every 2–4 hours to ensure safety and integrity of the treatment
- Inspecting, cleansing and dressing the pin sites according to the institution's policy (e.g. every 4–8 hours)
- Changing the individual's position every 2 hours to prevent the complications of immobility. The 'log-rolling' technique or the Stryker frame is used to turn the individual to maintain the vertebral column in neutral position
- Using various devices (e.g. pillows, a foot board, a cervical roll) to maintain good body alignment. When the individual lies supine, the arms and legs are positioned in extension with support to maintain the feet in dorsiflexion. The hands are placed in a functional position and a cervical roll is used to maintain hyperextension of the neck. When the individual is in a lateral position, the arms and legs are positioned in extension, and pillows are placed to support this position (LeMone et al 2014).

## Preventing complications

Because prolonged immobility can lead to various complications, specific preventive measures must be implemented. (Information on preventing the complications associated with immobility is provided in Chapter 28.)

## Meeting basic needs

Individuals with impaired motor and sensory function require assistance to meet their needs for hygiene, safety, elimination, nutrition and fluids, temperature regulation and pain relief (NSW Agency for Clinical Innovation 2013a). (Information on assisting individuals to meet these basic needs is provided in other chapters.)

## Providing psychological support

A severe spinal cord injury has a devastating affect on the individual and their significant others, and they will experience

a range of emotional responses, from the time of injury and through the rehabilitation process. The individual will have to adapt to the loss of motor function and sensory deprivation, both of which severely threaten self-concept and body image. It is important that the nurse is aware of the impact that the injury has on the individual's emotional and psychological equilibrium. The nurse must be sensitive to the emotional and psychological response of the individual to the injury, and be supportive as they deal with the impact of the injury. The nurse can help to support the individual by:

- Establishing a climate of trust
- Accepting behaviour, without being judgmental
- Encouraging expression of feelings
- Listening empathetically and attentively
- Allowing the individual to make decisions and maintain control
- Providing information as necessary
- Supporting a positive self-concept and self-esteem
- Informing the individual that it will take time to adjust to the disability (NSW Agency for Clinical Innovation 2013b; LeMone et al 2014).

See Nursing Care Plan 35.1.

## Promoting rehabilitation

In most instances of spinal cord injury the individual will require long-term rehabilitation. Rehabilitation after spinal cord injury is a lifelong process of learning to live with a disability. The individual and family together with the healthcare team members contribute to the development of the rehabilitative plans. (Information on rehabilitation is provided in Chapter 40.)

### CRITICAL THINKING EXERCISE 35.6

An 18-year-old male has been admitted to the neuro rehabilitation ward after complete transection of his spinal cord at C7 level following a motor bike accident. What motor and sensory function would you expect the individual to have? The individual says he is looking forward to learning to use special equipment. Do you think his emotional response is appropriate? How would you respond? What elimination issues may emerge? How would you deal with these?

## NURSING CARE PLAN 35.1

**Assessment:** Mr W, 72, had a posterior lumbar interbody fusion L3–4, L4–5 2 days ago following a fall down the stairs. Pt is alert and orientated, full power in both upper limbs and left leg; however, mild weakness in right leg and normal sensation. Mr W has a pain score of 6/10 in his surgical site, worse on mobility. He is mobilising to the bathroom with assistance of one. When not mobilising he is resting in bed.
**Issue/s to be addressed:** Immobility related to lumbar fusion
**Goal/s:** Mr W will remain free of complications of immobility

| Care/Actions | Rationale |
|---|---|
| Positioning | |
| Teach and encourage how to sit on the side of the bed independently | Encourages independence during transfer and positioning. Maintains alignment during position change |
| Physiotherapy and exercise program | Assists to strengthen muscles used to transfer and mobilise |
| Provide pain relief prior to mobilising | Reduces pain on transfer and mobilisation |
| Provide education regarding transfer, mobilisation and safety to decrease falls risk | Decreased falls risk and anxiety |
| Skin integrity | |
| Ensure the skin is checked for non-blanching redness, oedema, localised heat and integrity after repositioning | Monitors for pressure injuries<br>Documents skin integrity each shift |
| Reduce risk of pressure injury related to immobility | |
| Ensure moisture is removed from the skin caused by urinary and faecal incontinence | Reduces risk of impaired skin integrity related to incontinence |
| Circulatory care | |
| Ensure graduated compression stockings or intermittent pneumatic compression (SCDs) are used until fully mobile | To facilitate venous return from the lower extremities and prevent venous stasis and venous thrombosis |
| Assess both lower extremities for skin colour, temperature, skin condition, oedema and Homans' sign (pain in calf with passive dorsiflexion of the foot) | To reduce peripheral oedema |

## NURSING CARE PLAN 35.1—CONT'D

| Care/Actions | Rationale |
|---|---|
| Encourage leg exercises while awake | |
| Assist to sit on the side of the bed before transferring to chair | Reduces orthostatic hypotension |
| Administer anticoagulant | Prophylaxis to assist in prevention of venous thromboembolism (VTE) |

**Evaluation**

Skin integrity observed and documented each shift.
Mr W able to mobilise with minimal assistance of one.
Pain relief offered prior to mobilisation.
Calves assessed each shift.

*(LeMone et al 2014; Berman et al 2015)*

## Summary

The nervous system is a complex system, responsible for communication within the body and between the body and its environment. It is divided into two primary divisions: the central nervous system and the peripheral nervous system.

Nervous tissue is commonly described as grey and white matter. The grey matter is composed of cells and the white matter is made up of fibres. Neurons are the primary components of nervous tissue, which are bound together by neuroglia. Neurons have two functional properties, irritability and conductivity. This means that neurons are able to respond to a stimulus, convert it into an impulse and transmit the impulse to other neurons, muscles or glands. Impulses are transmitted through spaces, called synapses, between neurons.

The central nervous system consists of the brain and the spinal cord. The brain is a large organ composed of the cerebrum, diencephalon, brainstem and cerebellum. Each part of the brain has specific functions. The spinal cord lies within a canal inside the vertebral column, extending from the base of the skull to the first or second lumbar vertebra. The spinal cord receives sensory impulses, conveys motor impulses and is the centre through which reflex actions take place. The meninges are three membranes that cover the brain and spinal cord to protect them against physical injury. Cerebrospinal fluid is a clear watery fluid produced in the ventricles of the brain, which circulates in the subarachnoid space surrounding the brain and spinal cord. It protects the brain and spinal cord and provides a medium for the exchange of nutrients and waste products.

The peripheral nervous system consists of 12 pairs of cranial nerves and 31 pairs of spinal nerves. The nerves of the peripheral nervous system may be: sensory, carrying impulses to the brain and spinal cord; motor, carrying impulses away from the brain and spinal cord; or mixed. The motor nervous system is divided into somatic and autonomic nervous system divisions. The autonomic nervous system division is composed of the sympathetic nervous system and the parasympathetic nervous system. It is the section of the peripheral nervous system concerned with the involuntary activity of the body. Sympathetic nerves have a stimulating effect on most organs, while parasympathetic nerves tend to slow down body processes.

Normal function of the nervous system may be impaired as a result of congenital disorders, inflammatory or infectious conditions, trauma, neoplasia, degenerative conditions or metabolic and endocrine disorders. The major manifestations of nervous system disorders are headaches, sensory changes, motor changes, reflex changes, altered states of awareness or consciousness and seizures. Disorders of the nervous system can be classified as those occurring from congenital or hereditary defects, from multiple causes, degenerative disorders, immunological disorders, infectious or inflammatory conditions, neoplastic or obstructive disorders and trauma.

Diagnostic tests used to assess nervous system function include the neurological examination, radiographic examination, magnetic resonance imaging and electroencephalography. Care of the individual with a nervous system disorder includes promoting a clear airway, maintaining fluid and nutritional status, preventing and managing alterations in elimination, promoting effective communication, promoting safety, promoting mobility, preventing the complications of immobility, providing psychological support, assessing neurological status, providing a suitable environment and promoting rehabilitation.

## DECISION-MAKING FRAMEWORK EXERCISE 35.1

Jenna is a student Enrolled Nurse on an acute neurological unit where she is caring for Mr H, a 62-year-old male.

Mr H had a stroke 10 days ago. He is opening his eyes to verbal command; however, he remains drowsy with inappropriate words his best verbal response.

Mr H has had a nasogastric tube inserted for administration of medications and enteral feeds.

The previous shift reported that Mr H's NG had been reinserted after he pulled it out and suggested that Mr H be restrained to prevent the nasogastric tube being removed again.

Jenna has been informed by the RN supervising her to tie Mr H's hands to the bed rail to prevent the tube being removed. Jenna is aware that this would be a form of restraint.

Using the decision-making framework answer the following questions:

1. What should Jenna consider when making this decision?
2. What is the hospital policy regarding the restraint of an individual?
3. Have alternatives to restraining Mr H been considered?
4. Have any potential risks of restraining Mr H been considered?
5. Does Jenna have the required level of education to restrain Mr H?
6. Should the medical officer caring for MR H be informed?

## Review Questions

1. What is anosmia? What is the impact on the individual? What are the only tastes you can sense on your tongue? Why is education prior to discharge important?
2. An individual arrives on your ward diagnosed with a left fronto-temporal brain tumour. What deficit may he have? What can you do as his nurse to help him?
3. An individual who was in an accident 30 minutes ago reports she is unable to move her legs. Do you tell her about rehab? Do you caution her about seatbelt use? Do you say she has spinal swelling? Do you say initial swelling may make the assessment inaccurate and re-assessment will be done when the swelling has resolved?
4. The family of an individual with a ruptured aneurysm says she was seen by her doctor a few months ago and was given a clean bill of health. They worry that their GP missed something. What can you tell them to reassure them, about the nature of aneurysms? The individuals's sister also had an aneurysm last year. What should the family be advised to do?
5. An 18-year-old man has been admitted for a cranioplasty, following recent MVA resulting in head trauma, raised ICP and craniectomy. He is confused and impulsive. What specific care is needed for this individual in relation to positioning in bed and mobilising? What can be done about impulsiveness, climbing out of bed, etc?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing assessment and management of endocrine health

*John P Elias*

CHAPTER 36

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define key terms
- Describe the locations and basic anatomy of each endocrine gland and the factors which control hormone synthesis and release from them
- Define and explain the actions of the hormones secreted by each endocrine gland
- Identify and describe the disorders associated with each endocrine gland
- Discuss the pathophysiological influences associated with endocrine gland and hormone disorders
- Explain the effects, signs or symptoms of endocrine disorders
- Understand the rationale behind the diagnostic tests that may be used when assessing endocrine function
- Assist in the planning and implementation of nursing care for the individual with an endocrine disorder

## KEY TERMS

acromegaly
Addison's disease
adrenal glands
Cushing's syndrome
diabetes insipidus
diabetes mellitus (type 1)
diabetes mellitus (type 2)
dwarfism
dysfunction
gigantism
glucose
goitre
Graves' disease
homeostasis
hormone
hyperglycaemia
hypersecretion
hypoglycaemia
hyposecretion
insulin
metabolism
myxoedema
pancreatic islets
parathyroids
phaeochromocytoma
pituitary gland
polycystic ovary syndrome
thyroid gland

## CHAPTER FOCUS

The endocrine system is comprised of a number of small glands which secrete hormones, chemical messengers which aid in maintaining homeostasis in the body. Hormones are involved in physiological processes such as metabolism, growth, fluid balance and reproduction. Over- or under-production of these hormones can have widespread effects because of the close relationship between the endocrine and other systems in the body. An understanding of the function of these hormones, and the effects of hormone imbalances, gives healthcare professionals the ability to interpret dysfunction and to care for individuals with an endocrine disorder.

## LIVED EXPERIENCE

I was always a very fit and active person until I started to notice that my heart rate would increase rapidly when simply walking up stairs and I would become hot and sweaty for no reason and unable to sleep. Then one day a few minutes into a jog I had heart palpitations and I was completely out of breath: I was terrified. My doctor tested my blood pressure and my heart for a murmur and I had blood tests for a whole range of things. While waiting for the results I lost 4 kg in just 3 days! This coincided with an enormous increase in appetite—I was eating 5 meals a day!

My blood test results showed I had Graves' disease. I had never even heard of it before. And neither had anyone in my family.

After being diagnosed with Graves' disease it took months of cycling from hyperactive to underactive while adjusting my medication until I felt 'normal' again. Some days I would be hot, sweaty and intolerant to heat, have an increased appetite, lose weight and be unable to sleep. Then I would just as quickly be cold and tired; I would feel depressed and I would put on weight.

**Carli, 33-year-old fitness instructor**

Carli just started getting really restless and hyperactive. I told her it was because of all the exercise she was doing, but it didn't make sense. I couldn't even sleep in the same bed! She would toss and turn and kick off the doona.

When she started eating two breakfasts every morning and chocolate every night, and she was losing weight, we knew it was something more than just nerves.

The problem is that Carli's radioactive treatment worked too well—now she has to take thyroid hormone replacement for the rest of her life.

**Ian, Carli's husband**

# STRUCTURE AND FUNCTION OF THE ENDOCRINE SYSTEM

## Endocrine glands and hormones

The endocrine system is a cellular communication system involving the secretion of hormones by glands. A **hormone** is a chemical regulator that integrates and coordinates cellular activities. Once secreted, hormones are transported to areas of the body where they stimulate a specific cellular activity in a target organ (Patton & Thibodeau 2012). Figure 36.1 illustrates the major endocrine glands and their location. Hormones are either steroids or proteins, and despite being circulated widely by the blood, only target cells with specific receptors have the ability to respond to a specific hormone. Binding to these receptors initiates a response that may take seconds or days: compared to the nervous system, the effects of hormones are much more prolonged (Marieb & Hoehn 2014).

The effects of many hormones are widespread and diverse, while others are quite tissue specific. The major bodily processes controlled by the endocrine system are: reproduction; growth and development; maintenance of fluid electrolytes; maintenance of blood nutrients; and cellular **metabolism** and energy regulation (Marieb & Hoehn 2014). Most hormones are continuously secreted at a rate determined by stimulation of the gland that releases them. Endocrine gland secretion may be enhanced or depressed by blood-borne stimuli, neural input or other hormones: some hormones can exert control over other endocrine glands and other hormones by influencing their action, metabolism, synthesis and transport. The activation or inhibition of endocrine glands relies on negative feedback to maintain homeostatic levels of hormones and their effects (Patton & Thibodeau 2012). Disruption of this **homeostasis** presents as endocrine and hormone imbalances and pathologies. Table 36.1 lists all the major hormones, their effects and the endocrine glands responsible for their production and release.

## The pituitary gland

The pituitary gland, or hypophysis, is about the size of a pea and is positioned at the base of the brain in a depression in the sphenoid bone. The **pituitary gland** (Figure 36.2) is often referred to as the 'master gland' of the endocrine system (Marieb & Hoehn 2014). This term reflects not only the number of hormones it secretes, but the influence of many of these hormones in controlling other endocrine tissues as well. It lies just beneath the hypothalamus, to which it is physically connected by a stalk containing blood vessels and nervous tissue. It has two functional lobes: the anterior lobe comprised of glandular secretory tissue; and the posterior

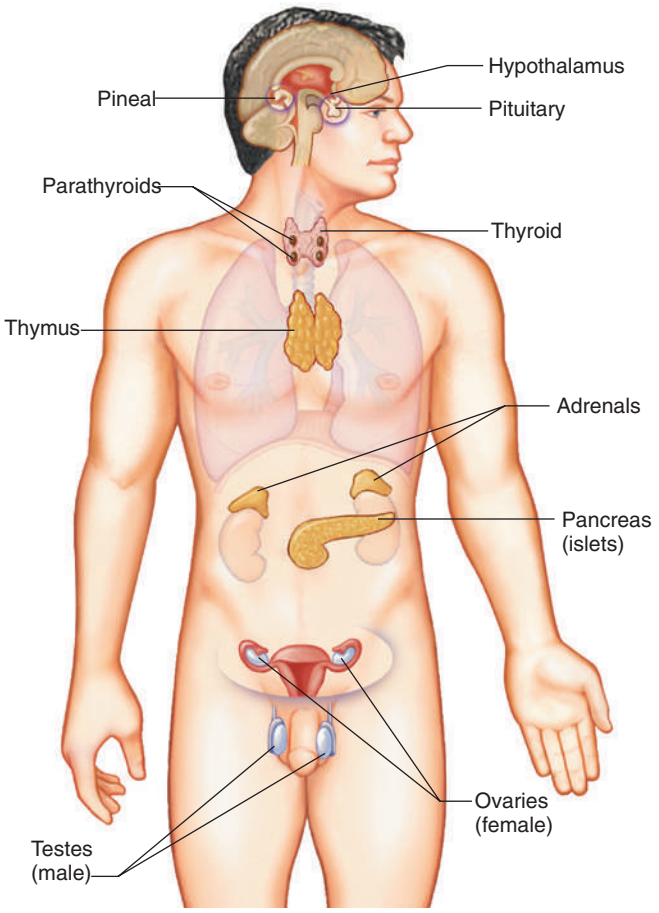

**Figure 36.1** The endocrine system
*(Patton & Thibodeau 2012:547)*

lobe which is nervous tissue. Each lobe performs specific functions which reflect their embryological origin.

The anterior lobe or adenohypophysis produces and releases:

- Growth hormone (GH), which is a metabolic hormone concerned with body growth, particularly that of skeletal muscles and long bones
- Thyrotrophic hormone (TH), also referred to as thyroid-stimulating hormone (TSH), which is responsible for controlling the growth and activity of the thyroid gland
- Adrenocorticotrophic hormone (ACTH), which regulates the activity of the cortex of the adrenal glands in hormone production
- Prolactin (PRL), also referred to as lactogenic hormone, which stimulates the mammary glands to secrete milk after the birth of a baby
- Gonadotrophic hormones, which control the development and functions of the ovaries and testes. These hormones are:
  - follicle-stimulating hormone (FSH), which in the female stimulates the maturation of the ovarian follicle and ovum and the secretion of oestrogen, and in the male stimulates the seminiferous tubules to produce sperm
  - luteinising hormone (LH), which in the female triggers ovulation and stimulates ovarian production of oestrogen and progesterone (the corpus luteum which forms after ovulation secretes progesterone), and in the male stimulates the testes to secrete testosterone.

**TABLE 36.1 | The major endocrine glands, hormones and their roles**

| Endocrine gland | Hormone | Target | Role or effect |
|---|---|---|---|
| Anterior pituitary | Growth hormone (GH) | All body tissues | Promotes growth and metabolism |
| | Thyroid-stimulating hormone (TSH) | Thyroid gland | Regulates production and release of thyroid hormones |
| | Adrenocorticotrophic hormone (ACTH) | Adrenal cortex | Regulates secretion of corticosteroids |
| | Follicle-stimulating hormone (FSH) | Ovaries | Stimulates maturation of ovarian follicle and production of oestrogen |
| | | Testes | Regulates production of sperm |
| | Luteinising hormone (LH) | Ovarian follicle | Triggers ovulation and stimulates production of oestrogen and progesterone |
| | | Testes | Promotes production of testosterone |
| | Prolactin (PRL) | Breasts | Stimulates milk production |
| Posterior pituitary | Oxytocin | Uterus | Stimulates uterine contractions and initiates labour |
| | | Breasts | Stimulates milk secretion |
| | Antidiuretic hormone (ADH) (vasopressin) | Renal tubules | Regulates reabsorption of water |
| | | Vascular muscle | Vasoconstriction |
| Thyroid | Thyroxine ($T_3$ & $T_4$) | All body tissues | Regulates metabolic rate, regulates growth |
| | Calcitonin | Bone | Decreases plasma calcium levels |

*Continued*

**TABLE 36.1 | The major endocrine glands, hormones and their roles—cont'd**

| Endocrine gland | Hormone | Target | Role or effect |
|---|---|---|---|
| Parathyroids | Parathyroid hormone (PTH) | Bone<br>Kidneys | Increases plasma calcium levels<br>Regulates reabsorption of calcium and excretion of phosphorus; activates vitamin D |
| Adrenal cortex | Glucocorticoids (e.g. cortisone)<br><br>Mineralocorticoids (e.g. aldosterone)<br>Sex hormones (e.g. androgens, oestrogens) | All body tissues<br><br>Renal tubules<br><br>Widespread | Regulates metabolism of protein, fat and carbohydrate<br>Suppresses inflammation<br>Stress response<br>Regulates sodium and potassium balance<br><br>Maintenance of fluid balance<br>Weak influence on development of secondary sexual characteristics and growth |
| Adrenal medulla | Adrenaline and noradrenaline | Widespread | Sympathetic effects<br>Response to stress<br>Secretion of ACTH |
| Pancreatic islets | Insulin<br><br>Glucagon | Widespread<br><br>Liver<br>Muscles<br>Adipose cells | Stimulates decrease in plasma glucose and cellular uptake<br>Stimulates increase in plasma glucose and glycogenolysis |
| Gonads (ovaries) | Oestrogen<br><br>Progesterone | Reproductive tissues<br>Breasts<br>Uterus | Development of secondary sexual characteristics, maturation of sexual organs and function<br>Development of mammary tissue<br>Preparation for implantation and maintenance of pregnancy |
| Gonads (testes) | Testosterone | Widespread | Development of secondary sexual characteristics, maturation of sexual organs and function |
| Thymus | Thymosin | Immune system | Lymphocyte development |
| Pineal | Melatonin | Hypothalamus<br>Midbrain | Circadian rhythm |

*(Brown et al 2015; Marieb & Hoehn 2014; Patton & Thibodeau 2012)*

The posterior lobe receives, stores and releases the following hormones which are synthesised in the hypothalamus:

- Oxytocin, which stimulates uterine contraction and the initiation of childbirth, and causes the ducts of the mammary glands to contract and expel breast milk
- Antidiuretic hormone (ADH), which stimulates the kidney tubules to reabsorb water, resulting in decreased excretion of water in the urine (Marieb & Hoehn 2014).

TSH, ACTH, FSH and LH may all be considered as trophic hormones in that they affect the activity and secretion of other hormones from other endocrine glands. To this effect, alterations in pituitary gland function or health have widespread consequences (Patton & Thibodeau 2012).

## The pineal gland

The pineal gland is a small cone-shaped structure situated in the roof of the third ventricle of the brain. The endocrine function of the pineal gland is unknown but it is believed to secrete the hormone melatonin, which appears to rise and fall during the course of the day and night and is believed to establish the body's day–night wake–sleep pattern (Marieb & Hoehn 2014). A rare neoplasm of the pineal gland (pinealoma) may obstruct the flow of cerebrospinal fluid, causing hydrocephalus (Farrell & Dempsey 2013).

## The thymus

The thymus gland is positioned in the upper thorax posterior to the sternum. It is large in infants and children, reaching its maximum size at puberty, then decreasing in size and function throughout adulthood (Patton & Thibodeau 2012). The thymus produces a hormone called thymosin, which promotes the growth of lymphoid tissue in the body and aids in the body's immune response. While endocrine dysfunction of the thymus gland is uncommon, congenital thymic hypoplasia causes deficient cellular immunity, making the individual more susceptible to infections.

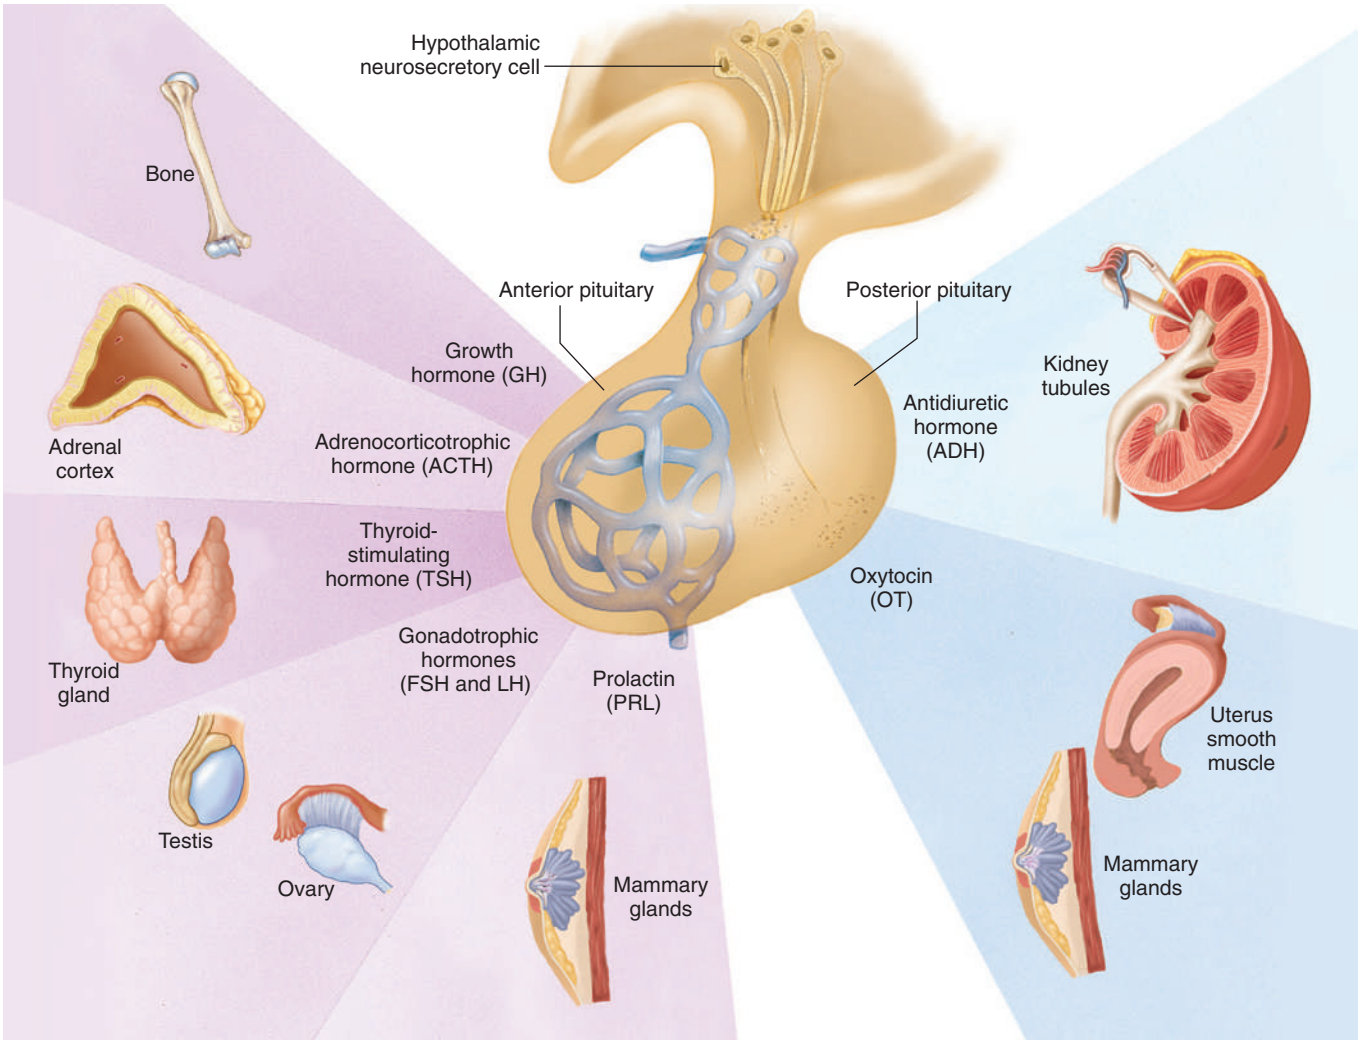

**Figure 36.2** The pituitary gland and hormones
*(Patton & Thibodeau 2012:565)*

## The thyroid gland

The **thyroid gland** lies in the anterior neck just inferior to the larynx. It consists of two lateral lobes positioned either side of the trachea. The lobes are joined together by a central mass called the isthmus, which lies anteriorly across the trachea. The thyroid gland is covered by a connective tissue capsule that forms trabeculae, which then pass inwards and divide the gland into lobes. It is richly vascularised, which presents surgeons with a tricky and dangerous task. The thyroid gland is the largest pure endocrine gland in the body, and produces two main hormones: thyroid hormone and calcitonin (Patton & Thibodeau 2012).

Thyroid hormone (TH) is actually two iodine-containing amine hormones: thyroxine ($T_4$) and triiodothyroxine ($T_3$). Thyroid hormone contains large quantities of iodine which is derived from the diet and stored in the thyroid gland, and is produced by the follicles of the thyroid gland. Thyroid hormone largely controls cellular metabolism, thereby affecting virtually every cell in the human body. In doing so, TH influences:

- Growth and physical development
- Neural and mental development
- Nutrient metabolism and metabolic rate
- Body temperature.

Calcitonin, also referred to as thyrocalcitonin, is produced by the parafollicular cells of the thyroid gland, and decreases blood calcium levels by stimulating calcium uptake and deposition in the bones. In humans, the relative role of calcitonin is not important: individuals who have had thyroid surgery or removal are not adversely affected by the loss of calcitonin secretion. However, individuals with skeletal disorders such as Paget's disease may be administered calcitonin therapeutically (Marieb & Hoehn 2014).

## The parathyroid glands

The **parathyroids** are four small glands embedded in the posterior surface of each lobe of the thyroid gland. The parathyroid glands produce parathyroid hormone (PTH), also referred to as parathormone, which is primarily responsible for the regulation of blood calcium and phosphate levels.

Parathormone release is triggered by falling blood calcium levels and is antagonistic to calcitonin: it promotes release into the blood of calcium and phosphate from bone; enhances reabsorption of calcium and excretion of phosphate by the kidneys; and also promotes the activation by the kidney of vitamin D, which assists in calcium absorption by the gut (Marieb & Hoehn 2014).

## The pancreas

The pancreas is largely an exocrine gland, secreting enzyme-rich digestive juices destined for the small intestine (see Chapter 30). Scattered among these cells are the **pancreatic islets**, small clusters of endocrine cells formerly referred to as the islets of Langerhans. They produce two hormones, insulin from beta (β) cells and glucagon from alpha (α) cells, which both help to regulate blood glucose level (Patton & Thibodeau 2012).

Insulin and glucagon are antagonistic hormones, and their general effects and relationship are illustrated in Figure 36.3. **Insulin** promotes **hypoglycaemia**, which happens when the pancreas detects high or elevated glucose levels (the presence of some amino acids and fatty acids also stimulate or increase insulin release). The major effects of insulin are to lower blood **glucose** by increasing the uptake of glucose into the cells and reducing the release of glucose from the liver. Insulin also promotes the conversion of glucose to fatty acids within the liver, and generally stimulates protein synthesis. Insulin is essential for the use of glucose by the cells of the body; without it, most cells would be unable to access or utilise glucose for energy (Marieb & Hoehn 2014).

Glucagon in contrast promotes **hyperglycaemia**. It is released in response to a reduction or decrease in blood glucose level. Its output is reduced in the presence of raised blood glucose and insulin and thus acts as an antagonist of insulin. Glucagon raises blood glucose levels by stimulating the breakdown of glycogen in the liver (glycogenolysis), inhibiting glycogen synthesis and enhancing the production (gluconeogenesis) and release of glucose (Patton & Thibodeau 2012).

## The adrenal glands

The paired **adrenal** (suprarenal) **glands** are located on top of each kidney. Each gland is surrounded by a capsule and

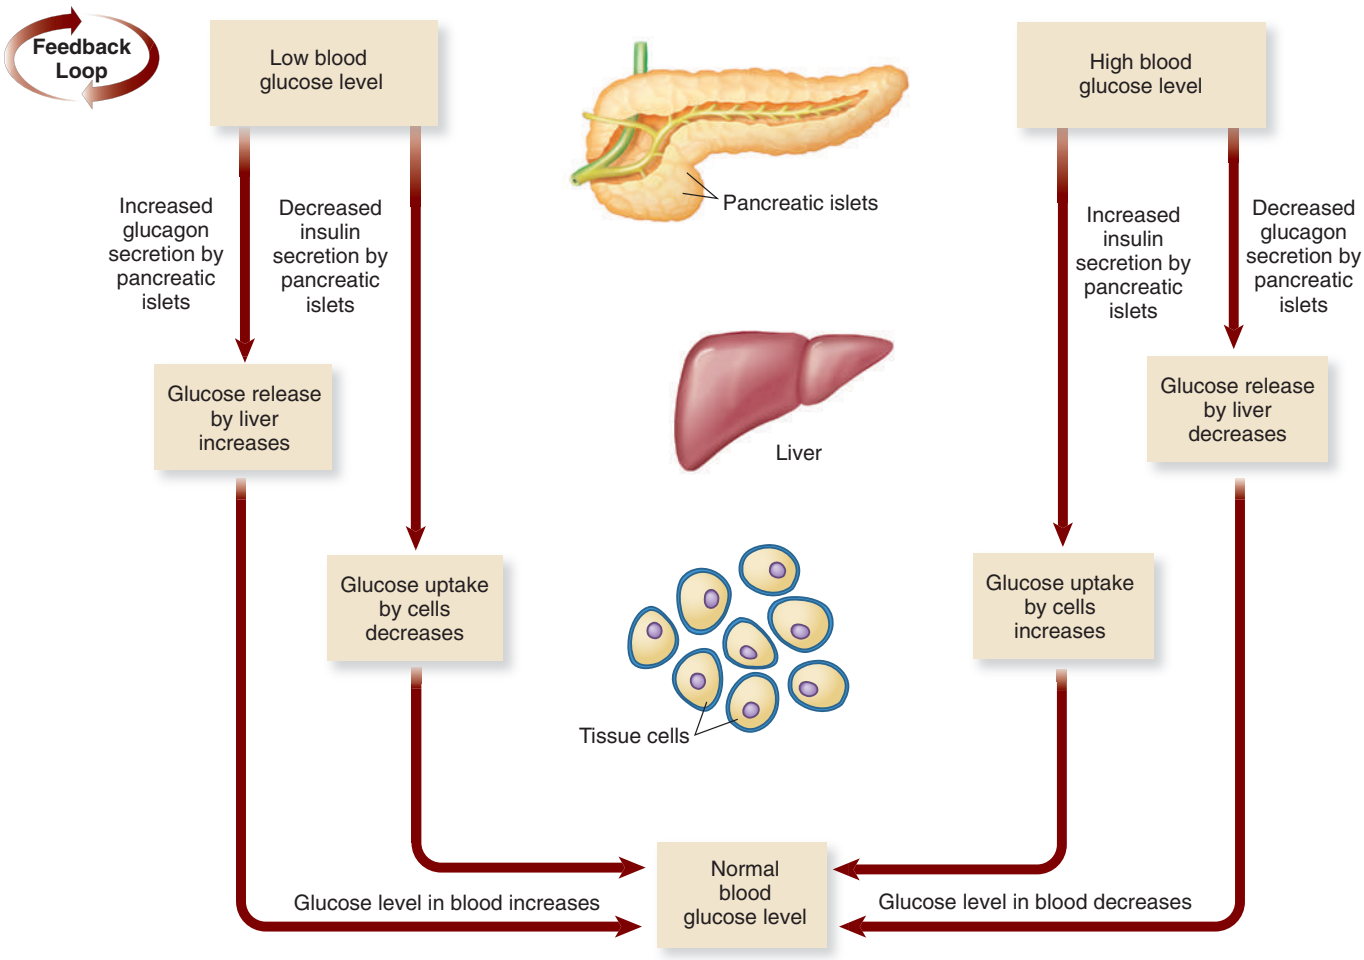

**Figure 36.3** Homeostasis of glucose—insulin and glucagon
*(Patton & Thibodeau 2012:583)*

contains an outer cortex and an inner medulla. The cortex and medulla synthesise different hormones and, just like the pituitary gland, reflect different glandular and neural embryological origins (Marieb & Hoehn 2014).

### The adrenal cortex

The cortex is divided structurally and functionally into three zones. Each zone is responsible for the secretion of a different class of steroid hormones, collectively called corticosteroids. The adrenal cortex, and therefore the corticosteroids, are under the influence of ACTH released by the anterior pituitary gland (Patton & Thibodeau 2012).

The following are examples of hormones synthesised and released by the adrenal cortex:

- Mineralocorticoids: mostly aldosterone, which is concerned with the reabsorption of sodium ions and the elimination of potassium ions in the kidneys. Aldosterone thus helps regulate both water and electrolyte balance in body fluids
- Glucocorticoids: which include cortisone, hydrocortisone (cortisol) and corticosterone and are concerned with:
  - Metabolism of protein, fat and carbohydrate (promote glucose synthesis and release)
  - Response to stress
  - Depression of inflammatory and immune responses
  - Potentiation of the effects of the catecholamines, TH and GH

  Given their role in glucose metabolism, glucocorticoids are often referred to as hyperglycaemic hormones
- Gonadocorticoids: (sex hormones—androgens and oestrogens) are concerned with the development of secondary sexual characteristics and the functioning of the reproductive organs. Both male and female hormones are produced by the adrenal cortex, regardless of gender. These gonadocorticoids released by the adrenal cortex are relatively weak and in low concentration compared to the hormones released by the gonads (Marieb & Hoehn 2014).

### The adrenal medulla

The medulla, or inner portion of the adrenal glands, produces two similar hormones referred to as catecholamines: adrenaline (also referred to as epinephrine) and noradrenaline (also referred to as norepinephrine). When the medulla is stimulated by neurons of the sympathetic nervous system, the two hormones are released into the bloodstream. The physiological responses to the medullary hormones mimic those of the sympathetic nervous system, which are:

- Cardiac and skeletal vasodilation; visceral and dermal vasoconstriction
- Increase in heart rate and contractility; increase in blood pressure
- Dilation of the bronchial tubes
- Reduction of peristalsis in the digestive system
- Stimulation of the liver to release more glucose into the bloodstream
- Dilation of the pupils
- An increase in the metabolic rate.

Adrenaline prepares the body for fight or flight, and its secretion is increased when the person feels threatened or experiences strong emotions such as fear, anger or excitement, thereby helping the body to cope with a stressful situation (Marieb & Hoehn 2014).

## The gonads

The female gonads are the ovaries and the male gonads are the testes (see Chapter 37). The female and male gonads produce sex hormones identical to those produced by the adrenal cortex, but in greater concentrations and potency. During and after puberty, the gonads assume the major role in reproductive hormone production.

The hormones produced by the ovaries are oestrogens and progesterone. In females, oestrogens influence development of the reproductive organs and the secondary sexual characteristics. Oestrogen also promotes oogenesis and ovulation, and stimulates the lining of the uterus to thicken in preparation for a fertilised ovum to develop. Progesterone promotes the final thickening of the uterine lining and inhibits uterine contraction, enabling implantation of the fertilised ovum. Progesterone also inhibits ovulation during pregnancy and stimulates the mammary glands to produce milk.

The testes produce the androgen testosterone, which stimulates the development of male characteristics and the growth and function of the reproductive organs. Testosterone and androgens generally masculinise the human body, irrespective of gonadal sex (Patton & Thibodeau 2012).

# ENDOCRINE DISORDERS

## Disorders of the pituitary gland

Abnormalities of the pituitary gland are generally associated with hyper- or hyposecretion of its products. Diseases of the pituitary gland, diseases of the hypothalamus, radiation therapy to the head or neck, trauma or tumour interfere with pituitary function and thus the function of other trophic glands like the thyroid, adrenals and gonads. Therefore pituitary problems potentially affect the homeostasis of other hormones and their effects are widespread. Individuals with anterior pituitary disorders require nursing interventions to assist them to cope with the physical and emotional changes and also to prevent complications involving other organs (Farrell & Dempsey 2013). Major endocrine disorders are summarised in Table 36.2.

Hyperfunction of the pituitary gland commonly results from a tumour, which may create pressure on cerebral structures and cause neurological manifestations, such as severe headaches and visual disturbances, or excessive secretion of pituitary hormones, with consequent increased stimulation of the target organs (Brown et al 2015; Patton & Thibodeau 2012). In adults, **hypersecretion** of the anterior pituitary gland most commonly involves ACTH or GH and results in Cushing's disease and syndrome or acromegaly, respectively.

**TABLE 36.2 | Summary of major endocrine imbalances**

| Disorder | Gland or hormone implicated | Homeostatic imbalance |
|---|---|---|
| Acromegaly | Pituitary—GH | Hypersecretion in adults |
| Cushing's disease | Pituitary—ACTH | Hypersecretion |
| Diabetes insipidus | Pituitary—ADH | Hyposecretion or insensitivity to insulin |
| Gigantism | Pituitary—GH | Hypersecretion in children |
| Pituitary dwarfism | Pituitary—GH | Hyposecretion in children |
| SIADH (syndrome of inappropriate antidiuretic hormone secretion) | Pituitary—ADH | Hypersecretion |
| Cretinism | Thyroid—TH | Hyposecretion during development |
| Graves' disease | Thyroid—TH; or TSH from pituitary | Hypersecretion |
| Hypothyroidism: Hashimoto's disease, myxoedema | Thyroid—TH | Hyposecretion |
| Hyperparathyroidism | Parathyroid—PTH | Hypersecretion |
| Hypoparathyroidism | Parathyroid—PTH | Hyposecretion |
| Diabetes mellitus—Type 1 | Pancreas—insulin | Hyposecretion/Hypoactivity |
| Diabetes mellitus—Type 2 | Pancreas—insulin | Resistance or insensitivity to insulin |
| Cushing's syndrome | Adrenal cortex—corticosteroids | Hypersecretion or overuse |
| Hypoadrenalism—Addison's disease | Adrenal cortex or ACTH from pituitary—corticosteroids | Hyposecretion |
| Primary aldosteronism—Conn's syndrome | Adrenal cortex or ACTH from pituitary—aldosterone | Hypersecretion |
| Phaeochromocytoma | Adrenal medulla—catecholamines | Hypersecretion |
| Osteoporosis | Ovary—oestrogen | Post-menopausal hyposecretion |
| Polycystic ovarian syndrome | Ovary—numerous | Hypersecretion of androgens |

Hypersecretion of prolactin is also common. Diseases of the posterior pituitary are rare: hypersecretion of the posterior pituitary is most commonly associated with the syndrome of inappropriate antidiuretic hormone (SIADH).

## Gigantism

Disturbances to GH release are chronic progressive disorders marked by hormonal dysfunction and skeletal overgrowth, which most commonly can appear in two forms: **gigantism** and acromegaly. Hypersecretion of GH in childhood results in gigantism, and begins before epiphyseal closure (Marieb & Hoehn 2014). Children with gigantism may grow up to 15 cm a year, reach a height of 2.4 m, exhibit slow sexual development and may have slow mental development. Radiation therapy, surgical removal of the tumour and drug therapy may be used to decrease secretion of the growth hormone and slow down the excessive growth pattern (Craft et al 2014; Urden et al 2014). With this treatment, prognosis for the individual with gigantism is generally good (Brown et al 2015).

## Acromegaly

**Acromegaly** is the manifestation of GH hypersecretion and occurs in adulthood after epiphyseal closure. It is characterised by atrophy of skeletal muscle and formation of new bone and cartilage. The long bones are unable to grow in length, but the smaller bones of the hands, feet and face grow, giving the individual a characteristic appearance, with an enlarged lower jaw, bulging forehead and thickened ears and nose (Figure 36.4). The extremities become elongated and enlarged, resulting in large hands and feet (Patton & Thibodeau 2012). Thickening of the tongue may cause the voice to sound deep and hollow, associated with slurred speech. Acromegaly is a chronic disfiguring disease that often shortens life expectancy, as it may lead to respiratory, cerebrovascular and congestive heart diseases (Urden et al 2014). Surgical intervention to

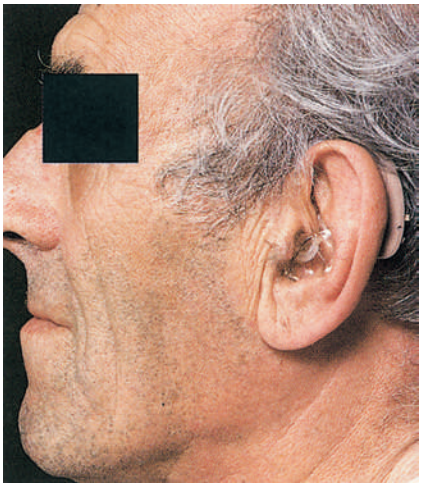

**Figure 36.4** Acromegaly: typical facial appearance

Clinical Examination

*Fourth Edition Copyright © 2008, Elsevier Limited. All rights reserved*

remove the pituitary tumour may lead to hypopituitarism (Australian Pituitary Foundation 2015a).

## Prolactinoma

The most common tumour resulting from hypersecretion is prolactinoma (Australian Pituitary Foundation 2015b). Hypersecretion of prolactin often results in gynaecomastia and galactorrhoea (breast swelling and milk production) in both males and non-breastfeeding females, and may be accompanied by menstrual or libido alterations. Evidence suggests that despite around 10% of the population possessing microprolactinomas, only 0.1% will be clinically affected each year in Australia (Australian Pituitary Foundation 2015b).

## SIADH

The syndrome of inappropriate antidiuretic hormone (SIADH) includes excessive ADH secretion from the posterior pituitary, but it may also be non-endocrine in origin. Individuals with pulmonary problems such as carcinoma, severe pneumonia and other lung dysfunctions often also suffer from SIADH (Craft et al 2014). As a result, a consideration of pulmonary health is important in the nursing care and management of SIADH.

Individuals with this disorder display enhanced renal water retention which leads to imbalances in sodium balance and blood osmolarity. Hyponatraemia is induced due to the relative increases in water, and is common in hospitalised individuals (Hannon & Thompson 2010). Hyponatraemia suppresses the release of renin from the kidneys, which in turn regulates aldosterone release. The result is a loss of sodium in the urine. Diagnoses of SIADH include low serum osmolarity and sodium and urine hyperosmolarity; the symptoms are determined by the extent of severity of the continued ADH release.

Restricting and monitoring fluid intake, as well as the possible administration of diuretics, may reduce the underlying cause (Brown et al 2015). Careful fluid restrictions for individuals with SIADH of 0.5–1 L daily are suggested to allow sodium levels to increase slowly. Likewise, monitoring urine output and quality, weight and blood chemistries are indicated for individuals at risk (Urden et al 2014).

Hypofunction of the anterior pituitary gland can also result from a tumour in the gland, secondary to trauma of the hypothalamus or infection (Urden et al 2014). Hypopituitarism results in an absence or deficiency of GH and gonadotrophins and is marked by growth retardation, which in children causes dwarfism and delay of puberty. It can present in three forms, which share the characteristics of delayed or retarded growth, and decreased mentation and sexual development: Fröhlich's syndrome, commonly caused by an anterior pituitary tumour; **dwarfism**, which results from **hyposecretion** of growth hormone and is characterised by proportionately small individuals; and Simmonds' disease, atrophy of the anterior lobe of the pituitary gland, which is a rare disorder with widespread effects (Farrell & Dempsey 2013).

Treatment of hypopituitarism commonly involves hormone replacement of the target gland hormone (Australian Pituitary Foundation 2015c; Endocrinology Expert Group 2014). Constant monitoring and adjusting of hormone levels is required to attain optimal results.

## Diabetes insipidus

**Diabetes insipidus** is a rare condition characterised by a deficiency of ADH and may be of neurogenic (posterior lobe damage, resulting from head trauma, tumour or surgical or irradiative interventions) or nephrogenic in origin (kidneys failing to respond to adequate levels of ADH) (Craft et al 2014). Without ADH, the individual exhibits polyuria, passing vast quantities of dilute, colourless urine (volumes vary, but may be as high as 20 L daily), the osmolarity and specific gravity of which is very low (see Case Study 36.1). To compensate for the dehydration from the excessive fluid loss, the individual experiences polydipsia (excessive thirst, especially for cold drinks) and drinks large amounts of fluid (Farrell & Dempsey 2013).

Diagnostic procedures centre on fluid management. A fluid deprivation test in which the individual is unable to concentrate urine or continually passes large volumes is indicative of diabetes insipidus. This test is based on the principle that withholding fluid for several hours stimulates secretion of ADH. Other procedures include measurement of plasma ADH and osmolarity, or IV infusion of hypertonic saline (Craft et al 2014; Farrell & Dempsey 2013). Treatment for individuals with diabetes insipidus involves medication as opposed to limiting fluid intake, because the high volume of fluid loss through urine is independent of fluid intake. The replacement of ADH with synthetic analogues such as vasopressin or desmopressin has a good prognosis (Endocrinology Expert Group 2014; Urden et al 2014). During the acute

## CASE STUDY 36.1

You are a nurse and you have just begun your shift. You first deal with a 27-year-old male who shows no abnormalities during a routine physical examination and whose vital signs are all within range. He tells you that he cycles regularly and tries to keep fit. He has had blood tests and has had a urine sample taken for urinalysis earlier in the day. While you are reading his information and flicking through his charts, you ask him how he has been feeling. He tells you that recently he has been feeling very thirsty and drinking a lot, and also frequently urinating large volumes of urine.

1. What are the clinical terms for these conditions, and what common disorder are they typical of?

You ask him whether he has been eating differently as well as drinking a lot, and he tells you that he has made little change to his diet.

'Would you say that you eat a lot of sweets or cakes or sugar?' you ask.

'No more than normal,' he replies.

You check the blood serum tests and find that fasting glucose is normal. You also look at the urinalysis results and find they are negative for glucose.

2. What is the rationale behind asking about diet and sugar intake, and do the blood and urine results confirm or rule out your original assumption?

'I'm always drinking and going to the toilet,' he says. 'It's really interrupting my work.'

You suspect that there may be an imbalance in the amount of antidiuretic hormone (ADH), as this is a major hormone of water balance in the body.

3. What are the two major endocrine disorders associated with imbalances in ADH levels?
4. What are the typical signs or symptoms of these disorders?

'What do you think it could be?' he asks.

You explain that the blood and urine glucose levels indicate that it probably isn't diabetes mellitus, but you're not sure, so you make a closer inspection of the chart and results. The blood tests also indicate that the individual's plasma osmolality is high, with sodium levels more than 145 mmol/L.

5. What does this mean? Do you think this might be classified as hyper- or hyponatraemia?

You check the corresponding information on the urinalysis results and find that the previous nurse noted a low specific gravity (1.001) and that the urine was pale and almost colourless. The volume was considerable.

'It looks like you passed a lot of weak urine for your test,' you say.

'Exactly! That's what I told my doctor and the other nurse this morning,' he replies.

6. Given what you know about the blood and urinalysis results, which disorder of ADH do you think he may be suffering from? Explain your rationale.
7. Was there anything in his history that confirms your conclusion?
8. Do you think the information that the individual provided while you were chatting to him assisted your conclusion?

During your rounds you revisit this individual and ask him how he's going.

'Fine, but I'm thirsty again,' he says.

You ask him if he has had a drink recently and he tells you that he can't, as he has been asked to undertake a 'fluid deprivation test' and an MRI of his head.

9. What purpose would withholding water from this individual serve, and why would an MRI of his head be important?

stage of this condition, individuals need supportive care in relation to their polyuria and increased need for fluids.

### Diagnostic tests

Pituitary function may be assessed by estimating the level of trophic hormones and by measuring the response to stimulation or suppression tests (Brown et al 2015). The most common tests for evaluating anterior pituitary function are the serum growth hormone test and the insulin intolerance test. The insulin intolerance test, also called the growth hormone stimulation test, provides information about the secretion of growth hormone and ACTH. Investigations may also include x-ray, magnetic resonance imaging (MRI) or computerised tomography (CT) scan of the skull (Farrell & Dempsey 2013). Testing posterior pituitary function includes the water-deprivation test, which is performed when the individual's symptoms indicate diabetes insipidus.

## Disorders of the thyroid gland

### Hyperthyroidism

Hyperthyroidism is one of the more common endocrine disorders and about 2% of Australian women will experience some hyperthyroidism (Queensland Health 2014a). Hyperthyroidism may be caused by many factors, such as thyroiditis or hypersecretion of TSH. An increase in the secretion of the thyroid hormones $T_3$ and $T_4$ affects the basal metabolic rate, as well as the functions of other body systems. The manifestations of hyperfunctioning are generally related to increased metabolic processes, and exhibit characteristic signs and symptoms which reflect heightened metabolism or adrenergic stimulation, and are sometimes collectively referred to as thyrotoxicosis. The presenting condition is often nervousness. The condition can also be caused by genetic or immunological factors (Bahn et al 2011), thyroid gland nodules or

chronic inflammation of the thyroid gland (Craft et al 2014). Table 36.3 lists the most common signs and symptoms of hyperthyroidism and hypothyroidism.

## Graves' disease

An autoimmune disorder, **Graves' disease** is the most common hyperthyroid disease (Craft et al 2014; Farrell & Dempsey 2013; Thyroid Australia 2007). Elevated levels of circulating TSH receptor antibodies stimulate the thyroid gland, leading to the production and release of high concentrations of thyroid hormones and potential glandular hypertrophy. Graves' disease more commonly affects young women, and is eight times more prevalent in females (Farrell & Dempsey 2013) (see Lived Experience). It may appear after a stressful episode, illness or shock. Symptoms include all the characteristics of hyperthyroidism: tachycardia, nervousness, hyperactivity and excitability. The individual will have a voracious appetite but loses weight and can be quite underweight. Diarrhoea is common, as peristaltic rate increases. Excessive sweating and extreme thirst are also common, because of the increased metabolic rate. One outstanding characteristic of Graves' disease is that of exophthalmos, or protrusion of the eyeballs, which is due to oedema in the tissues behind the eye, and does not resolve even when the hyperthyroidism is corrected (Craft et al 2014) (Figure 36.5). A serious complication of Graves' disease is thyroid crisis (or storm), which is discussed in Clinical Interest Box 36.1.

**TABLE 36.3 | Some common signs and symptoms of hyperthyroidism (including Graves' disease) and hypothyroidism**

| Hyperthyroidism | Hypothyroidism |
|---|---|
| Nervousness, hyperexcitability and irritability | Apathy, fatigue, low mental energy |
| Cardiac palpitations and arrhythmias, tachycardia and increased systolic blood pressure | Bradycardia, oedema |
| Poor heat tolerance | Cold intolerance, lowered metabolic rate |
| Alterations (usually increase) in appetite and dietary intake | Cold dry skin |
| Weight loss and possible diarrhoea | Weight gain, constipation |
| Possible exophthalmos and goitre | Goitre, coarse facial features, myxoedema (advanced), impaired speech |

*(Craft et al 2014; Urden et al 2014)*

## Goitre

An enlarged thyroid gland (**goitre**) may be the result of thyroiditis, neoplasia, hyper- or hypoactivity. Goitre can cause local problems by exerting pressure on the trachea, which may produce dysphagia or respiratory distress (Urden et al 2014). Simple goitre (non-toxic goitre) is due to an iodine deficiency that causes a compensatory enlargement of the thyroid gland in an attempt to maintain thyroid hormone production. Introduction of iodised salt has reduced the incidence in Australia and in most other western countries (Australian Thyroid Foundation 2014; Farrell & Dempsey 2013), although localised iodine deficiency still persists in Australia (Blumenthal et al 2012; Endocrinology Expert Group 2014). Exophthalmic goitre occurs in hyperthyroidism (Figure 36.5).

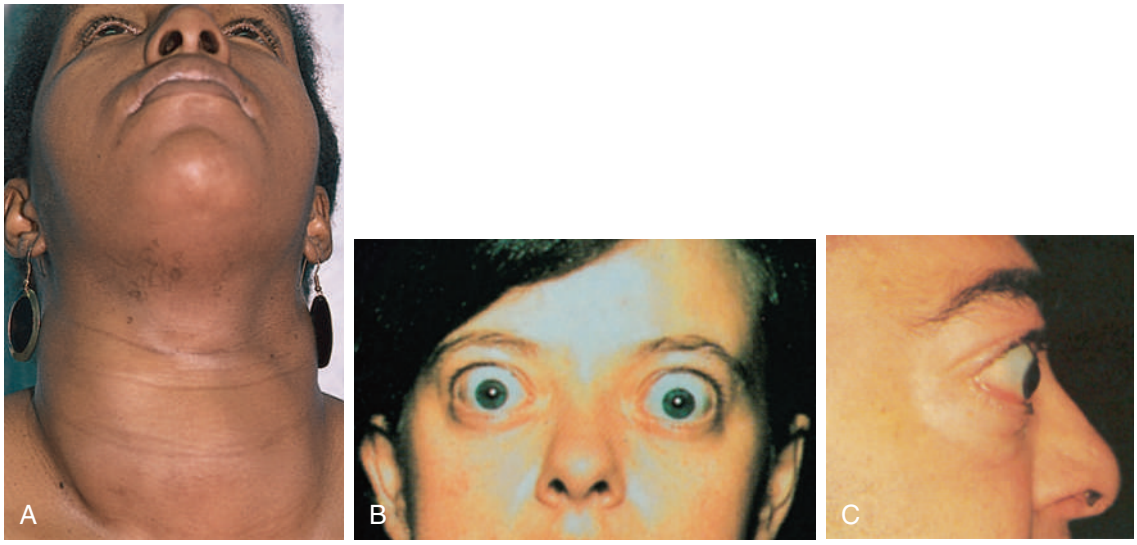

**Figure 36.5** Exophthalmos and/or goitre

*(A. Swartz 2002; B. Stein et al 2000; C. Swartz 2006)*

## Hypothyroidism

Hypothyroidism is the most common disorder of the thyroid and occurs more commonly in women (6–10%) (So et al 2012; Endocrinology Expert Group 2014). The prevalence rises with age—up to a quarter of women over the age of 65 years may be affected. Men are also affected, but less frequently (Queensland Health 2014b). Hypothyroidism is characterised by a decreased secretion of thyroid hormones and may be congenital or it may develop later in life. Cretinism is the congenital form of hypothyroidism and typically results from absence or underdevelopment of the thyroid gland or from severe maternal iodine deficiency during pregnancy. The manifestations of cretinism are related to a marked depression of metabolic processes and progressive mental impairment. Typically the infant is overweight, lethargic, has dry thick skin, coarse features, a broad flat nose and protruding tongue and abdomen (Marieb & Hoehn 2014). If the disease goes unchecked, sexual organs fail to develop and muscle growth is retarded. Treatment is started as soon as diagnosis is made and involves lifelong thyroid hormone replacement therapy (HRT). Hypothyroidism can also result from surgical intervention used to correct hyperthyroidism.

The most common natural cause of hypothyroidism is an autoimmune disorder, Hashimoto's disease. Symptoms of hypothyroidism are the opposite of those of hyperthyroidism (see Table 36.3). The individual is fatigued, drowsy and sensitive to cold temperatures, gains excessive weight, has thin nails and brittle hair, decreased pulse and respiratory rates and irregular menstruation (Urden et al 2014) (Figure 36.6). Advanced hypothyroidism may produce personality and cognitive changes characteristic of other mental dysfunctions such as dementia or depression. Depression has been linked to, both causatively and symptomatically, and misdiagnosed as hypothyroidism (Chueire et al 2007; Krausz et al 2007). Diagnosis of hypothyroidism may be difficult due to the nonspecific nature of the symptoms, which are often diverse and atypical (Endocrinology Expert Group 2014). Despite this, hypothyroidism responds well to HRT and symptoms may disappear after a few months of treatment.

**Myxoedema** is the characteristic sign of severe or prolonged hypothyroidism. The name refers to oedema in the dermis of the skin, especially around the eyes, hands and feet (Brown et al 2015) (Figure 36.6). Myxoedema and myxoedema coma, however—the decompensated state of severe hypothyroidism in which an individual may lose consciousness—if left untreated may lead to death. Maintenance of vital functions and monitoring for increasing severity of signs and symptoms is a major nursing intervention (Urden et al 2014).

### CLINICAL INTEREST BOX 36.1 Thyroid crisis (thyroid storm or thyrotoxicosis)

This situation is a sudden, severe form of hyperthyroidism, and usually occurs in a person already with advanced hyperthyroidism. It is typically characterised by high fever, severe tachycardia, tachypnoea and an altered mental state: all symptoms of excessive thyroid hormone. An individual presenting with thyroid crisis requires immediate attention and supportive nursing care, as it is considered a medical emergency and is life threatening. It can be instigated by emotional stress, infection, trauma, cardiovascular disease or following thyroid surgery. Management involves lowering body temperature, providing sufficient oxygen and IV fluids containing carbohydrate and interfering with thyroid hormone release.

*(Craft et al 2014; Farrell & Dempsey 2013)*

**Figure 36.6** Myxoedema (A) and hypothyroidism (B)

*(A. Talley & O'Connor 2009; B. Dr P. Marazzi/Science Photo Library)*

### Diagnostic tests

A combination of tests is generally performed to evaluate thyroid function, including direct tests of thyroid function, tests that measure concentration and binding of the thyroid hormones and tests involving the use of scanning or imaging techniques (LeMone et al 2014). Blood tests are performed to measure serum hormone levels. The best screening test of thyroid function is the measurement of serum TSH concentrations, due to its sensitivity. This may be augmented by assessing serum free or bound $T_3$ and $T_4$. Radioactive iodine tests, such as the radioactive iodine uptake test, evaluate thyroid function by measuring the amount of orally ingested iodine that accumulates in the thyroid gland over a time regimen (Brown et al 2015). Thyroid scanning is visualisation of the thyroid gland after administration of a radioisotope. Thyroid ultrasonography helps evaluate thyroid structure and differentiation between a cyst and a tumour on the thyroid gland. If an individual is to have thyroid tests, the nurse must ascertain medications taken by the person (especially if they contain iodine) (Farrell & Dempsey 2013).

Most people with classic hyperthyroidism rarely need hospitalisation. Critically ill individuals, those with extreme manifestations of thyrotoxicosis plus a significant concurrent illness, require inpatient acute care on a medical unit. Management of hyperthyroidism involves assisting the individual and their family to manage the symptoms associated with hyperthyroidism until it is controlled with medication (hormone replacement therapy is the preferred option) or surgery if indicated. Surgical intervention may involve a subtotal or even total removal (especially if the gland is cancerous). A person who has had a total thyroidectomy requires long-term hormone replacement (Australian and New Zealand Endocrine Surgeons 2013).

The nurse should assess the nutritional and emotional status of an individual with hyper- and hypothyroidism, and manage appropriately. The nurse should also reassure the individual that the emotional reactions, especially with hypothyroidism, are normal for that condition (Farrell & Dempsey 2013).

## Disorders of the parathyroid glands

### Hyperparathyroidism

Hyperparathyroidism results in an overproduction of PTH. This condition can be caused by hereditary factors, tumours or enlargement of the glands. It is more common in postmenopausal women (MacKenzie-Feder et al 2011). Secondary hyperthyroidism can be caused by renal disease or other calcium perturbations such as osteomalacia or rickets. Excessive PTH production leads to hypercalcaemia (excessive calcium in the blood) as the hormone stimulates resorption of calcium from bone, the kidney and gut (Marieb & Hoehn 2014). As the calcium is pulled from the bones, individuals with this condition display manifestations that are widespread and include symptoms such as backache, bone curvature and pathological fractures from bone weakness (Farrell & Dempsey 2013). Renal stones may develop because of the excess calcium output in the urine, especially in conjunction with metabolic acidosis and alkaline urine. The digestive system increases absorption of calcium, causing abdominal pain, vomiting and constipation. Hypercalcaemia leads to hyperactivity of muscles, causing impaired neuromuscular coordination and cardiac arrhythmias (Marcoci & Cetani 2011). Interestingly, vitamin D deficiency is also correlated with hyperparathyroidism (Rankin 2011).

### Hypoparathyroidism

Hypoparathyroidism is relatively uncommon and is indicated by deficiency in PTH secretion. Causes may include familial hypoparathyroidism, autoimmune disorders or, most commonly, surgical removal of parathyroid glands in an effort to treat other thyroid disorders (Clarke 2015). Low or lack of circulating PTH causes hypocalcaemia and hyperphosphataemia (high phosphate levels in the blood), resulting in neuromuscular symptoms ranging from paraesthesia to tetany. Manifestations include muscle spasm, anxiety, hyperreflexia and laryngeal spasm (Wheeler & Shoback 2015).

Tetany results from hyperexcitability of nerves and skeletal muscles because of low calcium blood levels. It begins with tingling in the fingertips, toes and around the mouth (Brown et al 2015). The tingling increases and produces muscle tension and spasms, with consequent adduction of the thumbs, wrists, elbows and toes (carpopedal spasm). The tetany associated with hypoparathyroidism mainly affects the face and hands, causing uncontrolled contraction of these muscles.

### Diagnostic tests

The general diagnosis of both hyper- and hypoparathyroidism is often difficult due to the vague symptoms of pain or fatigue. Tests used to assess parathyroid function therefore include estimation of serum calcium and serum phosphorus levels (LeMone et al 2014). Elevated serum calcium alone is not definitive as blood calcium may be influenced by diet and medications also. A 24-hour urine collection may be performed to measure the total urine calcium, as hyperparathyroidism causes increased excretion of calcium in the urine, and hypoparathyroidism causes decreased excretion of calcium. Scans or x-rays to ascertain bone changes and antibody parathyroid tests may also be implemented. Testing for hypocalcaemia and hypoparathyroidism involves checking for a positive Chvostek's sign (facial muscle spasm occurring when the facial nerve is tapped) and a positive Trousseau's sign (hand muscle spasm when pressure is applied to the nerves and vessels of the upper arm) (Farrell & Dempsey 2013).

Treatment of hyperparathyroidism is directed at the cause and often results in good prognosis for the individual. Surgical removal of tumours or removal of the parathyroid glands may be necessary, leaving half of one parathyroid gland, which is all that is required to maintain normal PTH levels. Other treatments include hydration or diuretic therapy to force increased excretion of calcium by the kidneys, decreasing calcium intake in the diet (Farrell & Dempsey 2013) or a vitamin D supplement (Rankin 2011).

## CRITICAL THINKING EXERCISE 36.1

The following is an account of a series of true events experienced by Natasha, a mother of three children.

*I was 35 weeks pregnant and, as usual, I came to the end of my day feeling tired, irritable, nauseous and emotional; all normal pregnancy symptoms! But that night was different. I was experiencing heart palpitations and the nausea and vomiting was worse than usual. I started to shake and despite thinking everything was most probably fine, I felt I should go to the ER department of our local hospital just to make sure. To my surprise, the nurses admitted me and I began undergoing immediate tests.*

*During that night, they discovered that the _____ levels in my blood were very high and the staff told me that this was most likely the result of a tumour on one or more of my _____ glands. The endocrinologists, together with the obstetrics team, decided to deliver my baby the next day by caesarean section.*

*Two weeks after the birth, I underwent an MRI scan to locate the tumour and 2 weeks later I was operated on. The following few days were spent in hospital, and I had nurses and doctors giving me 2–3 blood tests daily to ensure that my _____ levels were coming down.*

*Days later, now at home and recovering from the operation, I began to experience severe numbing and a pins-and-needles-type feeling in my hands and feet and around my mouth. I woke during the night with major tingling in my arms, legs and face. Within minutes of waking I was almost completely paralysed, my face contorted and my hands spasming. Speaking became impossible. I no longer had control over any of my movement. My husband woke to find me unable to speak and with my muscles locked, and I was rushed to hospital in an ambulance.*

*My _____ levels had plummeted too low and as a result my muscular system had been majorly affected. It was like nothing I had ever experienced! I was absolutely terrified! Once at the hospital, the nurses set me up with a _____ drip and within 2 hours my body was back to normal. I then went into a deep sleep for several hours, much like a person after a severe epileptic fit. I was completely exhausted.*

*Today, I am feeling 100% and take just one _____ tablet to keep my levels in check. I still have 3-monthly check ups with my endocrinologist. Who would ever have thought _____ plays such an important role in our bodies?*

1. Fill in the gaps: given the signs and symptoms Natasha had experienced, which basic nutrient, vitamin or mineral do you think might be involved? Explain your answer.
2. Which hormone, and therefore which gland, is implicated in the above? What is the major role of this hormone?
3. Based on your answers for the above two questions, can you suggest any physiological reasons as to why a tumour might affect this gland, and why there was such a change in the homeostasis of this nutrient, vitamin or mineral following removal of this tumour?
4. What general terms (prefixes) do we tend to give conditions involving an abnormally high or low secretion of hormone (or level of substance in the blood)?

An important aspect of the nursing care is health education and management of dietary calcium and phosphate intake. Treatment of hypoparathyroidism with mineral supplements gives a good prognosis (McCance & Huether 2013). Parathyroid autotransplantation, where the individual's parathyroid glands are replaced during a thyroidectomy, is being implemented more often in Australia (Ebrahimi et al 2009). Following thyroidectomy, hypocalcaemia and tetany may occur. In this instance the individual is infused with calcium intravenously. Parenteral PTH may also be administered.

## Disorders of the adrenal glands

### Disorders of the adrenal cortex—hyperadrenalism

Hyperadrenalism is usually confined to the cortex of the gland. It may be caused by neoplasia or hyperplasia, or it may be iatrogenic; that is, a condition caused by medical treatment or procedures. Other factors resulting in hyperfunctioning of the cortex include tumours or hyperplasia of the pituitary gland, whereby the negative feedback control of the adrenal cortex by ACTH is disturbed. Manifestations of hyperfunctioning are generally related to an excess of glucocorticoids, mineralocorticoids and sex hormones. Three major disorders can result.

***Cushing's syndrome*** **Cushing's syndrome** is a collection of endocrine disorders due to excess corticosteroids (Brown et al 2015). This condition may result from excessive use of corticosteroids, hypersecretion of pituitary ACTH (Cushing's disease) or a tumour of the adrenal glands or pituitary (Australian Pituitary Foundation 2015d). Manifestations of this condition are related to hyperglycaemia, abnormal distribution of lipids and protein wasting. Classic symptoms include obesity of the trunk with a pad of fat across the shoulders (buffalo hump), a moon face, striae on the breasts, abdomen and legs, muscle weakness, osteoporosis and skin fragility (Craft et al 2014; Farrell & Dempsey 2013) (Figure 36.7). Persistent hyperglycaemia may develop into diabetes mellitus. Elevated cortisol levels exacerbate catecholamine effects and, as a result, hypertension is a common feature. This may lead further to atherosclerosis, ischaemic heart disease and nephrosclerosis.

Women are more likely to develop Cushing's syndrome, and excess androgen production causes virilisation in females of all ages (Farrell & Dempsey 2013). Male traits such as

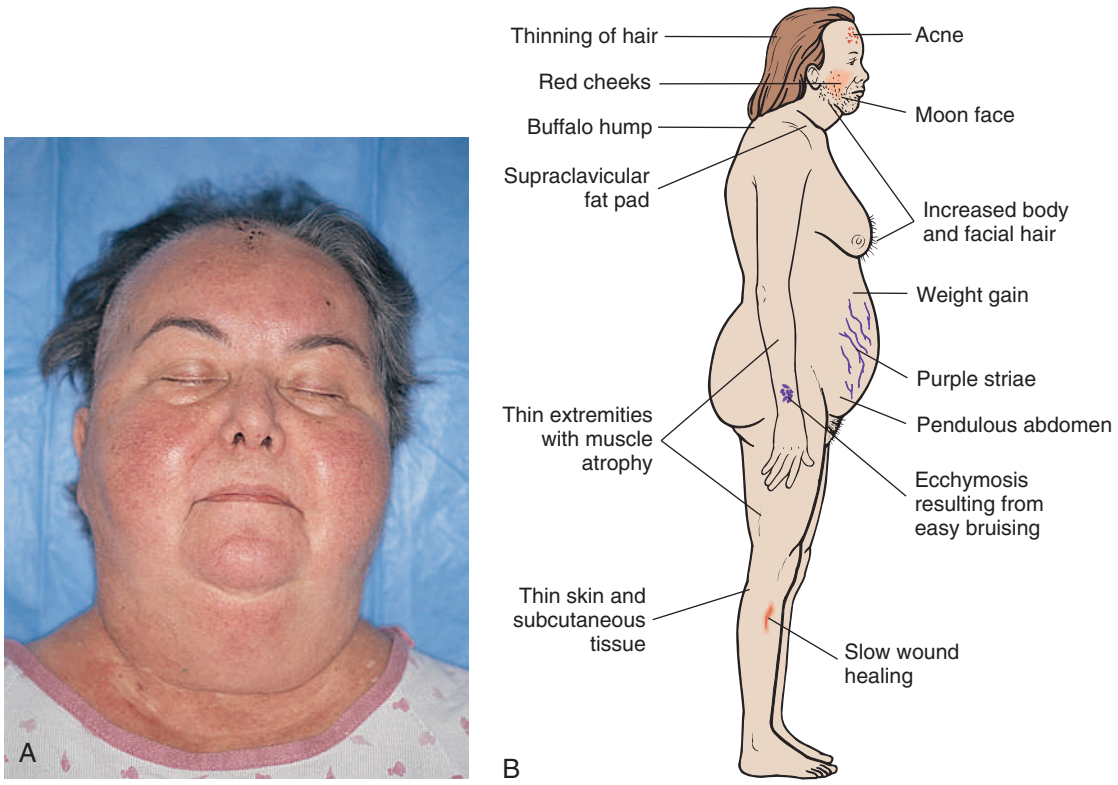

**Figure 36.7** Cushing's syndrome

*(A. Seidel et al 2006; B. Lewis et al 2011)*

## CLINICAL INTEREST BOX 36.2 Cortisone, cortisol and Cushing's syndrome

Cortisone is a therapy used to treat inflammatory conditions such as arthritis because of its anti-inflammatory properties. It does not cure the disease but gives individuals pain relief enabling them to continue their daily lives with as much normality as possible. Problems arise, however, because cortisone and other glucocorticoids like cortisol also depress the body's immune system. Hypersecretion, long-term use or abuse and over-administration of cortisone or cortisol may lead to the development of Cushing's syndrome, so the nurse needs to monitor these individuals for symptoms of this syndrome. Additionally, due to the enhanced anti-inflammatory response, infections become overwhelmingly severe before producing recognisable symptoms. The nurse should also therefore protect the individual from infection. Sadly, without treatment, almost half of the individuals with Cushing's syndrome die within 5 years of onset due, in part, to complications with infection and hypertension.

*(Craft et al 2014; LeMone et al 2014; Marieb & Hoehn 2014)*

hirsutism and voice deepening and breast atrophy may occur. A complication of Cushing's syndrome is the individual's decreased immune response and increased susceptibility to infection (see Clinical Interest Box 36.2).

***Primary aldosteronism*** Primary aldosteronism, also known as Conn's syndrome, is usually caused by an adrenal tumour and is the result of hypersecretion of the mineralocorticoid aldosterone (Craft et al 2014). Conn's syndrome leads to impaired reabsorption of sodium and water in the renal tubules, resulting in hypertension, hypokalaemia, muscle weakness, polyuria, polydipsia, metabolic acidosis and neuromuscular dysfunction (Brown et al 2015). Given the high incidence of hypertension in Australia (see Chapter 25), alterations of aldosterone function should be of consideration and interest in the nursing assessment.

***Androgenital syndrome*** Hypersecretion of androgens may result in androgenital syndrome, especially in prepubertal children. Excessive secretion of androgens may cause contradictions in secondary sexual characteristics. For example, female children are seen with excessive hair growth on the legs, chest and abdomen, an enlarged clitoris, a deepened voice and amenorrhoea (features exhibited also by individuals suffering Cushing's syndrome). Male children may experience precocious puberty (premature sexual development) and gynaecomastia (breast development) (Congenital Adrenal Hyperplasia Support Group Australia 2013).

## Disorders of the adrenal cortex—hypoadrenalism

***Addison's disease*** Hypofunctioning of the adrenal cortex may be caused by primary insufficiency, resulting in a condition known as **Addison's disease**, or adrenocortical

insufficiency. This is a rare condition thought to be due to an autoimmune reaction, infection, acquired immunodeficiency syndrome (AIDS), cancer or adrenal gland atrophy (O'Connell & Siafarikas 2010; Rushworth & Torpy 2014). Up to 90% of the cortex can be destroyed before the symptoms become evident; as a result, the disease is often advanced before it is diagnosed (Australian Addison's Disease Association 2011; Brown et al 2015). The manifestations are related to a deficiency of all corticosteroids. The lack of mineralocorticoids depletes sodium, which leads to diarrhoea, dehydration, weakness, weight loss and hypotension. The lack of glucocorticoids affects blood sugar levels, leading to hypoglycaemia (Marieb & Hoehn 2014). An increased ACTH level, due to disturbed negative feedback control, may lead to brown pigmentation or bronzing of the skin and mucous membranes, affecting the palms, elbows, scars, skin folds and areolae (Australian Addison's Disease Association 2011). Addison's disease may also have profound effects on an individual's mental state, with individuals exhibiting depression, confusion or apathy (Brown et al 2015).

Congenital adrenal hyperplasia (CAH) is often classified together with Addison's as general adrenal insufficiency. Similar to Addison's disease, cortisol and aldosterone are either partially or not produced. The condition may be classified as 'classic' (congenital, a genetic defect in steroid synthesis) or 'late onset' (early adult onset). Growth and adrenal problems may develop, as for other adrenal insufficiencies (Endocrinology Expert Group 2014). Treatment centres on replacement of the corticoids with analogues such as dexamethasone and fludrocortisone.

### Disorders of the adrenal medulla

***Phaeochromocytoma*** **Phaeochromocytoma** is a generally benign tumour of the medulla or of the sympathetic chain, which causes over-secretion of adrenaline and noradrenaline. Incidence peaks in middle age and is also high in familial members, and may occur as part of multiple endocrine neoplasia (MEN) (Farrell & Dempsey 2013; Rare Cancers Australia 2015). The resultant increase in sympathetic activity manifests as episodes of hypertension, tachycardia, chest pain, pallor, sweating, headaches, anxiety, tremor, nausea and vomiting and frequency of urination. These symptoms can cause life-threatening scenarios for the individual, so early diagnosis and treatment is imperative (Clifton-Bligh 2013).

### Diagnostic tests

Typically, blood and urine tests are performed that enable measurement of the levels of adrenal cortical hormones. Blood tests determine the level of serum aldosterone, serum cortisol or serum catecholamines (LeMone et al 2014). These levels aid in the diagnosis of adrenal function; for example, serum cortisol levels are increased in Cushing's syndrome, while decreased serum cortisol levels are seen in Addison's disease. A 24-hour urine collection may be performed to estimate the total daily free cortisol, aldosterone or catecholamine levels. A CT scan or suprarenal venography may also be used to aid in the diagnosis of tumours.

Surgical removal of the tumour or the dysfunctional adrenal gland (adrenalectomy) may correct Cushing's syndrome for the individual (LeMone et al 2014). Lifetime hormone therapy to replace the cortical hormones is then required. Clinical Interest Box 36.2 provides an insight into cortisone therapy. Nurses should decrease risk of injury and infection, encourage rest and activity, promote skin care and stimulate mental activity for individuals with Cushing's syndrome. Treatment and nursing care for Addison's disease and CAH includes corticosteroid therapy, and the assessment and management of fluid levels, signs of shock and careful monitoring of symptoms (Craft et al 2014; LeMone et al 2014).

Measurements of blood and urine for catecholamines are the most direct and conclusive tests for disorders of the adrenal medulla like phaeochromocytoma. Likewise, the presence of hypertension, headache, hypermetabolism and hyperglycaemia indicates phaeochromocytoma. Imaging studies may also be carried out to identify the location of the suspected tumour, which is preferably removed surgically. Treatment and nursing management procedures include those for high blood pressure, high blood glucose and tachycardia, and HRT is often indicated following surgery (Brown et al 2015; Rare Cancers Australia 2015).

**CRITICAL THINKING EXERCISE 36.2**

A 47-year-old male under your care presents with hypertension (160/101 mmHg), tachycardia and increased respiratory rate. Given what you know about the endocrine system, which hormones might be responsible for these signs? Is there more than one endocrine gland or imbalance that might be responsible for his condition?

**CRITICAL THINKING EXERCISE 36.3**

You are caring for Navdeep who has recently been diagnosed with Cushing's syndrome. Cushing's syndrome is a pathophysiology of excess of which hormones? Cushing's syndrome has a number of signs and symptoms; however, what do you think is the most important nursing intervention when caring for Navdeep? Why do you think this is so?

## Disorder of the gonads

### Hypergonadism and hypogonadism

Gonadal disorders may reflect interruptions in the normal control by the pituitary, a tumour or congenital syndromes such as Turner's or Klinefelter's (Endocrinology Expert Group 2014; Craft et al 2014). Hypergonadism, as opposed to hypersecretion of gonadotrophins by the pituitary gland or androgenital syndrome, results from increased gonadal hormone production before puberty and leads to precocious sexual development and enhanced sexual characteristics in both sexes. Causes of hypergonadism are primarily unknown

but some cases have been caused by ovarian tumours and testicular tumours (Sembulingam & Sembulingam 2012). Treatment for both sexes involves removal or radiation of the tumours, and hormone therapy to suppress or counteract the effects of the sex hormone.

Hypogonadism results from decreased sex hormone production by the age of normal puberty. Due to the control of gonad function by the pituitary and adrenals, hypogonadism prior to puberty reflects abnormalities of these endocrine glands. Treatment with testosterone or oestrogen is usually effective (Endocrinology Expert Group 2014).

Endocrine deficiencies of the gonads in the adult female, for example, are implicated in two common disorders: osteoporosis and **polycystic ovary syndrome** (PCOS). This reflects the strong interrelationship between endocrine organs and hormones in the human body. Osteoporosis and PCOS are discussed further in Clinical Interest Boxes 36.3 and 36.4 respectively.

### Diagnostic tests

Diagnoses of disorders of the gonads is based on a positive clinical history and, as for other disorders, are confirmed by blood tests showing elevated sex hormone levels.

## Disorders of the pancreas

### Diabetes mellitus

Diabetes mellitus (DM) is a group of metabolic disorders characterised primarily by abnormal glucose metabolism, with the key feature of elevated blood glucose (hyperglycaemia). Diabetes mellitus affects a great number of Australians, with more than 5% of the Australian population under the age of 34, and 28% of Australians between the ages of 65 and 74, having diabetes (Australian Institute of Health and Welfare (AIHW) 2015a). Type 2 diabetes mellitus is more common than type 1, with over 95% of all diabetic individuals having type 2. Incidences and death rates in Australia are higher for males than females, and Indigenous Australians are almost three times as likely to be diagnosed (Australian Institute of Health and Welfare 2015b). Such is the increasing prevalence in diabetes worldwide that diabetes nursing is becoming more specialised, with distinct nursing career and competency frameworks being developed (Davis et al 2008). Diabetes Australia (2014c) has published Best Practice Guidelines, developed by medical experts and researchers for health professionals to address the prevention, diagnosis and management of diabetes.

Diabetes mellitus is a disorder of glucose regulation characterised by abnormal metabolism of carbohydrate, protein and fat (Farrell & Dempsey 2013). A feature of the disorder is some degree of hyperglycaemia. Diabetes mellitus results from hyposecretion or hypoactivity of insulin, intolerance to insulin (hyperinsulinaemia) or from the production of substances antagonistic to insulin, which cause it to be ineffective. It may be caused by genetic or hereditary factors, pancreatic disorders or by disorders of other endocrine glands such as the pituitary or adrenal glands (recall that these endocrine glands secrete hormones that affect glucose

### CLINICAL INTEREST BOX 36.3 Osteoporosis and oestrogen

Osteoporosis is characterised by an imbalance between bone formation and bone resorption, where bone cells called osteoclasts digest bone faster than it can be deposited. Nurses and individuals usually become aware of osteoporosis only when the weakened bones break and individuals are admitted as a result of fractures. While osteoporosis is strongly linked to calcium intake, calcium metabolism is controlled by the parathyroid glands and PTH. Likewise, the appearance or acceleration of bone weakening with the onset of menopause in females is closely related to the levels of oestrogen: oestrogen secreted by the ovaries actually exerts inhibition over the osteoclasts, preventing them from digesting too much bone and calcium. Decreasing levels of oestrogen post-menopause may therefore contribute to osteoporosis. The use of hormone replacement therapy (HRT) and dietary supplements helps to address this endocrine imbalance.

*(Marieb & Hoehn 2014; Osteoporosis Australia 2014)*

### CLINICAL INTEREST BOX 36.4 Polycystic ovarian (ovary) syndrome (PCOS)

Despite the misleading name, polycystic ovarian (ovary) syndrome (PCOS) is a hormonal disorder in females in which excessive androgen production is triggered by inappropriate secretion of gonadotrophins. This is perhaps better reflected by the alternative name 'hyperandrogen anovulation syndrome'. Surprisingly it is the most common endocrine disturbance affecting women, affecting from 5% to 12% of reproductive-age women in Australia.

PCOS develops as a result of ovarian hypersecretion of androgens, with an overall result of increasing testosterone levels. Hyperinsulinaemia is thought to stimulate this hypersecretion of androgens. Elevated levels of androgens lead to elevated levels of oestrogen and testosterone, which trigger an imbalance in the pituitary gonadotrophins FSH and especially LH.

Clinical signs or symptoms of PCOS reflect the interruption of ovulation and the elevated male hormone levels. Various signs or symptoms exhibited by individuals mirror those of other endocrine disorders (especially those of the thyroid, adrenal cortex and gonads generally), thus nursing assessment of PCOS may be difficult. Manifestations include dysmenorrhoea or amenorrhoea, hirsutism or androgenic alopecia, obesity and infertility. Women with PCOS also appear to be at greater risk of developing hyperglycaemia, cardiovascular disease and type 2 diabetes mellitus later in life.

*(Craft et al 2014; Endocrinology Expert Group 2014)*

metabolism). It is also thought to be autoimmune in origin: the destruction of β cells by the body may be a response to molecular mimicry by a pathogen, or due to possible diabetes susceptibility genes (Craft et al 2014; Farrell & Dempsey 2013; Marieb & Hoehn 2014).

A deficiency of insulin causes changes in the metabolism of glucose, which results in numerous physiological effects (Figure 36.3). In the liver glycolytic enzymes are inhibited, gluconeogenic enzymes are activated and amino acids are used to form glucose. Consequently, additional glucose is liberated into the bloodstream. Without insulin, glucose is unable to cross the cell membranes into muscle and fat cells, and hyperglycaemia ensues (Marieb & Hoehn 2014). The blood glucose level eventually exceeds the renal threshold, and the excess glucose is excreted in the urine (glycosuria). The most significant effect of elevated blood glucose level is dehydration of the tissue cells because the increased osmotic pressure in the extracellular fluids causes osmotic transfer of water out of the cells. In addition, the loss of glucose via the urine causes diuresis (polyuria), because of the osmotic effect of glucose in the renal tubules. The result is extreme thirst, or polydipsia (Urden et al 2014).

Gestational diabetes is one form of the disorder and appears only during pregnancy (about 5% of pregnancies) (AIHW 2010; Diabetes Australia 2015), and is characterised by impaired glucose tolerance. A woman who has had gestational diabetes runs a greater risk (50–60%) of developing diabetes mellitus later on in life (AIHW 2010; Craft et al 2014). **Diabetes mellitus** itself is classified into two major types: **type 1**, or insulin-dependent diabetes mellitus (IDDM) (formerly known as juvenile-onset diabetes); and **type 2** (formerly known as non-insulin-dependent diabetes mellitus (NIDDM)). A third minor type, type 3c diabetes, may contribute to diabetes mellitus or Alzheimer's (de la Monte & Wands 2008; Hardt et al 2008) and is believed to be generally un- or misdiagnosed. The diagnosis of diabetes mellitus is confirmed, among other tests, by the presence of an elevated blood glucose level. The manifestations of diabetes mellitus vary according to the type.

***Type 1 diabetes mellitus*** Type 1 diabetes mellitus is characterised by the genetic or autoimmune destruction or deficiency of the pancreatic β cells that produce insulin and usually progresses so quickly it is often diagnosed in childhood; hence its previous name of juvenile-onset diabetes (Farrell & Dempsey 2013) (see Case Study 36.2). It can occur, however, at any age from infancy up to about age 40. There is a sudden onset of signs and symptoms related to hyperglycaemia, which includes weight loss, polyuria and polydipsia (related to osmotic diuresis), fatigue and the presence of glucose and ketones in the urine (glycosuria and ketonuria) (Craft et al 2014). Hyperglycaemia and dehydration accelerate the development of metabolic acidosis and, if untreated, can lead to coma and death.

***Type 2 diabetes mellitus*** Type 2 diabetes mellitus is characterised by hyperglycaemia despite the availability of insulin (insulin resistance at the cell) and is more likely to occur after age 40. The signs and symptoms develop slowly and the individual is generally obese: obesity and metabolic syndrome are significant risk factors and often precursors for type 2 diabetes mellitus (Craft et al 2014). Type 2 diabetes mellitus may often go undetected, as the signs and symptoms of fatigue, polyuria and polydipsia can be quite insignificant. Diagnosis occurs when the individual presents with another disease, which is a common complication of diabetes mellitus (McDowell et al 2007). The individual with diabetes mellitus is prone to a range of complications, especially if the blood glucose level is uncontrolled. Complications include:

- Hyperglycaemia
- Hyperinsulinaemia
- Diabetic ketoacidosis
- Hyperosmolar non-ketotic hyperglycaemia
- Retinopathy
- Neuropathy

## CASE STUDY 36.2

You are a nurse. Joan, a diabetes educator, visits you and introduces Mr Lei, a 60-year-old male. Joan explains that he has type 2 diabetes mellitus and would like you to assist in educating Mr Lei about his condition.

Mr Lei feels shy and confused, and says, 'Joan, she is nice lady, but I no understand all she say about my diabetes and my blood. I am having to test all the time and take these.' He shows you a list of medications that Joan has indicated he may be required to take.

You begin by explaining to Mr Lei about his blood sugar levels and ask, 'Do you know what your blood glucose levels should be?'

Mr Lei cannot remember, so you remind him.

1. What is a normal blood sugar/glucose level?

'What you mean fasting? I can eat, can't I?' Mr Lei asks.

'Of course you can,' you answer, reassuring him. 'Did Joan explain to you when you should test your blood?'

'Yes, in the morning before my breakfast. Why?'

2. What is meant by fasting in this instance? And why should Mr Lei test his blood glucose prior to breakfast each day?

He sighs and admits, 'This is no easy. She say I have to do many other things, like diet. It is very much for me to handle.'

3. Regarding his diet, what general suggestions can you make to assist Mr Lei in monitoring and controlling his condition?
4. What about his lifestyle? Do you have any suggestions as to what sorts of changes or considerations Mr Lei could make to his habits?

You feel that Mr Lei is overwhelmed, so you comfort him and reassure him that his concerns are normal and that his questions are valid.

5. Other than Joan, his specific diabetes educator, which other health professionals could you refer Mr Lei to, or at least make him aware of?

Mr Lei smiles and says, 'Thank you, you make it easy for me and now I feel much better. Thank you.'

- Cardiovascular and peripheral vascular disease
- Nephropathy
- Hypoglycaemia (imbalance of food, exercise and medications).

It is these complications that the nurse may need to assess and monitor. The maintenance of blood glucose levels are achieved by a balance between blood-borne stimuli, nervous input (e.g. the sympathetic nervous system) and hormonal influences. As such, there are a number of influences on blood glucose levels that the nurse should take into consideration.

## Complications of diabetes mellitus

Complications may develop rapidly or progress insidiously over years before they become evident. The two main complications that occur because of uncontrolled blood glucose levels are hypoglycaemia and hyperglycaemia.

***Hypoglycaemia*** Hypoglycaemia, sometimes referred to as insulin shock, is an abnormally low blood glucose level (3.5–4.0 mmol/L) (Diabetes Australia 2013) and may be caused by excessive insulin, delayed or decreased food intake, excess physical activity and carbohydrate use (Farrell & Dempsey 2013). Hypoglycaemia may develop when glucose levels drop rapidly and early manifestations are hunger, pallor, sweating, tachycardia, yawning, nausea, blurred vision, slurred speech, confusion or irrational behaviour (Brown et al 2015). If the hypoglycaemia is not corrected rapidly, the person will become comatose and, if the coma is prolonged, permanent brain damage or death may occur (Farrell & Dempsey 2013).

**Management and intervention** Mild symptoms can often be reversed by ingesting a simple carbohydrate, such as fruit juice or honey. People with type 1 diabetes should ensure that they always have ready access to some form of carbohydrate that is easily absorbed, such as barley sugar or jelly beans (Farrell & Dempsey 2013). If the person is unable to ingest a carbohydrate substance, intravenous administration of glucose (up to 50%) (Endocrinology Expert Group 2014) or the hormone glucagon will be necessary. Glucagon can also be administered subcutaneously or intramuscularly. The Somogyi effect is a complication that may follow a hypoglycaemic episode or administration of too much insulin, and results in rebound hyperglycaemia (McDowell et al 2007). Management of this phenomenon involves lowering the insulin dosage (Craft et al 2014).

***Hyperglycaemia*** Hyperglycaemia is an abnormally high blood glucose level and is a clinical feature of diabetes. It may be caused by low insulin levels, incorrect diet high in carbohydrate, lack of physical activity or stress (with infection being a common stressor). Glucose and lipids are not able to enter target cells, depriving them of nutrients. This is turn stimulates increased hunger and food intake (polyphagia). Together, polyphagia, polyuria and polydipsia are the three main symptoms of hyperglycaemia (Craft et al 2014). If hyperglycaemia is not corrected, metabolic acidosis occurs, producing vasodilation and hypotension. Severe acidosis, if untreated, results in coma and death. Hyperglycaemia develops gradually over a period of hours or days, and the early manifestations are thirst, anorexia, nausea, vomiting, abdominal pain, muscle cramps, polyuria and drowsiness. Deep rapid respirations (Kussmaul's breathing) develop in an attempt to control acidosis (Brown et al 2015). Dehydration and electrolyte imbalance occur as a result of osmotic diuresis.

Ketones, produced by the liver as fat, are broken down instead of glucose (diabetic ketoacidosis), glucose is excreted in the urine and the breath smells of ketones (sweet fruity odour). Diabetic ketoacidosis (DKA) develops primarily in individuals with type 1 diabetes mellitus, and in the absolute deficiency of insulin. As a result of altered liver metabolism, acidosis ensues, which may lead to coma or death (LeMone et al 2014). Advanced diabetic ketoacidosis is an emergency requiring nursing and medical care. Similarly, hyperglycaemic hyperosmolar state (HHS) occurs in people with type 2 diabetes and is characterised by higher than normal blood osmolarity, greatly elevated blood glucose and altered levels of consciousness. It is a serious medical emergency with a slow onset (Farrell & Dempsey 2013; LeMone et al 2014).

**Management and intervention** Management of hyperglycaemia focuses on correcting the fluid and electrolyte imbalances and lowering blood glucose levels to normal (Diabetes Australia 2014c). Intravenous fluids such as normal saline are administered together with intravenous short-acting insulin. After the initial decrease in blood glucose level, the insulin dosage is reduced. This allows the blood glucose levels to return to normal more slowly, and prevents the development of hypoglycaemia. If the individual becomes comatose as a result of hyperglycaemia and ketoacidosis, care is directed at preventing the complications of unconsciousness (Brown et al 2015; McDowell et al 2007).

## Long-term complications

***Cardiovascular diseases*** Atherosclerosis is a relatively common complication of diabetes mellitus, with coronary artery disease being the major complication. Myocardial infarction, cerebrovascular accident and renal failure are among the major causes of death in people with diabetes (AIHW 2015b). Peripheral vascular disease is often widespread, causing manifestations of peripheral ischaemia—cold lower extremities, intermittent claudication, diminished or absent pulses, ulcers, infection and gangrene. Hypertension is also a common complication of diabetes mellitus (AIHW 2015b). It affects 20–60% of all individuals and is a major risk factor for cardiovascular disease and microvascular complications such as neuropathy and retinopathy (LeMone et al 2014).

***Neuropathy*** Neuropathy (inflammation and degeneration of the peripheral nerves) gives rise to disturbances of sensation such as tingling and numbness, particularly in the lower limbs (Farrell & Dempsey 2013). Another form of neuropathy is characterised by a decreased sense of position (proprioceptive disturbances) and diminished sensation to touch, pain and temperature. These sensory deficits increase the possibility of injury and increase the chance of injuries being unnoticed by the individual. Peripheral motor involvement results in muscle weakness and atrophy, which may lead to

deformities, particularly of the feet (Charcot's arthropathy) (Farrell & Dempsey 2013). Early identification of peripheral neuropathy is an important part of preventative foot care (Endocrinology Expert Group 2014).

***Retinopathy*** Retinopathy is a disorder of retinal blood vessels, characterised by haemorrhages and leakage of blood and serum into the retina. Repeated vitreous haemorrhage may result in retinal detachment or blindness. Glaucoma and cataracts may also develop in the presence of diabetes mellitus. Individuals should consider consulting or be referred to an ophthalmologist or optometrist (Farrell & Dempsey 2013).

***Nephropathy*** Nephropathy, or kidney disease, may occur over a period of many years, and few signs or symptoms occur until the presence of blood proteins in the urine (microalbuminuria), uraemia and oedema develop (Farrell & Dempsey 2013; LeMone et al 2014). Diabetic nephropathy is more likely to develop if diabetes is poorly controlled. Renal function is gradually impaired by glomerulosclerosis, and it may progress to chronic renal failure. Preventing and treating any condition that may impair renal function, such as urinary tract infections or hypertension, reduces the development of diabetic nephropathy (McDowell et al 2007).

***Sexual dysfunction*** Impotence occurs in about half of all men with diabetes (LeMone et al 2014). In addition to the psychological causes of impotence, the condition is thought to be caused by damage to the nerve endings as a result of diabetic neuropathy, where the nerves controlling reflex blood flow to the penis are affected by persistently altered blood glucose levels. Controlling blood glucose levels may therefore help to prevent or alleviate the problem of impotence associated with diabetes. Possible complications in women include decreased vaginal lubrication and libido, and increased urinary tract infections and vaginitis (LeMone et al 2014).

### Diagnostic tests

Laboratory evaluation of the pancreatic islets is mainly concerned with levels of glucose in the blood (see Clinical Skill 36.1: Measuring blood glucose) and urine. Urine is typically examined for the presence of glucose and ketones (see Chapter 31). As a result of increased lipolysis, excess ketone bodies accumulate and are excreted in the urine. Urine may also be tested for the presence of protein (microalbuminuria), which may detect the early onset of nephropathy. Blood tests measure the body's use of glucose and include:

- Glucose tolerance test. This test evaluates glucose absorption after its oral or intravenous administration. The individual fasts overnight before the administration of glucose; glucose levels are then measured at intervals to diagnose diabetes mellitus
- Fasting serum glucose test. Also referred to as fasting blood or plasma glucose (FBG, FPG), this test measures glucose level after the individual has fasted for an 8-hour period; the blood glucose level is then measured. In diabetes mellitus, the absence or deficiency of insulin allows persistently high serum glucose levels above 7.8 mmol/L (LeMone et al 2014)
- Two-hour postprandial serum glucose. This test provides information about the body's utilisation and disposal of glucose after a meal. An elevated blood glucose level is indicative of diabetes mellitus
- Tolbutamide tolerance test. An intravenous injection of the drug tolbutamide usually stimulates the secretion of insulin. Normally, after administration of the drug, the serum glucose level will fall rapidly and return to normal baseline levels in 3 hours. In diabetes mellitus there is a slow initial drop and a prolonged time to return to pre-set levels
- Glycosylated haemoglobin ($HbA_{1C}$) test. This test is performed to review the control of diabetes mellitus over the previous 2–3 months. Results reflect the average glucose level attached to haemoglobin within erythrocytes rather than the serum glucose level, and the timeline reflects the average longevity of the erythrocyte. In diabetes mellitus it may be elevated to three times the normal level
- Serum cholesterol, triglyceride and electrolytes (Brown et al 2015; LeMone et al 2014; McDowell et al 2007).

## CARE OF THE INDIVIDUAL WITH AN ENDOCRINE DISORDER

Because of the complexity of the endocrine system and its interrelation with other body systems, **dysfunction** of any endocrine gland can have widespread effects (Clemmons 2012). The possibility of an endocrine cause needs to be kept in mind in a wide range of medical emergencies. Most endocrine disorders result from hyper- or hypoactivity of the gland or tissue. The manifestations and effects resulting from a glandular disorder therefore relate to the hormone the affected gland secretes.

### Effects of endocrine dysfunction

Endocrine dysfunction has widespread effects, and the medical management and nursing care depends on the diagnosis of a specific disorder. When care is being planned, the nurse must consider the effects that the disorder may have on the individual, and any issues the individual may be coping with. While individual treatments and care suggestions have been listed for a number of conditions already discussed, below are major nursing care considerations.

### A major change in lifestyle

As a result of an endocrine imbalance, the individual may have to depend on lifelong medication, dietary and fluid intake modifications, reductions in activity or exposure to stressors, and potentially irreversible physical and physiological changes (Clemmons 2012). In addition, individuals may experience sexual dysfunction, an often neglected complication of endocrine disorders (Bhasin et al 2007). For example,

## CLINICAL SKILL 36.1 Measuring blood glucose

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Blood glucose meter<br>Reagent strips<br>Tissues or cotton balls<br>Peripheral blood access device (lancet)<br>Sharps container<br>Disposable gloves<br>Warm washcloth<br>An appropriate chart for documentation |

| **Skill activity** | **Rationale** |
|---|---|
| Determine the need for BGL assessment and validate the medical orders in the individual's record | Ensures correct procedure is about to take place<br>Physical signs and symptoms such as confusion, drowsiness and limb weakness may indicate alterations in neurological function |
| Prior to commencing the procedure introduce self, identify the individual, validate and explain the rationale for the procedure, obtain consent, locate and gather the necessary equipment<br>Ensure therapeutic interaction<br>Assess for any contraindications | Ensures consent<br>Ensures efficiency<br>Reduces the incidence of performing an activity on the incorrect individual<br>Reduces anxiety/apprehension and gains trust and cooperation<br>Promotes participation in care and understanding of health status<br>Ensures correct procedure is about to take place |
| Critically think through the assessment data and problem solving (e.g. identify indications and rationale for performing the activity, state normal range for result (demonstrating knowledge of target range for individual), why and when they should be performed) | Evaluate each aspect and its relationship to other data to help identify specific problems and modifications of the procedure that may be needed for the individual |
| Place the equipment in a convenient location near the bedside<br>Raise the bed to the appropriate working position based on your height<br>Position the individual | Ensures all equipment is at individual's bedside to maximise efficiency<br>Facilitates performance of the procedure and promotes functional body alignment and body mechanics while the procedure is being performed |
| Perform hand hygiene<br>Don appropriate PPE as per infection control protocols | Prevents cross-infection and contamination |
| Dilate the capillaries by applying a warm compress | Promotes vasodilation |
| Assist the individual to wash hands with soap and warm water then dry them | Promotes skin cleansing, even the smallest bits of food can alter a reading<br>Warm water increases the peripheral circulation due to vasodilation, facilitating blood flow from the puncture site. Make sure the site is entirely dry because even water can affect results |
| Select the site, usually the side of the fingers<br>Gently massage at the base of the finger and stroke towards the puncture site. Place finger in a dependent position | There are fewer nerve endings on the sides of the fingers; therefore, it is less painful<br>Increases vasodilation and blood flow |
| Prepare the glucometer as per the manufacturer's instructions<br>Check the machine has been calibrated with the test strip<br>Check the date on the reagent strip and ensure the lid is closed securely | Glucometers require recalibration to ensure accuracy of result<br>Reagent strips are affected by moisture in the air |

*Continued*

| CLINICAL SKILL 36.1 Measuring blood glucose—cont'd | |
|---|---|
| Insert the reagent strip into the glucometer<br>Follow manufacturer's guidelines as to when to insert the strip | This is generally before the blood is applied to the strip |
| Obtain the blood specimen<br>Prepare the lancet<br>Place firmly against the side of the finger<br>Pierce the finger quickly | Ensures the skin is pierced<br>Reduces discomfort. The fingertip is the most accurate test site because it registers changes in blood glucose more quickly than the rest of the body. To avoid calluses, soreness and infection, prick the finger on the side not the pads<br>Ensure adequate blood for accuracy of result. Do not squeeze finger immediately after prick, as this will actually decrease blood flow. Instead wait a moment and then gently milk the finger |
| Allow the blood to drop onto the test strip | This may differ depending on the monitor<br>The blood should cover the test strip<br>Some strips fill from the side |
| Apply pressure to the puncture site with tissue or cotton swab | Promotes haemostasis |
| Timing is determined by the manufacturer | Ensures accurate results<br>Most glucometers display a digital read out |
| Read the digital result from the glucometer | Note result to allow comparison with normal blood glucose level |
| Turn off the meter, remove the test strip and dispose of supplies appropriately<br>Place used lancet in sharps container<br>Remove used PPE and dispose of appropriately<br>Perform hand hygiene<br>Clean glucometer as per manufacturer's instructions. Return to appropriate storage area | Reduces risk of transmission of infection |
| Lower the bed and assist the individual to reassume a comfortable position<br>Ask the individual to report any complications during and post procedure if able | Promotes rest and relaxation, monitors for adverse effects |
| Record results accurately on chart and in correct location in healthcare record. Share the result with the individual and then report the observation to the Registered Nurse. Report abnormal result to medical officer as per facility/organisation policy | Keeps individual informed. Documentation provides a record of the reading<br>Provides relevant information to other members of the healthcare team<br>Allows for the planning and implementation of care |
| *(Australian Diabetes Society 2012; Australian Commission on Safety and Quality in Health Care 2012; 2015; Berman et al 2015; Dempsey et al 2014; Diabetes Australia 2014c; Rebeiro et al 2013; Sparkes et al 2014)* | |

individuals with diabetes mellitus may have to depend on lifelong medication and dietary alterations, and a lifelong commitment to monitoring blood glucose. All individuals with chronic conditions should also be encouraged to wear a medical alert bracelet.

## The prospect of facing major surgery

Removal of the thyroid gland may be indicated in the presence of hyperthyroidism, goitre or carcinoma of a gland. Likewise, adrenalectomy may be the preferred intervention with adrenal gland tumour or hypersecretion of corticosteroids or catecholamines. A similar approach may be taken, in addition to medication, for pituitary tumours. Individuals facing major surgery should be educated and counselled on the preparation for surgery, the procedure and care required postoperatively.

## Possible postoperative changes

Surgical intervention may result in the balance of hormones shifting in the opposite direction. For example, thyroidectomy

for hyperthyroidism or hyperparathyroidism may result in hypofunction of the gland after removal of much of the tissue. Individuals should be educated in the likelihood of having hypofunction of the gland and the reliance on medication to address these changes.

## Alterations in nutritional status

Weight gain often occurs in hypothyroidism, whereas weight loss is common in people with type 1 diabetes mellitus. Nutritional status may also be affected if the individual is experiencing anorexia, nausea or vomiting. Hyperthyroidism is associated with increased cellular metabolism and individuals often experience rapid weight loss: management of calorific intake is therefore a concern. In addition, iodine intake may need to be restricted or increased in individuals with goitre or thyrotoxicosis.

Nursing care plans should also consider the reduction or management of dietary intake of calcium for individuals with parathyroid imbalances. Diabetes mellitus obviously requires the management of glucose intake by health professionals and educators, and most especially by the individual.

## Alterations in fluid and electrolyte balance

Excessive loss of fluid (polyuria) may occur in diabetes mellitus or posterior pituitary gland disorders such as diabetes insipidus. Loss of fluid may also occur if the individual has diarrhoea, and may be present in disorders such as hyperthyroidism and Addison's disease. To address polyuria, the increased thirst (polydipsia) and fluid intake of individuals with diabetes mellitus and diabetes insipidus should be considered.

Conversely, retention of fluid may occur in disorders such as Cushing's syndrome, the oedema associated with hypothyroidism (and myxoedema) and SIADH. Careful fluid restrictions for individuals with SIADH are suggested to allow sodium levels to increase slowly. Where the effects of aldosterone are compromised or enhanced (e.g. primary aldosteronism), electrolyte intake (especially of sodium) as well as fluids should be considered.

## Management of discomfort

Many endocrine disorders result in problems related to body temperature regulation. A person with hypothyroidism is very sensitive to cold, whereas an individual with hyperthyroidism is commonly intolerant to heat. Other factors that may cause discomfort include pruritus associated with hyperthyroidism or diabetes mellitus, and joint pain associated with acromegaly. Anxiety and nervousness associated with certain disorders such as hyperthyroidism, or hypertension and headache with phaeochromocytoma, may also cause discomfort as the individual is restless and finds it difficult to relax. Apathy and difficulty in concentration may occur in hypothyroidism.

Calcium imbalances potentially affect nervous and muscular function, and individuals with hyper- and hypoparathyroidism may experience anxiety, uncomfortable nervous tingling and muscle spasms, or backache associated with calcium resorption from bones.

## Reduced independence

Extreme fatigue often accompanies endocrine disorders, and the individual may require assistance to carry out activities of daily living. Certain disorders (e.g. Cushing's syndrome or hyperparathyroidism) may be accompanied by alterations in mental status, learning and memory (McCance & Huether 2013). Altered states of awareness or consciousness (hypothyroidism, decreases in fluid electrolyte levels) will also reduce the individual's level of independence.

Hypertension and arteriosclerosis associated with disturbances to glucose and lipid metabolism (e.g. diabetes mellitus, Cushing's syndrome) may also restrict individuals to less exertive activities and a greater reliance on assistance.

## Altered body image

Individuals may experience both physical and mental alterations to body image and subsequent changes in behaviour to address these concerns. Healthcare professionals should be prepared to explain the manifestations to the individual, and to consult and counsel the individual in the event of changes in self-esteem or behaviour associated with physical changes (Clemmons 2012).

Obvious changes in physical appearance occur with Cushing's syndrome (e.g. buffalo hump, moon face), and exophthalmos and possible goitre associated with hyperthyroidism (Clemmons 2012). Individuals may also exhibit changes in height and appearance with gigantism and acromegaly. Hirsutism associated with adrenal, pituitary or gonadal dysfunction may severely affect the self-esteem of individuals (especially females), and children suffering from androgenital syndrome are especially likely to suffer from psychological effects of an altered body image. Individuals with Addison's disease may experience increased skin pigmentation (bronzing).

The plan of care that the nurse designs for an individual should specifically address the need for comfort, psychological support and maintenance of nutritional and fluid status. Individuals should also be given information regarding professional support and self-help groups and should be encouraged to contact these organisations for further support and information. A list of organisations and websites is provided in online resources.

### CRITICAL THINKING EXERCISE 36.4

A 38-year-old mother of two has been admitted with a possible adrenal tumour. Considering the role of the adrenal gland, what possible endocrine disorders might the individual suffer from? What might be their physical manifestations, and how can you best explain to the individual what she might be experiencing?

### CRITICAL THINKING EXERCISE 36.5

Louise, 46, is an active community care worker who has arrived at a medical clinic for assessment, concerned by the gradual onset of several symptoms. She complains of weight gain. She also conveys to you a feeling of generally 'slowing down', describing symptoms such as constipation, tiredness, an impaired memory and feeling cold despite the warm spring evenings. She speaks slowly, occasionally slurring her words.

1. On examination, you observe a bradycardia of 52 beats per minute, and note the individual's dry skin, oedematous eyelids and enlarged tongue. What endocrine disorder is Louise likely to be suffering from?
2. Louise is started on medication with the aim of normalising her thyroxine levels. If these oral thyroid medications cause her to become hyperthyroid, what signs and symptoms would you educate her to be aware of?
3. What further education will Louise require to help her cope with the diagnosis?

## Care of the individual with diabetes mellitus

The main aims of management of the individual with diabetes mellitus are to maintain the blood glucose level within an acceptable range and to implement measures to assist the person to live as normal a life as possible (Diabetes Australia 2014c). Diabetes can be controlled at present, but not cured; management is therefore aimed at controlling it and preventing complications. Care of an individual with diabetes involves regulating the blood glucose level by diet, exercise and insulin or oral hypoglycaemic agents, preventing infection and monitoring blood and urine glucose levels. The overall aim for the individual is self-management of the disorder, which makes education of the individual in all aspects of care an essential part of management (Diabetes Australia 2014c) (see Nursing Care Plan 36.1).

### Diet, nutrition and energy requirements

Diet is an important aspect in control of both type 1 and type 2 diabetes mellitus. A dietitian works with the individual to develop a well-balanced, healthy food intake. It is essential that the individual gains understanding of the principles and can then modify and adapt the diet to meet demands experienced during illness, injury, emotional stress or major changes in lifestyle. The aims of the diet for a person with diabetes are to:

- Satisfy hunger
- Improve health and prevent or delay complications
- Provide for normal growth rate in children
- Provide a balanced dietary intake
- Attain and maintain a desirable body weight
- Meet energy requirements and
- Maintain the level of blood glucose within the normal range to prevent hypoglycaemia and hyperglycaemia.

Normal or average blood glucose is around 5 mmol/L (4–6 mmol/L fasting), with a range of 3.5–8 mmol/L. Fasting plasma glucose in a non-diabetic individual is usually less

### NURSING CARE PLAN 36.1

**Assessment:** Janine Wells underwent setting of carpal fracture yesterday. No complications from surgery and reports of little pain or discomfort. Janine has type 2 diabetes and is exhibiting fatigue; she is lethargic, lacks energy and is unable to maintain her normal feeding and bathing routine. Janine has been asked numerous times about her general wellbeing and her pain regarding the recent surgery—she appears disinterested and unenthusiastic. Janine is non-committal regarding assistance to accomplish her tasks.
**Issue/s to be addressed:** Lack of motivation, listlessness and inability to maintain enthusiasm or routine
**Goal/s:** To encourage and assist Janine to maintain daily tasks and to increase energy levels, interest and awareness of her surroundings

| Care/Actions | Rationale |
|---|---|
| Discuss with Janine the need for activity (ambulation—no risk for wrist). Plan with Janine activities or assistance with activities to avoid fatigue | Education and participation may provide motivation to increase activity level even though Janine may feel too weak or disinterested |
| Ensure Janine undertakes periods of supervised activity alternating with rest | To prevent excessive fatigue |
| Monitor pulse, respiratory rate and BP before and after activity | Indicates physiological levels of tolerance |
| Increase Janine's participation in ADLs as tolerated | Increases confidence level, self-esteem and tolerance level |
| Involve Janine in discussions on strategies to conserve energy during tasks such as bathing (or activities as planned) | She will be able to accomplish more with a decreased energy expenditure and may increase tolerance of activity and/or confidence |

**Evaluation**

Janine managed to bathe and complete her meal unassisted and is more receptive to questioning. Janine has managed an uninterrupted afternoon rest and has reported she feels a little less lethargic.

than 6.1 mmol/L, and a repeated fasting level of at least 7.0 mmol/L is indicative of hyperglycaemia (LeMone et al 2014). The Heart and Diabetes Institute of Australia recommends goals for dietary and nutrition management (Heart and Diabetes Institute of Australia 2011).

Alcohol should be limited, as not only is it high in sugar and may cause adverse reactions to some medications used in the treatment of diabetes mellitus, it may also mask hypoglycaemia (Endocrinology Expert Group 2014). The dietitian will supply the individual with instructions for planning nutritious and varied meals within the prescribed limitations. The importance of regular meals and snacks is emphasised, particularly an evening snack to prevent nocturnal hypoglycaemia. The diet is continually evaluated and adjusted as required. When the individual is in hospital it is important that the nurse observes the amount of each meal eaten because if nutrients are not all consumed the person may experience hypoglycaemia (Brown et al 2015; Craft et al 2014; Farrell & Dempsey 2013).

## Exercise

The amount of exercise required by the individual should be estimated and planned to balance with the dietary intake and insulin (Farrell & Dempsey 2013). A well-planned program of regular exercise that is adjusted as necessary is beneficial in weight control, in its physiological and psychological effects and in terms of blood glucose control. Regular gentle exercise stimulates the uptake of glucose by muscle cells, lowering blood glucose levels and increasing the absorption of injected insulin. For these reasons, exercise can increase the likelihood of hypoglycaemia. To prevent hypoglycaemia after exercise, the individual needs to either increase the nutritional intake or decrease the insulin dosage. Education is essential for the individual to gain understanding to correctly balance the level of exercise with dietary intake and insulin dosage under varying conditions. Exercise also has the benefits of decreasing cholesterol and triglycerides, and reducing the risk of cardiovascular disease (LeMone et al 2014). Strenuous exercise, however, can trigger the release of hyperglycaemic hormones, such as adrenaline and glucagon, so should be avoided (Brown et al 2015). For a sample of an entry in progress notes see Progress Note Example 36.1.

## Insulin

As insulin is essential for the normal metabolism of glucose, it is a major factor involved in the regulation of blood glucose levels. Many types of insulin are available and these may be rapid onset-fast acting, short-, intermediate- or long-acting, or mixed (Diabetes Australia 2008). The different types of insulin vary in the time of onset and the duration of action, and are selected according to the time of day, activity and nutritional intake. As soon as possible after diagnosis, the individual is given instruction on insulin administration and care for the equipment required. Insulin may be administered via syringe and needle (now less commonly used), specialised pens or by pump (CSII—continuous subcutaneous insulin infusion) (Diabetes Australia—Vic 2010; LeMone et al 2014; McDowell et al 2007). Individuals are also instructed on rotating injection sites around the abdomen and thighs to prevent tissue atrophy or hypertrophy at regularly used injection sites. The abdomen provides the fastest and most consistent rate of absorption and is an accessible site for the person to use (Figures 36.8 and 36.9).

Short-acting insulin may also be delivered continuously at a basal rate subcutaneously by a CSII pump, with dosages entirely self-determined and monitored by the individual. Individuals choosing this insulin regimen need to be motivated, and educated by a nurse or diabetes educator (Australian Diabetes Educator Association 2015). Insulin pumps and associated equipment are subsidised in Australia by the NDSS (National Diabetes Services Scheme) (Endocrinology Expert Group 2014; Diabetes Australia–NDSS 2015).

## Oral hypoglycaemic agents

Oral hypoglycaemic agents may be prescribed in the management of type 2 diabetes mellitus unresponsive to diet alone. The medications used in the treatment of diabetes mellitus act in a variety of ways, by stimulating the pancreas to release insulin (secretogogues), reducing insulin resistance

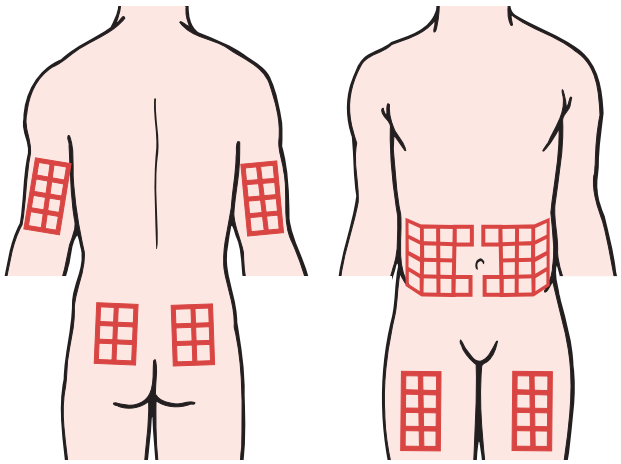

**Figure 36.8** Insulin injection sites
*(Lewis et al 2011)*

### PROGRESS NOTE EXAMPLE 36.1

| | |
|---|---|
| 02/03/2015<br>0950 hrs | Nursing: Janine supervised with exercise (walk around floor) due to general lethargy and unresponsiveness. Activity completed and Janine able to return to bed. Was instructed to call for assistance when bathing. Janine indicated that she felt more capable and will request assistance only if she is feeling too tired. |

(sensitisers), the promotion of glucose use or delaying glucose absorption across the gut (Endocrinology Expert Group 2014).

## Hygiene and preventing infection

People with diabetes mellitus are susceptible to infection as a result of impaired body defence mechanisms and elevated glucose providing an environment for bacterial growth (Craft et al 2014). The person with diabetes is particularly at risk of developing urinary tract infections, fungal infections such as *Candida* and infected skin lesions (Brown et al 2015). To minimise the risk of infection the person should understand the importance of good control of blood glucose levels, of maintaining a high standard of personal hygiene and of avoiding unnecessary exposure to infection (LeMone et al 2014). The skin should be kept clean and free from excessive irritation, friction or pressure. All injuries to, or infections of, the skin, however minor, should be cleaned with a mild antiseptic solution and covered with a dressing (McDowell et al 2007).

Skin lesions of the feet commonly occur in people with poorly controlled diabetes mellitus (Heart and Diabetes Institute of Australia 2011; Santamaria et al 2004). Such lesions result from, or are exacerbated by, impaired circulation and peripheral neuropathy (Craft et al 2014). If a minor injury or lesion is undetected or untreated, ulceration and infection may develop (Figure 36.10). Between 50% and 75% of lower extremity amputations are performed on people with diabetes (Farrell & Dempsey 2013). The nurse should also consider the lesion or aberration to be of different origin: melanomas of the feet have been misdiagnosed as diabetic foot ulcers (Rogers et al 2007; Yesil et al 2007). Care of the feet and prevention of foot lesions is therefore of prime importance and national guidelines on the prevention, identification and management of foot complications in diabetes are available (Heart and Diabetes Institute of Australia 2011).

## Guidelines for foot care in individuals with diabetes

- Wear well-fitting socks or stockings, and shoes. Socks should be made from natural fibre (e.g. wool or cotton) with care taken to avoid hosiery with seams under the feet
- Practise daily cleansing, drying and inspection of the feet. A mild soap is used and the feet should not be soaked for long periods. After washing, the feet should be patted dry rather than rubbed. Dry feet may be gently massaged with lanolin or oil to prevent fissures
- Consult a podiatrist if corns or calluses need attention
- Trim the toenails straight across, to avoid damage to the surrounding skin
- Keep the feet warm but avoid placing them close to heating devices, to prevent possible skin damage. If an electric blanket is used to warm the bed, it should be turned off before the person gets into bed
- Avoid walking barefooted or on hot surfaces
- Perform foot and leg exercises to increase circulation
- Avoid constrictive clothing (e.g. socks with elasticised tops) and crossing the legs, both of which may reduce blood flow

- Seek immediate attention from the podiatrist or medical officer if there is any injury, colour change, infection or discharge of pus or blood (Craft et al 2014; Diabetes Australia 2014a; 2014c; Farrell & Dempsey 2013; LeMone et al 2014; McDowell et al 2007).

## Monitoring blood glucose levels

Blood glucose monitoring is an accurate method of assessing the effectiveness of diet, exercise levels and medication therapy and to gain information regarding an individual's current blood glucose level (Diabetes Australia 2014b; 2014c). Blood glucose monitoring is described in Clinical Skill 36.1, and is usually performed by obtaining a drop of capillary blood, which is applied to a reagent strip and read by one of the many types of glucometers available on the market. Most meters available currently show acceptable reading precision, and errors are clinically insignificant (Cohen et al 2006; Rebel et al 2012). A digital display of the glucose level is provided, or the colour of the strip may be compared with a standard, either visually or with a reflectance meter. A variety of blood glucose monitoring machines are available, including ones with automatic finger-pricking, which run either on batteries or from mains power (Figure 36.11).

The aim of self blood glucose monitoring is to assist individuals with diabetes to assume more independence in managing their condition. Each person using blood glucose monitoring receives individual instruction in the technique from a diabetes health educator; for example a member of the Australian Diabetes Educators Association. People with diabetes are advised on the appropriate times at which to perform the test and are shown how to make suitable adjustments to their insulin dose if the blood glucose levels are above or below those recommended. If the nurse is required to perform blood glucose monitoring they should also receive instruction in the technique and should become familiar with the manufacturer's instructions accompanying each monitoring device (see Clinical Skill 36.1).

Although not as accurate or desirable, blood glucose and ketone analysis may be augmented by urinalysis, performed by either a nurse or the individual at home. Glycosuria is also indicative of other disorders such as Cushing's syndrome. As a result, information on the effects of treatments or severity of other endocrine disorders may be provided by the specific gravity, presence of ketones or pH recorded on urinalysis strips. For further information on urinalysis, see Chapter 31.

## Education

The person with diabetes mellitus has to learn to accept the condition and the resulting lifestyle changes that need to occur. They need to gain confidence in managing the condition, which requires learning a considerable amount of medical information and technical skills. A well-planned education program helps alleviate anxiety, creates autonomy in management and results in well-managed individuals. Involving family members and close friends in the education program also assists the individual. The aims of an education program are that the individual will:

- Accept the condition and understand the importance of good diabetic control
- Acquire the technical skills needed to monitor blood glucose levels and administer medications

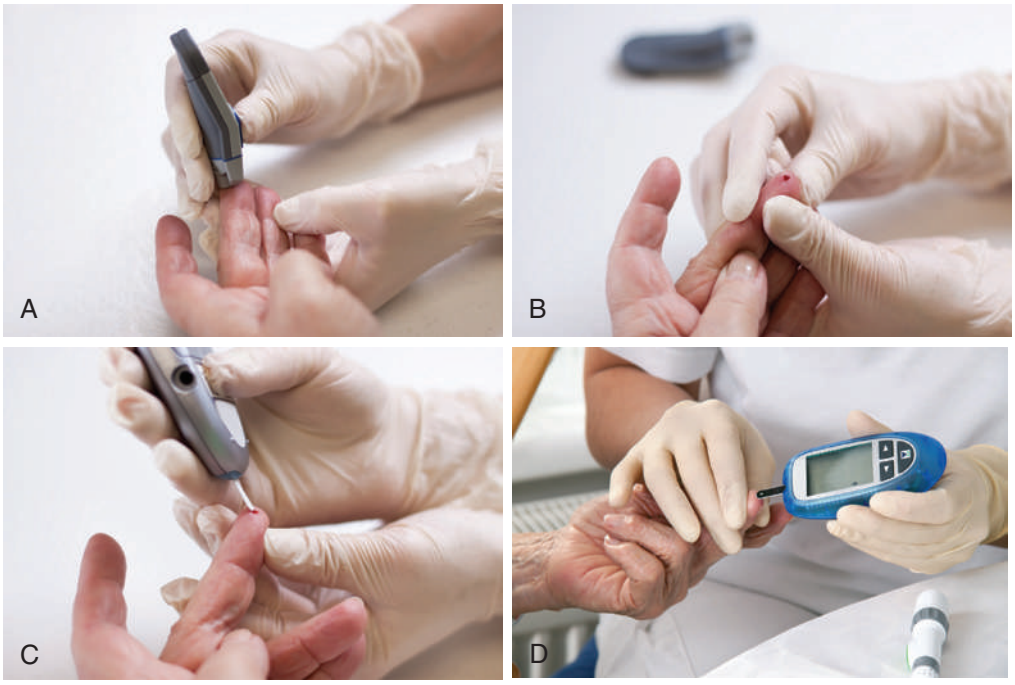

**Figure 36.11** Blood glucose meter and monitoring

*(**A**, **B**, **C**: © Miriam Doerr/Shutterstock; **D**: © Lisa S./Shutterstock)*

- Understand the importance of diet, exercise and medications in maintaining blood glucose levels
- Recognise disturbances of blood glucose levels and the development of complications.

A person with diabetes mellitus should always carry a form of diabetic alert identification with them, such as a card, bracelet or medallion. This ensures that appropriate care will be administered if a medical emergency occurs. Individuals suffering from diabetes mellitus or at risk may be referred by their health professional to the Australian Government National Diabetes Services Scheme for access to subsidised products to assist in home blood testing (Australian Diabetes Educators Association 2015; Diabetes Australia–NDSS 2015).

### CRITICAL THINKING EXERCISE 36.6

Paul is an obese 54-year-old man with a 4-year history of type 2 diabetes mellitus. Despite his best efforts, he tells you that he is finding it difficult to alter his diet and activity levels. His doctor has recently told him to take extra care with his feet. He asks you, a nurse, why this is important. What do you say to him about skin care in people with poorly controlled diabetes mellitus?

## Summary

The endocrine system is made up of a number of glands that secrete chemical substances called hormones directly into the bloodstream. Each hormone has a specific purpose in the body, and their effects are often wide-ranging and prolonged. The endocrine system influences major bodily processes as diverse as growth, sexual maturation, blood calcium and fluid balance. All glands and hormones work in concert to maintain homeostasis.

Hormone imbalances and endocrine dysfunction may result from autoimmune reactions, trauma, tumours and genetic disorders, among other factors. More common or recognisable endocrine health problems include Graves' disease, Cushing's syndrome, acromegaly and diabetes mellitus. Diagnostic tests to assess gland function include estimating serum hormone and metabolite levels, urine tests, scanning and ultrasonography. A number of disorders are characterised by definitive signs and symptoms and nursing intervention and care varies according to the specific disorder. The nursing care is designed to support and help individuals meet all their needs.

Diabetes mellitus is specifically a disorder of blood glucose regulation. Management of diabetes mellitus includes monitoring diet and blood glucose, activity levels, use of insulin and the prevention of complications.

### DECISION-MAKING FRAMEWORK EXERCISE 36.1

You are a Diploma of Nursing student who is on clinical placement for the second time. You have just successfully completed the medication administration unit and are assisting with the care of a person who has Graves' disease, a condition that affects the thyroid gland.

Your buddy nurse asks you to speak with this person and to either administer their medication (antithyroid tablet) or assist the person to do so. The buddy nurse will be close by as they will be dealing with an individual on the other side of the room.

1. Before you undertake this action, do you have the necessary education in order to administer or assist with the administration of oral medication?
2. You are not an Enrolled Nurse yet—as a student on placement, what authority do you have in regards to performing this practice? Do you need assistance? Of what importance is the proximity of the buddy nurse?
3. You do not feel confident in undertaking this action. Should you go ahead anyway?
4. Given you have completed your stage two only a week or so prior to placement, and this is your second placement round for your Diploma, are you competent to perform this action? Explain why or why not.

## Review Questions

1. Describe how the pituitary gland regulates the thyroid and adrenal glands, and the gonads.
2. Describe gigantism. Does gigantism occur before or after epiphyseal closure? How does this differ to acromegaly?
3. What is the function of antidiuretic hormone? Blood tests of one of your individuals shows they are suffering from hyponatraemia, serum hypo-osmolarity and urine hyperosmolarity. What sort of endocrine imbalance might be occurring? Which gland do you think is responsible?

4. Explain the difference between diabetes insipidus and diabetes mellitus. A dysfunction of which endocrine glands might be responsible for these conditions?
5. How do you account for the hyperactivity, tachycardia and nervousness which are typical signs of Graves' disease?
6. List three (3) situations that could instigate a thyroid storm or thyroid crisis.
7. The parathyroid glands secrete parathormone (PTH). What is the action of this hormone? What is the name and source of the hormone which is antagonistic to PTH? Where else do we find hormones with opposite actions? (Give an example of complementary hormones.)
8. Describe the main functions of glucocorticoids such as cortisol. What possible health problems may develop with prolonged secretion or administration of cortisol?
9. Explain how problems with the adrenal cortex might manifest in body fluid imbalances.
10. How is it that the adrenal medulla has an identical, but more prolonged, influence on your body than the sympathetic nervous system?
11. What sort of signs or symptoms would you expect a female individual with an excess of androgens to exhibit?
12. Describe the two types of diabetes mellitus. Is diabetes necessarily a problem with the pancreas, or a product of the pancreas? Explain.
13. Describe the significance of finding a high level of ketones in the urine of an individual with type 1 diabetes mellitus.
14. Where is the best location on a person's finger to perform a blood glucose test and why?
15. Match the list of endocrine organs/tissues below with their hormones.

| Gland | Hormone |
|---|---|
| Pancreas | Adrenaline |
| Adrenal | TH |
| Thyroid | GH |
| Pituitary | Insulin |

CHAPTER
37

# Nursing assessment and management of reproductive health

*Christine Baker*

## KEY TERMS

amenorrhoea
balanitis
candidiasis
circumcision
contraception
dysmenorrhoea
dyspareunia
endometriosis
epispadias
erectile dysfunction (ED)
gamete intrafallopian transfer (GIFT)
hydrocoele
hypospadias
in vitro fertilisation (IVF)
infertility
mastitis
oogenesis
Papanicolaou (Pap) test
phimosis
priapism
prostate-specific antigen (PSA)
prostatitis
spermatogenesis
testicular self-examination (TSE)
testosterone
transurethral resection of the prostate (TURP)
varicocoele
vasectomy

## LEARNING OUTCOMES

At the completion of this chapter and with some further reading, students should be able to:

- Define key terms
- Describe the physiology of the male reproductive system
- Describe the physiology of the female reproductive system
- Consider alterations in health status that affect male and female reproductive systems
- Discuss factors that influence reproduction
- Identify factors that may affect sexual and reproductive health
- Discuss major clinical conditions which may affect sexual and reproductive health
- Identify diagnostic tests used to assess reproductive function
- Develop individual management strategies for the management of sexual and reproductive disorders
- Identify nursing responsibilities in relation to child sexual abuse
- Understand the physical and social implications of sexually transmitted infections
- Discuss the impact of disability on sexual health

## CHAPTER FOCUS

This chapter looks at the important aspects of reproductive health as they affect individuals throughout the lifespan. It looks briefly at the normal anatomy and physiology of the male and female reproductive systems and discusses common alterations that impact on reproductive health. The chapter also looks at common diagnostic tests and examinations conducted to assess an individual's health status and the role of the nurse in identifying individual needs and implementing a management plan.

## LIVED EXPERIENCE

Last week I finally consulted my GP about getting 'the snip'. My wife and I have four healthy children. My wife had started using contraception after the birth of our third child, but after a bad cold she fell pregnant and before we knew it we were planning for the birth of our fourth. We have discussed the decision at length and both agree that we don't want to have any more children so it is time for me to take some responsibility and book in for a vasectomy. I am a bit nervous; what if something goes wrong?

**Peter, 40-year-old father**

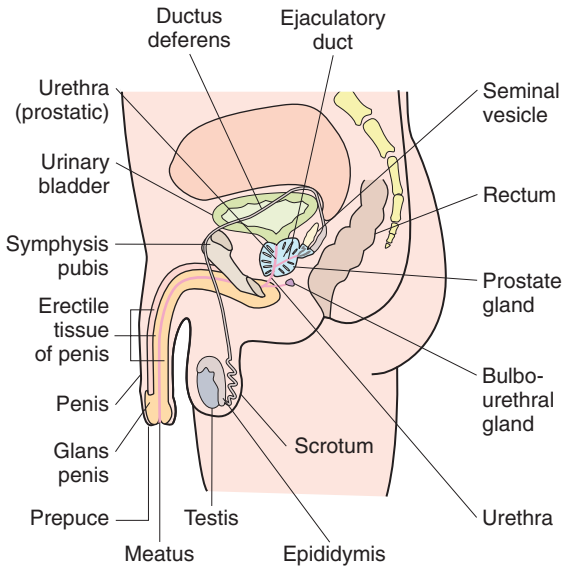

**Figure 37.1** The male genital system

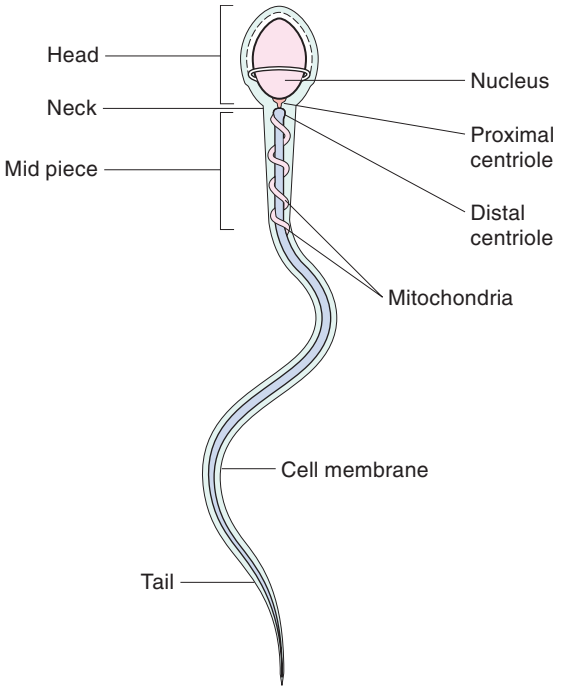

**Figure 37.2** The structure of a sperm cell

# THE MALE REPRODUCTIVE SYSTEM

The male reproductive system (Figure 37.1) is comprised of the testes, epididymis, ductus deferens, seminal vesicle, prostate gland, penis and urethra. The penis comprises a passage for both semen for semen during ejaculation and urine, travelling to the outside via the urethra which is common to both the urinary and the reproductive systems.

## Spermatogenesis

**Spermatogenesis**, the production of sperm cells, is a process occurring in the testes during puberty. In early fetal life, the testes remain suspended in the abdomen and descend at birth or soon after, through the inguinal canal into the scrotum, suspended in place by the spermatic cords.

Spermatogenesis is triggered by an increase in gonadotrophin-releasing hormone (GnRH) by the hypothalamus. Luteinising hormone (LH) and follicle-stimulating hormone (FSH) are secreted by the anterior lobe of the pituitary gland as a result of GnRH stimulation. With the release of LH, the Leydig's cells located in the testes release testosterone. FSH acts on the Sertoli cells in the seminiferous tubules to stimulate cell division and sperm production.

The mature sperm consists of a head, which contains the genetic material of the cell; a mid-piece, which comprises the mitochondria; and the tail, which helps to propel the cell as it travels through the female reproductive tract (Figure 37.2).

### Testosterone

The effect of **testosterone** on the body depends on both age and sex. During puberty, testosterone is associated with the development of secondary sex characteristics (hair growth, increase in muscle mass, change in voice and libido and enlargement of sex organs).

Production of testosterone continues throughout the adult life of the male. Testosterone levels may decrease in older age and as a result of injury, disease or radiation and after surgeries such as a vasectomy.

## DISORDERS OF THE MALE REPRODUCTIVE SYSTEM

A majority of disorders affecting the male reproductive system are due to developmental or age-related causes. It is important to consider early corrective surgery for congenital or structural defects of the genitourinary tract if the physical and psychological impact of the defect is to be limited. The nursing interventions during this time mainly focus on providing support to both the child and the family during the preoperative and postoperative phase. This can be accomplished by providing adequate time to express concerns and fears as well as educating the family and, if appropriate, the child about what to expect before and after the procedure. Often the use of appropriately targeted fact sheets is successful in providing this information.

Disorders affecting the male reproductive system are referred to as genitourinary disorders due to the shared anatomical structures of the urinary and reproductive systems. Conditions are usually characterised according to the type of alteration such as:

- Alteration in elimination
- Alteration in sexual function
- Alteration in urethral discharge.

### Disorders of the penis

#### Hypospadias and epispadias

Both **hypospadias** and **epispadias** are congenital defects affecting the urethral opening. Hypospadias is classified according to the position of the urethral meatus which may be on the underside or dorsal side of the penis. In epispadias the urethral opening occurs on the ventral or upper surface of the penis. Surgery for both defects involves closure of the abnormal opening and extending the urethra to the normal location (Matthew et al 2015).

#### Phimosis and paraphimosis

**Phimosis** is characterised by narrowing of the prepuce orifice, which prevents retraction due to an infection, an inflammation or a congenital lesion. The condition predisposes to infection and, if present in the adult, leads to difficulties during sexual intercourse. Where the condition is complicated by a forcible retraction of the prepuce over the glans penis inflammation of the prepuce collar can lead to swelling and constriction, a complication called paraphimosis. The treatment is **circumcision**.

**CRITICAL THINKING EXERCISE 37.1**

Circumcision is a potential treatment option for the individual diagnosed with phimosis. While most commonly the procedure is performed as an infant or child there are occasions when it may be performed as an adult. Would post-surgical management of the circumcised penis be different if performed as an adult?

**CASE STUDY 37.1**

Ian is a 17-year-old male who has come to the sexual health clinic where you work extremely anxious and agitated. After some time you manage to discover Ian had fallen asleep after having sexual intercourse with his girlfriend several nights ago when he used a condom that he stated had been in his wallet for the past 12 months. Ian explains that his penis is painful to touch and there is a slight 'cheesy' smell. Ian is scared that he may have an STI. An examination of Ian's penis reveals he is not circumcised. What is the possible reason for Ian's symptoms?

#### Balanitis

**Balanitis** is a common condition characterised by inflammation of the glans penis which can occur at any age. The condition is more common in non-circumcised males who do not retract the foreskin when cleaning the penis. The common causative organism is *Candida albicans*. It can also develop as a result of an allergic response to chemicals such as latex and soaps or be an indicator of diabetes. While the condition can cause discomfort it is easily managed by finding and treating the cause. Treatment may involve circumcision to limit the recurrence of infection. (See Case Study 37.1.)

#### Peyronie's disease

This condition is characterised by hardening of penile tissue (fibrosis) which sometimes causes a palpable lump or area of scar tissue (plaque). The affected area limits the ability of the erectile tissue in the penis to respond during an erection and can appear as if the penis has a bend. The condition can sometimes occur after an injury to the penis; however, a majority of cases do not have a specific link to an event.

Treatment may include surgery to excise the scar tissue, implantation of a prosthesis to assist with maintenance of a satisfactory erection or plication of the penis (a tuck is put into the lining of the penis on the opposite side to the bend to straighten the penis). The procedure will result in slight penile shortening (Chung & Brock 2013).

#### Cancer of the penis

Penile cancer usually presents on the skin surface as a painless wart-type growth or ulcer. If left untreated the cancer

will infiltrate tissues and cause urinary symptoms. Diagnosis of penile cancer involves biopsy of the lesion to confirm the diagnosis, chest x-ray, CT scan and lymph node biopsy to check for metastases. After confirmation of the diagnosis, management involves surgery and a combination therapy of internal and external radiation and chemotherapy. Surgical procedures can range from circumcision, laser or cryotherapy treatment to partial or total amputation of the penis.

Penile cancer in Australia is rare, with the annual incidence of 0.8 per 100 000 in 2007 (Grulich et al 2010). The incidence of penile cancer is considered to have a link to diagnosis of human papillovirus (Morris et al 2012).

Nursing management of the individual before and after diagnosis is based on providing emotional support and ensuring counselling is readily available. Education should be offered to manage the physical and psychological impact of the related loss of sexual function and the cosmetic impact of a penile amputation.

## Erectile conditions

***Erectile dysfunction*** **Erectile dysfunction (ED)** is considered to be one of the most common male sexual conditions in Australia owing to the fact that a majority of cases probably go undiagnosed. The prevalence of moderate-to-severe ED increases from 10% in younger men (under 35 years) to 28% in men aged 55–74 years (Adams et al 2013).

ED is usually characterised as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It is a common condition with an increased incidence in males as they get older. Causes may be due to psychological, neurological, hormonal, arterial or cavernosal impairment or from a combination of these factors (Table 37.1). The condition can be classified as psychogenic, organic or mixed psychogenic and organic. Psychogenic factors may include performance anxiety, lack of arousability, relationship difficulties or mental health disorders such as depression and schizophrenia.

The management for a person with ED is dependent on the underlying reason and should include investigation for a chronic disease such as heart disease or diabetes. For most men, a cure for erectile dysfunction may not be possible although treatment may allow for improvement.

The three main types of treatment include:

1. Non-invasive methods such as oral medications (phosphodiesterase-5 (PDE5) inhibitors) and use of external devices including rings and vacuum pumps
2. Penile injections
3. Surgery such as the insertion of a prosthesis or vascular surgery.

New treatments for erectile dysfunction include the use of low-intensity extracorporeal shock wave therapy which acts on the blood vessels (Andrology Australia 2014c). (See Case Study 37.2.)

***Priapism*** This condition is characterised by a persistent and often non-pleasurable erection lasting for longer than 6 hours, usually only affecting the corpus cavernosum, and not

**TABLE 37.1 | Causes of erectile dysfunction**

| Cause | Presentation |
|---|---|
| Psychosocial problems | Performance anxiety<br>Sexual attitudes and upbringing<br>Relationship problems<br>Employment and financial pressures<br>Depression<br>Psychiatric disorders |
| Nerve function interference | Spinal cord trauma<br>Multiple sclerosis<br>Diabetic neuropathy<br>Prostate or bowel surgery<br>Parkinson's disease<br>Alzheimer's disease |
| Reduced blood flow | Atherosclerosis |
| Medication, alcohol and other drugs' interference | Alcohol and drug abuse<br>Drugs such as:<br>• Antihypertensives<br>• Lipidaemics<br>• Antidepressants and psychiatric medications<br>• Prostate medications |

### CASE STUDY 37.2

Nathan is a 64-year-old man who was diagnosed with diabetes mellitus when he was in his thirties. Five years ago he started having difficulty achieving and maintaining his erections, which has prevented him from having a normal relationship with his wife. An article in the newspaper over the weekend highlighted the latest treatments available for people with similar issues to Nathan. What treatments are available for Nathan?

induced by stimulation of sexual desire. There are two types of **priapism**:

1. Low-flow priapism—most common form, caused by increased blood viscosity that slows blood flow. This type of priapism is considered an emergency as it may lead to permanent damage.
2. High-flow priapism—less common, usually caused by trauma to penile structures (Yeng et al 2012).

**Priapism** may develop due to a complication of diseases such as sickle cell disease, leukaemia, malaria, carbon monoxide poisoning or use of some anaesthetic agents such as papaveretum. Excessive use of drugs used to treat erectile dysfunctions may also lead to priapism which is not able to be resolved through usual methods. A sustained erection leads to a build-up of toxins in the blood often called 'black blood' which will lead to anoxia and necrosis of tissue. The blood must be aspirated from the blood vessels in the penis in order for the erection to be resolved. If left untreated a priapism may lead to erectile dysfunction.

## Conditions affecting the testes

### Cryptorchidism (undescended teste)

At birth the prevalence of cryptorchidism is estimated to be one in 20 boys with the rate becoming one in 50 boys by 6 months (Andrology Australia 2015). The cause of the condition can be either congenital or acquired. Congenital causes occur more commonly in premature males where one or both of the testes fail to descend into the scrotum at birth. It may also be due to hormonal or genetic reasons. Acquired cryptorchidism occurs where the spermatic cord fails to grow at the same rate as the rest of the body and so the shortened cord pulls the testes back into the groin.

The condition is diagnosed by the absence, on palpation, of one or both of the testes in the scrotum. There is believed to be a link between a diagnosis of cryptorchidism and other health conditions such as hernias, testicular cancer and infertility in later life. The condition may be treated with hormone injections or surgery. Surgical placement of the testes in the scrotum (**orchiopexy**) is recommended before the second year of age to preserve sperm-forming cells that require a lower temperature than that of the abdomen. If the condition is not treated before puberty there is a risk of atrophy and sterility. The affected testis tends to be smaller and contain more fibrous tissue than the unaffected one.

### Carcinoma of the testes

Cancer of the testes is the second most common cancer in young men between 18 and 39 years (AIHW 2012a). The rate of testicular cancer is reported to have increased by 50% in the past 30 years (Cancer Australia 2015a); the reason for this is unknown; however, in a majority of cases treatment is successful and there are very few recorded deaths.

Men between the ages of 20 and 40 years are at most risk, with 98% of testicular tumours determined to be germ-cell in original (Shanmugalingam et al 2013). Recognised risk factors for testicular cancer are shown in Table 37.2. There is no proven link between the incidence of testicular cancer and the wearing of tight clothes, hot baths or testicular injuries.

**TABLE 37.2 | Risk factors for testicular cancer**

| | |
|---|---|
| Undescended testes (cryptorchidism) | Ten times the chance of developing testicular cancer. The incidence decreases significantly where correction of the undescended testis has occurred prior to 12 months of age |
| Previous history of testicular cancer | One in 25 males with a diagnosis of testicular cancer in one testis will be diagnosed with the condition in the other testis |
| Previous history of male infertility | Pre-cancer cells have been found in biopsies taken to diagnose infertility issues |
| Familial history | A minor risk where another male member of the family has been diagnosed with testicular cancer |
| Down syndrome | A considered increased genetic risk |

*(Adapted from Andrology Australia 2014a)*

Early diagnosis and improved treatment modalities such as chemotherapy have contributed to improved outcomes for men diagnosed with the condition; this can be seen in a 5-year survival rate of 96.8% for all age groups under 60 years (Shanmugalingam et al 2013). An early stage indicator is the presence of a smooth painless lump in the scrotum or a dull ache located in the testes or lower abdomen. Other metastatic symptoms include bowel or urinary obstruction and abdominal pain.

If a lump is detected in the testes, the male who seeks medical advice will have the diagnosis confirmed with an initial physical examination, ultrasound of the scrotum and collection of blood for presence of blood serum markers. Elevated levels of alpha-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) will be detected in testicular cancer. Ultrasonography differentiates between a solid and a cystic lesion. Tests to detect potential metastases include chest x-ray and CT scans of the chest, abdomen and pelvis.

Treatment for testicular cancer is dependent on the type and stage of the cancer. Surgical removal of one or both testicles (orchidectomy) is usually performed for all cases of testicular cancer. The testis is then sent to pathology for confirmation of the type and stage of the cancer. Following surgery, chemotherapy and radiotherapy usually follow surgery to kill any remaining cancer cells which may be located in other parts of the body.

Treatment often leads to infertility, which is a major consideration in the management of the male in the pretreatment phase. For the male who may still want children,

possible sperm banking should be considered. The male should also be reassured that the condition should not affect their virility and should not affect their ability to achieve an erection. The individual may be referred to support services outside the hospital and should be educated in testicular self-examination. It is recommended that he carry out periodic examinations, as there is an increased risk of a second tumour occurring. It is important to reassure the individual that removal of one testis does not necessarily lead to a loss of sexual function and there are options, both medical and surgical, available to manage cosmetic abnormalities.

### Torsion of testis

Torsion of testis is a condition in which the testis becomes twisted around itself. It is more commonly seen in young athletic males after violent movement or trauma and may also occur due to abnormality of the male anatomy. The twisting results in obstruction of venous blood flow that may lead to infarction. If left untreated, necrosis and total lack of function may occur. The condition may present with severe pain, scrotal swelling and nausea and vomiting. Urgent medical attention is necessary to preserve the viability of the testis as permanent damage may occur within 4–6 hours of the torsion developing (Boettcher et al 2013).

### Hydrocoele

**Hydrocoele** is a painless collection of fluid within the tunica vaginalis of the testis from defective or inadequate reabsorption of fluid normally produced within the testis. The condition is fairly common in male infants where it is the most common cause of testicular swelling. In infants the accumulation of fluid is due to unhindered drainage from the abdomen, whereas in adult males it may be associated with infections, trauma or tumours. The individual may experience a feeling of heaviness or pain associated with increased scrotal size and may feel embarrassed because of the appearance of the scrotum.

Ultrasound and transillumination are diagnostic tests used to differentiate between hydrocoele and other causes such as tumours. If a hydrocoele is present, transillumination will allow transmission of light through the scrotum. Treatment is not usually required unless there is compromised testicular circulation. However, a scrotal support can be worn to increase comfort.

### Varicocoele

A varicocoele more commonly affects the left testis and occurs when the valves within the veins prevent blood from draining fully from the testis. This leads to pooling and swelling of the vein above the testis. **Varicocoele** is often described as a varicose vein of the spermatic cord. The individual will usually present describing their symptoms as a 'pulling' sensation, dull ache in the scrotum, pain and scrotal swelling. On palpation the scrotum feels like a 'bag of worms'. If left untreated, the condition can lead to a reduced sperm count, atrophy of the testis and can cause infertility. Treatment of a varicocoele can be either by surgery—the affected vein is ligated—or by an embolisation which can be performed under local anaesthetic. Post procedure the individual may require mild analgesics for discomfort and the intermittent use of ice packs to reduce swelling. Wearing a scrotal support can also reduce oedema and discomfort. Strenuous activity should be avoided until after review by the surgeon.

## Disorders of the prostate gland

### Prostatitis

**Prostatitis** is an inflammatory or infective condition of the prostate gland which may be bacterial (usually *Escherichia coli*). Up to 8% of males report experiencing urinogenital pain at some time in their lives; of these 15% suffer symptoms of prostatitis (Dickson 2013). It generally develops in association with an obstruction in the urinary tract in elderly males with prostatic hyperplasia, a urinary tract infection (UTI) or a sexually transmitted infection. Clinical manifestations include urinary symptoms of urgency, frequency, nocturia and dysuria. Bacterial prostatitis is characterised by sudden chills and a moderate to high fever. Pain in the perineum, rectum and lower back during ejaculation are other symptoms. Diagnosis is based upon urine, urethral and prostatic fluid cultures. Digital rectal examination frequently reveals a tender swollen prostate. Treatment of acute bacterial prostatitis is usually with an appropriate antibiotic and analgesic or, where an abscess has formed, the surgical drainage of the pus. Oral antispasmodic agents may provide relief from urinary frequency and urgency. The nurse can support the individual with comfort measures such as salt baths to relax the muscles of the pelvic floor. Stool softeners can reduce pressure on the prostate gland and are given as prescribed. Fluids should be encouraged to mechanically flush out the urinary tract. Repeated episodes of prostatitis may lead to scarring and thickening of the prostate.

### Prostatic hyperplasia

Prostatic hyperplasia is a widespread condition which increases with age, often occurring after the age of 40 years. The hormone testosterone stimulates the growth of the prostate resulting in it doubling in size between the ages of 21 and 50. The prostate gland will double in size again between the age of 50 and 80 years. In a majority of males the condition is benign, referred as benign prostatic hyperplasia (BPH). Hyperplasia of the prostate can compress the urethra laterally at the neck of the bladder which can impede urinary flow. Symptoms of BPH may be classified as either noticeable or obstructive (Table 37.3).

Noticeable changes begin as the prostate becomes progressively more enlarged and will eventually lead to a referral to a urologist for management. An International Prostate Symptom Score (IPSS) is a validated tool used to determine the need for therapy and treatment response (Table 37.4). (See Case Study 37.3.)

The cause of BPH is not well known. There has been some research suggesting there is a genetic or familial link. There has also been research which links old age and testosterone to the development of BPH as it is known that the condition occurs in the presence of testosterone.

**TABLE 37.3 | Symptoms of benign prostatic hyperplasia (BPH)**

| | |
|---|---|
| **Upper urinary tract symptoms—voiding** | • Weak stream<br>• Hesitancy<br>• Intermittency<br>• Abdominal straining<br>• Incomplete bladder emptying |
| **Upper urinary tract symptoms—storage** | • Frequency<br>• Nocturia<br>• Urgency<br>• Urinary incontinence |
| **Post-micturition symptoms** | • Sensation of incomplete bladder emptying |
| **Other** | • Perineal pain<br>• Dysuria<br>• Haematuria |

*(Adapted from Woo et al 2011; Andrology Australia 2015)*

Diagnosis of the condition is based on the symptoms and may include urinalysis to eliminate urinary tract infections, voiding analysis charts, ultrasounds, digital examination which detects changes in the surface of the prostate and blood tests such as a **prostate-specific antigen** (PSA) test which measures the level of PSA, a glycoprotein produced by the prostate gland. In the presence of BPH, the PSA levels may be raised. Biopsy of the prostate may also be performed. Biopsies are collected during a transrectal ultrasound (TRUS) which may also be used when there is a strong suspicion of prostate cancer.

Treatment options for BPH range from:

- No treatment
- Drug therapies
- Natural therapies
- Surgical intervention—transurethral resection of prostate (TURP), transurethral incision of prostate (TUIP), open or retropubic prostatectomy.

No treatment may in many cases be the best option where the symptoms are mild. It involves close monitoring of the condition. Drug therapy involves the use of medications to relax the muscles in the prostate gland, bladder neck and urethra (alpha blockers) or the use of medications to block the release of testosterone to help shrink the size of the prostate (alpha-reductase inhibitors). Some men may also try natural therapies or surgery if the condition is severe.

The type of surgery will depend on the size of the prostate, location of the enlargement, whether surgery on the bladder is also needed and the individual's age and physical condition. The most common surgical management for BPH is **transurethral resection of the prostate (TURP)**. Surgery relieves symptoms quickly, typically doubling the urinary flow within weeks. A fibre optic scope is passed through the urethra to the prostate. Using a tiny blade or an electric loop, the surgeon pares away the lining of the urethra and bits of excess prostate tissue to expand the passageway. After a TURP, the individual usually stays in hospital until the prostatic bed stops bleeding and they are able to void normally with minimal haematuria, which may be up to 48 hours. The individual should be educated on the importance of remaining well hydrated after removal of the urinary catheter to ensure they void regularly and do not develop retention due to a micro-clot in the urethral bed. Possible risks of surgery should also be provided to the individual prior to surgery, which may include erectile dysfunction, urinary incontinence, urinary tract infections and urethral strictures. Standards for recognising and responding to the deterioration of an individual in the healthcare setting should be accessible to assist in the effective management (Australian Commission on Safety and Quality in Health Care 2012; 2015). (See Case Study 37.4.)

Other approaches to management of the condition which usually have a shorter stay in hospital and recovery include:

- Laser therapy—green light prostatectomy
- Transurethral microwave therapy (TUMT)
- Transurethral needle ablasion (TUNA)
- High-intensity focused ultrasound (HIFU)
- Electrovaporisation (TVP)

### CASE STUDY 37.3

Stephan is an active 65-year-old man who has presented to his local health clinic with concerns about his ability to pass urine. When questioned he tells you that over the past month he almost always needs to get up at night with the sensation of needing to pass urine, but when he tries only a small amount of urine is passed and half the time he has the feeling of not completely emptying his bladder. Often Stephen's urine flow is weak, almost always stopping and starting. When you question Stephan further he admits the he usually needs to strain to begin urinating and feels the need to pass urine every couple of hours.

Using the IPSS chart provided how would you score Stephan? Does Stephan have a possible hyperplasia of his prostate?

### CASE STUDY 37.4

Peter, a 72-year-old male, has been admitted for a transurethral resection of the prostate gland. Peter first visited his doctor a week ago after noticing it was becoming increasingly more difficult to pass urine and he was only able to void small amounts with each attempt. Peter describes that he always feels as if he has a full bladder. What is likely to be wrong with Peter and what are his treatment options?

## TABLE 37.4 | International Prostate Symptom Score (IPSS)

| | Not at all | Less than 1 in 5 | Less than half the time | About half the time | More than half the time | Almost always | Score |
|---|---|---|---|---|---|---|---|
| **Incomplete emptying:** over the past month, how often have you had a sensation of not emptying your bladder completely after you finish urinating? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Frequency:** over the past month, how often have you had to urinate again less than 2 hours after you finished urinating? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Intermittency:** over the past month, how often have you found you stopped and started again several times when you urinated? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Urgency:** over the past month, how difficult have you found it to postpone urination? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Weak stream:** over the past month, how often have you had a weak urinary stream? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Straining:** over the past month, how often have you had to push or strain to begin urination? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Nocturia:** Over the past month, how many times did you most typically get up to urinate from the time you went to bed until the time you got up in the morning? | 0 | 1 | 2 | 3 | 4 | 5 | |
| **Total Prostate Symptom Score** | | | | | | | |
| | **Delighted** | **Pleased** | **Mostly satisfied** | **Neither satisfied or dissatisfied** | **Mostly dissatisfied** | **Unhappy** | **Terrible** |
| Quality of life (QOL) due to urinary symptoms. If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that? | | | | | | | |

*(Adapted from Woo et al 2011. © Copyright 2011,* The Medical Journal of Australia, *Reproduced with permission)*

Most of the newer treatment methods are based on destroying, vaporising or dissolving hyperplasia and can be done with little more than a local anaesthetic on an outpatient basis. While less invasive options usually allow individuals to go home on the day of the procedure, there is a possibility that symptoms will return.

**CRITICAL THINKING EXERCISE 37.2**

The average length of stay for the individual who has undergone a TURP is 24 to 48 hours. Individuals will usually be discharged with haematuria and moderate discomfort. For this reason, discharge education of the individual is important. What discharge information should you give the individual?

### Prostate cancer

Prostate cancer occurs mainly in males over the age of 50 years, tends to grow slowly and may have metastasised before it is detected. Prostate cancer is considered to be the most common diagnosis of cancer in Australia and the third most common cause of cancer death with 13% of cancer deaths in men during 2012 being due to prostatic tumour (AIHW 2015).

Initially the person with prostate cancer may be asymptomatic. When symptoms appear, they are often similar to those caused by BPH: difficulty urinating, a weak stream, a frequent urge to urinate, nocturia, painful or burning urination and haematuria. Because prostate cancer tends to metastasise to the bone, bone pain, particularly in the back, can be another symptom. Usually the younger the individual, the more aggressive the cancer. The two main methods of diagnosis include digital rectal examination and prostate-specific antigen (PSA) levels. A biopsy may also be taken if there is a high level of suspicion. A procedure called a **transperineal ultrasound** may be performed to collect biopsies. It involves the insertion of a probe into the rectum and collection of biopsies which are viewed in the laboratory and given a grading using the Gleason Score. Aggressive tumours will be rated between 8 and 10.

***Treatment*** Prostate cancer may be treated by radiotherapy, chemotherapy, hormone therapy (palliative) or by open prostatectomy. Surgery for prostatic cancer is often done for palliative reasons because of the late onset of symptoms resulting in the condition being in the late stages on diagnosis and metastases often already being present. Radiotherapy may be performed to reduce the size of the tumour. Alternatively, hormonal therapy may be used in the short term, which also reduces the size and slows the rate of tumour development. It is usually only successful while the tumour relies on hormonal levels to sustain itself; after time it will become independent and growth becomes rapid again.

***Prostatectomy*** Open prostatectomy may involve either a radical or a partial procedure. A radical prostatectomy is used for individuals who are in good health and less than 70 years. A prostatectomy for prostate cancer is considered to extend the life of the recipient an additional 10 years. The procedure can be performed using either a perineal or a retropubic approach. The retropubic approach involves an incision through the lower abdomen to remove the prostate and possibly the pelvic lymph nodes whereas the perineal approach requires an incision through the perineum. The retropubic approach is associated with a larger number of blood transfusions and longer operative times. By contrast with the perineal approach there is a reported higher level of impotence and incontinence with the retropubic approach.

Most prostatectomy procedures are performed using a laparoscopic approach which involves the use of a remotely assisted controller-subordinate system—the da Vinci® surgical system. This procedure is essentially robotic surgery which involves multiple, small incisions into the abdominal wall and the introduction of instruments required to perform the surgery.

Nursing management involves supporting the individual prior to surgery and maintenance of hydration and fluid status. An indwelling or suprapubic catheter may be necessary to establish and monitor urinary output. Bowel preparation may include drinking 2–3 L of a cathartic and administration of an evacuant enema. Postoperatively the nurse should maintain bladder irrigation and drainage, and monitor for clots and haemorrhage. Post-procedural and discharge education needs to take physical and psychosocial factors into consideration.

*Discharge education* After a radical prostatectomy, an indwelling urinary catheter (IDC) may remain in situ for about 2 weeks, so education of the individual should concentrate on care of the catheter including changing or emptying the leg bag and the importance of maintaining a high fluid intake to reduce the risk of clot formation.

## Systemic diseases and ageing

Sexual function declines with age even in healthy men. The period between sexual stimulation and erection increases, erections are less turgid and ejaculatory force and volume is less. Conditions such as diabetes mellitus, chronic renal failure and cardiovascular disease are believed to be linked to erectile dysfunction.

A thorough medical, sexual and psychosocial assessment should be undertaken. Urinalysis, full blood count and fasting serum glucose, creatinine, cholesterol, triglycerides and testosterone are recommended laboratory tests. Treatment depends upon the cause. It can include a variety of drug therapies, which may be administered via the oral, transurethral, subcutaneous or intracavernous injection route.

## Surgical procedures

### Vasectomy

A **vasectomy** is a surgical procedure commonly performed on males who have children and do not want to father any more. It is estimated that in Australia between 15 000 and 16 000 vasectomies are performed annually with 1%

performed for males under 25 years and 90% performed for males between 30 and 49 years of age (Woolcott 2014). A number of males (4–5%) will seek reversal of their vasectomy.

The procedure can be performed under general anaesthesia; however, a majority will be performed under local anaesthesia in a fertility clinic, day procedure unit or a general practice. The procedure involves a small incision being made either side of the scrotum and the ductus deferens being brought to the surface. Either a ligature is placed around the ductus deferens to seal off the passage of sperm past the blockage or, in the majority of cases, a small segment of the ductus deferens is removed and the ends diathermied to seal the ends.

There is usually no alteration to the male's ability to maintain a sexual relationship or the effectiveness of their erection. Ejaculation is still possible; however, there should be no sperm in the fluid as it will have been prevented from travelling past the epididymis where it is reabsorbed into the body. Postoperatively the male may have minor discomfort and swelling related to the procedure which settles after 24 to 48 hours. The wound heals quickly without the need for specialised care. The individual should be advised to abstain from unprotected sex until a clear seminal fluid analysis has been completed (between 6 and 12 weeks) which shows no evidence of sperm in the ejaculatory fluid. In a small number of cases the procedure may be unsuccessful and the individual may need to undertake further surgery.

## Assessment and diagnostic tests

Anxiety and embarrassment may be experienced during physical examination and discussion of his sexual history. A calm insightful approach is required, as is preservation of the person's individuality and dignity throughout. Cultural and religious customs such as circumcision should be considered.

### Examination of external genitalia

A complete history of the individual should be collected prior to any procedure. For the male who presents with a condition affecting their reproductive system, this history should concentrate on the presence of urinary problems and symptoms which suggest alteration in normal sexual function. It may be necessary to conduct a physical assessment of the male genitalia and inguinal canal which may detect or confirm the presence of penile discharge, tenderness, lesions, swelling, lumps or asymmetry.

### Testicular examination

**Testicular self-examination (TSE)** should be performed on a regular basis. The testes are examined for size, shape, symmetry and texture. It is important that both testes are checked at the same time (see Clinical Interest Box 37.1).

### Digital rectal examination

Digital examination of the prostate involves the insertion of a gloved finger inside the rectum to palpate the prostate. The examination detects the size, shape and firmness of the prostate through the wall of the rectum.

### CLINICAL INTEREST BOX 37.1 Individual teaching—testicular self-examination

- It is often easier to perform this examination after a warm bath or shower when the skin of the scrotum is relaxed
- It is important to check both testes at the same time
- Use the palm of the hand and support the scrotum (Note: it is not unusual for one testis to be slightly larger than the other)
- It is important to be familiar with the feel of the texture and size of the testis so you are able to detect reportable changes
- Roll one testis gently between the thumb and fingers to feel for lumps or swellings
- Repeat with the other testis. The surface of the testis should feel smooth and firm
- Use the thumb and fingers to feel along the epididymis for any swelling
- Even if you have had testicular cancer or are being treated, it is still important to perform a testicular self-examination as one in 25 men may develop testicular cancer in the other testis

*(Adapted from Andrology Australia 2015)*

### CLINICAL INTEREST BOX 37.2 PSA testing

Most research suggests PSA testing is not indicated in males 75 years or older unless there is a known diagnosis of cancer.

Results of the PSA test are usually resulted in ng/mL with levels of total PSA >4.0 ng/mL considered to be abnormal. The test may be repeated every 1–3 months if an abnormal result is reported.

*(Brett 2011, reprinted 2014)*

### Prostate-specific antigen test

This test measures the level of PSA which is a protein produced by cells of the prostate gland. The test is performed by taking a sample of blood and sending it for analysis. A high PSA is suggestive of a condition affecting the prostate but may not necessarily mean the individual has prostatic cancer. (See Clinical Interest Box 37.2.)

### Transrectal ultrasound (TRUS)

In transrectal ultrasound a small probe that emits and picks up high-frequency sound waves is inserted into the rectum. The reflected waves are detected and a visual image displayed on a monitor. The test does not provide sufficient information to make it a good screening tool by itself but is useful as a follow-up to a suspicious digital rectal examination or PSA test. It is also used to guide biopsies in sampling

abnormal areas of the prostate, to estimate the volume of the prostate for calculating PSA density and to position radiotherapy implants (Andrology Australia 2015).

### Biopsy

Biopsies of the prostate gland are usually performed in combination with the transrectal ultrasound to detect abnormal cells. A needle is inserted through the perineal skin and a quantity of prostate tissue is aspirated. Biopsy specimens of tissue are sent for cytological examination.

### Urethral culture

A small swab is inserted 3–5 cm into the urethra to obtain a specimen for microbiological analysis. A preliminary result of findings for this test will usually be available within 24 hours of collection, with a more definitive result after 48 hours.

### Semen analysis

A sample of semen is obtained and the sperm examined for motility, morphology, quantity and quality. The test requires the individual to provide a fresh sample of ejaculatory fluid which is sent for analysis as soon as possible after collection. Results of semen analysis are usually available within 24 hours.

### Urological tests

A series of tests may be performed to evaluate the urinary tract. These include cystoscopy, intravenous pyelogram, urine flow studies, urogram and ultrasound.

### Blood samples

Specific blood tests include hormone levels for infertility; alpha-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) for testicular cancer; and blood urea nitrogen (BUN), creatinine and urea to evaluate renal function.

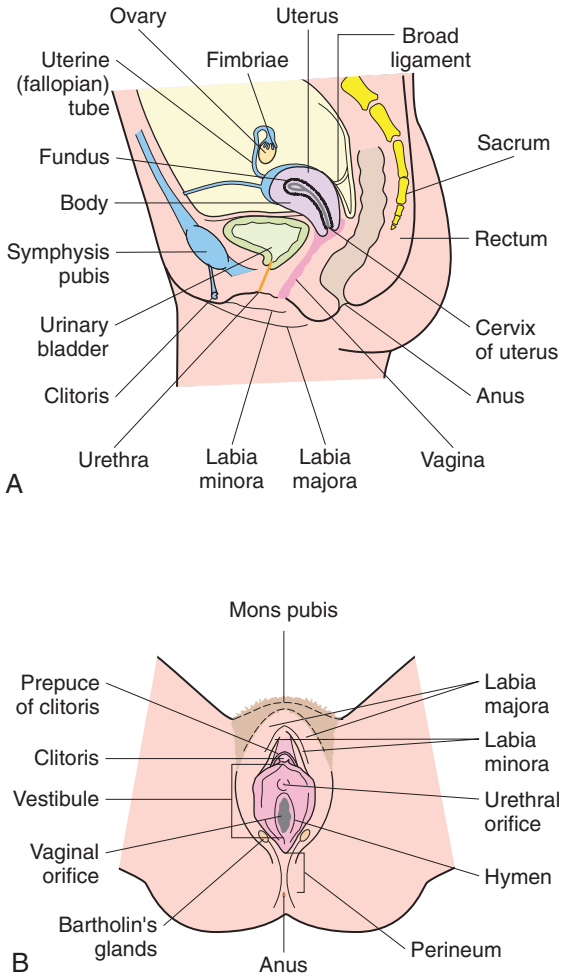

**Figure 37.3** A: The normal female reproductive system B: The vulva

## NURSING INTERVENTIONS IN MALE REPRODUCTIVE HEALTH

The man with a condition affecting his reproductive system would be expected to experience concerns about sexual function, fertility, urinary problems and the effects of the condition they are diagnosed with. The nurse should be aware of these concerns and provide supportive services such as counselling in their approach to care, provision of supportive services and the promotion of a healthy lifestyle.

## THE FEMALE REPRODUCTIVE SYSTEM

The female reproductive system (Figure 37.3) functions to secrete hormones, produce ova, receive sperm and allow for fertilisation, implantation, development and birth of the baby. The female reproductive system consists of essential and accessory organs.

The external structures of the female reproductive system include the mons pubis, labia majora, labia minora, Bartholin gland and clitoris. The area between the anus and vaginal opening is referred to as the **perineum**. Internal reproductive structures include the vagina, uterus, cervix, fallopian (ovarian) tubes and the ovaries.

### Oogenesis

The ovaries function to produce ova (**oogenesis**) and hormones. Production of ovarian hormones begins at puberty. Oestrogen influences the development of the female secondary sexual characteristics including changes in the breast, development of pubic and axillary hair, onset of menses and widening of the pelvis. Oestrogen is also responsible for preparing the uterus for the implantation of a fertilised ovum (see Clinical Interest Box 37.3).

### Mammary glands

Mammary glands are accessory glands of the reproductive system. The breast is a complex structure composed of a glandular and ductal network, fat, connective tissue, fascia, blood vessels, nerves and lymphatic vessels (Figure 37.4). Each breast contains 15–20 lobes that radiate around the nipple and are separated from each other by adipose tissue. Within the lobes are lobules that contain clusters of

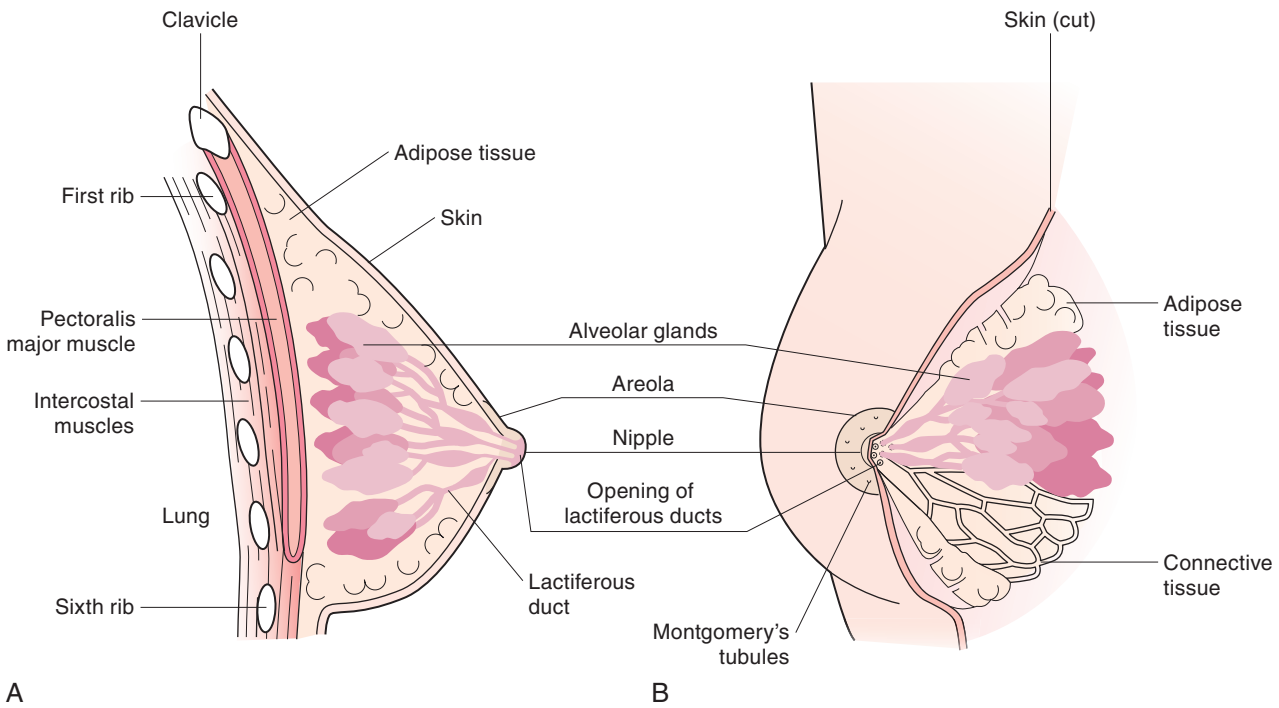

**Figure 37.4** The breast
A: Sagittal section B: Anterior section

## CLINICAL INTEREST BOX 37.3 Oogenesis

In utero, the fetus is thought to have 6–7 million oocytes. This number decreases to 1–2 million by the time of birth, and no further oocytes will be produced.

By puberty, the number of oocytes have reduced to 300 000. Of this number only 400 are believed to be released during a lifetime. Pre-menopause the number of oocytes drops further until nil remain by menopause.

*(Porter & Kaplan 2011)*

## CLINICAL INTEREST BOX 37.4 hCG levels

hCG levels are often used to confirm pregnancy, with levels increasing in the first trimester. Reference intervals for hCG can vary between different testing laboratories based on their numeric test result methods. Intervals can also vary dependent on age, gender and sample population. Ranges generally represent values in 95% of individuals in the 'normal' population.

*(Lab Tests Online 2015)*

milk-producing cells called alveoli. Lactiferous ducts drain the alveoli into openings in the nipple. Breast development at puberty is influenced by ovarian hormones. The mammary glands have the function of synthesising, secreting and delivering milk to the newborn, during which time the gland will reach 'a mature developmental stage through hormonal changes' (Hassiotou & Geddes 2013). After cessation of lactation, the breast will return to its normal 'resting' stage.

### The menstrual cycle

The menstrual cycle consists of a series of cyclic changes occurring at regular intervals, involving the reproductive organs. The average menstrual cycle is about 28 days but may vary from 24 to 35 days (Figure 37.5) and has three phases: follicular, ovulatory and luteal. Hormones produced during the menstrual cycle are summarised in Table 37.5. If fertilisation of an ova occurs a hormone called human chorionic gonadotropin (hCG) is produced which stimulates the corpus luteum to maintain progesterone levels until the fetus is capable of producing its own hormones. (See Clinical Interest Box 37.4.)

## DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

### Common symptoms

The symptoms most commonly observed in a female with a disorder of the reproductive system include bleeding, pain, vaginal discharge, pruritus, urinary problems and breast changes.

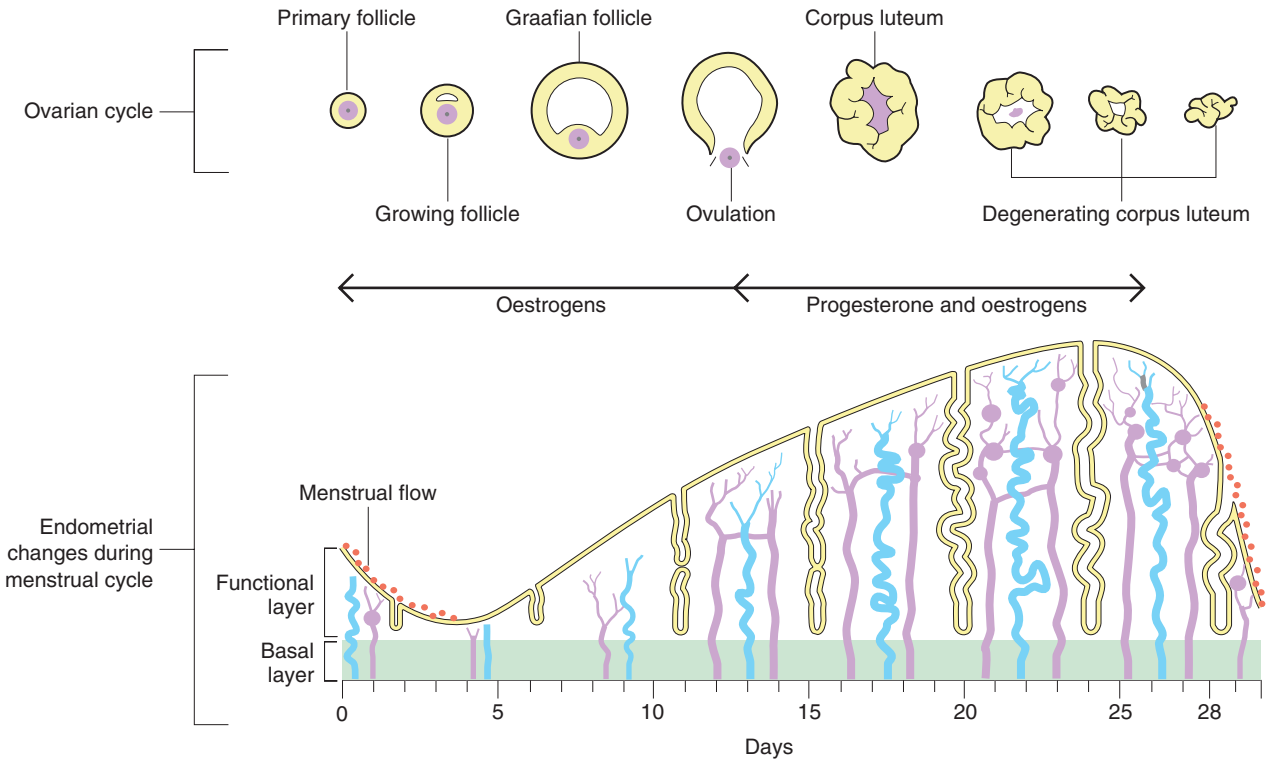

**Figure 37.5** The normal menstrual cycle

**TABLE 37.5 | Hormones affecting the menstrual cycle**

| Hormone | Secreted from | Function |
|---|---|---|
| FSH | Anterior pituitary | • Stimulates growth of follicle<br>• Stimulates oestrogen secretion from developed follicle |
| Oestrogen | Ovaries | • Development of endometrium<br>• Stimulates LH secretion |
| LH | Anterior pituitary | • Increase leads to ovulation<br>• Development of corpus luteum<br>• Stimulates progesterone secretion |
| Progesterone | Ovaries (corpus luteum) | • Thickens endometrium<br>• Inhibits LH and FSH |

*(IVF Australia 2015)*

## Bleeding abnormalities

**Amenorrhoea** is the absence of menstrual bleeding in women. It is normal before puberty, during pregnancy and after menopause. Primary amenorrhoea is considered the failure of menstruation by the age of 14–16 years. Secondary amenorrhoea generally results from anovulation due to hormonal dysfunction after menarche. In women of reproductive age, a diagnosis of amenorrhoea will usually only be made after first eliminating pregnancy as a possible aetiology.

**Oligomenorrhoea** is a condition where menses occurs at intervals longer than 35 days apart. Common reasons may be due to the lead up to menopause, following childbirth or after cessation of a pregnancy due to miscarriage or termination. It may also be a symptom of an underlying condition and should be investigated.

**Menorrhagia** is excessive and/or prolonged bleeding associated with erosive lesions, endometrial hyperplasia, bleeding disorders or neoplasms (tumours). Post-menopausal bleeding may result from the administration of oestrogen (hormone replacement therapy (HRT)), from an oestrogen-producing ovarian neoplasm, uterine hyperplasia, carcinoma or vaginitis. Metrorrhagia, or intermenstrual bleeding, can occur at the time of ovulation, or it may be due to factors such as hormonal imbalance or neoplasms.

### Pain

Pain may occur as **dysmenorrhoea** (painful menstruation) which is the most commonly experienced type of pain in women with prevalence between 16% and 91% of women of reproductive age. Between 2% and 29% of women will experience severe pain (Hong et al 2014). Pain may be described as intermittent, cramping lower abdominal pain, and it can radiate to the back, thighs and groin. Dysmenorrhoea can have a primary cause where pain occurs with no underlying pathological pelvic disease and is generally seen in women 20 years old when menstrual cycles have been established. Secondary dysmenorrhoea occurs when there are underlying pelvic conditions such as endometriosis, uterine fibroids or pelvic inflammatory disease (PID) and is usually in women over 20 years of age (Lentz et al 2012).

Pain may occur in the lower back due to menstruation, infection, inflammation or neoplasm and may be due to conditions such as torsion of an ovarian cyst or a ruptured ectopic pregnancy. If blood from the ruptured fallopian tube tracks to the diaphragm and stimulates the phrenic nerve, shoulder-tip pain may be evident.

Sexual intercourse may result in pain (**dyspareunia**), which is the result of conditions such as vaginal or vulval infections, endometriosis, neoplasms or PID. Decreased vaginal lubrication may also result in dyspareunia.

### Vaginal discharge

Normal vaginal discharge should be clear or white. An offensive odour or changes in the character or amount of discharge may be suggestive of an underlying problem of the vagina or cervix.

### Pruritus

Pruritus is an irritating symptom suggestive of inflammation, vaginal infection or possibly contact dermatitis.

### Urinary problems

Urinary problems associated with female reproductive problems are common and often present as dysuria, stress incontinence caused by infection, neoplasm and cystocele.

### Breast changes

Changes may occur in breast tissue which may present as pain or tenderness in the breast, a discharge from the nipple, inversion of the nipple or the presence of lumps.

## Vulval and vaginal changes

The adult vagina is generally very resistant to infections due to the presence of a characteristic normal flora which creates an environment which is unsuitable for the growth of most microorganisms. When the normal balance of the vagina's pH is disturbed, which may occur with certain medications, diseases and debility, it becomes predisposed to infections.

### Vulvovaginitis/vaginitis

Vulvovaginitis is inflammation of the vulva and vagina. Causes of vaginitis include infection, vaginal mucosal atrophy, vulval atrophy, chemical irritants and poor personal hygiene. Yeast infection results from the presence of *Candida albicans* in mucous membranes and on the skin. Under certain circumstances overgrowth and infection can occur. Predisposing factors include diabetes mellitus, pregnancy, broad-spectrum antibiotic therapy and the use of oral contraceptives. Clinical indicators include pruritus and a thick, white vaginal discharge. Haemophilus vaginitis is caused by the bacterium *Haemophilus vaginalis*. Sexually transmitted infections (STIs) such as gonnorhoea, chlamydia and trichomoniasis are often characterised by vaginitis.

### Candidiasis (thrush)

It is estimated that approximately 75% of women will experience the symptoms of a thrush infection at least once in their lifetime. Half of these women will have more than one episode and 5% will be diagnosed with recurrent thrush (Foran 2013). Thrush hardly ever occurs in females before the onset of menses.

**Candidiasis** is caused by an overgrowth of a yeast-like fungal organism. In 85% of cases the causative organism will be *Candida albicans* (Foran 2013). The condition is characterised by pruritus, vaginal and vulval redness, a thick, white or creamy vaginal discharge and discomfort and pain during sex. Treatment may include the use of anti-fungal medication, probiotics and good hygiene practices.

**CRITICAL THINKING EXERCISE 37.3**

Thrush can develop due to conditions such as diabetes, stress and different medications including antibiotics, immunosuppressive therapy and contraceptives. How would you educate the individual on how to prevent thrush?

### Genital herpes

Genital herpes is an infection caused by the herpes simplex virus and is transmitted through vaginal, oral or anal sex. Genital herpes is characterised by flu-like symptoms and painful blisters in the genital area within 2–14 days of exposure. (See Case Study 37.5.)

**CASE STUDY 37.5**

Susie is 18 years old and has only recently become sexually active. After a one-night stand at a party 3 weeks ago she has presented to the medical clinic with a history of discomfort and itchy labia. The doctor performed a physical examination and discovered five small lesions on her labia, each the size of 5-cent piece.

1. Should Susie try to contact the person she had a one-night stand with?
2. What tests would the doctor order to confirm diagnosis of Susie's condition?
3. How would Susie's condition be managed?

### Genital warts

Genital warts are caused by particular types of the human papilloma virus (HPV) and are transmitted through vaginal, oral and anal sex. The warts appear on the vulva, clitoris and cervix, inside the vagina and urethra and in or around the anus. HPV is linked to cervical cancer; participation in the Australian Cervical Screening Program has led to halving of cervical cancer incidence and mortality rates (Budd et al 2014).

In 2007, Australia introduced a HPV vaccination program in schools capturing females aged 12–13 years. In the first 5 years of the program the incidence of HPV declined by 90% (PapScreen Victoria 2011). The vaccination protects against both the most common high- and low-risk HPV types and is generally well tolerated. To be fully protected against HPV, the vaccination needs to be administered as three injections over 6 months. If a pre-existing HPV infection exists the vaccine is not considered helpful. The vaccine is also offered to boys via the school-based program.

## Disorders of the internal reproductive organs

### Pelvic inflammatory disease (PID)

Pelvic inflammatory disease (PID) is any acute, sub-acute, recurrent or chronic infection of the uterus and uterine tubes that can extend into the pelvic cavity. Causative organisms of PID include *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Symptoms of PID may include pain, discharge and pyrexia. Treatment tends to be symptomatic with the use of antibiotics, analgesics and antipyretics. Nursing care of the woman with a PID includes education to ensure regular perineal hygiene is observed, regular changing of pads where vaginal discharge is present and counselling about the potential complications of PID which include chronic abdominal pain, ectopic pregnancy and infertility. The impact on fertility may be significant if the woman is planning to have children (see Case Study 37.6).

#### CASE STUDY 37.6

Casey is a 21-year-old female who has been admitted to the ward complaining of lower abdominal pain which has been present for the past 10 days and is increasing. On admission she reveals that she went to a party with a boyfriend 2 weeks ago and had unprotected sexual intercourse. She describes a vaginal discharge which is heavy and has an odour. Casey also describes a desire to pass urine frequently along with pain and burning on urination. She has already conducted a home pregnancy test which was negative.

1. What do you think may be causing the lower abdominal pain?
2. What signs and symptoms above are suggestive of your decision?
3. What nursing management and tests would you recommend?

## Disorders of the uterus

### Endometriosis

**Endometriosis** is a common condition found in approximately 10% of women between the ages of 20 and 40 years (Shadbolt et al 2013). It is characterised by the presence of functioning endometrium outside the lining of the uterus, usually confined to areas in the pelvic cavity. The cause is unknown, but research suggests that some endometrium is expelled from the uterus into the pelvic cavity at the time of menstruation.

The symptoms of endometriosis are dependent on the location and the extent of the tissue affected. In mild cases the condition may be asymptomatic or there may be only slight discomfort or pain during menstruation. In severe cases there may be dysmenorrhoea, dyspareunia, menorrhagia, dysuria, diarrhoea or constipation, abdominal distension, premenstrual tension and infertility. The use of the oral contraceptive pill (OCP) has been found to protect against the development of endometriosis. The OCP may also be used to manage the condition by altering the menstrual cycle through hormonal manipulation (Black & Fraser 2012). The aim is to produce a pseudo-pregnancy, pseudo-menopause or persistent anovulation, thereby creating an environment in which the endometrium does not grow or is not maintained. The ectopic endometrial tissue will not be subject to the normal menstrual cycle stimulation and the pain associated with endometriosis will be diminished.

Surgical treatment is also widely used to treat endometriosis. The conservative option is removal of all obvious ectopic endometrial implants from the abdomen and pelvis. A laparotomy or laparoscopy is performed, with the latter approach having a lower cost and recovery time. Endometrial tissue is destroyed using a variety of techniques, including vaporisation or excision. Surgery to remove all endometrial tissue involves removal of the ovaries and sometimes the uterus. Treatment for endometriosis is aimed at the ectopic implants but the symptoms can be managed directly. Non-steroidal anti-inflammatory drugs have proved to be of benefit as first-line treatment. Surgical intervention to interrupt neural pathways for pain conduction may be of benefit in selected cases. Doctors have also recommended that women with endometriosis should become pregnant as the altered hormone levels and not having a menstrual cycle for 9 months have in some cases been successful in reducing the symptoms.

#### CRITICAL THINKING EXERCISE 37.4

A laparoscopic hysterectomy may be performed when non-surgical options have not been successful in treating endometriosis. Length of stay in hospital is usually 2 to 3 days. What discharge considerations should you educate the individual on prior to them going home?

### Pelvic organ prolapse

Pelvic organ prolapse is characterised by the downward displacement of pelvic organs, mostly the uterus, urinary bladder

and rectum through the vaginal opening and will probably affect up to 50% of the women, with 19% requiring surgical interventions to manage symptoms (Liang 2014).

Uterine prolapse occurs when muscles and ligaments that suspend the uterus become stretched, damaged or weakened through sustained forces brought about by events such as pregnancy and straining. These muscles and ligaments no longer provide the support to prevent the uterus from falling into the vagina. The collapse can be either a complete collapse where it protrudes outside the body, or partial (Table 37.6). (See Clinical Interest Box 37.5.)

Risk factors for uterine prolapse include:

- Pregnancy
- Vaginal delivery
- Large fibroids or tumours
- Ageing and menopause
- Obesity
- Chronic coughing, constipation and straining
- Heavy lifting
- Genetic conditions
- Previous pelvic surgery
- Spinal cord and other muscle atrophy conditions
- Familial or racial history (Liang 2014).

Depending on the stage of prolapse, women will experience symptoms of the condition ranging from backache, a 'dragging' sensation and cervical erosion to bleeding and urinary difficulties. Stress incontinence is a common problem experienced by women and may lead to urinary tract infections. Where the posterior aspect of the urinary bladder protrudes into the uterus (cystocele), there may be a feeling of pelvic pressure and where the rectum herniates into the uterus (rectocele) there is often a feeling of rectal fullness, faecal urgency and incomplete defecation.

Management of the condition may be conservative or surgical. Where the condition is managed conservatively, the woman may be required to perform a series of pelvic floor exercises to strengthen the pelvic floor muscles. Exercises consist of regular tightening then relaxation of muscles surrounding the entrance of the vagina, urethra and anus. Each time the muscle is tightened it is held for 5–10 seconds and then relaxed. The exercise is repeated a number of times and the woman is encouraged to repeat the exercises several times a day. There are devices like balls which can be inserted into the vagina to ensure the exercises are being performed correctly.

Surgical management of uterine prolapse includes procedures such as a hysterectomy using either the vaginal or the abdominal approach and a procedure called a sacrohysteropexy which involves an abdominal incision and insertion of a mesh to reinforce and strengthen the abdominal muscles.

**TABLE 37.6 | Stages of uterine prolapse**

| Stage | Results |
|---|---|
| I | Descent of the uterus to any point in the vagina above level of the hymen |
| II | Descent of uterus to level of hymen |
| III | Descent of uterus beyond hymen |
| IV | Total eversion of procidentia |

*(Adapted from Kuncharapu et al 2010)*

**CLINICAL INTEREST BOX 37.5**
**Clinical scenario uterine prolapse**

*I first experienced symptoms of my prolapse after my second child. It started with passing a little bit of urine when I laughed too much and then I noticed that it was the same if I lifted anything too heavy such as the shopping bags or the basket of washing. I thought it would get better. I did some pelvic floor exercises that I read about in a pamphlet and for a while it did. It was after a day of gardening that I noticed my body didn't seem to feel the same. When I went to see my doctor she told me my uterus had prolapsed and I would need to see a specialist to have it repaired. They had to do a complete pelvic floor repair involving my bladder and uterus. It's fine now but I think I was lucky. I have heard other women have to have a hysterectomy and are left with residual incontinence problems.*

## Disorders of the ovaries

### Ovarian cysts

Ovarian cysts are usually non-cancerous and develop in women of reproductive age when an ovarian follicle fails to burst and release the mature egg, resulting in the accumulation of a fluid-filled sac. Cysts can be either single or multiple small cysts developing about 10 mm in diameter, although they have been known to grow to about 6–7 cm in diameter. They are filled with a clear fluid which is high in oestrogens. In many cases the cysts remain asymptomatic; however, if they rupture they can cause severe abdominal pain and bleeding. Other symptoms may include haemorrhage, torsion and compression of abdominal and pelvic organs depending on size. Diagnosis can be made by pelvic examination, ultrasound, CT scan, MRI scan and possibly a blood test for tumour markers. Generally the cysts resolve without the need for treatment but a small number of women may require surgery (laparoscopy and/or laparotomy).

### Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is a common hormonal condition affecting 12–18% of women of reproductive age, with 21% of those affected being in the high-risk category (e.g. Indigenous women (Jean Hailes 2014)). PCOS is often associated with the presence of multiple, large cysts in the ovary which may cause health complications if left untreated.

Most symptoms associated with PCOS are caused by increased androgen levels in the body. Many women will experience difficulty maintaining an optimal weight and there may be fertility issues and psychological effects, due to either hormonal imbalance or anxiety related to infertility. (See Table 37.7.)

## Tumours of the female reproductive system

### Ovarian cancer

Ovarian cancer is the seventh most common cause of cancer mortality in Australian women (Budd et al 2014).

Tumours affecting the ovaries can vary in their size, diversity and occurrence (see Table 37.8). This is one of the more common of the cancers affecting women. Both germ cell and sex cord–stromal cell tumours respond well to treatment and are often curable. If only one ovary is affected and therefore removed there is a good chance the woman will still be able to have children.

In 2014 it was estimated that approximately 1470 Australian women would be diagnosed with ovarian cancer; an estimated 1640 are expected to be diagnosed in 2020 (AIHW 2014). Diagnosis of ovarian cancer is definitively made only after surgery during which biopsies and removal of a frozen section are performed to determine the presence of cancer cells. The woman may have a transvaginal ultrasound (TVU) and blood taken to detect the presence of the tumour marker CA125. It may be possible to detect irregularity on palpation of the abdomen or physical examination if the tumour is large. TVU, which involves the use of a probe inside the vagina to detect the presence of a tumour, and other imaging tests such as abdominal x-rays, CT scans or magnetic resonance imaging (MRI) are occasionally used.

Diagnosis of ovarian cancer is difficult due to its vague presentation. For this reason most cases of ovarian cancer present as advanced tumours with a survival rate of less than 20%. If detected early the survival rate can be greater than 90%.

Symptoms of ovarian cancer include:

- Abdominal and pelvic pain
- Increase in abdominal size or persistent abdominal bloating
- Urgency and frequency of urination
- Feeling of fullness after eating
- Changes in bowel habits
- Unexplained weight loss or gain
- Unexplained bleeding
- Excessive fatigue
- Back pain
- Indigestion and nausea (Ovarian Cancer Australia 2014).

**TABLE 37.7 | Symptoms related to PCOS**

| Symptom | Management |
|---|---|
| Irregular menstrual cycles | Use of hormonal contraception such as:<br>• Low-dose oral contraceptive pill<br>• Progesterone (such as an IUD)<br>• Hormonal implants<br>• Vaginal contraceptive rings<br>• Insulin-sensitising medications such as metformin (where women develop symptoms associated with insulin resistance) |
| Excess hair growth | • Waxing, laser hair removal, electrolysis<br>• Reduce androgen levels in the body<br>• Hormonal contraception<br>• Insulin-sensitising medications such as metformin |
| Acne | • Medications such as topical creams, antibiotics, Roaccutaine, insulin-sensitising medications<br>• Reduce androgen levels in the body (hormonal contraception, anti-androgen medications) |
| Infertility | • Weight management<br>• Monitor ovulation<br>• Ovulation induction |
| Psychological effects | Depression and/or anxiety related to difficulty getting pregnant, miscarriage, symptoms associated with PCOS and hormonal imbalance |

*(Adapted from Jean Hailes 2014)*

**TABLE 37.8 | Types of ovarian cancer**

| Type | Clinical behaviour |
|---|---|
| Epithelial | Most common type of ovarian cancers. Accounts for 90% of cases |
| Borderline tumours | A group of epithelial tumours which are not as aggressive as other epithelial tumours. They are often referred to as 'low malignancy potential' (LMP) tumours. Prognosis is good regardless of when diagnosed |
| Germ cell tumours | Begin in cells that mature into eggs. Account for 5% of tumours and more commonly in women under 30 years |
| Sex cord–stromal cell tumours | Begin in ovarian cells that release female hormones. Account for 5% of cases and can affect women at any age |

*(Ovarian Cancer Australia 2014)*

Treatment for ovarian cancer may initially involve a laparotomy where biopsies are taken and sent for analysis to confirm diagnosis. On confirmation of diagnosis, the surgeon will remove the affected ovary. Where the tumour has spread to affect other structures, it may be necessary to perform a partial or total hysterectomy.

## Cervical cancer

Cervical cancer is relatively uncommon affecting approximately 1.7% of Australian women. Since the introduction of the Cervical Screening Program in 1991 (Clinical Interest Box 37.6), the incidence and mortality associated with cervical cancer was shown to have halved by 2006 (Cancer Australia 2015b). Cervical cancer may be one of two types: a squamous cell carcinoma, which accounts for approximately 80% of cases, or an adenocarcinoma.

Cervical cancer begins as a change in the epithelial covering of the cervix and, if not treated, eventually involves the epithelial layer. Invasive carcinoma extends beyond the surface, involves the body of the cervix and may spread via the lymphatic system to surrounding structures. Clinical signs of cervical cancer do not appear in the early stages. Later manifestations are 'spotting' between menstruation, postmenopausal bleeding, bleeding after sexual intercourse or a brown vaginal discharge.

Diagnosis of cervical cancer can initially be made with a routine Pap smear combined with presenting symptoms. The stages of cervical cancer are described in Table 37.9.

## Endometrial cancer

It is estimated endometrial cancer, also referred to as uterine cancer, will affect 2830 Australian women by 2020 (AIHW 2012a). It is most common in menopausal women; however, a quarter of cases may occur in premenopausal women.

The benign form presents as **fibroids** which grow in the wall of the uterus of women in their forties. They are usually asymptomatic and as the woman enters menopause the fibroids tend to get smaller. If they cause heavy bleeding they may need to be surgically treated. Other presentations may be as endometriosis and endometrial hyperplasia.

The usual management for women who have malignant neoplasms (cancers) is surgical intervention with a combination of chemotherapy and radiotherapy to eliminate any remaining cancer cells. The typical surgical procedures conducted include:

- Hysterectomy with bilateral salpingo-oopherectomy
- Pelvic lymphadenectomy (unless early-stage disease present)

Vaginal vault brachytherapy may also be performed for endometrial cancer. This involves insertion of small hollow tubes inside the vagina through which small amounts of radioactive agents are administered. The treatment takes approximately 30 minutes to perform.

Hysterectomy is the surgical removal of the uterus and may also involve the removal of other structures depending on the extent of infiltration or damage to reproductive organs. Prior to any woman undergoing a hysterectomy, it is important they are aware they will no longer menstruate or be able to conceive a child. For some this prospect may bring relief, while for others it may be distressing. A compassionate approach to nursing care is important.

The main four types of hysterectomy operations (see Table 37.10) performed in Australia are:

1. Sub-total or partial hysterectomy: involves removal of fallopian tubes, upper two-thirds of uterus and preservation of cervix. Not commonly performed in Australia
2. Hysterectomy with ovarian conservation: involves removal of fallopian tubes, uterus and cervix and preservation of the ovaries. Procedure is often referred to as a 'total hysterectomy'
3. Hysterectomy with oopherectomy: involves removal of fallopian tubes, uterus and cervix and either one or both ovaries
4. Radical or Wertheim's hysterectomy: involves removal of fallopian tubes, uterus, cervix, ovaries, nearby lymph nodes and upper portion of the vagina.

With all types of hysterectomy it is important the woman is fully aware of the procedure to be performed and the

### CLINICAL INTEREST BOX 37.6 National HPV vaccination program

In April 2007 the Australian government commenced the National HPV Vaccination Program. The program is offered to school-age females 12–13 years of age and males 14–15 years of age. Initially the program also offered the vaccine free for girls and young women aged between 14 and 26 years.

Young women not in school and under 27 years were provided access to the vaccination through their GP.

The vaccine is given in a series of three injections, spread out over a 6-month period, at 0, 2 and 6 months.

*(Australian Government, 2014b. © Commonwealth of Australia)*

**TABLE 37.9 | Cervical cancer stages**

| | |
|---|---|
| Stage 1 | The cancer is found only in the tissue of the cervix |
| Stage 2 | The cancer has spread outside the cervix to the upper part of the vagina or other tissue next to the cervix |
| Stage 3 | The cancer has spread to the tissue on the side of the pelvis (pelvic sidewall) and/or the lower part of the vagina |
| Stage 4 | The cancer has spread to the bladder or rectum, or beyond the pelvis to the lungs, liver or bones |

*(Cancer Australia 2015b)*

**TABLE 37.10 | Types of hysterectomy**

| Surgery | Description of procedure | Advantage | Disadvantage |
|---|---|---|---|
| Vaginal hysterectomy | An incision is made into the upper portion of the vagina and the uterus is removed through the vagina | Less pain and shorter hospital stay; absence of a visible scar | Does not allow free access to pelvic organs<br>If fibroids are large or there is extensive endometriosis, uterus is difficult to remove; may need to change to an abdominal approach |
| Abdominal hysterectomy | Can be performed using a 'bikini-line' approach or via a vertical incision which is from umbilicus to pubic hairline | Less obvious scar associated with the bikini-line approach and a shorter recovery time<br>Main advantage of procedure is the lower incidence of damage to urinary tract and blood vessels<br>Allows good vision of pelvic structures and possible repair of prolapse at same time<br>Allows removal of large uterus, fibroids | A more painful approach and requires a longer hospital time<br>Costs more than a vaginal hysterectomy<br>Leaves a visible scar on the abdomen if vertical approach |
| Laparoscopically assisted vaginal hysterectomy (LAVH) | Part of the procedure is performed using a laparoscope which involves four small incisions into the abdomen | Shorter hospitalisation and possibly recovery time compared to other procedures | May lead to longer operation time depending on how much of procedure performed by laparoscope<br>Higher risk of damage to urinary tract<br>May need to change to an abdominal approach if uterus/fibroids are large |

*(Women's Health Queensland Wide 2011)*

implications associated with the surgery. There may be issues with feelings of altered self-image, loss of femininity and sexuality. The woman may need counselling to help her work through these feelings. The surgical procedures have a long convalescence postoperatively; the individual is unable to return to normal activities for anywhere between 6 weeks and 3 months. It is also important the woman be aware of what to expect in the immediate postoperative phase, such as whether she will have an indwelling catheter, drain tubes or vaginal pack.

A vaginal pack may be inserted after a vaginal hysterectomy and remains in situ for 24 hours. Postoperatively the nurse is required to assess the volume of discharge from the vagina and if there are any difficulties with voiding. If a urinary or suprapubic catheter has been inserted during the operation it may be necessary to commence bladder retraining prior to the removal of the catheter to assist in re-establishing normal bladder sensation and control.

## Conditions affecting menstruation

At some time in a woman's life she is likely to experience some form of benign menstrual problem which will often be painful and debilitating. The main menstrual symptoms include dysmenorrhoea, dyspareunia, menorrhagia and pain.

### Premenstrual syndrome

This is a term used to describe the symptoms experienced by some women in the lead-up to the onset of menstruation. The common symptoms experienced in the 4–7 days before menstruation include transient fluid retention, which may result in oedema in the legs, fingers and abdomen; breast tenderness; headaches and mood swings.

### Menopause

Menopause is often described as the 'change of life' and signals the end of a woman's reproductive life. During menopause eggs are no longer produced by the ovary and the production of oestrogen and progesterone ceases. In most women, menopause will occur between the ages of 45 to 50 years. Premature menopause occurs from 40 years and may occur due to a cessation of ovarian function, after a total hysterectomy or as the result of cancer. A woman is considered to be post-menopausal when 12 consecutive months without a menstrual cycle have elapsed.

The premenopausal woman often describes symptoms such as irregular periods, hot flushes, high sweats, palpitations, vaginal dryness, tiredness, mood swings and crawling sensations of the skin. The woman who believes she is premenopausal can have the diagnosis confirmed with blood tests to determine declining hormone levels. The management of menopause is often determined by the impact of symptoms. Many women try natural therapies such as black cohosh, vitamin E, dong quai, licorice and evening primrose to manage the symptoms. Alternatively, women may commence hormone replacement therapy (HRT) (see Case Study 37.7 and Clinical Interest Box 37.7).

## Disorders of pregnancy

### Spontaneous abortion

Spontaneous abortion is common, with approximately one in four pregnancies resulting in an abortion in the very early stages of a pregnancy. They often occur without the woman being aware of what is occurring. In the event that the abortion is incomplete and products of conceptions are retained in the uterus, there is a high risk of infection and this situation needs to be managed surgically to preserve the integrity of the uterus and to avoid infertility.

### Ectopic pregnancy

An ectopic pregnancy occurs where the fertilised ovum implants outside of the uterus. A majority of ectopic pregnancies occur in the fallopian tubes, with only a small number in locations such as the abdominal cavity or ovary. Generally ectopic implantation occurs where the woman has a disorder that slows the passage of the ovum to the uterus such as scarring, endometriosis and tumours. In the initial stages the woman's pregnancy will show normal signs of conception with amenorrhoea and hormonal changes; however, as the fetus develops, spotting and cramping may develop and the fallopian tube will rupture, resulting in severe pain and abdominal swelling. Once the tube has ruptured it is considered a surgical emergency if the woman is to survive the rapid blood loss and shock.

### Pre-eclampsia

Pre-eclampsia occurs in a small percentage of pregnancies. The condition usually presents with three characteristic signs: generalised oedema, hypertension and proteinuria. It usually develops about the 20th week of pregnancy. If detected, mild symptoms may be controlled with little risk to fetus or mother; however, in the event that symptoms become severe a multidisciplinary approach to management of both mother and baby is required.

## Breast disorders

The main disorders affecting the breast are:

- Mastitis
- Fibrocystic changes
- Tumours.

### Mastitis

**Mastitis** is an inflammatory condition which usually occurs during lactation and breastfeeding, when the infant causes damage to the nipple of the breast allowing entry of bacteria which causes an infection in the ducts of the breast. Most commonly the causative organism is *Staphylococcus aureus* and *Streptococcus* spp. Presentation of the condition includes inflammation, swelling, heat and pain. The infective process may cause abscess formation and cessation of milk flow. Treatment may include the use of cold compresses and antibiotics and, where an abscess is present, possible drainage of fluid (see also Chapter 45).

### Fibrocystic changes

Fibrosis of the breast is a benign condition caused by hyperplasia of the fibroblasts in breast tissue. Women between 30 and 40 years are more commonly affected and the condition is usually detected as a tender or painful mobile lump often felt just prior to menstruation. The condition is not believed to predispose the woman to cancer.

Cystic changes of the breast occur more commonly in women during the last half of their reproductive life (between

### CASE STUDY 37.7

Anna is a 50-year-old woman who has noticed over the past 4 months an increase in 'sweats and chills'. On further questioning she reveals she has observed increased emotional lability over the past couple of months—crying unexpectedly, feeling depressed and tired all the time. Anna has also noticed her periods have become irregular in the past 12 months. On occasions her periods are heavy, whereas in other months they are very light. She also states that some months she will miss menses. There has also been a loss of sexual drive, with dryness and decreased libido.

1. What tests would be ordered to confirm Anna's medical diagnosis?
2. How could Anna manage her problem non-pharmacologically and pharmacologically?

### CLINICAL INTEREST BOX 37.7
### Clinical scenario: menopause

*The hot flushes started when I was about 42 years old. They were infrequent and passed quickly so I didn't worry too much. It was another 5 years before I started to see changes in my normal menstrual cycle. There were months where I didn't get a period at all or they would alternate between heavy to a light flow of blood. I spoke to my doctor and she ran a few tests that confirmed my hormone levels were lower. It was probably another few years before I decided to start hormone replacement therapy.*

40 and 55 years) and are characterised with single or multiple lumps in the breasts. Each cyst is filled with a thin turgid fluid and, if large, may be visible as a bluish lump under the skin. Each cyst can be drained and the fluid analysed to determine malignancy.

### Tumours of the breast

Carcinoma of the breast usually occurs in women over the age of 50 years, although it may also be diagnosed in younger women. The woman may notice an alteration in the size of the breast, dimpling of the skin, a palpable mass and alteration in the shape, retraction of the nipple, a clear discharge and possibly ulceration (Clinical Interest Box 37.8). It should be noted that carcinoma of the breast can also occur in males. The incidence of breast cancer is steadily increasing with a recorded death rate in 2012 of 2795 women and 24 men (AIHW 2012b). Of the women diagnosed with breast cancer, there is a 5-year survival rate of 89%.

Possible causes of breast cancer include:

- Increasing age
- Familial history
- Inheritance of mutation gene (BRCA2, BRCA1 or CHEK2)
- Exposure to female hormones
- Obesity
- Excessive alcohol consumption.

**CLINICAL INTEREST BOX 37.8**
**Symptoms of breast cancer**

- Lump or thickening in breast or under arm
- Sore nipples
- Discharge from nipple
- Inversion of nipple
- Dimpling of breast tissue
- Rash or redness of the breast
- Pain is rare

*Cancer Australia 2015c*

Diagnosis of breast carcinoma will initially involve a physical examination of the breast and armpits, a diagnostic mammogram and possibly an ultrasound of the breast tissue. More definitive or invasive tests may be conducted to confirm diagnosis and may include:

- Fine-needle aspiration
- Core biopsy
- Open biopsy
- Hormone tests
- Lumpectomy.

## Care of the individual with a breast disorder

Surgical treatment of breast carcinoma may include a total mastectomy where the entire breast is removed along with lymph nodes from the axilla, or a more conservative approach may be taken—breast-conserving surgery, where the bulk of the breast tissue is conserved. Surgery is usually accompanied by radiotherapy and chemotherapy to eliminate any remaining cancerous cells.

Breast surgery may cause issues with body image, feelings of femininity and sexuality. While reconstructive surgery may be performed, this is often not an option until several months after the mastectomy. Reconstructive surgery involves the formation of a breast mound, nipple and areola. A prosthetic in the woman's bra may be used in the interim to give the appearance of a normal breast. Surgical reconstruction of the breast may be considered at a later date. Hormone therapy may also be indicated to reduce the size of the breast lump prior to attempting a surgical approach.

A sample of an entry into progress notes has been provided, which documents the care of a patient recovering from a mastectomy (see Progress Note Example 37.1).

### Preoperative preparation

As with any surgical procedure it is important that the woman is fully aware of the implications of the surgery she is undergoing and is provided with adequate emotional support. It is advisable that the woman be put in contact with a breast support nurse, psychologist and support networks.

**PROGRESS NOTE EXAMPLE 37.1**

| | |
|---|---|
| 12/10/2015<br>1330 hrs | Nursing: Mrs Cooper 2 days postoperative after left-sided radical mastectomy with axillary clearance complaining of pain (rating 6 out of 10) at site of wound. Describes a 'pulling' sensation at site of drain tubes × 2. Diagnosed with breast cancer 1 week ago on mammography and ultrasound. History of Ca Breast on mother's side of family. No relevant clinical past history. On physical examination wound appears clean and integrity of wound edges appear healthy. Sutures remain in situ. The medial drain tube has minimal drainage and 35 mL has drained into apical drain over past 8 hours. Pathology shows 6–12 positive lymph nodes. Observations all remain within normal parameters in comparison to baseline. Mrs Cooper is self-caring with assistance with dressing and management of drains. Maintaining nutritional status. Medications administered as per medication orders with request for additional analgesia 2–3 hourly requiring PRN medication for breakthrough pain. Request review from MO to adjust/assess pain management and possible r/o medial drain. Specialist appointments to be confirmed with oncologist and radiotherapist. Social worker to visit and discuss home supports for discharge and for spiritual/psychological support.<br>**C. *Baker* (Baker) EN** |

Breast prostheses are available in a range of styles. A soft, lightweight prosthesis is recommended initially while the incision is healing and until tenderness has decreased.

### Postoperative care

Physical postoperative care includes providing pain relief, promoting comfort, care of the wound, prevention of complications, exercise instruction and continued emotional support. The woman should be encouraged to perform a series of postmastectomy exercises to prevent shortening of the muscles and contracture of joints. Gentle exercise also decreases oedema and maintains range of movement in the arm.

**CRITICAL THINKING EXERCISE 37.5**

In the surgical management of conditions such as breast cancer, lymph glands are usually removed, either as an axillary clearance where between five and 30 nodes are removed, or sentinel removal, where only 1–2 nodes closest to the cancer are taken. The development of lymphoedema should be considered. What kind of exercises should be performed to avoid lymphoedema in the postoperative individual?

## ASSESSMENT AND DIAGNOSTIC TESTS

The performance of a physical examination for any woman is a time of great anxiety and embarrassment. For this reason it should be a priority for every nurse to make the experience as relaxing and comfortable as possible (see Chapter 19). The presence of a female nurse during the examination by a male practitioner is mandatory in most health facilities. Consideration should also be given to addressing social and cultural requirements when performing a physical examination.

### External examinations

#### Hysterosalpingogram

A hysterosalpingogram (HSG) is an x-ray of the cervical canal, uterine cavity and interior of the fallopian tubes. It usually involves the use of a radio-opaque dye which is injected through the cervix.

#### Ultrasonography

Ultrasonography uses high-frequency sound waves to obtain a visualisation of the pelvic organs. It is commonly used to evaluate symptoms of PID or to monitor pregnancy.

#### Breast examination

A physical examination of the breasts of men and women is referred to as a clinical breast examination. A clinical breast examination involves a thorough physical examination of the whole breast area, including breasts, nipples, armpits and up to the collarbone. Most of the breast tissue in men (a potential site for malignancy) is located behind the nipple, whereas women have breast tissue throughout the breast. It is recommended for a woman to perform a breast self-examination (BSE) once a month; this should be performed 3 to 4 days after the cessation of menstruation in young women. Despite this recommendation, only 20–30% of women perform BSE every month (Visser et al 2015).

***Inspection*** Inspect the breasts for size and symmetry. Note breast shape and any masses, flattening, retraction or dimpling. When inspecting the female breast, it may help the individual to know what to look for when she inspects her breasts so place a mirror in front of her so that she can see what to look for (Figure 37.6). The nipples are inspected for size, shape, colour, discharge and the direction they point.

***Palpation*** Palpation allows you to determine the condition of underlying breast tissue. Successful detection of a lump during palpation relies on the individual's familiarity with how their breast feels. Hormonal changes can also affect how breast tissue feels on palpation. Lumps can go undetected despite routine palpation, but palpation continues to be important in the detection of breast irregularities.

Use the pads of the first three fingers to compress breast tissue gently against the chest wall, noting tissue consistency (Figure 37.7). Palpation is performed systematically in one of three ways (Figure 37.8):

1. A back-and-forth technique with the fingers moving up and down each quadrant
2. Clockwise or counter clockwise, forming small circles with the fingers along each quadrant and the tail
3. Palpating from the centre of the breast in a radial fashion, returning to the areola to begin each spoke.

Until recently, breast self-examination was promoted as an early detection strategy for breast cancer in women. However, there is no evidence that use of specific breast examination techniques makes any difference to the detection

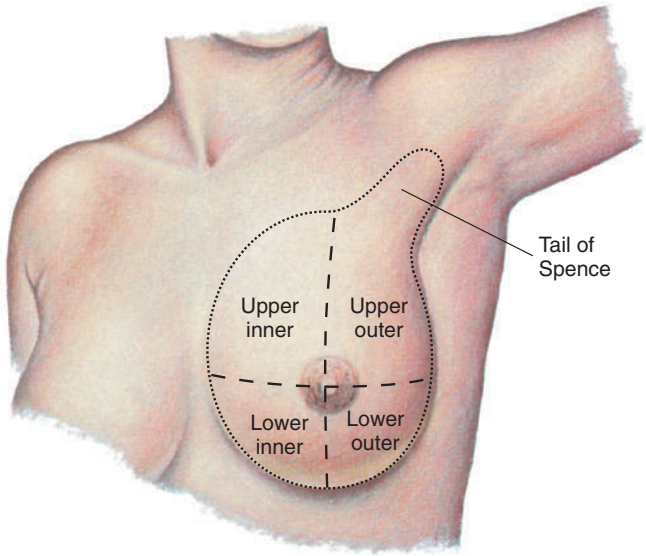

**Figure 37.6** Quadrants of the left breast and axillary tail of Spence
*(Seidel et al 2011)*

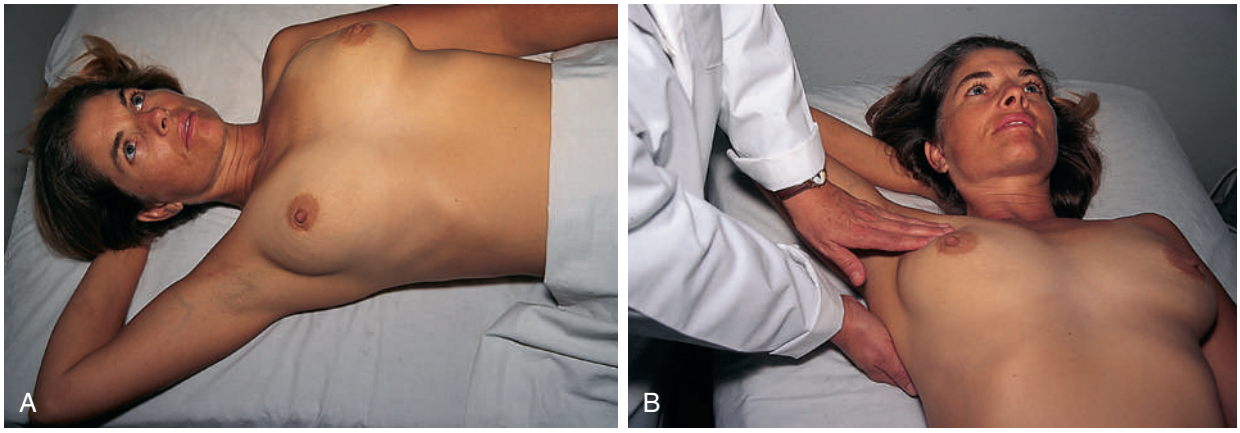

**Figure 37.7** **A:** The woman lies flat with arm abducted and hand under head to help flatten breast tissue evenly over the chest wall **B:** The nurse palpates each breast systematically
*(Potter & Perry 2004)*

*(Belcher 1995)*

of breast cancers. Instead, Cancer Council Australia (2015c) recommends the following guidelines for the early detection of breast cancer:

- Develop breast awareness strategies, which include:
  - viewing breasts in the mirror when dressing and undressing
  - feeling breasts while bathing or showering. It is recommended that the woman feels all of her breast from the collarbone to below the bra line and in the armpits as well. The National Breast and Ovarian Cancer Centre (NBOCC) website provides a tool to assist women to develop breast awareness
  - consulting a healthcare provider if any changes are noticed in the breasts
- Teach the woman to look for:
  - a new lump or lumpiness, especially if it is only in one breast
  - a change in the size or shape of the breast
  - a change to the nipple, such as crusting, ulcer, redness or inversion
  - a nipple discharge that occurs without squeezing
  - a change in the skin of the breast such as redness or dimpling
  - an unusual pain that does not go away.

### Mammography

A mammogram is one of the procedures used to detect or confirm the presence of a palpable lump in the breast. The mammogram is an x-ray which is usually provided free for women between the ages of 50 and 69 years as part of the BreastScreen Australia program. It is recommended that the test be done every 2 years. Where there is a familial link to the occurrence of breast cancer it may be recommended to commence screening earlier. Mammograms in younger women are often more difficult due to the elasticity of breast tissue prior to menopause. For this reason younger woman are usually screened by MRI.

### Breast ultrasound

Breast ultrasounds are often scheduled for women under 35 years who have detected a lump in the breast. The ultrasound allows the medical officer to identify whether the lump is fluid filled or solid. In the event of a fluid-filled cyst, the medical officer can perform an ultrasound-guided aspiration of fluid for analysis. The procedure is ideal for the pregnant woman who detects a lump because there is little risk to the growing fetus.

## Internal examinations and sampling

### Papanicolaou test

The **Papanicolaou (Pap) test** (Pap smear) involves the collection of superficial cells from the surface of the cervix which are examined under microscopic analysis to diagnose changes which may be suggestive of cervical cancer. Changes to cervical cells may occur due to acute or chronic inflammatory disease, benign tumours such as polyps and premalignant and malignant carcinoma. To perform the test, the medical officer inserts a vaginal speculum into the vagina and a cytobrush is used to scrape the surface of the cervix and collect cells which are then transferred onto a microscope slide and fixed with 'cytospray' before being sent for analysis. All women over the age of 18 years who have ever had sex should have a Pap smear every 2 years, even if they are no longer sexually active. Half

of new cases of cervical cancer occur in women 50 years or older (Australian Government Department of Health 2015).

### Pelvic examination

The pelvic examination is often performed in conjunction with the Pap smear; although where there is clinical indication it may be performed as a diagnostic method to palpate the ovaries and uterus. Initially the medical officer inserts two gloved fingers into the vagina and applies gentle pressure to the lower abdomen. A speculum is then inserted into the vagina to allow visualisation of the vagina and cervix.

### Colposcopy

A colposcopy usually occurs during a Pap smear or physical examination when, after the insertion of the speculum, a colposcope is used to magnify and illuminate the cervix. A biopsy of the cervix may be completed during the procedure.

### Cervical biopsy

A cervical punch biopsy is the removal of a small column of cervical tissue. The cervix is compared to a clock face and biopsy tissue labelled accordingly. Cone biopsy is the removal of a cone-shaped piece of tissue from the cervix. Possible complications after the procedure are haemorrhage and infertility due to the removal of mucus-producing glands, and the formation of scar tissue.

### Laparoscopy

Laparoscopic procedures are used to visualise the organs in the pelvic cavity and reproductive organs. Laparoscopy involves three to four small incisions into the abdomen and the use of probes which allow the surgeon to make a diagnostic examination, take biopsies or possibly to perform surgical procedures.

### Diagnostic uterine curettage

A dilation and curettage (D&C) involves the removal of the uterus lining (endometrium). It can be used to obtain a specimen for diagnostic purposes or to remove products of conception which have been retained after a miscarriage or post-partum.

## WOMEN'S HEALTH PROMOTION

There are a number of national health promotion strategies addressing target health risk areas throughout Australia. Information and education are available in many languages through state, territory and federal health departments. Strategies cover the prevention of sexually transmitted infections (STIs), choosing a suitable contraceptive method and screening for cervical, breast and ovarian cancer. The nurse plays an integral part in the promotion of health, education and support of the individual. The nurse should reinforce the medical officer's explanation about any implications for the individual's lifestyle and ensure that the information is understood. It may also be necessary to provide information about fertility control and prevention of STIs.

The nurse should be aware of the changes that occur to the normal reproductive structures and functions throughout the lifespan and be able to determine alterations. It is the role of the nurse to actively promote reproductive and sexual health through individual teaching, education and health promotion strategies. Individual teaching is implemented by educating individuals about normal developmental changes that occur throughout the lifespan.

Health-promotion strategies and programs should be adapted to local needs, taking into account social, cultural and economic structures.

### Breast screen

Breast examination by a healthcare professional is recommended as a health screening component when women present for regular Pap smears.

### Pap smear

Cervical cancer is one of the most preventable and curable of all cancers. It is estimated that most cases of squamous cell carcinoma could be prevented if cell changes were detected and treated early. The Pap smear is performed to obtain a scraping of cervical cells and is currently the best available screening tool for preventing the development of cervical cancer.

In 1991 Australia began what is now known as the National Cervical Screening Program. This joint federal–state/territory-funded program recommends and encourages women to have Pap smears every 2 years throughout their lives. States and territories maintain cervical cytology registries. Women automatically go on the register unless they specifically ask to be excluded. Confidential records and results are retained on a database. Reminders are sent to women on the register when Pap tests are overdue. (See Clinical Interest Box 37.9.)

### CLINICAL INTEREST BOX 37.9 Individual teaching—Pap smears

- All women with a cervix who have ever had sex in their life are at risk of cervical cancer
- Approximately half of new cases of cervical cancer each year are in women under 50 years of age
- Regular Pap smears every 2 years can prevent up to 90% of the most common types of cervical cancer
- Unless a woman has had a total hysterectomy she should be advised to have a Pap smear every 2 years
- If a woman is 70 years or over and has had two normal Pap smears in the past 5 years, she should be advised that she no longer needs to have this test.

*Royal Australian College of General Practitioners (2012)*

## CONTRACEPTION

A variety of contraceptive options are available for both men and women. The option chosen will be dictated by cultural, economic and personal factors and possibly the time available.

**Contraception** is used in females to prevent ovulation, fertilisation or the successful implantation and development of a fertilised ovum. Women have a number of options available, but there is limited choice for men—use of a condom or a vasectomy.

For most women, selecting and using a method of contraception is a significant decision. Choices about birth control are possible because of safe and available methods of contraception.

It should be noted that not all methods of contraception are 100% effective. Each method has a number of advantages and disadvantages (see Table 37.11). Birth control methods may be classified as:

- Mechanical barriers
- Chemical barriers
- Natural (ovulation)
- Intrauterine devices
- Hormonal contraceptives
- Sterilisation.

The **oral contraceptive pill (OCP)** was introduced into Australia just over 50 years ago, with Australia being the second country in the world to have access to 'the pill'. The combined oral contraceptive pill which is a combination of both oestrogen and progestogen is one of the most commonly used of the options. A low-dose alternative is the progestogen-only pill or mini-pill. The way the OCP works is by stopping the release of an ova from the ovaries and preventing pregnancy.

There are two types of the **intrauterine contraceptive device (IUD)**: one is copper bearing and the second, which is more commonly used, is hormone releasing. Both have long-acting benefits and can also reduce the blood loss during

**TABLE 37.11 | Contraceptive methods**

| Type | Description | Advantages | Disadvantages/side effects | Convenience | Effectiveness |
|---|---|---|---|---|---|
| Male condom | Sheath made of latex or polyurethane<br>Provides a barrier between the sperm and ova | Offers protection against STIs<br>Used only as required<br>High level of effectiveness<br>Easy to use | Irritation and allergic reactions<br>May break<br>May alter feeling and sensitivity during intercourse<br>May affect spontaneity<br>Pregnancy may result if not used correctly | Applied immediately before intercourse<br>Readily available; no prescription needed | 82–98% |
| Female condom | Sheath made of polyurethane<br>Provides a barrier between the sperm and ova | Offers protection against STIs<br>Does not interfere with the menstrual cycle<br>Used only as required<br>High level of effectiveness<br>Easy to use | Irritation and allergic reactions<br>May break<br>May alter feeling and sensitivity during intercourse<br>May affect spontaneity<br>Pregnancy may result if not used correctly | Applied immediately before intercourse<br>No prescription needed | 79–95% |
| Diaphragm/ cap | Diaphragm: thin, soft latex dome-shaped device that fits between vagina and pubic bone<br>Cap: Smaller latex or silicone device that fits over the cervix | Does not interfere with the menstrual cycle | May slip out of position<br>May alter feeling and sensitivity during intercourse<br>Possible irritation from the material<br>May affect spontaneity<br>Pregnancy may result if not used correctly | Applied any time before intercourse<br>Reusable devices<br>Must be left in place for 6 hours after intercourse<br>Fitted by health professional for correct sizing | 88–94% |

## TABLE 37.11 | Contraceptive methods—cont'd

| Type | Description | Advantages | Disadvantages/side effects | Convenience | Effectiveness |
|---|---|---|---|---|---|
| Spermicides | Spermicidal preparations in foam, creams, jellies and vaginal suppositories<br>Block the passage of sperm and render sperm inactive | Do not interfere with the menstrual cycle<br>Highly effective when used with a mechanical barrier<br>Help to provide vaginal lubrication | Used alone, without a mechanical barrier, contraceptive failure is high<br>May result in irritation of mucous membranes | Available without prescription | 70–80% |
| Natural methods | Based on abstinence from sexual intercourse during the fertile phase of the menstrual cycle<br>Methods include: rhythm/calendar, temperature measurement, cervical mucus observation | No disruption to menstrual cycle<br>Safe, easy and effective if practised correctly | Unreliable if menstrual cycles are irregular<br>Infection may alter temperature pattern<br>Needs practice to assess cervical mucus variations | All methods require considerable motivation and self-discipline<br>Requires frequent monitoring of body functions | 78–99% |
| Intrauterine device (IUD) | Device inserted into the uterus to prevent pregnancy<br>IUS (intrauterine system) releases low dose of hormone daily. Can be hormonal or copper based. | No disruption to the body's hormonal system<br>Continuous contraceptive coverage. High level of effectiveness<br>IUS is completely reversible | Increased menstrual bleeding, abdominal cramps, low back pain<br>May be expelled from the uterus<br>Risk of PID*, infertility, ectopic pregnancy if contraceptive failure | One-time insertion<br>May remain in place for up to 10 years depending upon type | 99% |
| Hormonal oral contraceptive (combined pill) | Combination of oestrogen and progestogen<br>Inhibits ovulation | High level of effectiveness<br>Regular menstruation, reduced menstrual bleeding<br>Protects against ovarian and endometrial cancer, PID | Nausea, weight gain, fluid retention, breast tenderness, breakthrough bleeding, mood changes, loss of libido. Rarely, cardiovascular disease, including thromboembolism and hypertension | Must be taken daily regardless of frequency of intercourse<br>Requires prescription | Declines with non-compliance, medications and illness |
| Hormonal oral contraceptive (mini-pill) | Contains progestogen only<br>Prevents thickening of the endometrium so implantation is unlikely<br>Alters composition of cervical mucus | High level of effectiveness<br>Reduced menstrual discomfort<br>Protects against ovarian and endometrial cancer, PID | Menstrual disturbances, weight gain, breast tenderness | Must be taken daily regardless of frequency of intercourse<br>Requires prescription | As above |

*Continued*

**TABLE 37.11 | Contraceptive methods—cont'd**

| Type | Description | Advantages | Disadvantages/side effects | Convenience | Effectiveness |
|---|---|---|---|---|---|
| Hormonal injection | Long-acting progestogen in injectable form<br>Inhibits ovulation, changes endometrial lining and cervical mucus | Continuous contraceptive coverage | Menstrual disturbances, weight gain, breast tenderness | One injection every 3 months<br>Requires prescription | 94–99% |
| Hormonal implant | Long-acting progestogen in implant form. Made up of matchstick-size rubber rods implanted under skin of upper arm | Continuous contraceptive coverage | Inflammation or infection at site of implant<br>Menstrual disturbances<br>Weight gain<br>Breast tenderness | Effective for up to 3 years<br>Requires prescription<br>Implanted by healthcare provider as minor surgical procedure | 99.8% |
| Morning-after pill | Combination of oestrogen and progestogen in high doses<br>Emergency measure after unprotected intercourse | High level of effectiveness<br>Provides birth control if mechanical barriers failed during intercourse, if unprotected intercourse occurred or if the woman forgot to take a contraceptive pill | Nausea<br>Spotting or bleeding a few days later | Should be taken within 72 hours<br>May require prescription | Depends on effective use |
| Sterilisation | Vasectomy for the male, tubal ligation for the female<br>Both methods are designed to prevent fertilisation | Generally effective and safe<br>Does not disrupt the normal menstrual cycle or sexual feelings | Should be considered as an irreversible process<br>Slight failure rate<br>Minor discomfort after surgery | One-time surgical procedure | 100% |

**PID = pelvic inflammatory disease*
*(Family Planning NSW 2013)*

menstruation. The device must be inserted into the uterus by a doctor and when in situ a nylon string comes out of the cervix into the vagina. This string helps when it needs to be removed. The hormone-releasing IUD causes mucus thickening, preventing sperm from entering the uterus.

**Contraceptive implants** are inserted under the skin of the inner arm and release a steady dose of progestogen to prevent ovulation. The implant can be effective for up to 3 years and is easily reversed. The implant commonly used in Australia is called Implanon.

**Injectable contraceptives** such as Depo Provera have the benefit of providing protection against pregnancy for up to 12 weeks. Unlike other methods of contraception the effects are not easily reversible, with fertility effects still possible up to 18 months after the injection.

Emergency contraception pills (ECP), commonly referred to as the morning-after pill, are designed to be used after unprotected sexual intercourse, a condom has broken or the OCP has been missed. Current ECPs use only progestogen and are most effective up to 72 hours after intercourse but can still be effective up to 120 hours. In recent years ECPs have become available without a prescription from pharmacies.

Less commonly used methods of contraception are also available such as the **diaphragm**. The advantage of the diaphragm is its relative low cost and ease of use. For effective

use the woman does need to be fitted to ensure the correct size. Alternatively, family planning clinics may suggest the use of devices such as the female condom, dams and vaginal rings.

## Termination of pregnancy

Pregnancy termination can be induced, where the pregnancy is actively terminated (abortion), or can be spontaneous, often called a 'miscarriage'.

The reasons an induced termination occurs may include:

- Family history of fetal chromosomal abnormalities where the fetus has been determined to have abnormalities
- Fetal death in utero when the fetus does not spontaneously terminate
- Unwanted pregnancy where after assessment and counselling it is determined to be in the best interests of all parties to terminate the pregnancy.

A termination may be performed either surgically or medically. Medical terminations are possible when the woman is less than 7 weeks pregnant. Performed under the supervision of a doctor, it involves taking two doses of a medication called mifepristone. The second tablet is taken 36–48 hours after the first tablet, with the woman experiencing a miscarriage shortly after. A surgical termination can take place between 7 and 12 weeks of pregnancy and involves the use of a suction curette that removes the lining and contents of the uterus. The procedure can be done as a day procedure at a clinic or hospital.

# DISORDERS OF REPRODUCTION

## Infertility

**Infertility** is defined as the inability of a couple to achieve conception after a year of unprotected intercourse, or the inability to carry pregnancies to a live birth. It is estimated that one in six couples suffers infertility (Figure 37.9), with a number undergoing both surgical and medical treatment and lifestyle changes. In many instances, no cause can be determined.

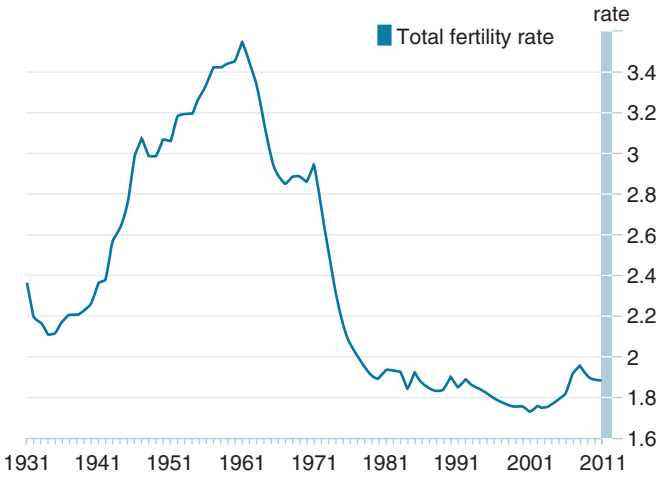

**Figure 37.9** Total fertility rates, Australia (1931–2011)
*(Australian Bureau of Statistics 2011)*

### Male factors

Many factors can affect the production, transport or ejaculation of sperm and the process can be interrupted by a number of causes, many of which have been discussed within this chapter; for example, excessive heat or tight clothing causing an increase in the temperature of the testes and inhibiting sperm production (see Table 37.12). Hormonal dysfunction of the anterior pituitary gland or hypothalamus will affect testicular function. Autoimmune factors may also be implicated. Diseases such as coeliac disease, diabetes mellitus and alcoholism may prevent normal spermatogenesis.

### Female factors

Most female infertility problems are the result of ovulation problems. Stress, diet or rigorous athletic training are lifestyle

**TABLE 37.12 | Known causes of male infertility**

| | |
|---|---|
| Sperm production problems | • Chromosomal or genetic causes<br>• Undescended testes (failure of the testes to descend at birth)<br>• Infections<br>• Torsion (twisting of the testis in scrotum)<br>• Heat<br>• Varicocoele (varicose veins of the testes)<br>• Medicines and chemicals<br>• Radiation damage<br>• Unknown cause |
| Blockage of sperm transport | • Infections<br>• Prostate-related problems<br>• Absence of ductus deferens<br>• Vasectomy |
| Sperm antibodies | • Vasectomy<br>• Injury or infection in the epididymis<br>• Unknown cause |
| Sexual problems (erection and ejaculation problems) | • Retrograde and premature ejaculation<br>• Failure of ejaculation<br>• Infrequent intercourse<br>• Spinal cord injury<br>• Prostate surgery<br>• Damage to nerves<br>• Some medicines |
| Hormonal problems | • Pituitary tumours<br>• Congenital lack of LH/FSH (pituitary problem from birth)<br>• Anabolic (androgenic) steroid abuse |

*(Adapted from Andrology Australia 2014b)*

factors that can affect hormonal balance. Conditions affecting the female reproductive system and which result in infertility in women have been identified; they include structural abnormalities, endometriosis and scarring from PID.

### Assessment of infertility

Assessment of infertility in males is based on the collection of a specimen of ejaculatory fluid to determine the number of viable sperm in the sample. The semen analysis is checked for the number or quality of sperm produced, which is normally 20 million per millilitre. It is also assessed for shape and mobility which can also affect fertility.

As the majority of sperm are situated in the first part of the ejaculate, it is important to educate the individual to collect the first part of the specimen. It is also important to educate them on the importance of not having intercourse or masturbating for 2 to 5 days before the test.

The first step in assessing the woman is to determine if she is ovulating. This may be done by testing basal body temperature and by examining cervical mucus.

Diagnostic tests include:

- Blood tests for hormone levels
- Ultrasound of ovaries to check for ovulation
- Hysterosalpingogram to check patency of uterine tubes
- Laparoscopy to check for disease of tubes or ovaries
- Endometrial biopsy to check if lining is normal.

### Treatment options

Treatment will depend upon the cause and could include the use of medications and surgical procedures.

***Assisted reproductive technology*** Assisted reproductive technology (ART) is the use of laboratory technology for fertilisation of the ova with a sperm. All reproductive clinics engaging in this technology are required to comply with the NHMRC *Ethical Guidelines on the Use of Assisted Reproductive Technology in Clinical Practice and Research* (2007) (ART Guidelines 2014). Many ART methods are very costly, both financially and emotionally. Common methods of ART used in Australia include the following.

*In vitro fertilisation* **In vitro fertilisation** (IVF) has been available for many years and was originally introduced to assist infertile women. The treatment involves sperm collection from the male which is mixed with the eggs of a female partner. The female partner will have undertaken an intensive regimen of fertility drugs to ensure they produce an increased number of eggs which will be removed during a simple surgical procedure or 'harvest'. The sperm is collected from a fresh specimen of sperm produced through masturbation the day of the female egg 'harvest'. Excess embryos may be frozen for future use if a number have been fertilised to enable use at a later date.

*Gamete intrafallopian transfer (GIFT)* **Gamete intrafallopian transfer (GIFT)** is based on IVF; the fertilised ova are placed into a functioning fallopian tube.

*Intracytoplasmic sperm injection (ICSI)* In the event that it is the male who is the infertile partner in the relationship, ICSI is more commonly used. The procedure involves a single sperm being injected into the egg through the outer covering of the egg (zona pellucida). The sperm can either be collected from ejaculate or be removed from the testes or epididymis.

Many couples will enter into the procedures involved in ART after years of trying to become pregnant, the inability to sustain the pregnancy to birth and the emotional roller-coaster of infertility testing to determine the cause and possible options available to them as a couple. Add to this months of tests and injections before each egg harvest and then implantation of a fertilised egg, followed by weeks of waiting to determine if the procedure has been successful, as well as all the counselling which is required to accompany each episode of ART: the process can be very challenging for a couple's relationship.

## SEXUAL ABUSE

Sexual abuse can occur at any age and to anyone, regardless of social or ethnic background. Females experience sexual abuse more often than males but males can also be targeted. It is the responsibility of the nurse, as it is for any healthcare provider, to be alert to situations where sexual abuse may be occurring. For the nurse, information may be gained from the presence of physical symptoms which would be suggestive of abuse and from discussions during the admission and individual assessment. The abuse may be happening currently or may be part of the individual's past experience.

Upon recognising potential sexual abuse, it is the nurse's responsibility to instigate the necessary supports which may be available. A person who has been raped may need to work through the experience and may need ongoing help before being able to resume comfortable intimate relationships. Family therapy may be indicated in cases of incest or other abuse.

During 2011–12, an estimated 51 200 (0.3%) Australians aged 18 years and over were a victim of sexual assault. Almost one-third (30%) of victims of sexual assault had the most recent incident they experienced reported to the police.

There is no standard profile to identify a person who has experienced sexual abuse, but a combination of clinical signs and symptoms and/or a pattern of behaviour or injury can arouse suspicion. It is the role of the nurse to be mindful of cultural practices (e.g. female circumcision) and certain disease processes that may result in variations from the usual.

More information on the symptoms which may suggest a child is being sexually assaulted can be found from:

- ReachOut.com
- Child Safety Australia
- White Ribbon
- SNAP.

## SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) (see Table 37.13) are infections that are passed on through close body contact or the exchange of body fluids (Australian Government

## TABLE 37.13 | Common STIs in Australia—causative organisms and routes of transmission

| STI and responsible organism | Main route of transmission |
|---|---|
| **Viral infections** | |
| Genital herpes (herpes simplex type 2 (HSV-2)) virus | Direct skin–skin contact with infected site during vaginal, anal or oral sex |
| Genital warts (human papilloma virus (HPV)) | Vaginal, anal or oral sex |
| Hepatitis B (hepatitis B (HBV) virus) | Vaginal, oral and especially anal sex<br>Contaminated drug needles<br>Skin pierced by contaminated medical instruments<br>Contaminated blood or blood products |
| Human immunodeficiency virus infection/acquired immune deficiency syndrome (HIV/AIDS) (HIV virus) | Vaginal, oral and especially anal sex<br>Contaminated drug needles<br>Infected blood or blood products<br>Transmitted from infected mother to infant in utero, during birth or while breastfeeding |
| **Bacterial infections** | |
| Bacterial vaginosis—common but not a true STI (caused by variety of bacteria of the vagina) | Believed to be due to changes in the vagina during and after sex |
| Chlamydia (*Chlamydia trachomatis*) | Vaginal and anal sex |
| Gonorrhoea (*Neisseria gonorrhoeae*) | Vaginal, anal or oral sex |
| Syphilis (*Treponema pallidum*) | Vaginal, anal or oral sex |
| Non-specific urethritis (NSU). Caused by a variety of organisms (any inflammation of male urethra not caused by gonorrhoea is classed as NSU) | Vaginal, anal or oral sex |
| **Fungal infections** | |
| Thrush (candidiasis) (*Candida albicans*) | Vaginal infection can be spread sexually |
| Protozoal infections | |
| Amoebiasis and similar conditions (parasites such as *Giardia lamblia*) | Anal or oral–anal sex |
| Trichomoniasis (*Trichomonas vaginalis* parasite) | Sexual contact but also possibly by contact with infected objects (survives on items such as washcloths) |
| **Parasitic infestations** | |
| Pubic lice ('crabs') (*Phthirus pubis* lice) | Any intimate contact—not necessarily sexual |
| Scabies (*Sarcoptes scabies* mites) | Any intimate contact—not necessarily sexual |

*(Australian Government Department of Health 2014a)*

Department of Health 2014a). Despite health promotion strategies the individual incidence of sexually transmitted infections are increasing.

Given the prevalence of sexually transmitted infection, the CDC recommends routine screening for the following high-risk groups:

- Women with multiple sexual partners
- Sexually active women under 20 years of age
- Women over 24 years of age with an inconsistent history of barrier contraception, or having a new or more than one sex partner during the past 3 months.

STIs are able to be transmitted via sexual contact which may include kissing, vaginal, anal, oral and oral–anal sex and the use of sexual aids such as vibrators. Some STIs can also be transmitted from a mother to her baby during pregnancy or during the birth process. Diseases such as human immunodeficiency virus (HIV) and hepatitis are blood-borne viruses present in body fluids and can therefore be transmitted through the exchange of body fluids. STIs can also be transmitted by viruses, bacteria or parasites.

Some STIs are relatively harmless and easily treated but others are dangerous and life threatening. The symptoms of STIs vary with each type but there are some common signs. Nurses should be aware of the symptoms of STIs and be prompted to explore the sexual history of individuals reporting any of the following:

- Itchiness, burning or discomfort in the genital or anal area
- Pain or discomfort during urination or sexual activity
- Unusual discharge of fluid from the vagina or penis
- Blisters, sores, ulcers, warts, lumps or rashes anywhere in the genital or anal area.

Some STIs may be asymptomatic. Some STIs start with mild symptoms that the individual might ignore until they disappear.

The impact of STIs on sexual and general health is enormous. It is easier to prevent infection than treat it, and prevention needs to be the concern of all health professionals.

## Diagnosis

The medical officer confirms diagnosis of an STI with swabs and blood tests. It is not uncommon for an individual to have more than one STI at a time.

## Human immunodeficiency virus (HIV)

Human immunodeficiency virus (HIV) is a virus that affects the immune system. The individual may be HIV positive for a number of years without showing symptoms, during which time the virus progressively damages the immune system and the virus is able to be spread to others through body fluid transmission.

HIV infection may be treated with combination therapies to reduce the amount of virus being reproduced in the body. It is recognised that HIV eventually results in acquired immune deficiency syndrome (AIDS), commonly about 10 years after infection but in some cases up to 17 years later. HIV and AIDS weaken the body's immune system, allowing opportunistic infections to cause serious health problems.

The individual with HIV/AIDS can present with a variety of complex needs at any time during their illness, each requiring careful nursing assessment. Sexuality issues include concerns with the effect on the relationship, the ability to find an accepting partner, the risk of transmission and the impact on decisions in relation to parenting. The individual with HIV/AIDS is encouraged to maintain a healthy lifestyle and many find alternative therapies helpful. Individuals are also treated with antiviral drugs. Drug therapy aims to promote repair of the immune system and increase the ability to fight infection. Side effects of the medication can cause unpleasant symptoms until a suitable combination of drugs is determined.

## Syphilis

Syphilis is sexually transmitted infection caused by the organism *Treponema pallidum*. If diagnosed and treated as a primary infection, syphilis is usually controlled. However, if untreated, it has the potential to become a chronic disease, which can have variable lengths of latency and presentation. Tertiary syphilis can present 10 or more years after initial infection. An exacerbation of the infection during pregnancy can lead to it transferring to the infant from the mother.

In Australia, there has been an increase in the number of reported cases of syphilis. This is thought to be due to an increase in unprotected sex, as a secondary HIV infection, having more sexual partners and an increase in recreational drug use. Diagnosis of infection is with a swab and dark-ground elimination. Penicillin is the treatment of choice, with the need for all sexual partners to be treated.

## Chlamydia and gonorrhoea

Chlamydia is caused by the bacterium *Chlamydia trachomatis* and for many people they remain asymptomatic, which makes diagnosis and treatment difficult. In males, infection can affect the prostate, urethra and testes and in females it can affect the cervix, uterus and pelvis. Diagnosis is based on either a urethral swab or a clean catch of urine and the infection is treated with antibiotics and good hygiene practices.

Gonorrhoea is caused by the bacterium *Neisseria gonorrhoea* and can present similarly to chlamydia; however, it tends to be more symptomatic. The rates in relation to gonorrhoea appear to be stable. Diagnosis is based on the presence of a thick yellow urethral discharge and dysuria which develops within a week of infection and is confirmed with a urethral swab and Gram-stain smear or clean catch of urine.

## Prevention of sexually transmitted infections (STIs)

Avoiding infection means responsible sexual behaviour. The only absolutely certain way to avoid infection is not to have sex. Nurses can reinforce, especially to young individuals, that they should never feel that they have to have sex if they don't want to. Nurses can also promote and educate people about safer sex practices. Safer sex reduces the risk of STIs, but the

risk is not completely eliminated. For example, protection by use of condoms provides some protection against HIV and gonorrhoea, but they are less effective in protecting against trichomoniasis and chlamydia and provide virtually no protection against HPV, the cause of genital warts. This is because any intimate contact may spread some STIs.

Education about safe sex practices includes discussing choices about:

- Limiting activity to sensual caressing, massage and mutual masturbation
- Having sex with only one person in a monogamous relationship (the nurse providing education needs to stress that being safe means knowing that neither partner has or will have any other sexual partners and that both are uninfected)
- Insisting on tests for STIs before engaging in sexual activity with a new partner
- The use of good-quality latex condoms, with knowledge of how to use them safely and effectively
- Not allowing drugs or alcohol to impair judgment.

Education about the prevention of STIs also includes stressing the need for:

- Prompt treatment of any infection
- Investigation and treatment of anyone who has had sexual contact with an infected person
- Avoiding sexual activity during the infective stage of the disease
- Avoiding sexual contact with a person known to be, or suspected of being, infected
- Those engaging in sexual activity with other than reliable sexual partners to have periodic health checks and tests for STIs, regardless of other preventive measures employed
- Advising sexually active women to have a Pap smear every 2 years
- Advising that the full course of any prescribed antibiotics must be taken
- Implementing the recommended blood and secretion precautions as effective infection control measures.

Nurses have a responsibility to promote the reduction of incidence of STIs and so limit the distress they cause. A knowledgeable and skilled nurse will successfully encourage individuals to discuss STIs, will inform about modes of transmission and treatments and will ensure that at-risk individuals recognise the manifestations of STIs if and when they occur. The education that nurses are often in a position to relay helps disseminate accurate information. This can increase the number of individuals that seek early medical advice, and so reduce the damaging physical and psychological effects of STIs. (Refer to Nursing Care Plan 37.1.)

## NURSING CARE PLAN 37.1

**Assessment:** Lucy is 16 years old and has attended her local primary health facility. You are responsible for performing an initial assessment within your SOP before Lucy sees the on-call medical officer. Lucy states she has burning with urination and admits she engaged in intercourse 48 hours previously. She has recently had to take time off work due to bronchitis. Lucy states she was given a commonly known antibiotic for her bronchitis and her prescription for the OCP ran out a couple of days ago. Lucy states they did not use a condom when she had intercourse and is scared that she may be pregnant or may have caught an STI. Lucy is too scared to tell her parents and has come to the clinic for advice and support.
**Issue/s to be addressed:** Maintenance of confidentiality vs support for Lucy during episode of care
Possible diagnosis of post-coital cystitis
Possible ineffective OCP coverage due to recent illness and antibiotic treatment leading to a possible diagnosis of pregnancy
Possible diagnosis of STI due to unprotected intercourse with partner
**Goal/s:** Eliminate possible issues and obtain definitive diagnosis
Maintain supportive environment to allow parents, partner to be informed of diagnosis
Provide education and options for treatment dependent on the diagnosis

| Care/Actions | Rationale |
|---|---|
| Perform a comprehensive assessment of the following:<br>Lifestyle choices—nutrition, exercise, rest, substance abuse, alcohol and drug use, occupation and financial details<br>Medications—OTC, non-prescription and prescription medications<br>Review of body systems—reproductive (Pap smears, previous STIs, sexual practices, menstrual history)<br>Surgical history | Assess Lucy's health status and possible risk to fetus if pregnant<br>Determine underlying issues that have not been identified<br>Determine underlying conditions, regularity of menstrual cycle and where in cycle intercourse took place to determine ovulation history |

## NURSING CARE PLAN 37.1—CONT'D

| Care/Actions | Rationale |
|---|---|
| Family history—medical conditions, genetic conditions (cystic fibrosis, bleeding, birth defects)<br>Sexual partner history<br>Past history—childhood diseases (chicken pox, measles), immunisation status, contraceptive history<br>Psychological history—family situation, occupation, cultural preferences<br>Physical examination—visual, BSE, tests | Any abdominal surgery, trauma<br>In the event of pregnancy decision to maintain pregnancy<br>How many previous partners, length of relationship, possibility of sexual health<br>Immune status and OCP coverage and effectiveness<br>Determine level of support if Lucy is pregnant or needs medical treatment, ability to support a baby, is Lucy still at school, possible barriers to treatment due to cultural/religious beliefs. Has Lucy spoken to partner in past 2 days?<br>Is Lucy well groomed (ability to look after self, financial, living situation), signs of malnourishment, injury? Evidence of infection? Has Lucy done a home pregnancy test? Collect urine for pregnancy test/ possible blood for analysis |

**Evaluation**

Urine test tests positive for pregnancy/await pathology results for βhCG results.
Discuss possible use of morning-after pill and treatment for possible STI.
Discuss possible need for D&C, relevant preoperative preparation and postoperative education.
Discuss need to involve family in ongoing management.
Refer to MO for pelvic examination and specimen collection for STI clearance.
Set up appointment for review in 1 week for further follow-up.

## Summary

The function of the male and female reproductive systems is primarily to reproduce. The female role is to produce ova, receive sperm and, after fertilisation (the fusion of a spermatozoon and an ovum to form one cell), development and birth of the baby. The male role is to produce the sperm which will ultimately fertilise the ova which will result in an embryo.

Conditions affecting both the male and the female reproductive system can limit the ability to reproduce and therefore continuation of the species. Remaining alert to symptoms which may suggest an infection or disease and referral for early investigations will go a long way towards preventing these conditions further limiting the reproductive health of individuals.

A large number of both nationally and state-based health promotion activities exist to provide a resource for information, support and education and are making a very positive impact on the health of all.

Choices concerning reproduction are influenced by physiological, psychological, social, religious, economic and environmental factors. In Australia the birth rate is declining due mainly to changing social attitudes and the availability of contraception.

Nurses who work in the area of sexual and reproductive health should be aware of cultural and religious beliefs as well as individual sexual practices and preferences. As health professionals they are actively involved in promoting reproductive and sexual health in a variety of healthcare settings. Nursing management of the individual with a disorder of the male or female reproductive system requires an acute awareness of the importance of providing psychological support as well as skilled clinical interventions.

## DECISION-MAKING FRAMEWORK EXERCISE 37.1

Luke is a 21-year-old male who presents to the accident and emergency department where you are working. He is holding a jumper in front of himself and walks with a gait suggesting he is in considerable pain. Luke appears embarrassed to answer questions in the triage area of the A&E.

Taking Luke into a private room he reveals that he took some of his father's medication the previous night before going out to a local nightclub. He states he has a partial erection which has been present for almost 8 hours. Further discussion reveals that he has tried several approaches to get rid of the erection but has only been successful at slightly reducing the swelling. Luke begs you to relieve his discomfort.

1. Is this considered a medical emergency?
2. Is there a protocol for the management of this situation?
3. What are the risks associated with the procedure?
4. Who needs to perform this procedure (EN/RN/MO)?
5. Is the procedure within your scope of practice?
6. How can you assist Luke?

## Review Questions

1. When collecting an individual assessment you suspect the male individual has an enlarged prostate. What symptoms would confirm your suspicions?
2. A diagnostic test that can be performed to determine the possibility of prostate cancer is the PSA test. Explain its use. What other diagnostic assessment may be performed to confirm diagnosis?
3. Erectile dysfunction is a condition that can affect young and older males. List the possible causes of erectile dysfunction.
4. When performing a TSE, what should be looked for?
5. An individual is due for discharge after a vasectomy. What education is important for this individual?
6. A torsion of the testes can lead to serious complications if not treated quickly. What complications may occur if torsion of the testes is left untreated?
7. Endometriosis can present with severe menstrual symptoms. How would a diagnosis of endometriosis be confirmed and what is the medical management?
8. Discuss the preoperative care for a woman who is scheduled for a radical hysterectomy.
9. What are your responsibilities if you suspect abuse of a child in your care?
10. The pregnant woman should be monitored for the onset of pre-eclampsia in the third trimester. What are the characteristic signs of possible pre-eclampsia toxaemia?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

## KEY TERMS

care of the dying
death and dying
empathic
end-of-life care
family-centred care
loss and grief
multidisciplinary palliative care
palliation
palliative approach
palliative care
person-centred
symptom management

## LEARNING OUTCOMES

At the completion of this chapter, and with further reading, students should be able to:

- Define the key terms
- Outline the philosophy of palliative care
- Describe a multidisciplinary approach to palliative care
- Identify a range of physical and psychosocial symptoms that may occur in the individual who is dying
- Identify nursing interventions to address physical and psychosocial symptoms
- Identify nursing interventions to support family
- Describe grief and the purpose of grief
- Identify nursing interventions to support grief responses in the individual and family
- Discuss how nurses may be supported in providing palliative care

## CHAPTER FOCUS

Palliative care is the specialised care of people who are no longer responsive to curative treatment and who are dying. The aim of palliative care is to provide symptom management by addressing pain and other physical symptoms, and by providing psychosocial and spiritual care. Multidisciplinary teams are required to provide high-quality palliative care and nurses are important members of the multidisciplinary team. Nurses provide person-centred and family-centred symptom management with the multidisciplinary team. A caring nurse–person relationship that facilitates psychological and spiritual wellbeing is central to quality palliative nursing.

## LIVED EXPERIENCE

The nurses told us that Dad would die in the next few days and encouraged us to call my brother, who was overseas. We were all very anxious that he would not get back in time, especially mum. My Dad died half an hour after my brother arrived at the hospital. Even though he wasn't conscious, it seemed as if he knew and had waited for my brother. We were all thankful that my brother was able to say goodbye. Saying goodbye for a final time is difficult but we were able to be together as a family and the nurses encouraged us to take the time we needed with Dad.

**Daughter, age 25**

## DEATH AND DYING

**Death and dying** is a part of life. However, the concepts of death and dying are uncomfortable for most people. Although death is common in older people it can occur at any age. Care of people and families experiencing death and dying is central to the nursing role (McLean Heitkemper et al 2015). Therefore, nurses require understanding of, and skills in, palliative care. This includes an understanding by the nurse of others' attitudes, feelings and beliefs about death and dying. Importantly, nurses require an understanding of their own attitudes and feelings about death and dying and how these might influence the nursing care they provide (Egan 2013; McLean Heitkemper et al 2015).

Understanding that people and families respond very differently to death and dying is essential to quality nursing care. People's responses to death and dying have been learned from their family of origin and also from the culture they come from (Berger et al 2013; Leininger & McFarland 2002). Feelings about death and dying can also reflect the individual and family adjusting to their pending loss. Where possible, the nurse builds a trusting, caring relationship with the individual and their family. When the person and their family trust the nurse they are more likely to disclose their beliefs and feelings about death and dying. The person and the family are the experts about their feelings and beliefs. Empathic listening is essential to quality nursing care (Egan 2013). The range of feelings people can experience during death and dying include sadness, anger and fear; or relief and acceptance of death as a natural event (Egan 2013). Some people experience considerable fear about dying. Common fears include:

- Fear of pain and isolation while dying
- Fear of loss of dignity
- Fear of the unknown, of nonexistence
- Fear of what happens after death (Berger et al 2013; McLean Heitkemper et al 2015).

A nurse needs to support the individual who is dying and their family in whatever feelings they experience. All people process and experience their feelings differently. There is no expected outcome per se and no 'right' or 'wrong' feelings or sequence of feelings in death and dying (Berger et al 2013). Some people will express feelings of acceptance and some people will not. This is demanding on the nurse as the nurse is faced with the challenge of tolerating very difficult feelings in the person and in themselves. A nurse needs to accept all feelings as valid and be respectful and **empathic** (Egan 2013).

A person who is facing their own death may ask the nurse difficult questions such as, 'Am I going to die?' Many nurses, understandably, will be uncomfortable with these questions. The nurse's response depends on many factors, such as:

- Has the person and/or their significant others been informed of the prognosis?
- What is the person's stage of growth and development, and their level of understanding?
- Have the significant others requested that the person's prognosis be withheld from them, and is this a reasonable request?
- Are the nurses caring for the person adequately supported by experienced and specialist nurses, and by the multidisciplinary team? Have they been prepared adequately to deal with such questions?

There are no standard answers to questions that may be asked by people who are dying. If a person asks the nurse such a question this indicates that they trust the nurse (Egan 2013). It also suggests that they wish to discuss their feelings about their death. Nurses may feel able to engage in a conversation about the person's feelings about death and dying. Alternatively, they may prefer to refer the person to an experienced nurse, a palliative care nurse specialist or relevant

member of the multidisciplinary team such as a counsellor or psychologist (Berger et al 2013). Additionally, the nurse can prepare themselves to improve their understanding of the issues that surround death and dying, and of relevant counselling approaches. For example:

- Reading recommended literature, particularly in relation to the individual dying in a healthcare setting
- Discussing aspects of death and dying and their own feelings and attitudes with experienced nurses, palliative care nurse specialists and bereavement counsellors
- Attending in-services, seminars, courses or other related educational forums to broaden skills and knowledge.

Discussing death and dying is still considered by many people to be morbid or in poor taste, and western culture tends to deny death (McLean Heitkemper et al 2015). The experience of death and dying is perceived by many in Western culture as a personal and private matter. It is interesting to note, however, that contemporary society's attitudes are changing (McLean Heitkemper et al 2015). Expressing grief is increasingly seen as a normal and healthy response. This is evident in recent world examples, such as the public responses to the deaths of thousands of people in Japan and New Zealand following the earthquakes affecting each in 2011.

## PALLIATIVE CARE

Palliative care is defined by the World Health Organization (2002) as 'an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual'. (See Clinical Interest Box 38.1.) Palliative care is the specialised care of people who are no longer responsive to curative treatment and who are dying (Palliative Care Australia 2015). The aim of palliative care is to achieve the best possible quality of life for both the person who is dying and for their family. This includes symptom relief, psychological and spiritual care, care in regard to grief and loss and care of the person who is dying and their family in the terminal phase of the illness (Crisp et al 2013). Palliative care aims to relieve distress and suffering, and keep the person comfortable without hastening or postponing death. Holistic care, that is person- and family-centred, is essential to quality palliative care and a 'good death'. Palliative care respects the dignity of the person who is dying and their family (Berger et al 2013; Palliative Care Australia 2015). The focus is on the person's and the family's needs and wishes in accordance with their cultural and spiritual beliefs. Where possible, care is provided in the environment of the person's choice such as in the home or in a hospice. Holistic palliative care is dependent upon multidisciplinary teams including nursing, medical and allied health professionals, and on volunteer services.

Those providing palliative care in a multicultural society require sensitivity to differences in the way people from various cultures understand issues surrounding death and dying. For example, pain and suffering, and quality and meaning of life, may be interpreted quite differently cross-culturally and intra-culturally (D'Avanzo 2008; Leininger & McFarland 2002). Sometimes judgments and care decisions are influenced by the nurse's personal cultural values. It is important to avoid making assumptions about the individual's wishes by asking the individual what is preferred in relation to all treatment, care and quality-of-life activities (Berger et al 2013). For example, prayer rites and readings from the Quran are important during death and dying for many Muslim people (Cheraghi et al 2005). Therefore, the individual and family may wish for an imam to support them during this experience.

Palliative care is not an alternative to other care but is complementary to and a vital part of total patient care. A person who receives palliative care will have an active, progressive and advanced disease with little or no prospect of cure (Palliative Care Australia 2015; Crisp et al 2013). In some settings where **end-of-life care** is provided by non-specialists, a **palliative approach** is used. A palliative approach is the term used to describe the care provided by generalist healthcare professionals who may consult with palliative care specialists. Alternatively, palliative care may be provided within a funded specialist service that provides care in partnership with generalist health practitioners, for example, in community-based home care (Kralik & van Loon 2011). Palliative care may also be provided solely by specialist services as, for example, occurs in many hospices. In some countries such as Australia, people receive palliative care within a funded specialist service, generally in the last 6 months of their life (Victorian Department of Human Services 2011).

### CLINICAL INTEREST BOX 38.1 Palliative care

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of care
- Offers a support system to help individuals live as actively as possible until death
- Offers a support system to help the family cope during the individual's illness and in their own bereavement
- Uses a team approach to address the needs of individuals and their families, including bereavement counselling, if indicated
- Will enhance quality of life, and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications.

*(World Health Organization 2002)*

### CLINICAL INTEREST BOX 38.2 Residential care—an Enrolled Nurse's experience of palliative care

Within the facility I work at we try to ensure that the end of life for our residents is as peaceful as possible. We ensure privacy of the person and invite the family to spend as much time as they need to with their loved one. I like that every staff member tries to ensure that the person is kept as comfortable as possible. We provide pressure care, hygiene, aromatherapy, chairs, music, lighting as per the individual's preferences. We ensure pain relief is timely and adequate. We also try to address any family concerns quickly and with compassion. This could include contacting clergy or funeral directors at the individual's and/or family's request. By listening to the person and their families I find most concerns can be addressed. I like that there is flexibility where I work to meet an individual's needs.

Throughout this chapter the term 'family' is used to represent all people identified by the person who is dying as being significant to them. Family therefore includes partners, relatives, friends, neighbours and anyone else providing support (Maher & Hemming 2005). Palliative care involves grief and bereavement support for the family that extends throughout and beyond the duration of the illness.

## Who can receive palliative care?

Anyone who has an illness that is not responsive to curative measures can receive palliative care, regardless of age, gender, class, culture, race and religion or belief system (Kralik & van Loon 2011). Most people receiving palliative care have cancer, but some have progressive chronic neurological problems such as motor neuron disease or multiple sclerosis. Others have acquired immune deficiency syndrome (AIDS), Alzheimer's disease or end-stage heart, lung or kidney failure. As the concept of palliative care develops, more specialist palliative care teams are caring for people with illnesses other than cancer (Berger et al 2013; Chang & Johnson 2014). Palliative care measures are also implemented for residents living in aged care facilities who are in the last stages of life. Clinical Interest Box 38.2 provides an example of how palliative care may be implemented in the residential care environment.

# PERSON- AND FAMILY-CENTRED PALLIATIVE CARE

Quality **person-centred** and **family-centred care** depends on empathic nurse–individual caring relationships. A quality nurse–individual caring relationship is built on trust and respect. This requires that the nurse has excellent interpersonal and communication skills, cross-cultural nursing skills, is able to listen empathically and tolerate hearing difficult feelings and attitudes that may or may not match the nurse's own beliefs (Maher & Hemming 2005). The relationship

### CLINICAL INTEREST BOX 38.3 A caring nurse–individual relationship facilitates discussing feelings about dying

Where I work there are many people from various cultural backgrounds. Maria, who I looked after as she was dying, was from an Eastern European background. She had strong religious beliefs and always carried rosemary beads. One shift, Maria was audibly distressed, but care staff were unsure about what to do: they said she said she wasn't in pain but kept chanting. When I went in to Maria's room, her daughter was there also, and I asked what was wrong. Maria's daughter explained that the loud chanting was Maria's way of coping with the emotional distress of dying. This led to a conversation of what Maria would like in her final days. I learnt a lot about how to approach difficult conversations from this experience. The main point is to start the conversation. I shared my discussion with all the team; we are all more aware of cultural differences and ensure we ask people about their own personal needs.

**Craig, Enrolled Nurse, working in aged care**

forms the foundation for the individual and their family to express their feelings, thoughts and beliefs about death and dying. At times, the nurse will not know what to say or how to respond to the person. It may be appropriate to share this with the individual and family (Stein-Parbury 2014). Importantly, a quality nurse–individual caring relationship can also provide a foundation for joy, remembering and finding meaning in life for the person and their family. Clinical Interest Box 38.3 provides an example of open communication between a nurse and an individual.

# MULTIDISCIPLINARY PALLIATIVE CARE

The provision of high-quality **palliative care** means that individuals and families need access to support from a coordinated **multidisciplinary** team (Victorian Department of Human Services 2011). This includes generalist healthcare professionals and those with specialty training in palliative care. The team includes medical officers, nurses, allied health workers, counsellors, chaplains and volunteers. The knowledge and expertise of the multidisciplinary team combines to help people live as fully as possible and maximise their quality of life within the increasing limits of the illness (Caresearch 2014). Individuals and their families are encouraged to actively participate in all aspects of their care including care planning and care delivery.

Palliative care aims to help individuals and their families feel in control of the quality-of-life and symptom-management decisions, including the decision about where care will be provided. Palliative care can be provided in the person's own home, a specialist inpatient hospice unit, an aged care residential unit (see Case Study 38.1), a hospital

## CASE STUDY 38.1

Lewis, a 69-year-old man, has recently been diagnosed with an inoperable brain tumour. He has been having severe headaches, balance problems, nausea and has had a number of seizures. Lewis has a number of comorbidities including obesity, diabetes (he is a type 2 diabetic requiring insulin), CCF and high blood pressure. Lewis has also noticed a recent deterioration in his eyesight and has been having difficulty managing his diabetes.

Lewis lives alone. His only relative is his sister Joan who is also unwell and lives an hour's drive away.

Lewis has decided not to have any radiotherapy or chemotherapy and wishes for palliative treatment only.

Lewis has decided that a residential aged care facility would be the best way to ensure his wishes regarding his declining health and his death are met. He has developed an advance care plan with his doctor, the palliative care team and the care manager at the facility. His biggest fears are dying in pain and alone, falling and being sent to hospital unnecessarily.

1. In what ways can a multidisciplinary palliative care team continue to support Lewis in an aged care facility?
2. What nursing actions can you take to assist Lewis in managing the symptoms associated with his illness?

or other healthcare facility (Chang & Johnson 2014; Crisp et al 2013).

## Home-based care

Many people wish to die at home (Kralik & van Loon 2011). Community-based generalist nursing services, palliative care services and general practice services provide care in partnership with **palliation** individuals and their families to enable this wish to be fulfilled. When a person prefers to die at home, nurses assist family members in providing care. The nurse may also be required to provide counselling and teaching services; for example, teaching a family member how to sponge the person in bed or how to assist them safely to a commode (Berger et al 2013; Crisp et al 2013). Nurses also support individuals and their families to manage symptoms associated with palliation.

Specialist palliative care services provide palliative care nurse specialist and medical specialist care, and offer a wide range of other services and supports (Kralik & van Loon 2011; Chang & Johnson 2014). These include counselling, bereavement support and pastoral care, occupational therapy, physiotherapy, relaxation and music therapy, dietary advice and loan of equipment. Many of these services and supports are offered at a day centre or, if the individual is unable to attend, in the home. Trained volunteers play an important role in providing various forms of assistance, including respite for family members and bereavement support (Victorian Department of Human Services 2011). Clinical Interest Box 38.4 provides an example of when home-based palliative care can help.

## CLINICAL INTEREST BOX 38.4 Home-based palliative care

Darcy was returning home with his family after relapsing for the third time with acute leukaemia. Darcy wanted to die at home, where he felt more comfortable. Darcy's biggest fear was dying in pain and he was very anxious about this. A multidisciplinary palliative care team became involved in Darcy's palliative care. Darcy and his family went home much less anxious, as the team had developed a clear plan with Darcy and his family on how to manage his care. At home Darcy and his family had access to 24-hour nursing care and doctors but, also importantly to Darcy, his family and friends could visit. They were also reassured that the hospice would be available to Darcy if needed. Darcy died peacefully at home surrounded by his family, as he wished.

**Darcy, aged 19 years**

## Hospice-based care

A hospice unit is an inpatient unit where specialist health professionals care for people with incurable illnesses (Palliative Care Australia 2015). Individuals are admitted to a hospice in the last stages of their illness and remain until death occurs, or they may be admitted for assessment and relief of pain or other distressing symptoms and then return home. Admission to a hospice can also provide support for an individual who is experiencing emotional distress or anxiety (Victorian Department of Human Services 2011). Sometimes individuals are admitted for a period of respite care. Respite care provides a break for a carer or family member. The aim of an inpatient hospice unit is to provide expert care in a calm environment that is as home-like as possible. Palliative care units in busy mainstream hospitals are not always able to provide the same calm atmosphere as a hospice (Kralik & van Loon 2011). Clinical Interest Box 38.5 provides an example of when hospice-based palliative care can help.

## Residential aged care

A residential aged care facility is a facility that provides support to people who require help because of illness or disability, or because of needs or family, friends or carer. Staff at an aged care home can provide assistance with personal care and 24-hour nursing care (Department of Social Services 2015). Many people enter a nursing home when they can no longer manage at home. Residential aged care facilities will aim to provide the best quality of life for individuals. For many people the staff in the facility will assist with managing their end-of-life care when needed. This may include managing pain and symptoms, emotional and cultural support, communicating with family about decisions with care and

### CLINICAL INTEREST BOX 38.5
### Bill's story—in hospice care

Having been diagnosed with terminal cancer, I found my disease was progressing faster than I expected. Being 86 years old, and my wife 84 years old, the physical debilitation was hard to manage. My wife couldn't help me in the shower any more, and I was getting weaker and weaker. Palliative care had been involved and we called them and the nurse discussed the hospice and found us a bed in the hospice. The staff are wonderful: they take care of all the physical aspects of my care and have encouraged my wife and me to talk more openly with the rest of the family. I am so glad I agreed to come here as I was feeling a burden on my family.

**Bill, aged 86, 1 week prior to dying of metastatic prostate cancer**

supporting family and friends (Department of Social Services 2015). Staff can provide a warm, caring environment for a dying resident in an aged care facility by providing a softly lit, quiet environment, encouraging family to stay with the individual and staying close to the individual and family.

Staff within the nursing home can engage with other health professionals as required to help support the individual. Some health professionals who may be accessed could include: general practitioners; medical specialists; palliative care teams; wound specialists; allied health professionals including physiotherapists; psychologists; therapists skilled in music, massage, aromatherapy or colour; and acute medical and nursing teams if necessary (Department of Social Services 2015).

### Acute/hospital-based care

The majority of palliative care is provided in the person's home in a community setting, but as the illness progresses the individual may require admission to an acute inpatient facility. The reasons for admission may include treatment for an acute medical or surgical condition, symptom control, respite for carers or to die (Chang & Johnson 2014). The Australian Commission on Safety and Quality in Health Care undertook a major work into understanding the complexity of issues and barriers affecting the delivery of safe and good quality end-of-life care in acute facilities. The outcomes found need for several changes to the delivery of end-of-life care in acute facilities, which may involve the development of safety and quality or clinical care standard criteria and training curricula (ACSQHC 2014). A *National Consensus Statement: Essential Elements for Safe High Quality End of Life Care* (ACSQHC 2015) sets out suggested practice for the provision of end-of-life care in settings where acute care is provided. The Consensus Statement aligns with the National Safety and Quality Health Service Standards, and provides recommended practice. It also aligns with the *National Consensus Statement: Essential Elements for Recognising and Responding to Clinical Deterioration* (ACSQHC 2010), and it is intended that these documents be applied together.

### CRITICAL THINKING EXERCISE 38.1

In what ways do the culture in busy acute care hospitals impact on the experience of individuals who are dying? How does it impact on their family members? How might nurses improve the circumstances for the individual who is dying and their family in this setting?

## SYMPTOM MANAGEMENT

Palliative care affirms life and regards dying as a normal process. All care is therefore aimed at relieving pain and other symptoms. The individual may have symptoms that relate to physical, emotional or spiritual concerns (Old & Swagerty 2007; Chang & Johnson 2014). Physical comfort is a priority and essential if palliative care work is to be effective (McLean Heitkemper et al 2015). However, emotional or spiritual concerns can affect physical symptoms. Therefore a holistic approach is necessary in **symptom management**. Many individuals experience multiple symptoms concurrently. Pain is a common symptom; however, not all people experiencing palliation report pain.

Symptom management requires thorough assessment and possibly referral to the relevant member of the multidisciplinary team (Maher & Hemming 2005). Excellent communication and discussion with the multidisciplinary team is essential to effective symptom management. Assessment must always precede intervention to establish the causes of the symptoms wherever possible (Kindler et al 2015). Cultural factors must be included in symptom assessment in order to tailor symptom management to the needs of the person and their family. Symptom management aims to minimise or eliminate pain and disability, and maximise comfort and functioning (Kindler et al 2015). Any concurrent additional disorders developing over the palliation episode of care (e.g. infections) are diagnosed and treated as necessary. Once treatment is initiated, nurses are involved in reviewing and evaluating the effectiveness of the intervention.

Symptoms other than pain are commonly experienced by people who are dying (Berger et al 2013). These include symptoms requiring physical care and psychosocial and spiritual care (Stein-Parbury 2014). Common physical symptom areas to be included in an assessment are pain, changes in body weight, nausea and vomiting, constipation or diarrhoea, fatigue and dyspnoea (difficulty breathing). Psychosocial and spiritual care issues include challenging emotions such as anxiety, depression and fear and grief and loss (Berger et al 2013). Quality nursing care is focused on meeting the person's treatment and physical care needs and psychosocial and spiritual needs.

### Pain

Pain is a common symptom, in particular when the person has a cancer illness. Woodruff (2004) defines pain as 'what

## NURSING CARE PLAN 38.1

**Assessment:** Graham is a 62-year-old man diagnosed with terminal pancreatic cancer. He is conscious; he has a subcutaneous narcotic infusion in situ to manage his pain. You have been allocated to look after Graham on your shift in an acute hospital. Graham is visibly upset and moaning with pain.
**Issue/s to be addressed:** Pain management.
**Goal/s:** To provide adequate pain relief and comfort measures.

| Care/Actions | Rationale |
|---|---|
| Assess Graham's pain:<br>Perform a comprehensive pain assessment including: location, characteristics, onset, duration, severity (e.g. 0–10 scale), and factors that have led to an increase in pain such as ambulation. Note any cultural issues impacting the pain. Determine individual's acceptable level of pain | Provides information to determine need for increase or change in pain management regimen, keeping in mind that verbal/behavioural cues may have little direct relationship to the degree of pain perceived<br>New pain may require a different pain relief strategy<br>Allows Graham to maintain a consistently acceptable level of pain |
| Provide education on asking for assistance sooner rather than later | May reduce need for/can supplement analgesic therapy, especially during periods when Graham would like to be more alert |
| Demonstrate and encourage use of positioning, relaxation techniques, guided imagery and meditation. Encourage family to assist Graham with this | Allows family to assist Graham practically |

**Evaluation**

Graham requested additional pain relief medication and changed position for further comfort. Graham's pain score was at a level he found acceptable.

the patient says hurts'. It emphasises that 'a patient's pain is what they describe and not what others think it ought to be'. Modern pain management means that palliative care individuals should be almost pain-free throughout their illness (Woodruff 2004; World Health Organization 2008). A variety of nursing interventions, including pharmacological and non-pharmacological approaches, provide relief from pain and physical discomfort (Kindler et al 2015). Nurses promote and undertake medication management including supporting individuals' self-management of analgesic medications through health teaching. Nurses also provide advice regarding application of heat and cold packs, positioning and support of limbs; for example, by application of a splint. They further advise the person and family about gentle exercise and rest (Kindler et al 2015). (See Nursing Care Plan 38.1.)

Assessment of pain is vital to effective pain relief. Pain can stem from injury and disease in any part of the body including internal organs and viscera, skin and connective tissue and nerves (Litwak 2009). Expert assessment is vital to identify the cause of the pain and the type of intervention and/or medication that will be most effective (Kindler et al 2015). Pain assessment is a core skill of the palliative care nurse and palliative care medical officer.

Analgesic medication is the primary method of controlling pain (Kindler et al 2015). Analgesic drugs include opioids, such as morphine, and non-opioid analgesics such as paracetamol and non-steroidal anti-inflammatory drugs. Analgesics may be administered as slow release oral preparations, rectally or as injections (Kindler et al 2015). Additionally, adjuvant medications may be prescribed. These medications are not analgesics; however, they have pain-relieving properties, particularly when prescribed with analgesics (Kindler et al 2015). Adjuvant drugs include antidepressants, anticonvulsants and corticosteroids (Kindler et al 2015; Foyle & Hostad 2007). Combination analgesic and adjuvant drug therapies are common in palliative care.

Advances in pain-reduction techniques have seen the introduction of analgesics such as fentanyl patches that can be applied to the skin (Kindler et al 2015). Fentanyl is a potent synthetic opioid medication. When a person is prescribed fentanyl patches, nurses must take extreme care in administering any additional opioid medications such as morphine because of the significant risk of overdose (Kindler et al 2015; Tiziani 2013).

Other pain-relieving medical interventions used in palliative care include surgery, radiotherapy, nerve blocks (injection of anaesthetic agent close to a nerve to cause temporary or permanent blockage in transmission of pain) and chemotherapy (McLean Heitkemper et al 2015). The benefits must outweigh the burden of these treatments, particularly when there are unwanted severe side effects. In quality palliative care, the person and their family are provided with sufficient information about the risks and benefits of any treatment in order to make an informed decision.

Allied health professionals can also provide effective pain relieving interventions; for example, physiotherapy techniques such as ultrasound and laser therapy can be helpful in managing pain (Kindler et al 2015). Additionally, complementary therapies, such as massage, aromatherapy and guided imagery, can be valuable and are often combined with medical and nursing care to enhance the effectiveness of pain-relief measures, to promote relaxation and to reduce anxiety. People

## PROGRESS NOTE EXAMPLE 38.1

| | |
|---|---|
| 20/07/2015<br>0745 hrs | Nursing: Graham visibly distressed and moaning, stating he had considerable pain. Pain assessed pain score 9/10. Graham stated that pain is the same as he has been having only worse. Graham has infusion for pain at 1 mL/hr subcutaneously. Reported to RN G. Bailey and breakthrough pain relief given. Graham repositioned. Within 30 minutes Graham's pain score at 3/10. Graham did not want any further pain relief. Education provided about managing pain, ensuring he asks for breakthrough pain relief when pain begins to escalate. Discussed with Graham and his family supplementary techniques that assist with pain, such as changing position on a regular basis and meditation. Graham has some guided meditation recordings to listen to.<br>***D. Beck* (Beck) EN** |

interpret their pain according to their life experiences, values and beliefs (Kindler et al 2015). Some people view the expression of pain as a sign of weakness or a sign that their condition is deteriorating. Some people are fearful of opiate drugs such as morphine because they believe they will become addicted or that it will hasten their death. The nurse plays an important role in counselling, supporting and educating the person and their family about the benefits and risks of analgesic medications and analgesic interventions. (See also Chapter 33.)

An example of how an entry in to progress notes might be documented has been provided on the subject of breakthrough pain relief and managing pain (see Progress Note Example 38.1).

## Symptoms requiring physical care

Nursing care is fundamental in addressing many symptom areas as identified in Table 38.1. This includes nursing care of activities of daily living, such as hygiene and mouth care; nursing care of continence difficulties, nursing management of mobility difficulties including positioning and nursing care to maintain skin integrity including pressure care (Foyle & Hostad 2007; McLean Heitkemper et al 2015). Individuals are encouraged to eat small nutritious meals frequently to maintain their energy requirements. Nurses encourage individuals to maintain hydration by drinking water frequently throughout the day.

Constipation and diarrhoea may be experienced by individuals and require thorough assessment to identify the cause prior to treatment (Foyle & Hostad 2007; McLean Heitkemper et al 2015). All people taking opioid medications will become constipated as this is an effect of these medications. Therefore, all people prescribed opioid medications should be prescribed aperient medication concurrently. (See Clinical Interest Box 38.6.)

Weakness and fatigue can be minimised by coordinating nursing and other care activities in accordance with the individual's wishes and by encouraging frequent rest periods (McLean Heitkemper et al 2015). Nausea and vomiting must be assessed in order to identify the cause prior to treating these symptoms. Generally, nausea and vomiting will be treated with anti-emetic medications. Dyspnoea is a challenging symptom as it causes anxiety in the affected person. Medical assessment and diagnosis is warranted prior to treatment (Foyle & Hostad 2007; McLean Heitkemper et al 2015). Depending on the cause of dyspnoea, acute medical interventions such as surgery or medication may be required. Conversely, in the terminal phases of the illness when the person is near death, dyspnoea is not generally treated because it is a characteristic of dying.

People who are experiencing a terminal illness commonly report insomnia (McLean Heitkemper et al 2015). Nursing assessment is required to ascertain the causes or factors contributing to the person's insomnia. These factors may be physical or psychosocial. Management will depend on the person's wishes and may include counselling or medication (McLean Heitkemper et al 2015; Stein-Parbury 2014). Complementary therapies may be effective; for example, relaxation and meditation.

Confusion and alterations in consciousness can occur. These symptoms are more likely in the terminal phases of the illness when the person is near death (McLean Heitkemper et al 2015). A thorough assessment is required to attempt to ascertain the causes of the alteration in consciousness. Management will depend on the cause and contributing factors. Pain, constipation, urinary retention and infections can promote confusion. These problems therefore should be identified and treated where necessary (McLean Heitkemper et al 2015). Alterations in consciousness are frightening experiences for individuals and their families. Nurses provide emotional support and reassurance. The nurse or family member should stay physically close to the frightened individual and provide verbal reassurance (McLean Heitkemper et al 2015). Nurses encourage family members to participate in care. Where possible, individuals with alterations in consciousness should be nursed in a quiet and calm environment.

Maintaining comfort depends on continuous reassessment of the individual's needs because physical changes can occur particularly quickly in advanced illness (McLean Heitkemper et al 2015). Pain can escalate rapidly and, because of fatigue, immobility, inadequate nutrition or emaciation, pressure ulcers can develop in a very short time. During all phases of care the nurse continually reassesses the situation while assisting the individual to be as independent as possible (Kindler et al 2015). Symptom management requires effective communication with the multidisciplinary team.

**TABLE 38.1 | Symptom management**

| Symptoms | Identification of issues | Nursing care |
|---|---|---|
| Pruritus (itching)<br>Diaphoresis (sweating)<br>Pressure areas | Impaired skin integrity | Assess skin for breakdown<br>Pressure area care<br>Keep skin clean and dry |
| Sore and dry mouth | Impaired oral mucous membrane | Assess oral mucosa for breakdown<br>Regular mouth care/denture care<br>Hydration |
| Continence difficulties | Urinary incontinence<br>Bowel incontinence | Assess urinary and bowel function<br>Use absorbent pads for urinary incontinence<br>Consider use of indwelling urinary catheter with multidisciplinary team<br>Encourage movement as tolerated<br>Encourage fibre in diet<br>Encourage fluids as appropriate<br>Consider use of aperients with multidisciplinary team |
| Changes in body weight (weight loss) | Imbalanced nutrition: less than body requirements | Assess the individual for anorexia<br>Provide frequent small meals in accordance with the individual's wishes and cultural preferences<br>Consider use of antiemetic therapies with the multidisciplinary team |
| Constipation or diarrhoea | Alteration in elimination<br>Constipation<br>Diarrhoea | Assess the individual for constipation<br>Encourage movement as tolerated<br>Encourage fibre in diet<br>Encourage fluids as appropriate<br>Consider use of aperients with multidisciplinary team<br>Assess the individual for diarrhoea<br>Assess possible contributing factors<br>Refer to multidisciplinary team |
| Nausea and vomiting | Nausea and vomiting | Assess the individual for nausea and vomiting<br>Assess possible causes of nausea and vomiting<br>Consider use of antiemetic therapies with the multidisciplinary team<br>Provide mouth care after the individual has vomited |
| Weakness | Fatigue | Assess the individual for fatigue<br>Encourage frequent rests<br>Time activities to conserve energy |
| Dyspnoea including cough | Ineffective airway clearance | Assess the individual for dyspnoea<br>Position the individual to facilitate airway and improve chest expansion<br>Administer oxygen<br>Refer to multidisciplinary team |
| Insomnia | Alteration in sleep patterns | Assess for insomnia, anxiety and fears<br>Explore the causes of insomnia with the individual<br>Consider referral to the multidisciplinary team<br>Encourage warm drink before bed<br>Listen to the individual and provide emotional support |
| Confusion, restlessness | Alterations in consciousness<br>Delirium | Assess for spiritual distress<br>Assess for delirium and refer to multidisciplinary team<br>Do not restrain<br>Provide a calm and quiet environment<br>Limit the number of people at the bedside |

*(Foyle & Hostad 2007; McLean Heitkemper et al 2015)*

## CLINICAL INTEREST BOX 38.6 Assessing constipation

Department of Health and Human Services Tasmania (2009) suggests that when assessing constipation in the palliative care person, contributing factors other than opioid-induced bowel dysfunction could include:

- Decreased fibre and fluid intake
- Reduced mobility
- Bowel obstruction or reduced rectal/anal tone and sensation
- Medications—serotonin blockers, iron, anticholinergics, some antihypertensives
- Metabolic disorders (e.g. hypercalcaemia, hypokalaemia, hypothyroidism, diabetic autonomic neuropathy)
- Changes in mood (e.g. depression)
- Closeness to death.

*(Department of Health and Human Services 2009)*

## Psychosocial and spiritual care

During a terminal illness, emotions such as anxiety, depression and fear are frequently experienced by individuals and their families (McLean Heitkemper et al 2015; Stein-Parbury 2014). Grief and loss are also part of the response to death and dying. People express grief and loss differently depending on their family and cultural background, and also depending on personal differences (Egan 2013).

Anxiety is a feeling of unease without knowing the cause, or where the cause or contributing factors are not easily identified (Egan 2013). Anxiety is related to fear. People are often more specific about what they fear and commonly report fearing pain, meaninglessness or the unknown. Depression can accompany anxiety (Stein-Parbury 2014). Causes of these challenging feelings can include poorly controlled symptoms such as pain, unwanted effects of medication, family issues or worry about the future for loved ones after the person has died. Nursing care in relation to psychosocial symptoms and spiritual care issues is dependent on the nurse's ability to listen empathically, build a trusting and respectful relationship and tolerate hearing about feelings that cannot necessarily be 'cured'.

A supportive and caring nurse–individual relationship forms the foundation for psychosocial and spiritual care (Egan 2013; Stein-Parbury 2014). Nurses talk to the individual and their family about their feelings and provide support (Egan 2013; Stein-Parbury 2014). Nursing interventions will depend on the nursing assessment findings and could include referral to a member of the multidisciplinary team such as a counsellor or bereavement counsellor, education to reduce anxiety and encouragement and ongoing emotional support. Medication management may be part of the treatment plan. At times anti-anxiety medications and antidepressant medications are warranted. In quality palliative care the individual and family are involved in all treatment decisions (McLean Heitkemper et al 2015).

Individuals, families, nurses and other members of the multidisciplinary team are involved in finding meaning in the death and dying experience (McLean Heitkemper et al 2015). This is understood as spirituality and may or may not include religion. Nurses and the multidisciplinary team are respectful of the different values, beliefs, spirituality and religions of individuals and families in palliative care (Brown et al 2015).

The spiritual dimension of each person is unique (Chaplin & Mitchell 2005; Egan 2013; Stein-Parbury 2014). For some people it may be connected to personal religious beliefs and practices. If the rituals and practices are followed the person is more likely to feel spiritually fulfilled, but if they are not observed the person may feel worried and anxious and suffer spiritual distress. Some people do not believe in a specific faith (Chaplin & Mitchell 2005). Their spirituality is nonetheless related to their sense of who they are and the meaning of existence. Nurses caring for people confronted with death may find them searching for understanding of these issues.

The spiritual dimensions of the individual who is dying may be reflected in a search for meaning in life, or in their suffering, or in their relationship with others (Egan 2013; Stein-Parbury 2014; Chaplin & Mitchell 2005). It may be reflected in a need for hope, love or a sense of forgiveness. Not all people who are dying experience the same needs, nor do they feel them with equal intensity. The nurse with expertise will be sensitive to the spiritual needs of each individual and will implement actions to help those needs to be met (Chaplin & Mitchell 2005; Egan 2013; Stein-Parbury 2014). Some people meet spiritual needs through the rituals associated with organised religion; others may find comfort and meaning in relationships, reading, music, art or meditation.

As with any aspect of caring for the individual who is dying, the multidisciplinary team identify how to provide spiritual support together with the individual (Chaplin & Mitchell 2005; Egan 2013; Stein-Parbury 2014). Religious leaders including chaplains or priests or pastoral care workers may be important people to involve in the person's care. The nurse often supports the individual in identifying the person they would like to speak to and may arrange a referral.

Hope is an important aspect of psychological and spiritual wellbeing (Crisp et al 2013). Effective communication is vital when nursing people who are experiencing loss of hope. Nurses are often confronted by individuals and families who experience a loss of hope during death and dying (Chaplin & Mitchell 2005; Crisp et al 2013). Nursing interventions focus on empathic listening. Additionally, nurses express hopefulness to individuals and families through psychosocial support. Nurses express hopefulness by reassuring individuals and families that the multidisciplinary team will provide expert management of symptoms (Chaplin & Mitchell 2005; Crisp et al 2013). Nurses also express hopefulness by supporting individuals to participate in their lives to the best of their ability. This includes encouraging individuals to

attend and participate in family or social events, encouraging humour where appropriate and discussing everyday issues.

Nurses further express hopefulness by supporting individuals and families to feel empowered (Chaplin & Mitchell 2005; Crisp et al 2013). Nurses facilitate empowerment by encouraging self-care and the participation of family members in care. Often family members want to care for the person during the illness and at the time of death. The nurse supports family members to provide care safely, in accordance with the individual's and family's wishes, by providing education regarding the focus of care; for example, hygiene or pressure care, that has been agreed to by the individual and family (Berger et al 2013). In the home setting, with support and education from visiting nurses, family members provide the specific care required by their loved one (Crisp et al 2013; Kralik & van Loon 2011). Empowering relatives supports their understanding of having contributed to a 'good death' for their loved one. This can be a source of comfort for family during bereavement after the person dies.

## LOSS AND GRIEF

People invariably experience **loss and grief** in response to death and dying (Crisp et al 2013). Loss can be actual or perceived, temporary or permanent, and occurs when someone or something can no longer be seen, heard, known, felt or experienced. Feelings of loss and grief can apply to many events. In palliative care, losses are generally related to life itself, relationships, health, lifestyle, independence, freedom and future hopes and dreams (Crisp et al 2013). All losses affect self-identity (Varcarolis & Halter 2014). The meaning attributed by an individual to a loss is related to the value placed by the individual on the loss. Loss and associated grief cannot be quantified, so it cannot be judged that one person's loss is greater or less than that of another person.

Loss of an aspect of the self can be devastating and can severely affect a person's body image and self-esteem (Crisp et al 2013). Individuals commonly experience grief over the loss of a body part or loss of a physiological function. However, many people adjust to losses throughout their lives and some people gain confidence after coping successfully with loss.

Most people experience grief in response to loss. People grieve very differently. Grief can be influenced by a number of factors including:

- The stage of an individual's growth and development
- Cultural and spiritual beliefs
- Socioeconomic status
- Relationships with significant others
- The meaning of the loss to the person
- Previous loss(es) and coping behaviours (Brown 2007; Cicero 2007).

Grieving is a human response to loss that is thought to assist an individual to adjust to the loss. It generally involves intense and painful emotions relating to loss. Painful feelings diminish with time but may never totally disappear. After any great loss, people return to their lives; however, it is likely that they are 'different' (Crisp et al 2013). A person faced with a serious loss may begin to grieve before the loss actually occurs. For example, older people may experience anticipatory grief as they anticipate the lifestyle changes and losses that old age brings. The process of grieving for a person who is dying is also anticipatory grief. It enables a degree of emotional preparation but, ultimately, the depth of grief is still acute when death eventually does occur (Cicero 2007; Old & Swagerty 2007). Acute grief is a reaction that begins at the time of a loss; for example, loss of a person through sudden death or the loss of a limb as the result of an accident.

While people experience grief in different ways, patterns of grieving have been observed and documented (Crisp et al 2013). Theorists often describe grief as a process that involves several stages or phases. The stages are identified according to descriptions of the responses commonly experienced by people as they face a loss. One well-known theory or model of the grieving process is that described in the late 1960s by Dr Elisabeth Kübler-Ross, a psychiatrist and renowned authority on the process of dying, who describes the grieving process as having five stages:

1. Denial and isolation
2. Anger
3. Bargaining
4. Depression
5. Acceptance (Kübler-Ross 1969).

By recognising the stages that a grieving person may experience, nurses are better able to understand what is happening and respond appropriately to that person (Crisp et al 2013). The grieving person may not experience every stage, or may experience the stages in a different order. Although grief may be observed to follow a logical sequence, it is not necessarily a linear process. For many people it is not simply a matter of 'moving on' if and when a previous stage is 'complete'. It is sometimes impossible to differentiate clearly between stages, as a person rarely moves neatly from one to another (Crisp et al 2013). Generally a person moves back and forth between the feelings of grief until final resolution or acceptance occurs.

The person must be allowed and encouraged to talk and 'work through' their grief (Egan 2013). The nurse requires a caring, understanding, empathic approach and an ability and willingness to listen. Nurses cannot grieve for the person, lessen the intensity of their feelings or protect or shield people (even children) from the pain of the grief experience (Crisp et al 2013). In caring for a grieving person the nurse needs to acknowledge the loss, facilitate the expression of thoughts and feelings and support the person as they move through the different feelings of grieving.

Where the person's health is significantly affected by their grieving, the nurse refers them to the multidisciplinary team such as the medical practitioner, bereavement counsellor or psychologist. (Case Study 38.2.)

## CARE OF THE DYING

**Caring for a person who is dying** is one of the most challenging tasks nurses face (Old & Swagerty 2007). It can be demanding and stressful but can also be very rewarding. Although a nurse cannot control the inevitability of death,

### CASE STUDY 38.2

Joe, 72, has lung cancer. He has been admitted to the hospice today. He has been a frequent visitor to the hospice day centre over the past few months, and several staff members have noted his positive attitude and how well he seems to have been coping physically and emotionally. Joe's condition has deteriorated now and he is not expected to live for more than a few more days. He is alert but extremely agitated at the moment. Margaret, his wife, can't understand this anxiety because he has been so calm throughout his illness. She and his three daughters are finding his agitation very distressing.

Consider factors that may be related to Joe's anxiety.

1. How would you explore his agitation with him?
2. What other health professionals may need to be consulted?

there is much that can be done to make the final stages of life as comfortable as possible for the individual and their significant others. It is important for the nurse to recognise that a person who is dying is also a living person and that, as long as people who are dying are alive, they have the same needs as anyone else (Berger et al 2013). As a result of the dying process, some of those needs assume a greater priority than others. Symptom management is an important priority of nursing care (Kindler et al 2015). The overall goal of care is the promotion of physical and emotional comfort and spiritual ease. Even during the dying process the individual should be helped to retain independence. When this is no longer possible, care should be provided in a manner that preserves self-esteem and dignity.

The nurse supports relatives to maintain a close relationship with the person who is dying right up until the time that death occurs (Berger et al 2013). It is helpful to reinforce that, although the sense of touch may be diminished, the individual may still be able to feel touch and find comfort in this. It is also often helpful to tell family members that hearing may remain intact up until death. If the person who is dying appears to be unaware of their surroundings and not responding, family are advised to speak to them as if they were conscious. It may be comforting for the person who is dying to be able to hear recognised voices or some favourite pieces of music, and relatives may take comfort in providing this solace for their loved one (Old & Swagerty 2007).

### CRITICAL THINKING EXERCISE 38.2

Imagine a specialist has just told you that you have a brain tumour that is inoperable and not curable. Reflect on your own values, attitudes and beliefs and consider what changes would happen in your life as a result of this prognosis. What would you need to help you cope? If you were living in a rural area 2 hours' drive from the nearest city, could you easily access health services to meet your needs?

## Physical care

The dying process is often accompanied by discomfort and nursing problems, including breathing difficulties and alterations in nutrition, hydration, elimination, mobility and sensory perception (Berger et al 2013). In addition, the person who is dying may experience acute or chronic pain. A nursing care plan is developed after assessing the person's needs and, while each individual may have different needs, there are some common problems and some general nursing interventions.

### Impaired mobility

When ambulation is no longer possible, maintenance of good body alignment is an essential comfort measure (deWit & O'Neill 2014). The individual should be positioned as comfortably as desired, with bedding and pressure-relieving mattresses and devices placed to enhance comfort. Individuals should be gently repositioned every 2–4 hours to promote maximum comfort and prevent muscle soreness, contractures and skin breakdown (see Chapter 29).

### Breathing difficulties

The individual may experience shortness of breath and may be unable to cough or expectorate to clear the airway. When possible, the person should be nursed in an upright or semi-upright position to facilitate breathing (Old & Swagerty 2007). When this is not possible, positioning should be on the side, to prevent aspiration of secretions. Oxygen therapy and oronasopharyngeal suctioning may be required to remove secretions and make breathing easier.

### Inadequate nutrition and hydration

If the individual is able to eat and drink, foods and beverages of choice should be provided at the times the individual feels like eating (Old & Swagerty 2007). Alcoholic beverages may stimulate appetite. Thirst may be relieved by chips of ice to suck or soda water. Semi-solid, soft or liquid foods may be offered in accordance with the individual's wishes. It is expected that appetite will decrease as death approaches (Berger et al 2013). Death is usually imminent when the individual can no longer eat and drink therefore medical interventions, including IV therapy for hydration, are not indicated in palliative care. Nurses provide regular mouth care and continue to provide symptom relief with the multidisciplinary team (Kindler et al 2015; Kralik & van Loon 2011). Additionally, families may require considerable support and education from nurses when their loved one is no longer able to eat and drink.

### Problems of elimination

Common problems experienced may include constipation, diarrhoea, impacted faeces, retention of urine and incontinence (of urine and faeces) (deWit & O'Neill 2014). Measures that may be implemented to prevent or alleviate these problems include:

- Laxatives to prevent constipation, if fluid or fibre intake are unable to be maintained
- Rectal suppositories to relieve constipation

- Catheterisation to relieve retention of urine or urinary incontinence
- Protective continence pads and specially designed sheets or external urinary drainage devices, to prevent discomfort and skin breakdown from urinary incontinence
- Maintenance of skin integrity, clean and dry bedding and an odour-free environment.

### Dry mouth

A clean and moist mouth is extremely important, particularly if the individual is unable to swallow (Berger et al 2013; deWit & O'Neill 2014). Mouthwash or rinses are appropriate if the individual is able to expectorate. To prevent the mouth from becoming dry and coated it should be cleansed gently every 2–4 hours. A light film of lip balm should be applied to the lips to prevent skin cracking or to relieve discomfort.

### Eye problems

Dryness and corneal irritation can occur as a result of decreased blinking reflexes (Berger et al 2013; deWit & O'Neill 2014). Measures to prevent or alleviate eye discomfort include cleansing the eyelids to remove crusts, instillation of artificial tears and instillation of eye lubricant ointment. (See Chapter 34.)

### Skin breakdown

If the individual is emaciated and lacks sufficient adipose tissue to support bony prominences, or is unable to move, the risk of developing decubitus ulcers is increased (Berger et al 2013; deWit & O'Neill 2014). To prevent breakdown, the skin should be kept clean and dry, with moisturising lotion applied to counteract any excess dryness. Pressure-relieving devices such as sheepskins or special mattresses including air mattresses could be used, and position changes should occur every 1–2 hours (Berger et al 2013; deWit & O'Neill 2014). (See Chapter 29.)

### Altered sensory perceptions

The person who is dying may experience decreasing visual acuity or tactile sensation (Berger et al 2013; deWit & O'Neill 2014). To minimise any anxiety associated with diminished sensory perception, the room should be softly lit and personal possessions should be placed where they can be easily seen or touched by the individual. Visitors should sit close by and, if the individual's vision is poor, visitors should tell the person who they are. It may be comforting for family to hold their loved one's hand.

The sense of hearing is usually not diminished, so it is important to continue to speak in a conversational tone (Berger et al 2013; deWit & O'Neill 2014). Even if the person who is dying appears to be unaware of surroundings, all family and personnel should assume that the person is still able to hear. Some individuals gain comfort from hearing their favourite pieces of music, and relaxation tapes may also be soothing. If the individual is unable to speak, the nurse should attempt to anticipate needs, and people should continue to make communicative attempts even though there may be no reply.

### Confusion and restlessness

Confusion and restlessness can be caused by physical discomfort such as pain, lack of sleep or retention of urine, or they may be related to medications, such as analgesics, hypnotics and anti-emetics (Kindler et al 2015). Restlessness may be related to anxiety or fear from a variety of sources. It is important to determine the cause and implement appropriate care. If no cause can be found, or if the individual remains restless and confused, mild sedation may be considered.

In palliative care contexts, death is generally precipitated by failure of one or more of the three major body systems: the central nervous system, the cardiovascular system or the respiratory system (Berger et al 2013; deWit & O'Neill 2014). As a person approaches death, the following physiological changes begin to occur:

- Loss of muscle tone, which results in relaxation of the facial muscles, difficulty in swallowing, decreased peristalsis, diminished body movement and decreased urine output, with possible incontinence of urine and faeces
- Slowing of the circulation that results in skin mottling, cyanosis of the extremities and cold skin
- Changes in the vital signs: decreased blood pressure, weaker pulse and changes in breathing. The respirations may become rapid, slow, shallow or irregular. Cheyne–Stokes respirations may occur; this is a cyclical pattern of respirations that gradually become more shallow, followed by periods of apnoea (no breathing) (deWit & O'Neill 2014).
- Changes in sensory perception: blurred vision and impaired sense of taste and smell.

Signs of imminent death include loss of reflexes, faster and weaker pulse, noisy breathing due to accumulating secretions in the throat (sometimes called 'the death rattle') and inability to move (Berger et al 2013; deWit & O'Neill 2014). It is important to remember that hearing is usually the last of the senses to fail.

Death occurs when breathing ceases completely and the heart stops (Berger et al 2013; deWit & O'Neill 2014). A central pulse may be palpable for a brief period following cessation of breathing. The pupils become fixed and dilated. This is the time of death.

## CARE OF THE BODY AFTER DEATH

Traditionally care of the body after death was attended to by the family, but today much care is completed by nursing staff. Every death and family is individual, so discussions with family and carers should be undertaken prior to death to establish how much involvement the family and carers would like. If the individual dies within a hospice, hospital or residential aged care facility, organisational policies and procedures will need to be followed.

Family and carers present at the time of death should be able to spend as much time as they need with their loved one. They should be encouraged to touch the body and some may wish to assist with washing the body. Families should be prepared for the changes that will occur in death, such as the cooling temperature of the body and rigor mortis (Caresearch 2014).

## CARE OF THE BEREAVED

After death has occurred, the significant others may experience shock and disbelief, even if the individual's death was anticipated (Crisp et al 2013). Reactions to the death will vary from numbness and immobility, to outbursts of weeping or wailing, or may include expressions of feeling relief or comfort from the fact that their loved one is no longer suffering. The nurse should not discourage bereaved persons from expressing their grief (Egan 2013). If the nurse is also affected by the death and feels like expressing sadness or crying with the bereaved, this may be appropriate. Alternatively, the nurse may prefer to express their own feelings and grief with a colleague in private.

If the significant others were not present at the moment of death the nurse should ask the family if they wish to view the body. Family members may prefer to view the body later at the undertakers. If family members choose to view the body of their loved one in the care facility or in the person's home the nurse should advise the family about what to expect (Crisp et al 2013). For example, the skin will be very pale, may be discoloured and will feel cold to touch. Depending on the family's wishes, the nurse may accompany the bereaved family into the room and remain or leave them in privacy for as long as they wish to be there.

### CASE STUDY 38.3

Tracey, 22 years old, has just died from leukaemia. You have been nursing Tracey for the past 2 weeks in the hospice and you developed a caring relationship with her over this period. On hearing that Tracey has died, you experience a sense of loss.

Reflect on your feelings. How might this experience influence your ability to nurse?

When the bereaved family are ready to leave their deceased loved one, it is appropriate to direct them to an area where they can sit down and where they can be given the opportunity to discuss their response to the experience (Egan 2013).

Bereaved family members are required to carry out various functions following a death, such as collecting the person's belongings (if the person died in an inpatient setting), informing friends and relatives, notifying a funeral director and arranging a funeral or memorial service. The nurse provides support according to the family's wishes and may inform the bereaved about relevant supports in the community.

## SUPPORT FOR THE NURSE

Care of the dying is challenging for nurses (Crisp et al 2013). It can be very satisfying and also demanding and stressful. Nurses need a network of support to help them cope with these demands. Supports that can help range from personal relaxation activities to professional workplace supports such as specialist education and training, critical incident reflection, clinical supervision and counselling (Crisp et al 2013). (See Case Study 38.3.)

## Summary

Palliative care is a speciality area of nursing. Nurses are valuable members of the multidisciplinary palliative care team and provide care to individuals with a life-limiting illness and their families. Palliative care takes place in many different settings, and many people prefer to die at home. In palliative care contexts, dying is a natural process and people who are dying should be empowered to live life as fully as possible within the limits of their illness. The palliative care team aims to meet physical, psychological and spiritual needs that arise for individuals at the end of their life and to support the individual's family. Quality palliative care and symptom management has the person and their family at the centre of care. Nurses are an important part of the multidisciplinary team supporting a 'good death' for individuals in the home and inpatient settings.

### DECISION-MAKING FRAMEWORK EXERCISE 38.1

You have just commenced working within a unit at the Sunray Residential Aged Care Facility as an Enrolled Nurse. Within this unit there are 25 residents, all with dementia, some of whom are palliative care. On this shift apart from you there are two care workers who both hold a Certificate III in aged care qualification, a diversional therapist and a volunteer. The aged care workers advise you that they will do the medications administration, and that you only need to do the dressings and assess any of the residents in case they exhibit challenging behaviours. The volunteer advises you that she is great with the residents when they become restless and will let you know so that you can give them their 'calming down' pills. You call your supervisor who advises you that this was the normal practice and task allocation.

Using the decision-making process address the following:
1. Do you accept this allocation of duties?
2. What (if any) are the issues that could potentially result in you working outside of your scope of practice?
3. Identify the potential and/or actual flaws within this scenario.

## Review Questions

1. List three (3) major functions of a multidisciplinary palliative care team.
2. Describe how you could provide a warm, caring environment for a dying resident in an aged care facility.
3. What is an advance care plan and how will this assist a palliative care person as their condition deteriorates?
4. List five (5) physical symptoms associated with incurable illness.
5. What nursing actions could help an emaciated individual whose pain is controlled but who cannot get physically comfortable in bed?
6. Describe five (5) ways you can promote a sense of wellbeing in the partner of a person who is dying in the acute care hospital setting.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER 39

# Mental health and mental illness

*Louise Alexander*

## KEY TERMS

constructive coping strategies
deinstitutionalisation
destructive coping mechanisms
mental health
mental illness
myths
self-concept
stigma
stress
theoretical models

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Understand the continuum of mental health and mental illness
- Identify factors that influence the development of mental health
- Reflect on the causes and impact of stigma on people with mental illness
- Understand the roles of the mental health nurse and the mental health team
- Gain an overview of the care issues involved when consumers experience anxiety or depression, or aggressive, self destructive, hyperactive or confused behaviour
- Develop an awareness of some of the basic legal and ethical issues in the field of mental health nursing

## CHAPTER FOCUS

The term 'individual' will be replaced in this chapter with the more contemporary and clinically acceptable term 'consumer' (Commonwealth of Australia 2010). Individuals within the mental health system are known as *mental health consumers*.

Mental health nursing is a specialised field of nursing; however, mental health *literacy* is important for all nurses regardless of their specialty area. One in every five Australians will have a mental illness in any 12-month period and the lifetime prevalence for developing a mental illness between the ages of 16 and 85 is over 45% (Australian Bureau of Statistics (ABS) 2008). It is estimated that by 2030 depression will be one of the leading causes of disease in Australia (Victorian Government 2007) resulting in considerable increase in government expenditure (Goss 2008). Research indicates that the mentally ill on average die prematurely compared with the general population—in some studies by around 25 years. This is significantly affected by socioeconomic status, access to healthcare and long-term side effects of psychotropic medications (Department of Health and Human Services 2012). A variety of educational programs are aimed at preparing mental health nurses (MHNs) to work specifically and effectively with consumers who have mental health disorders. A nurse who has not undertaken a course specific to mental health nursing is likely to be required to assist in caring for a consumer with a mental illness. The nurse may be required to work in a psychiatric unit or ward within a general hospital, or to assist in caring for a consumer who has been admitted to a general medical or surgical ward with a physical illness but who has a concurrent mental health problem. It is therefore important that every nurse has a basic understanding of mental health, mental illness and the principles of care related to consumers who are experiencing a disturbance in mental wellbeing. It is not the aim of this chapter to provide the reader with comprehensive knowledge and skills to care for consumers with mental health disorders. Rather, this chapter aims to introduce nurses to the basic concepts of mental health nursing, some of the theoretical frameworks that underpin psychiatric care and to raise awareness of some legal and ethical issues that confront MHNs. The texts and online resources listed at the end of this chapter provide more detailed information.

## LIVED EXPERIENCE

I would wake up in the morning feeling like I didn't want to face the day. There was a black cloud hanging over me. I wanted to stay in bed and shut out the world. I felt at these times that I was in an absolute pit of hopelessness and despair about life and I didn't want to go on. I was a burden to myself and my family. My sister took me to see my doctor and I was admitted to a psychiatric hospital. I didn't want to be there because I believed no one could help me. After some time the nursing care and antidepressant medication I was prescribed helped me to slowly climb out of my pit of despair. One day I found myself enjoying looking at the autumn leaves falling and I knew that I was getting better. Now I understand that depression is a severe illness and I will look for help if I feel myself slipping back.

**Maria, diagnosed with major depressive disorder at age 25**

# CONCEPTS OF MENTAL HEALTH AND MENTAL ILLNESS

Perhaps the most important aspect of understanding mental illness is being able to define the difference between mental illness and mental health. This first section aims to help nurses gain an understanding of mental health and mental illness and the factors that impact on both.

## What is mental health?

The concept of **mental health** is difficult to define, as mental health is much more complex than merely the absence of a mental illness; the two are not mutually exclusive (World Health Organization 2015). There are numerous definitions of what constitutes mental health. It has been defined as a state in which people are able to fulfil their own potential and manage recurrent stresses of everyday living in an acceptable way (WHO 2015). It has also been defined as the ability of people to cope well with stress, both internal and external (Antai-Otong 2008). According to the World Federation for Mental Health (2008, cited in Barkway 2013:123):

*Mental health is a state of complete physical, mental, spiritual and social wellbeing in which each person is able to realise one's abilities, can cope with the normal stresses of life, and make a unique contribution to the community.*

For most people, the experience of mental illness is non-linear; it is a continuum with ebbs and flows and can vary in intensity and duration. According to this view, mental health is a state that can change frequently and that can fluctuate according to specific circumstances. Touhy and Jett (2009) captured the concept of fluctuation in this definition:

*Mental health is like a violin with strings of interaction, behaviour, affect (mood) and intellect. All of this together may produce a pleasant or stimulating melody, or they may be discordant and irritating. The tune constantly changes. No one is entirely mentally unhealthy and no one is fully mentally healthy at all times.*

The terms 'mental health' and 'mental illness' are often used interchangeably but they should not be: the difference

between the two needs to be clear (Elder et al 2013). The American Psychiatric Association (APA 2013) defines mental illness or mental disorder as an illness or a syndrome with psychological or behavioural manifestations and/or impairment in functioning due to a social, psychological, genetic, physical/chemical or biological disturbance.

Table 39.1 illustrates some differences between mental health and mental illness.

## Development of mental health

Mental illness development is likely a multifactorial interplay between environment factors and biological characteristics. According to Hoffnung and colleagues (2013) the factors that influence the development of mental health relate to three main areas: inherited characteristics, nurturing during childhood and life circumstances.

### Inherited characteristics

It is believed by some theorists that the ability to maintain a mentally healthy and positive outlook on life is in part connected to a person's genetic makeup, just as inherited defective genes are thought to predispose particular people to illnesses such as schizophrenia and depression.

### Nurturing during childhood

Nurturing during childhood relates primarily to the relationships that develop between children, their parents and their siblings. It is thought that positive relationships, those that promote feelings of being loved, secure and accepted, facilitate the development of children into mature and mentally healthy adults. It is thought that negative relationships may result when children experience maternal deprivation, parental rejection, serious sibling rivalry and early communication failures. Such relationships are more likely to result in a poor sense of self-worth and a lower level of mental health (Hoffnung et al 2013). The quest for a sense of self begins in childhood; children who have positive nurturing experiences are more likely to have a stronger sense of identity than those who have negative nurturing experiences (Hoffnung et al 2013).

### Life circumstances

Life experiences can influence mental health from birth onwards. Positive life experiences include pleasurable times and success at school and with friends, a good job, financial security and good physical health. Negative experiences include poverty, poor physical health, unemployment and unsuccessful personal relationships (Shives 2011).

Different people will react to childhood experiences and life circumstances in different ways. Some, despite negative circumstances, will develop positive strategies for coping and will not become mentally ill. Generally it is people who have not achieved a strong sense of identity who are more prone to mental illness (Watkins 2001). Perhaps this is most clearly understood when considering the mental health of Indigenous populations. It is not difficult to imagine how the effects of colonisation, the removal of children from their families, the loss of traditional lifestyle and cultural practices and the resulting social disruption may impact negatively on mental wellbeing. It is generally understood that the difficulties involved in belonging and adjusting to two different cultural contexts can make it difficult to establish a strong sense of identity.

Nurses working with Indigenous people can better empathise and not negatively judge behavioural signs of mental illness if they recognise that it often stems from deep mental anguish and spiritual sorrow relating to the effects of European invasion (Hungerford et al 2015). Aboriginal and Torres Strait Islander (ATSI) peoples are hospitalised for mental illness at almost twice the rate of non-Indigenous Australians (Australian Institute of Health and Welfare (AIHW) 2011), have higher suicide rates (beginning at a younger age), demonstrate higher levels of self-harm (Department of Health 2013) and report higher levels of psychological distress (ABS 2011). Given that mental illness rates in the ATSI communities are disproportionately higher than in other demographics, ATSI mental healthcare is an important health practitioner consideration (Nadew 2012).

### Risk or vulnerability factors in mental illness

Risk, or as they are also known, vulnerability, factors are those circumstances which increase a consumer's vulnerability or susceptibility to develop a mental illness. While the presence of these factors does not equate to a certainty of developing a mental illness, they are good predictor of a consumer's susceptibility in developing a disorder. Risk factors are an interplay between consumer, familial and environmental factors which include:

- Lack of opportunities to exert control over one's life
- Genetic predisposition to mental illness (positive family history of mental illness)
- Poor health literacy
- Discrimination
- Low self-esteem
- Poverty, unemployment and homelessness
- Domestic and/or neighbourhood violence
- Political unrest or war
- Abuse (sexual, physical, verbal and neglect)
- Family conflict
- Poor conflict resolution skills
- Poor coping mechanisms to stressful situations (Compton 2010).

### Protective factors in mental illness

Given that risk or vulnerability factors may predispose or increase the likelihood a consumer will develop a mental illness, there are in contrast a number of factors that can aid in the prevention of mental illness. The presence of protective factors assists in the prevention of mental illness during times of stress and they include:

- Positive self-esteem and self-image
- Supportive relationships with peers and family
- Access to educational and employment opportunities

## TABLE 39.1 | Some differences between mental health and mental illness

| Signs of mental health | Signs of mental illness |
|---|---|
| **Happiness** | **Major depressive episode** |
| Finds life enjoyable<br>Can see in objects, people and activities the possibilities for meeting their needs<br>Can manage the day-to-day changes in life successfully | Loses interest or pleasure in all or almost all usual activities or pastimes<br>Describes mood as low, depressed, sad, hopeless, discouraged, 'down in the dumps'<br>Weight loss or gain<br>Sleep pattern changes<br>Feelings of hopelessness, excessive guilt or helplessness<br>Suicidal ideation<br>Concentration issues |
| | **Bipolar disorder (manic episode)** |
| | Experiences persistently elevated, expansive or irritable mood<br>Decreased need for sleep but remains energetic<br>Pressured speech<br>Inflated self-esteem<br>May present with psychotic features |
| **Control over behaviour** | **Control disorder: under-socialised, aggressive** |
| Can recognise and act on cues to existing limits<br>Can respond to rules, routines and customs of the group to which they belong<br>Has appropriate opportunities for control | Shows repetitive and persistent pattern of aggressive conduct in which the basic rights of others are violated |
| **Appraisal of reality** | **Schizophrenia** |
| Has an accurate picture of what is happening around them<br>Good sense of the consequences of both good and bad that will follow their acts<br>Can see the difference between the 'as if' and the 'for real' in situations | Delusions<br>Hallucinations<br>Thought disorder<br>Disorganisation in thoughts<br>Negative symptoms |
| **Effectiveness in work** | **Adjustment disorder with work (or academic inhibition)** |
| Within limits set by abilities can do well in tasks attempted<br>When meeting mild failure persists until determines whether they can do the job | Shows inhibition in work or academic functioning whereas previously there was adequate performance |
| **Healthy self-concept** | **Dependent personality disorder** |
| Sees self as approaching their individual ideal; as capable of meeting demands<br>Has a reasonable degree of self-confidence that helps them to be resourceful under stress | Passively allows others to assume responsibility for major areas of life because of inability to function independently<br>Lacks self-confidence (e.g. sees self as helpless or stupid) |
| **Satisfying relationships** | **Borderline personality disorder** |
| Experiences satisfaction and stability in relationships<br>Socially integrated and can rely on social supports | Shows patterns of unstable and intense interpersonal relationships<br>Has chronic feeling of emptiness<br>Engages in risk-taking behaviour<br>Mood fluctuations<br>Self-harm attempts or suicidal ideation |
| **Effective coping strategies** | **Substance dependence** |
| Uses stress-reduction strategies that address the problem, issue or threat (e.g. problem solving, cognitive restructuring)<br>Uses coping strategies in a healthy way that does not cause harm to self or others | Repeatedly self-administers substances despite significant substance-related problems (loss of employment, family and social networks)<br>Uses substances as a way of coping with daily stress or adverse events |

*(Compiled from Varcarolis & Halter 2010)*

- Effective self-regulatory skills such as healthy coping mechanisms, impulse control and the ability to emotionally regulate
- Suitable and appropriate role models
- Resilience (Compton 2010).

## What is mental illness?

Just as it is difficult to arrive at a precise definition of mental health, so too it is difficult to succinctly define mental illness because it is often related to what a given society considers is normal or acceptable behaviour and, as with mental health, mental illness is a matter of degree.

### What society considers normal

People tend to evaluate the behaviour of others based on their own social, cultural, ethical and behavioural standards. Therefore, behaviour that is regarded by one person as acceptable and normal may be perceived by another person as totally unacceptable. In addition, what is accepted as normal in a society may change over time. For example, homosexuality was previously considered a diagnosable clinical mental disorder but is now no longer classified as a mental disorder (Antai-Otong 2008). When a person's behaviour is in question it is appropriate to ask 'Who is qualified to decide whether this behaviour is acceptable or not?' and 'What is the meaning and relevance of this behaviour in relation to the context in which it is occurring and to the person's society, religion and culture?'

In every society and cultural group there are different interpretations of certain behaviours and events. For example, in Western psychiatric terms, visual or auditory hallucinations (images or sounds that are seen or heard by a consumer but by no one else) are viewed as abnormal and a sign of mental illness, whereas in some cultures these happenings are viewed as experiences of symbolic and spiritual importance and those experiencing them may be revered as visionaries rather than mentally ill (Varcarolis & Halter 2010).

### A matter of degree

Anxiety, fear, anger, sadness and the need to be alone are feelings commonly identified in mental illness but they are normal feelings experienced at different levels of intensity by most people at various times. Depending on the intensity of the emotions, people may not feel as mentally healthy as they do at other times but will not necessarily be classified as mentally ill. It is when the feelings are exaggerated and extend over longer periods of time than deemed normal that the person is likely to seek professional help and be diagnosed as having a mental illness. For example, a diagnosis of a depressive disorder is likely when sadness or feelings of being 'down in the dumps' become deep, long-lasting feelings of despair that the person cannot escape from without professional help. The ramifications of these negative feelings can impact on the consumer's ability to function at school or work, and in interpersonal relationships. Mental illness or mental disorder are therefore terms used to designate changes from normal mental functioning that are sufficient to become, and be diagnosed as, a clinical disorder. Broadly, **mental illness** can be defined as a state in which a consumer exhibits disturbances of emotions, thinking and/or action, but it can be defined in a multitude of ways.

Clinical Interest Box 39.1 provides a range of definitions of mental illness.

There is no clear line that divides mental health from mental illness, although the use of explicit diagnostic criteria is useful in identifying mental states which deviate from the 'norm'.

Table 39.2 provides some areas of comparison between the two but it should be noted that, while these are general

### CLINICAL INTEREST BOX 39.1 Definitions of mental illness

- Mental illness is a term that refers to all the different types of mental disorders. These include disorders of thought, mood or behaviour that cause distress and result in a reduced ability to function psychologically, socially, occupationally or interpersonally (APA 2013)
- A disease that causes mild to severe disturbances in thought and/or behaviour, resulting in an inability to cope with life's ordinary demands and routines (National Mental Health Association (USA) 2012)
- A disorder causing abnormal behaviour more often than in most people (Shives 2011)
- Psychopathology exhibiting frequent irresponsibility, the inability to cope, being at odds with society and an inaccurate perception of reality (Shives 2011)
- The absolute absence or constant presence of a specific behaviour that has social implications regarding its acceptance (Shives 2011)
- The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) is a classification system for mental illness (APA 2013). In the fifth edition (DSM-5), mental illness is defined as being a clinically significant behaviour or psychological syndrome or pattern that occurs in a consumer and that is associated with present distress (e.g. painful symptom) or disability (i.e. impairment in one or more areas of functioning) or with a significantly increased risk of suffering death, pain, disability or an important loss of freedom. In addition, this syndrome or pattern must not be merely an expectable culturally sanctioned response to a particular event; for example, the death of a loved one. Whatever its original cause, it must currently be considered a manifestation of a behavioural, psychological or biological dysfunction in the consumer. Neither deviant behaviour (e.g. political, religious or sexual) nor conflicts that are primarily between the consumer and the society are mental disorders unless the deviance or conflict is a symptom of a dysfunction in the consumer, as described above.

*(APA 2013)*

**TABLE 39.2 | Areas of comparison between mental health and mental illness***

| Attribute | The mentally healthy person | The mentally ill person |
|---|---|---|
| **Self-concept** | Accepting of self and others. Able to develop talents and potential to fullest extent<br>Adequately in touch with self and able to use the personal resources identified<br>Acknowledges personal strengths and limitations | Poor self-image, low sense of self-worth and unable to recognise talents, so cannot achieve personal potential<br>Lacks confidence and feels inadequate<br>Tends not to recognise personal strengths and limitations |
| Relationships | Able to form close, meaningful and lasting relationships. Can communicate emotions and can give and receive<br>Can accept authority<br>Can share with people and grow from the experiences<br>These factors often mean the presence of a strong social support network that aids coping in times of stress | Inability to cope with stress can result in disruption, disorganisation, inappropriate responses and unacceptable behaviour that make it difficult to meet the expectations of others in work or social environments. This means that there may be an inability to establish or maintain meaningful relationships. These factors may result in a limited social support network |
| Outlook on life | Optimistic and positive view, sense of purpose and satisfaction | Tends to a pessimistic negative view of present and future |
| Coping and adaptation | Able to tolerate stress and return to normal functioning after stressful events. Can cope with feelings such as frustration and aggression without becoming overwhelmed | Can feel overwhelmed by even minor levels of stress and may react with maladaptive behaviour |
| Judgment/decision making | Uses sound judgment to make decisions and is able to problem solve<br>Is able to learn the consequences of behaviour and apply it to new situations | May display poor judgment and avoid problems rather than attempting to solve them |
| Characteristics/traits | Can delay gratification | May feel an urgency to have personal wants and needs met immediately and may demand immediate gratification |
| Level of functioning | Accepts responsibility for own actions<br>Can function effectively and independently | May act irresponsibly, be unable to accept responsibility for own actions and may blame others for outcomes<br>May exhibit dependency needs because of feeling inadequate |
| Perceptions | Able to differentiate between what is imagined and what is real because can test assumptions by considered thought. Can change perceptions in light of new information | May be unable to differentiate reality |

*(Shives 2011; Sadock et al 2015; Varcarolis & Halter 2010)*

*It should be noted that these are general points only. Different types of mental illness manifest with different effects and, while there are traits that mentally healthy people tend to share, many mentally healthy people may experience several areas of dysfunction at different periods in their lives. Mental illness may occur as a temporary inability to cope; it may occur episodically with long periods of mental health in between; or it may occur as a chronic condition that is constantly present.

traits that mentally healthy or mentally ill people tend to share, different types of mental illness manifest with different effects and with different levels of intensity. In addition, mentally healthy people may experience more than one type of mental dysfunction at different periods in their lives. For some consumers, more than one mental illness may occur concurrently, or over time, or a consumer may develop a substance misuse disorder in addition to a mental illness (known as dual diagnosis).

## Signs and symptoms of mental illness

Symptoms of mental illness occur on a continuum and range from minimal to severe. The journey is seldom linear with ebbs and flows (Hungerford et al 2015). A person usually

receives a diagnosis of having a mental illness when the level of mental distress causes them to seek professional help or when others in society perceive that they need professional psychiatric help. It is important to recognise that, in relation to the differences between mental health and mental illness, there is a 'grey' area into which all consumers may enter from time to time. Those with a severe and long-term psychiatric disorder may dip back into relative mental health and reality-based living for a while and, similarly, sometimes the stresses of everyday living are so overwhelming that the well-adjusted 'normal' person may experience marked irrational thoughts, feelings and actions. Therefore, as in the case of physical illness such as diabetes, heart disease or cancer, anyone can develop a mental illness. A mental illness is not the fault of the person affected, and the cause may be related to a combination of biological, psychological and sociocultural factors or interplay of all these factors simultaneously.

Symptoms of mental illness include changes in personal habits, social withdrawal and changes in mood and thinking. While particular symptoms occur with specific disorders, there are warning signs that may indicate the presence of a mental health problem. Clinical Interest Box 39.2 provides examples of early warning symptoms of mental illness that may occur in children, adolescents and adults.

### Who is most at risk of developing a mental illness?

Anyone can develop a mental illness but some groups of people in society are particularly at risk. Clinical Interest Box 39.3 identifies groups of people at greater risk of mental illness.

Many people from all age groups and of different social, educational and cultural backgrounds cope with highly stressful events and accumulative stressors.

## Classification of mental disorders

There are more than 260 classified forms of mental illness. These include:

- Neurocognitive disorders (e.g. dementia, delirium)
- Substance-related and addictive disorders (e.g. alcohol abuse or dependence, drug abuse or dependence)
- Anxiety disorders (e.g. phobias, panic disorder)
- Obsessive–compulsive and related disorders
- Schizophrenia spectrum and other psychotic disorders (e.g. schizophrenia, schizophreniform disorder)
- Trauma and stressor-related disorders (e.g. PTSD)
- Dissociative disorders (dissociative identity disorder, formerly multiple personality disorder)
- Mood disorders (e.g. depression, bipolar disorder)
- Personality disorders (e.g. antisocial personality disorder, dependent personality disorder)
- Sexual and gender identity disorders
- Feeding and eating disorders
- Sleep-wake disorders
- Sexual dysfunctions
- Disruptive, impulse-control and conduct disorders
- Paraphilic disorders (APA 2013).

## Diagnosis

The American Psychiatric Association's (2013) *Diagnostic and Statistical Manual of Mental Disorders 5th edition* (DSM-5) is a respected and influential classification system under which a mental illness is determined according to the symptoms experienced and the clinical features of the illness. The International Classification of Disease (ICD) is produced by the World Health Organization and is mainly used In Europe. It also assists with diagnosis and classification. In Australia, New Zealand and the United States the fifth edition of the DSM (DSM-5) (APA 2013) is most commonly used.

There are many categories of classification but mental illness is mainly classified within the following areas:

- Thought disorders, such as schizophrenia and psychosis, which disrupt the ability to think and perceive things clearly and logically and can impair a person's perception of reality
- Mood disorders, which affect how a person feels and can result in persistent low mood (depression) or cycles of low and elevated moods (bipolar disorder)
- Behavioural disorders, which involve people acting in potentially destructive ways, including eating disorders such as anorexia nervosa and bulimia
- Personality disorders, which involve pervasive patterns of internal experience that deviate considerably from what others experience
- Mixed disorders, which have components of two or more of the other categories (APA 2013).

Diagnosis according to the DSM-5 (APA 2013) has the benefit that consumers may feel great relief when they have a diagnosis that helps them make sense of what is happening to them, and a medical diagnosis can guide clinical treatment. But this diagnostic system has a disadvantage in that a diagnosis can also be a label that has negative connotations; for example, a label of schizophrenia or a personality disorder is associated with significant social **stigma**. The impacts of stigma on consumers suffering mental illness are significant and range from reduced self-esteem, delay in treatment-seeking behaviour to treatment and medication non-adherence and suicide (Hansson et al 2011; Martinez et al 2011; Reavley & Jorm 2011). Diagnostic labels describe certain types of behaviour but they indicate very little about the nature or causes of the experience.

Mental health nurses develop nursing diagnoses in response to the consumer's experience, emotions and behaviours. Nursing care responds holistically to the consumer's biological, psychosocial, spiritual and environmental needs and specifically addresses the consumer's feelings and behavioural responses to those feelings, many of which are common across several different medically classified conditions. Examples of some nursing diagnoses commonly used in mental health nursing are provided in Clinical Interest Box 39.4.

A mental disorder can be categorised as temporary, episodic or chronic/enduring, according to the way it manifests:

- Temporary: a temporary inability to cope; for example, a single experience of depression. The vague definition

## CLINICAL INTEREST BOX 39.2 Warning signs and symptoms of mental illness

People may have one or two of these or other symptoms at any one time. This does not necessarily mean there is cause for alarm, but it is advisable they be assessed professionally. A combination of multiple symptoms is a strong signal that professional assessment and help should be sought as soon as possible.

In younger children:

- Decline in standard of performance in school work or activities that does not pick up again over time
- The child is not managing or coping with tasks as expected at their developmental age
- Suggestions from teachers that there may be a learning difficulty, a behavioural problem or a problem making friends
- Hyperactivity
- Persistent crying, waking at night or nightmares
- Persistent disobedience or aggression
- Frequent temper tantrums
- Excessive anxiety (e.g. preoccupation with fears of burglars, barking dogs, parents getting killed)
- Constant fighting with other children, and reports from school of the child being 'angry or disruptive'
- Refusal to go to school
- Refusal to go to bed, inability to sleep or a need to sleep with, or close to, parents
- Decreased interest in playing
- The child tries to stimulate themself in various ways (e.g. hair pulling, rocking of the body, head banging)
- The child constantly says things that indicate low self-esteem (e.g. 'I'm stupid', 'I never do anything right', 'No one likes me', 'I'm too skinny', or too fat, too tall, too ugly, etc)
- The child is preoccupied with fire, or sets fires
- The child is physically aggressive to people or animals.

In older children and adolescents:

- Frequently asks or hints at the need for help
- Fears or phobias that interfere with normal activities
- Substance misuse
- Change in sleeping/eating/hygiene habits
- Isolating self from others excessively
- Exhibits violence to others
- Inability to cope with problems and usual daily activities
- Excessive complaints about physical aches and pains
- Emergence of bizarre or unusual behaviour or thoughts
- Defiance of authority, truancy, theft and/or acts of vandalism
- Intense fear of weight gain
- Frequent outbursts of anger
- Demonstrates ritualistic behaviours (e.g. preparing for bed, a meal or going out) using routines that are exact, precise and never vary
- Provocatively sexual behaviour that is not appropriate
- Participates in mutilating or killing animals
- Persistent and prolonged low mood (a major concern, especially if accompanied by poor appetite or thoughts and talk of death or signs of self-mutilation)

In adults:

- Confused thought processes
- Prolonged periods of sadness/low mood and apathy or prolonged periods of excessive happiness
- Feelings of extreme highs and lows
- Persistent irritability
- Excessive anxiety/worrying
- Unrealistic or excessive fears
- Strange or grandiose ideas
- Social withdrawal
- Marked changes to eating/sleeping/hygiene or other habits
- Strong feelings of anger/outbursts of violent behaviour
- Increasing inability to cope with usual activities of everyday life
- Denial of anything being wrong even in light of obvious problems
- Numerous unexplained physical ailments
- Substance misuse
- Delusions or hallucinations
- Thoughts/talk about suicide or homicide (professional help needed immediately)

*(APA 2013; National Mental Health Association (USA) 2012)*

## CLINICAL INTEREST BOX 39.3 People at risk of mental illness

Anyone can develop a mental illness, but people at particular risk include:

Life stages:

- Adolescents: adolescents face a period of enormous physical, psychological and social change. Some adolescents may not have sufficient resources to cope with the demands placed on them at this challenging stage of life and to complete the developmental tasks necessary to move successfully from adolescence to adulthood. Erik Erikson's theory of personality development (Erikson & Erikson 1997) is one that is useful to explore in relation to life stages and developmental tasks. Childhood is a particular period of vulnerability to abuse and neglect, both of which increase the likelihood of mental illness developing
- New parents: new parents face a multitude of stressors (things that trigger a stress response) as well as many pleasures connected with a new baby. Stressors may include conflict over the acceptance of the pregnancy, transition from being a couple to being parents, loss of financial income, a baby's constant demands and anxiety about the infant's welfare
- Women: women face factors such as a disadvantaged status in society, internal conflict arising from decisions about whether to pursue a career, become a home-maker or try to achieve both, or being subjected to domestic violence or abuse. These are social factors that may possibly predispose some women to mental illness
- Older adults (male and female): older adults may face many stressors, including loss of work role status because of retirement, reduced income, fear of declining physical and mental abilities, relocation, death of a partner and/or friends and siblings of similar age. The effect of these multiple losses may accumulate and leave some older adults at risk of mental illness.

Populations:

- Refugees and migrants: these people may experience a grief reaction on leaving their homeland, friends and family to live in a country where the cultural practices, values and beliefs are different and where they may be considered of low status and worth. It may be difficult for some migrants to work successfully through their grief because of language barriers, the stress from job and financial uncertainty and lack of support from relatives and friends left behind. Some refugees and migrants may experience problems of adjustment, isolation and loneliness, each of which may contribute to mental illness. In some cases refugees have experienced torture and trauma in their country of origin, which creates a high risk of developing a post-traumatic stress disorder (Griffiths et al 2003)
- Aboriginal and Torres Strait Islander (ATSI) peoples
- Homeless
- Unemployed
- Physically or intellectually impaired persons: factors such as isolation, lack of meaningful relationships, social restrictions caused by disabilities, poor self-esteem and negative stigmatising community attitudes towards people with disabilities are all aspects of experience that can elevate the risk of mental illness, particularly anxiety and depression (Dewer & Barr 1996).

Individual risk factors:

- Alcohol and other drug use
- Physical health
- Genetics.

Community-level risk factors:

- Social exclusion
- Discrimination
- Bullying.

of 'a nervous breakdown' is a common non-medical term for this kind of isolated non-recurring illness

- Episodic: an illness that occurs episodically; for example, recurrent episodes of a disabling condition such as bipolar disorder (once known as manic depression) or schizophrenia. While the condition is disabling when it occurs, the person affected can often enjoy a comparatively normal life for much, if not most, of the time
- Chronic/enduring: a constant disabling and unrelenting illness that is extremely challenging for the affected person and their families to deal with; for example, chronic schizophrenia or bipolar disorder or irreversible dementia can be disabling.

Although use of the terms psychosis and neurosis to describe particular illnesses is no longer favoured, nurses need to be aware of the meanings associated with each as the terms are still used in some contexts. The terms are out of favour because symptoms ascribed to each condition can occur in the other, and this causes confusion. The term psychosis refers to disorders that are so marked and incapacitating that the person who is afflicted experiences altered sensory perceptions, unusual or bizarre thoughts and speech or behaviour that is disorganised. Psychosis was the term traditionally used to describe disorders such as schizophrenia and bipolar disorder,

## CLINICAL INTEREST BOX 39.4 Examples of identification of issues by nurses used in mental health nursing

- Impaired social interaction: insufficient or excess quantity or ineffective quality of social interactions
- Ineffective coping: inability to form a valid appraisal of the stressors, inability to use available resources
- Chronic low self-esteem: long-standing negative feelings about self or own capabilities
- Self-care deficit: impaired ability to perform or complete activities of daily living (e.g. hygiene, toileting, nutrition)
- Imbalanced nutrition, less than body requirements: intake of nourishment insufficient to meet the body's metabolic needs
- Powerlessness: perception that one's own actions will not significantly affect an outcome; a perceived lack of control over a current situation
- Disturbed thought processes: disruption in cognitive abilities and activities
- Disturbed sensory perceptions: alteration in the amount or patterning of incoming stimuli accompanied by a diminished/exaggerated/distorted/impaired response to the stimuli (often used for consumers who are experiencing delusions, hallucinations or illusions or have impaired awareness of self/environment)
- Impaired verbal communication: diminished, delayed or impaired ability to understand or transmit verbal messages
- Dysfunctional grieving: prolonged unsuccessful use of strategies and responses by which people attempt to work through the process of grieving
- Risk for injury: potential for injury as a result of environmental conditions interacting with the consumer's adaptive and defensive resources
- Risk for self-directed violence, risk for other-directed violence: existence of the potential for a consumer to be physically, emotionally or sexually harmful to self or others
- Risk for suicide: potential for self-inflicted life-threatening injury

*(Fortinash & Holoday Worret 2011; Varcarolis & Halter 2010)*

in which the symptoms experienced were quite different to those experienced by other people and included delusions and hallucinations (Elder et al 2013). Psychosis is typically seen in schizophrenia, severe mania and sometimes in severe depression. Clinical Interest Box 39.5 provides explanations and examples of delusions and hallucinations.

Unlike people suffering from a psychotic disorder, those with what used to be termed a 'neurosis' have insight into their condition. For example, a person who has an obsessive–compulsive disorder may experience persistent and intrusive thoughts (obsessions) about personal cleanliness (APA 2013). To decrease the level of anxiety the person may wash their hands hundreds of times a day, even if their hands become red and raw (compulsion to act). When they are extreme, such thoughts and acts may be so unusual and disrupt the person's life to the degree that to the observer the person is mentally ill. Unlike those experiencing a psychotic disorder, the affected person is aware that the behaviour is abnormal (there is insight into the behaviour and the illness). Despite their condition, people who have what was once classified as a neurosis can often continue to function in society, whereas a person who is psychotic may not function effectively (Varcarolis & Halter 2010). Nursing diagnosis should always be developed through the lens of a consumer-centred approach which respects the consumer's social and individual experience of their illness.

## Theoretical models and causation of mental illness

Historically the medical profession was prominent in the care of people with mental illness and as a result there has been, and still is, a strong focus on identifying physical causes of mental illness. However, others have looked at psychological, sociocultural, interpersonal and human development factors and there are now many **theoretical models** used to explain the presence of a mental disorder. Mental health nurses select concepts from the various relevant models that best explain the consumer's behaviours, problems and needs. They then draw on these concepts as a basis for the consumer's assessment and then for planning, conducting and evaluating care (Varcarolis & Halter 2010). The following provide very basic examples of a small selection of theoretical models. To work effectively in the area of mental health, however, nurses need a deep and sound understanding of a wide range of models.

### The medical or biological model

This model explains mental illness as being caused by physiological malfunction in the body. Physical causes can be separated into acquired and non-acquired factors. Acquired causes include head injury, cerebral infection and substance misuse. Non-acquired causes include genetic transmission, electrical conductivity changes in the brain or alterations to the production and/or activity of neurotransmitters (Elder et al 2013). There is evidence to support biological explanations. For example, studies indicate that depression and schizophrenia may be linked to abnormal neurotransmitter function, and that genetic factors may be linked to both (Elder et al 2013). A medical approach to treating mental illness tends to focus primarily on medication and sometimes includes electroconvulsive therapy (ECT), both of which aim to correct chemical imbalance in the body believed to be caused by abnormal neurotransmitter function in the brain. Emil Kraepelin (1856–1926) is a theorist associated with the origins of the medical model.

### Psychological and psychodynamic models

The psychoanalytical model, first conceptualised by Sigmund Freud (1856–1939), is possibly the best-known model in

## CLINICAL INTEREST BOX 39.5 Delusions and hallucinations*

**Delusion**: a fixed false thought or belief that is not reality based or true, is not consistent with the person's level of education and development or cultural background and is not amenable to reason. It is categorised as a thought disorder

| Type | Example |
|---|---|
| Somatic delusions (a false belief involving a body part or function) | A young woman believes her body is rotting away from the inside, her heart is made of ice and is gradually melting because she doesn't deserve to live |
| Nihilistic delusions (false feeling that the self, others or the world is non-existent) | A consumer refuses to eat, saying there is no need for him to eat because he has no body |
| Delusions of persecution (over suspiciousness: the person falsely believes themself to be the object of harassment) | A consumer believes the staff belong to a cult, are watching his every move and are out to get him. He is afraid to go to sleep for fear of what the staff might do to him |
| Delusions of control (false belief that one is being controlled by an external source) | A consumer believes her feelings, thoughts and actions are being controlled by aliens who send messages to her via the television, instructing her on what to do |
| Delusions of grandeur (exaggerated beliefs about personal importance or powers) | A consumer believes he is God and controls the universe |
| Delusions of self-depreciation (beliefs of unworthiness) | A consumer believes she is ugly and sinful, saying, 'I don't deserve to be loved—look at me—it shows that I am full of sin' |
| Delusion of erotomania (beliefs that someone usually of a higher status) has romantic feelings for them | A young man believes that a Hollywood actress is in love with him and they are going to marry |

**Hallucinations**: false sensory perceptions that are not founded on any external stimuli. They may involve any of the five senses. They are most commonly visual or auditory

| Type | Example |
|---|---|
| Visual hallucination | A consumer tells you that he sees demons when he looks out his bedroom window |
| Auditory hallucination | A 26-year-old consumer tells you the devil communicates to him saying 'You are worthless, you don't deserve to live' |
| Gustatory (taste) hallucination | A middle-aged consumer with organic brain syndrome complains of a constant metallic taste in his mouth |
| Olfactory hallucination | A 30-year-old consumer states that she smells 'rotten garbage' in her bedroom although no one else can smell anything unusual or unpleasant |
| Tactile hallucination | A middle-aged woman undergoing symptoms of alcohol withdrawal reports feeling ants crawling all over her body although no ants are present |

*(Fortinash & Holoday Worret 2011; Shives 2011)*
*Consumers can experience delusions and hallucinations together. For example, A consumer who claims to hear the voice of God whenever he walks past a place of worship believes that he has been chosen to do God's work by preaching to 'sinners'.

this group. Freud's model viewed human personality as developing predominantly within the first 5 years of life and focused mostly on unconscious, non-rational and instinctual parts of human behaviour (Varcarolis & Halter 2010). Freud attributed disrupted behaviour in the adult to developmental tasks that were not accomplished successfully at earlier developmental stages. For example, within this theoretical framework a mental illness may be linked to a failure during adolescence to move successfully from dependence on parents to independence. Freud's mode of treatment was

psychoanalysis, which aimed to bring unconscious problems to conscious awareness.

Carl Jung (1875–1961), Melanie Klein (1882–1960) and Erik Erikson (1902–1994) are some of the theorists who expanded on Freud's thinking about the nature of human development and behaviour. Erikson's theory has provided nurses with a developmental model that encompasses the entire lifespan. Erikson studied healthy personalities and focused on human strengths as well as weaknesses, emphasising how people who failed to achieve developmental milestones at various life stages could rectify these failures at later stages (Elder et al 2013).

It was Freud who identified the manner in which humans develop and used defence mechanisms to ward off anxiety that might otherwise be overwhelming and incapacitating (Varcarolis & Halter 2010). Defence mechanisms prevent conscious awareness of threatening feelings and can be a helpful response in adapting to **stress**, but their over-use can be a sign of maladaptation to stress and an indicator of mental ill health. They are particularly relevant in understanding stress-vulnerability and stress-adaptation models of health and illness. Stress-vulnerability/adaptation models recognise that throughout life there is a need for everyone to adapt to change; for example, to adjust to school and then work life, to living with a partner or to becoming a parent or a grandparent and then to retirement and perhaps the death of a spouse. The model views that some people find it more difficult than others to adapt to life's changes and to cope effectively with the stressors that change can bring. When life results in a stressful situation or there is an accumulation of multiple stressors, people who have been unable to develop and establish adequate coping skills and coping resources are at the highest risk of developing a mental illness.

### Social and interpersonal models

Social/interpersonal models draw attention to the impact of factors within a person's social environment on mental wellbeing. The basic concept is that negative social factors such as low status, low levels of support, isolation and poverty contribute to and increase the risk of developing a mental illness such as depression (Elder et al 2013).

Interpersonal models encompass the premise that internal conflict within one's personality and particular behaviours may be derived from unresolved conflicts within personal relationships, sometimes during early life experiences. This model also encompasses the premise that a consumer's wellbeing is dependent on the amount of stress experienced and the effectiveness of personal coping strategies in dealing with that stress. Karen Horney (1885–1952), Harry Stack Sullivan (1892–1949) and Hildegard Peplau (1909–1999), a nurse theorist, are some of the important theorists who have conducted research related to social and interpersonal factors and mental health.

### Cognitive behaviour models

Cognitive behaviour models stem from the assumption that behavioural responses are learned. Ivan Pavlov (1849–1936) developed the understanding of learned behaviours when he found that when a bell was repeatedly rung each time dogs were given food the dogs began to salivate just at the sound of the bell. This conditioned reflex was termed classic conditioning and is acknowledged as a form of learning that applies to humans, learning in which a previously neutral stimulus comes to elicit a given response through association. For example, behavioural theorists would suggest that children who observe parents responding to every minor stress with anxiety would soon learn the response and would develop a similar pattern of behaviour (Elder et al 2013). According to the behavioural model, this early learning experience would be considered a significant factor in the cause of an anxiety disorder and limited constructive coping strategies in later life.

BF Skinner (1904–1990) added to behavioural theory by introducing the concept of operant conditioning. Operant conditioning refers to the use of reinforcers to motivate the repetition of particular behaviours. The use of positive reinforcement (the continual rewarding of desired behaviours) forms the basis of behaviour modification therapy used to help motivate consumers to change undesirable behaviours. It has been effective for consumers with phobias, alcohol addiction and a variety of other conditions (Elder et al 2013).

Aaron Beck was one of the early founders of cognitive behaviour therapy (CBT), now a common and often very successful form of psychological treatment. It is based on the view that dysfunctional behaviour is linked to dysfunctional thinking, and that thinking processes are shaped by underlying beliefs. For example, the consumer with depression believes, 'I am no good at anything, I'm worthless, and nobody likes me.' Cognitive behaviour therapy is based on helping consumers recognise, challenge and change dysfunctional thinking. Beck's work has primarily focused on helping people with depression but he has expanded the use of CBT to include working with people who have complex disorders such as borderline personality disorder and schizophrenia, and there are distinct signs of success (Elder et al 2013).

Mental health, like physical health, is clearly affected by a multitude of factors. Consequently, MHNs and psychiatrists are concerned with all the aspects of people's lives that distinguish them as human beings. The mental health nurse uses knowledge from the psychosocial and biophysical sciences, and theories of stress vulnerability, personality and behaviour, to develop a framework on which to base the art of nursing. The mental health nurse is an integral part of the interdisciplinary team required to meet the needs of consumers who have a mental illness.

## THE PROVISION OF CARE

### The multidisciplinary team

Many people may be involved in assisting a person who is experiencing a disruption or potential disruption to their mental health. Mental healthcare commonly employs an interdisciplinary team approach to care management. The

## CLINICAL INTEREST BOX 39.6 Some members of the healthcare team

- The psychiatrist: a consultant physician whose specialty is mental disorders and who is responsible for diagnosis and treatment. A psychiatrist has the legal power to prescribe and to write treatment orders and, as such, is often the team leader
- The mental health nurse: a nurse with experience and expertise in clinical psychiatry, who promotes a holistic approach to care
- The clinical psychologist: a psychologist who has undertaken specialised education in the area of mental health and whose function includes applying and interpreting psychological tests and the implementation of specific therapies such as behaviour modification programs and sexual, marital or family therapy
- The psychiatric social worker: a social worker in the field of mental health, whose function includes assisting the consumer to prepare a support system that will help maintain their mental health on discharge into the community from an inpatient facility. A social worker may liaise with employers, contacts in day-treatment centres and those providing training and educational programs. The social worker may also assist the consumer to locate and access sources of financial aid and accommodation
- Occupational, recreational, art, music and dance therapists: according to their specialist areas of expertise, these various therapists assist consumers to gain skills that assist them to cope more effectively, to gain or retain employment, to use leisure time in a way that promotes their mental wellbeing and to express their emotions in healthy ways.

*(Sadock et al 2015; Varcarolis & Halter 2010)*

consumer's care, according to individual needs, is planned and implemented by a team composed of MHNs, psychiatric social workers, counsellors, clinical psychologists, general or specialist medical officers (depending on the consumer's physical status) and pharmacists. Additional team members may be required and, depending on individual needs, these may include: a dietitian; an occupational therapist; a recreational, art, music or dance therapist; complementary healthcare therapist; and a chaplain or other spiritual support person. (See Clinical Interest Box 39.6.)

It should never be forgotten that the most important member of the team is the consumer, and often consumers know what they need to promote their own recovery. Some consumers have reflected on the times when they have been at their most vulnerable. For example, some consumers who have experienced admissions to acute care settings have identified that what they need most at times of severe mental distress is somewhere they can feel safe and supported, somewhere they can relax and calm down and someone to be with them who will listen and really hear them (Hungerford et al 2015). While the consumer may feel the need for medication, it is not appropriate or helpful to implement other therapeutic interventions, such as group therapy, recreational therapy or family therapy, until the consumer is feeling less distressed and can collaborate in decisions about what sort of interventions will be most helpful. Skilled helping involves actively listening to the consumer and working collaboratively with the consumer to achieve a process of recovery. (See Chapter 8 for information concerning active listening as a therapeutic measure.) The therapeutic process involves health professionals, including nurses, as facilitators who use their knowledge to help the consumer become more resourceful and self-reliant. This helping relationship needs to be a participative but never a directive process (Elder et al 2013). The model of helping relationships established by Carl Rogers (1961) and the model of skilled helping established by Gerard Egan (1994) are consumer-centred models of caring on which MHNs can reliably base their therapeutic interactions with consumers.

## Responsibilities of the mental health nurse

Mental health nursing may be described as an interpersonal process in which the nurse uses the presence of self, interpersonal communication skills and knowledge of physiology, psychology and sociology to help consumers in mental distress. A combined understanding of biological processes and psychodynamic processes is essential for the MHN because many people with mental illness have a concurrent physical problem, and the two are often interconnected (Elder et al 2013).

Mental health nurses are very involved in psychiatric inpatient services and in community mental health services. They play a major role in education and health promotion, as well as in the provision of continuing care and counselling for people with mental health problems. For some experienced MHNs the role may include conducting specific psychological therapies such as cognitive behaviour therapy, solution focused therapy and acceptance and commitment therapy.

Nursing care aims to help consumers cope with the experience of mental illness, prevent relapse and to promote a return to mental health through a successful rehabilitation program. The primary aims of mental health nursing are to help individual consumers to:

- Identify and clarify their needs and problems and advocate for the consumer
- Create a better future for themselves (e.g. **empower** consumers by developing self-help strategies)
- Create strategies to enable them to move forward (e.g. consumers can become stuck in a particular way of responding to situations)
- Adopt a recovery-focused approach to care by empowering the consumer and their carer to actively participate in this process.

Rehabilitation is important for people who have been discharged from a psychiatric ward or unit. Some people need minimal support but others represent a population of chronically ill consumers who return to hospital periodically over many years and require support in several different areas of their lives. The community mental health nurse and other members of the community mental health team may be involved in:

- Monitoring medication
- Consumer and family therapy
- Crisis intervention
- Social skills training
- Medical care for concurrent physical problems
- Vocational training and support (Shives 2011).

## Recovery and mental illness

The concept of recovery has been apparent for the past few decades and is manifest mainly in policy at various levels such as health services management, practitioners and consumer/survivors of healthcare services (Edward et al 2014). Many consumers, some of whom were mental health professionals, began to speak about their experiences of mental illness and their individual journey of recovery which led to the development of the consumer-recovery movement (Deegan 1988; Lovejoy 1984). In the United States the consumer-recovery movement was boosted by William Anthony, a rehabilitation expert who challenged the state health system on its vision of recovery that was based on a belief that mental illness was essentially a 'chronic' condition with very little hope of getting back to full health (Anthony 2000). According to Anthony (2000), mental health services need to be grounded in the idea that people can recover from mental illness, and that the construction of the service delivery system must be based on this knowledge. From that period of time most Western countries adopted an approach to recovery that is based on practices and principles of autonomy and self-determination.

Contemporary mental health nursing care is now based on the recovery principles that refer to the person's rights to self-determination and inclusion in community life regardless of their diagnosis of mental illness. The implementation of

### PROGRESS NOTES EXAMPLE 39.1

18/4/2016
1725 hrs

Nursing: Jason is a 23-year-old-man admitted via ED following referral from GP requesting psych assessment for ? psychotic symptoms. Jason describes ongoing increasing feelings of paranoia towards mother (Pam).
Social: 5th year Law student. Stated he is failing this semester after being previously high-achieving student. Lives at home with his mother Pam. Recently separated from girlfriend of 4 years, 'I can't trust her.' Mother describes recent decline in social contacts with friends. Recently lost his part-time job at a legal firm after becoming argumentative with his supervisor over a security camera in the hallway.
P/H: No past psychiatric history, neuroleptic naïve. Past medical history includes mild asthma as a child.
Appearance & Behaviour: Dishevelled young man, average weight & height. Poor eye contact. Appears hypervigilant, frequently looking towards door and requiring ++ reassurance no one else is listening to our conversation. Generally cooperative with interview process; however distracted at times.
Mood: Congruent; however anxious at times. Rated mood 5/10, when asked to elaborate 'well how would you feel if your mother was trying to kill you?' Describes ongoing insomnia related to need to be vigilant during the night. Stated he sleeps for no longer than 2–3 hours at a time. Recently separated from girlfriend, last sexually active 2/12. Appetite poor, believes his food is being 'tampered' with by his mother. Eats mostly pre-packaged foods.
Affect: Blunted.
Speech: Disorganised at times.
Perception: Describes hearing the voice of a 'demon' (male, not recognised) who informs him of who can and cannot be trusted. Finds this voice 'distressing'. Also describes seeing this same 'demon' 'lurking in the shadows' and finds this experience highly distressing. Command hallucinations 7/7 telling him to hurt his mother and himself. Would not elaborate. Denied presence of perceptual disturbance during interview, yet seemed ++ distracted and distressed at one point.
Thought: Themes involving demonology and the need to read occult material to 'keep the demon quiet' were expressed frequently. Preoccupied with intrusive need to 'stay alert' to protect himself from his mother and friend Joey. Paranoid delusions expressed. Thoughts loosely associated and at times difficult to follow. Evidence of thought blocking.
Cognition: Intact. Memory good (recent, remote, past)
Judgment: Poor
Insight: Poor. Does not believe he is unwell. Refusing to try oral medication ('it's poison!').
Drug history: States he is a social drinker. Denies use of illicit drugs.
Risk:
Risk of nutritional deficits as evidenced by paranoia re food tampering
Risk of interpersonal violence as evidenced by command hallucinations telling him to kill others
Risk of self-directed violence as evidenced by command hallucinations telling him to kill himself.

***O. Garcia*** **(Garcia) RN**

peer support models of recovery in Australia has seen the advancing role of the consumer in sharing their journey of the lived experience in helping those currently experiencing mental illness (Davies et al 2014). Recovery principles are based on an approach that hope is central to recovery and that shifting the focus from symptom management and diagnostic labels to one which keeps people well gives their lives value and meaning. Personal and social recovery is the primary focus of contemporary mental health nursing care.

**CRITICAL THINKING EXERCISE 39.1**

Describe how a peer support model of recovery would be beneficial to consumers with mental illness.

## Facilitating development of constructive coping mechanisms

The nurse's role in stress and stress management has some specific points that need to be highlighted here. To recognise and deal with stress, consumers need to be provided with information about, and helped to recognise:

- Issues and events related to health and illness, and the importance of adhering to sound health practices (e.g. adequate nutrition, sleep, exercise and relaxation) as a way of promoting mental wellbeing
- The dimensions of potential stressors, possible outcomes and the consumer's own established positive and negative coping mechanisms and coping resources
- Their existing strengths and develop and maximise their abilities in problem solving, tolerating stress and dealing effectively with interpersonal relationships
- Where and how to gain access to additional coping resources (e.g. vocational training, support groups and counselling).

There is a wide variety of activities that consumers may find helpful in promoting coping, but there is no one right or best activity. What works for one person may not work for another. Nurses have a responsibility to provide consumers with information and options, but only the consumer can know what feels appropriate, so the choice of what activities to attempt or to become involved with should ultimately rest with the consumer. Clinical Interest Box 39.7 provides examples of **constructive coping strategies**, coping resources and **destructive coping mechanisms**.

## The nurse's role in educating the public and reducing stigma

One particularly important facet of the community mental health nurse's role is educating the public about mental illness to reduce the stigma that for many mentally ill people is the biggest hurdle to overcome (Hungerford et al 2015). There is a general lack of knowledge in the community about what constitutes mental illness and about the prognoses of mental disorders; this ensures that mental illnesses are often surrounded by mystery, misinformation and stigma (Elder et al 2013). Despite positive interventions in recent years, people

### CLINICAL INTEREST BOX 39.7 Examples of constructive coping strategies, coping resources and destructive coping mechanisms

**Constructive coping strategies**

- Postpone major life changes
- Resolve personal conflicts
- Take part in enjoyable activities
- Keep work under control
- Seek help
- Practise breathing and muscle relaxation techniques
- Do some research
- Establish good sleeping patterns
- Keep active
- Reduce alcohol and other drugs (Beyond Blue, www.beyondblue.org.au)

**Coping resources**

- Economic assets
- Established abilities and skills
- Social supports
- Personal motivation
- Physical health, strength and energy
- Positive beliefs about self
- Established problem-solving and social skills
- Social and material resources
- Knowledge and intelligence
- Strong sense of identity
- Cultural stability
- A clear and stable system of values and beliefs
- An orientation towards preventive measures in health

**Destructive coping mechanisms**

- Always being submissive to others and so failing to get own needs met
- Excessive use of alcohol and/or other drugs or overeating (seeking comfort in substances)
- Promiscuity (seeking love and acceptance in a way that does not improve self-esteem)
- Overuse of defence mechanisms to cope with unacceptable or ambivalent feelings. Defence mechanisms commonly used in a maladaptive manner (Elder et al 2013) include:
  - Regression: reverting to behaviour synonymous with earlier developmental stage (e.g. tantrums)
  - Projection: blaming others for what is happening
  - Denial: denying there is a problem (e.g. 'I am in control of my anger')
  - Rationalisation: avoiding dealing with an issue (e.g. 'What does a bit of shouting and banging matter? The children know I would never actually hit them')

*(Sadock et al 2015; Varcarolis & Halter 2010)*

suffering from mental illness remain among the most stigmatised, discriminated against, marginalised, disadvantaged and vulnerable members of society (Hungerford et al 2015; Elder et al 2013).

Review Case Study 39.1 that explores the stigma of mental illness.

### CASE STUDY 39.1 THE STIGMA OF MENTAL ILLNESS

John was diagnosed with schizophrenia 2 years ago. Getting a diagnosis was such a relief, because then we knew what had caused such a big change in him. The nurses taught us about the illness and now, because we know what to look for, we pick up the early warning signs. He knows where to get help and most of the time he avoids a relapse.

John's pretty much in control of his illness now, but the thing that's upset him and us most is the way some people have treated him. He lost his part-time job in the supermarket and even one of his lecturers at college told him he should consider leaving his engineering course because of it. Even my own sister won't have him babysit his young cousins anymore. John now feels it is not safe to tell anyone about it. How do you think that makes him feel? If it was diabetes that made him ill I wonder if people would have reacted the same.

**Marjorie, mother of John, age 21**

How would you respond to Marjorie?

Several **myths** about mental illness create fear of those affected and this fear serves to increase stigmatising behaviours and attitudes. For example, there is a widely held perception that people with mental illness are often out of control, unpredictable and may pose a threat. The truth is that most people with mental illness do not behave in this way; however, severe mental distress is often highlighted in the media, and this links images of dangerous behaviour with mental illness in the minds of the public (Hungerford et al 2015). In fact consumers with a mental illness are more likely to be *victims* of crime, rather than perpetrators (Appelbaum 2013; Pollack 2013; Putman 2008). The notion of perceived dangerousness in relation to mental illness probably stems from the media's propensity to portray the mentally ill as dangerous and unpredictable, and facilitates the isolation and stigmatisation of the mentally ill (Jorm & Reavley 2013). Overall, violence in society associated with mental illness is not significant (Elder et al 2013). The Sane Australia *Stigmawatch* website monitors misuse, misrepresentation or inappropriate references to mental illness in the media (Elder et al 2013).

The lack of accurate knowledge about mental illness that leads to fear, mistrust and sometimes violence against people living with mental illness and their families can also serve to:

- Lower the morale and self-esteem of people living with mental illness
- Prevent people with mental illness from admitting the problem and seeking professional help
- Prevent people with mental illness from gaining paid employment
- Contribute to people with mental illness becoming non-adherent to treatment regimens
- Result in social disadvantage and discrimination for people with mental illness
- Limit the participation of people with mental illness in community activities and force them into a reclusive lifestyle, further exacerbating their illness
- Cause families and friends to turn their backs on the mentally ill person when support is most needed.

The picture is not always as dismal as this. Many mental healthcare users are themselves excellent ambassadors for people with mental illness. By calling themselves consumers they have empowered themselves to become advocates for other people experiencing mental health disorders. Mental healthcare users or consumers now have a vital role to play in participating and planning the delivery of mental health services (Hungerford et al 2015). Consumer advocacy groups now exist in every state and territory of Australia and in New Zealand to promote participation of consumers in planning, implementation and evaluation of mental health services. Accordingly, most consumers live and work within a local community, use the same facilities (e.g. shops, library, cinema, sports centres) as everyone else, are accepted by the people within the community and experience no harassment and attract no hostility from the local residents (Markowitz 2007). All nurses can play a part in highlighting and reducing stigma by:

- Acknowledging the person by using respectful language; for example, never referring to someone as a 'manic depressive', but rather referring to them as a person with a bipolar disorder
- Discouraging the use of disrespectful language; for example, terms such as 'schizo, lunatic, psycho, crazy, nut case' or 'barmy'. The nurse can advocate for people with mental illness by alerting someone to the fact that they are expressing a stigmatising attitude. Many people do this automatically without realising the hurt they are causing and the negative impact on the person with the illness or their family members
- Emphasising the person's abilities rather than their limitations
- Avoiding representing a successful person with a mental illness as superhuman.

## Mental Health First Aid

Mental Health First Aid (MHFA) is a relatively new concept associated with the management of a mental health crisis by 'first responders' until a person capable of managing these types of situations arrives. This type of intervention is akin to the medical management of a patient during a medical emergency (or MET) call; the only difference being, it is *psychological* management. Individuals working in healthcare environments are often confronted with situations arising

from consumers and/or their families in distress and appropriate, sensitive and safe management, based on an understanding of mental illness and crisis, is important. Examples of a situation that may require MHFA include a threatened or attempted suicide, an incidence or threat of deliberate self-harm, distress related to psychotic symptoms such as acute paranoia, or an anxiety or panic attack. The first responder should remain calm, and engage the consumer in a compassionate and gentle manner. The Mental Health First Aid Australia (2015) and New Zealand (2015) websites are a useful resource for all nursing and healthcare students. These sites contain useful information regarding common mental illnesses, and the management of crisis situations.

### CRITICAL THINKING EXERCISE 39.2

There are many reasons why consumers delay seeking treatment for mental illness; however, stigma is one of the major reasons. Discuss the effects of stigmatisation of mental illness, including the implications to:

- The consumer
- Mental health practitioners
- Society.

In part it is the way people with mental disturbance were treated in the past that influences current perceptions of mental illness and the associated stigma. The next section provides a brief overview of historical perspectives relevant to understanding societal attitudes today.

## HISTORICAL PERSPECTIVES AND MENTAL HEALTHCARE

In the past, when emotions, thoughts or actions were deemed to be abnormal, the terms 'madness' and 'insanity' were linked to those affected. Reasons for the perceived abnormalities were once attributed to a variety of factors such as the influences of magic, witchcraft, possession by the devil or evil spirits, loss of the soul or punishment by the gods. Healing methods included exorcism, magical ritual and incantation (Videbeck 2013). Later it was proposed that an imbalance of 'body humours' was responsible—body humours being blood, black bile, yellow bile and phlegm—and such imbalances were corrected by bloodletting. During the medieval period, beliefs returned again to those connected with magic and demonology but also included beliefs that the moon influenced madness (lunacy). Some of those perceived as mad or lunatics were flogged, tortured and starved and those whose illness resulted in violent behaviour were shackled in prisons or put out to sea as a means of ridding them from society. Fear and lack of knowledge resulted in significant cruelty.

In the late 19th and early 20th centuries, those with behaviours that were not manageable, who were misunderstood or were simply not acceptable in society were placed in custodial care inside large public mental hospitals or asylums. It can only be imagined how being confined and isolated inside large institutions might have caused feelings of abandonment and rejection. During this period doctors classified the symptoms of mental illness but had limited understanding of the sources of mental anguish (Wilson & Kneisl 1996).

Increased understanding of mental distress was promoted by the psychological, psychosocial and interpersonal theories to explain behaviour espoused by theorists such as Freud, Erikson and Stack Sullivan. The introduction of psychotropic drugs, such as chlorpromazine (Largactil) in the 1950s, helped staff members manage large numbers of consumers with challenging behaviours, who were often accommodated in crowded conditions in the large institutions. In the 1990s (the time known as the decade of the brain) biological, scientific and technological concepts combined to expand on earlier understandings of mental illness. As a result, advanced brain-imaging techniques now allow direct viewing of the structure and function of the living brain while it is functioning (Wilson & Kneisl 1996).

In the latter part of the 20th century the negative impact of institutionalisation for people with mental illness was recognised. This recognition was in part the stimulus that shifted public policy to one of **deinstitutionalisation** and community-based care for people with mental illness. The push towards community-based mental health services also came from the human rights movement and the philosophy of normalisation for people with disabilities of all kinds. (See Chapter 41 for explanations about the principles of normalisation and people with disabilities.) The discovery of psychotropic drugs in the 1950s also contributed to the current predominance of care in the community because these agents helped to modify challenging behaviours (Jewell & Posner 1996).

### Mental healthcare today

Mainstreaming of mental healthcare has resulted in the provision of psychiatric care to consumers in general hospitals with an inpatient psychiatric unit, hostels and other residential care facilities and sometimes in forensic centres for the mentally impaired who have committed crimes. However, mental healthcare is primarily provided in the community and in Australia the community setting has become the place where most consumers receive their care. Not only is this a human rights directive, but most Australian states' mental health legal frameworks/Acts stipulate that consumers with mental illness be treated in the least restrictive environment.

Nurses may meet with consumers in a variety of community settings, including:

- The consumer's home
- The consumer's foster home
- Community care units
- Special residential units
- Day and drop-in centres
- General practitioner clinics
- Boarding houses
- On the street (homeless consumers).

Current healthcare policy promotes not admitting people to a treatment centre unless essential, and, when it is

necessary for consumers to be admitted to treatment centres, they are discharged back into the community as early as possible. Ideally, community-based mental health services provide appropriate networks of supports and resources for those who need it. The aim of service providers is to ensure that there are caring interventions aptly suited to assist each person to rehabilitate successfully and to cope well in society. The policy of community-based care has enabled many of those who once lived in psychiatric institutions to resettle successfully in the community and to be well supported. It is important to remember that the environment in which the consumer is seen affects the therapeutic relationship. In community settings the mental health nurse enters the home of the consumer as a guest, engaging with the consumer on a more relational and contextual basis.

Unfortunately, however, there are other instances in which the deinstitutionalisation process has not been supported with adequate community care. The result of this is that some people who experience mental illness have merely been relocated to substandard boarding houses or other semi-institutionalised accommodation, or face homelessness (Grigg et al 2004).

While there are still many problems for mentally ill people and health professionals to contend with and resolve, there is now more cause for optimism in relation to mental illness than in the past. Success rates for the treatment of many common mental disorders such as bipolar disorder, major depression and schizophrenia now equal or exceed the success rates for many other medical disorders (Hungerford et al 2015).

While this chapter does not aim to inform the nurse about the range of treatments available to assist consumers with specific disorders, the next section provides a summary of possible nursing responses to some common emotional and behavioural problems that challenge consumers with mental illness. The terminology used in mental healthcare, some of which is contained in the next section, is extensive and different from terms used in other areas of nursing. Some of the more common terminology is defined in Table 39.3.

## CARE OF CONSUMERS WITH SPECIFIC EMOTIONAL OR BEHAVIOURAL CHALLENGES

Here we address some of the more common mental states that consumers being cared for in non-psychiatric hospital settings may experience. Information is provided on caring for a person who is anxious, depressed, aggressive, displaying self-destructive behaviour, hyperactive, confused or disoriented.

### The consumer experiencing anxiety

Anxiety disorders are the most commonly diagnosed mental illness (Hungerford et al 2015). Anxiety is an internal feeling usually experienced as an unpleasant or uncomfortable emotion and which is frequently associated with conflicts and frustrations. While a certain mild degree of anxiety can be beneficial when it stimulates motivation and energy, severe anxiety can be devastating and is the basis of many mental health disorders. Anxiety differs from fear in that anxiety attacks the person at a deeper level than fear, and the source of the anxiety may be unknown. Sometimes, in extreme anxiety, a person may experience panic attacks that result in markedly disturbed behaviour. The person may be unable to process what is happening in the environment and may lose touch with reality. During a panic attack behaviour may be erratic, uncoordinated and impulsive. There are three different forms of panic attack: 'out of the blue' attacks, which are not brought on by a trigger; situation-bound attacks which are brought on by exposure to a trigger; and situation-predisposed attacks which are comparable to situation-bound but which do not happen every time the person is exposed to a trigger.

Anxiety invades the very centre of a person's being. Severe anxiety is profound and persistent and can erode and destroy a person's sense of self-esteem and self-worth that contribute to a sense of being fully human (Varcarolis & Halter 2010).

Anxiety is experienced in a wide variety of situations and is generally the result of a threat to a person's self-esteem or physical integrity. Threats to self-esteem include factors such as interpersonal difficulties, change in job status, social or cultural group pressures, a change in role or confusion over one's identity. Threats to physical integrity include factors such as decreased ability to perform the activities of daily living, for example, as a result of injury or illness, or lack of basic requirements such as food, shelter and clothing. Mild and moderate levels of anxiety can alert the person to the fact that something is wrong and may be the stimulus to take appropriate action. Severe levels of anxiety interfere with problem-solving abilities, so that those affected have difficulty finding effective solutions to problems. For example, someone who experiences panic attacks may use unproductive relief behaviours to avoid the attacks from occurring, such as refraining from leaving the house to avoid the risk of a panic attack when driving the car, at work or at the supermarket. Unproductive relief behaviours perpetuate the cycle of anxiety (Varcarolis & Halter 2010).

Whether the source is known or unrecognised, anxiety can produce physiological responses, behavioural changes and emotional reactions. The type and extent of response depends on the level of anxiety experienced. Table 39.4 lists some physiological and other responses to different levels of anxiety. Emotional reactions are usually apparent in the person's descriptions of their experience. For example, they may state that they feel apprehensive, irritable, angry, depressed, helpless, on edge, unable to concentrate or remember things or they may feel detached from events and the environment. The person may experience angry outbursts or a tendency to cry frequently.

Specific treatment and care of a person experiencing anxiety depends on the level of anxiety experienced and the effects on the consumer, but generally interventions are directed towards reducing intense anxiety to a more manageable level and helping the person to develop self-help strategies to prevent overwhelming anxiety. Cognitive behaviour

| TABLE 39.3 \| Terms associated with mental illness | |
|---|---|
| Addiction | Physical or emotional dependence, or both, on a substance, such as alcohol or other drugs |
| Affect | Current, observable state of emotion, feeling or mood such as sadness, anger or elation |
| Aggression | Forceful behaviour that may be physical or verbal, as well as subtle manipulation |
| Akathisia | A condition of excessive restlessness that causes a person to move about constantly, fidget or pace. This can be a side effect of certain medications used in psychiatry |
| Anhedonia | Reduced or complete inability to feel pleasure from activities previously enjoyed |
| Amnesia | Loss of memory of events for a period of time that may range from a few hours to many years |
| Anxiety | A feeling of apprehension, dread or unexplained discomfort, associated with a sense of helplessness, arising from internal conflict |
| Apathy | Lack of feeling, emotion, concern or interest |
| Asylum | A place of safety or sanctuary; a refuge from the stresses of life. Historically the term asylum was associated with institutions that provided custodial care for people with a mental illness. Unfortunately, they were often associated not with the real meaning of asylum but with mistreatment and cruelty |
| Autism | Preoccupation with the self and inner experiences; a process of introspective thinking that is often rich in fantasy |
| Behaviour | Any human activity, either physical or mental. Some behaviour can be observed while other behaviour can only be inferred |
| Behaviour modification | A method of changing or controlling behaviour through the application of techniques based on the principles of classical conditioning |
| Bipolar disorder | A type of mood disorder that causes alternating periods of low and high moods; a combination of depression and mania |
| Body image | The conscious and unconscious attitudes a person has towards their body (e.g. feelings about size, function and appearance) |
| Catatonia | A state characterised by muscular rigidity and immobility (stuporose type) and which, at times, is interrupted by episodes of extreme agitation (excited type) and is usually associated with schizophrenia |
| Compensation | Process by which a person makes up for a deficiency in their self-image by strongly emphasising some feature of themself that they regard as an asset |
| Compulsion | An uncontrollable persistent urge to perform an act repetitively in an attempt to relieve anxiety. Compulsive behaviour often accompanies obsessions and may be directly linked to them |
| Confabulation | The fabrication of experiences or situations recounted in a plausible way to fill in and cover gaps in the memory. Used most often as a defence mechanism and most commonly by people with head injuries, dementia, amnesic disorders or alcoholism, especially those with Korsakoff's syndrome |
| Confusion | A cluster of abnormalities constituting disturbances of judgment, orientation, memory, affect and cognition |
| Coping mechanisms | Any effort directed towards stress management. They can be unconscious (defence) mechanisms that protect the consumer against anxiety, or conscious attempts to solve a problem that is creating stress |
| Deinstitutionalisation | A shift in the location of treatment from large public hospitals to community settings |
| Delusion | A fixed false belief resistant to modification. A delusion of grandeur is a false belief that one has great prestige, power or money, which may be manifested in the belief that the consumer is a famous person. A delusion of persecution is a consumer's belief that they are in danger, being harassed, are under investigation or are at the mercy of some powerful force. A somatic delusion is a belief that one's body is changing and responding in an unusual way |

**TABLE 39.3 | Terms associated with mental illness—cont'd**

| | |
|---|---|
| Dementia | A mental disorder characterised by a gradual onset of usually irreversible cognitive impairments |
| Depression | A mood state that may be mild or short lived or more severe and persistent. The latter, a mood disorder, is characterised by extreme sadness, feelings of hopelessness, low self-worth and little or no conviction that things can ever improve |
| Disorientation | Lack of awareness of the correct time, place or person |
| Electroconvulsive therapy (ECT) | A therapeutic procedure in which an electric current is briefly applied to the brain to produce a seizure. This is used in treatment of severe symptoms that do not respond to other measures, most commonly used in the treatment of severe depression |
| Hallucination | A sensory experience that is not the result of an external stimulus; may be visual, auditory, tactile, gustatory or olfactory |
| Hyperactive | Excessively or unusually active |
| Illusion | Misperceptions and misinterpretations of real external stimuli; may be visual or auditory or, less commonly, olfactory or tactile |
| Labile | Subject to frequent or unpredictable changes: the term is commonly used with reference to emotions |
| Mania | A mood characterised by an intense feeling of elation or irritability, often accompanied by increased activity, rapid speech and poor judgment |
| Mood disorder | A group of disorders in which the predominant feature is disturbance in mood |
| Obsession | A persistent thought, idea or impulse that cannot be eliminated from consciousness by logical effort |
| Obsessive-compulsive disorder | An anxiety disorder characterised by intense, unwanted and distressing recurrent thoughts (obsessions) and repeated behaviours (compulsions) that are beyond the affected person's ability to control |
| Panic attack | A period of sudden intense anxiety, often associated with feelings of impending disaster and accompanied by strong physiological symptoms, including shortness of breath, pounding heart or palpitations and dizziness |
| Paranoia | A serious personality distortion in which the person is markedly suspicious and mistrusting of others and may be convinced that they wish to harm them, seen in schizophrenia |
| Phobia | An intense fear of some situation, person or object, so that the danger is magnified out of proportion and may result in a panic attack |
| Psychosis | A state in which a person's mental capacity to recognise reality, communicate and relate to others is impaired. Psychosis includes the presence of delusions, hallucinations and disorganisation of thinking and behaviour |
| Psychotic | A person who is psychotic experiences delusions and hallucinations which cause disorganised thinking, unusual behaviours and a loss of touch with reality. Psychosis is an acute presentation often present in schizophrenia, mania and some illicit substance intoxicated states |
| Schizophrenia | A complex condition caused by brain dysfunction that results in hallucinations and delusions, distorted thinking and other disturbances |
| Self-harm | Harmful actions towards oneself where there is intention to harm but not die. Examples include cutting, burning, scratching etc. Commonly seen in borderline personality disorder and dysphoric emotional states |
| Suicidal ideation | Thoughts of suicide with an intention to end one's life |
| Tardive dyskinesia | A side effect of some antipsychotic medications (usually first generation, typical agents) that manifests with a variety of involuntary muscle movements including those that affect the face, jaw and tongue, the trunk and the extremities of the body. The involuntary movements are often irreversible. They are also referred to as extrapyramidal side effects |

*(Hungerford et al 2015; Elder et al 2013)*

**TABLE 39.4 | Physiological and other responses to anxiety**

| Mild anxiety | Moderate anxiety | Severe anxiety | Panic level of anxiety |
|---|---|---|---|
| Slight discomfort<br>Attention-seeking behaviours<br>Restlessness, irritability or mild agitation<br>Mild tension-relieving behaviour (e.g. foot or finger tapping, lip chewing, hair twisting, fidgeting) | Voice tremors<br>Change in voice pitch<br>Difficulty concentrating<br>Shakiness<br>Repetitive questioning<br>Loss of appetite<br>Diarrhoea/constipation<br>Memory impairment (e.g. interference with recall of events/facts)<br>Chain smoking<br>Increased use of alcohol or other substances<br>Somatic (bodily) complaints (e.g. urinary frequency and urgency, insomnia)<br>Increased respiration rate<br>Increased pulse rate<br>Increased muscle tension that may lead to backache or headache<br>More extreme tension-relieving behaviour (e.g. pacing, banging hands on table, constant wringing of hands) | Feelings of dread or impending doom<br>Confusion and bewilderment<br>Purposeless activity, lack of coordination of movements and actions<br>Worsening of somatic complaints (e.g. dizziness, nausea, headache, sleeplessness)<br>Hyperventilation<br>Tachycardia<br>Elevated blood pressure<br>Sweating<br>Facial pallor<br>Dry mouth<br>Difficulty in breathing<br>Withdrawal from interpersonal interactions<br>Disturbances in sexual function<br>Loud and rapid speech<br>Intense tension-relieving behaviour that may include threats and demands | Feelings of absolute terror; fear that death may result<br>Immobility or severe hyperactivity or flight<br>Dilated pupils<br>Chest pains/palpitations<br>Severe dizziness<br>Unintelligible communication or inability to speak<br>Severe tremors<br>Sleeplessness<br>Extreme psychomotor activity may lead to exhaustion<br>Severe withdrawal (e.g. agoraphobia)<br>Hallucinations and delusions may occur and the person may lose touch with reality |

*(Shives 2011; Videbeck 2013)*

therapy (CBT), for example, helps consumers develop strategies for controlling their anxiety and reducing the incidence of panic attacks. Minor tranquillisers such as diazepam (Valium) and lorazepam (Ativan) are sometimes prescribed short-term to suppress the consumer's feelings of anxiety but, as medications do not cure the condition and there are problems with dependence, long-term use is not advocated (Hungerford et al 2015). Antidepressants are generally well tolerated, safe and effective in the ongoing treatment of anxiety, with proven clinical efficacy (Meadows et al 2012). Examples used for the long-term treatment of anxiety include the selective serotonin reuptake inhibitors (SSRIs) fluoxetine (Lovan, Prozac) and sertraline (Zoloft). In addition to these medications, beta-blockers such as propranolol (Inderal) and atenolol (Tenormin) are also used to treat the physiological impacts of anxiety (Meadows et al 2012).

General care involves:

- Establishing and maintaining a trusting relationship
- Managing acute symptoms such as hyperventilation
- Attempting to identify the cause (stressors) of the anxiety and encouraging the consumer to take effective action
- Facilitating open and honest communication about the consumer's anxiety and/or problems
- Identifying existing coping mechanisms and coping resources
- Discussing with the consumer ways of resolving conflicts
- Providing information about, and teaching, constructive coping strategies that can help to manage stress.

The most common coping mechanisms taught and encouraged are:

- Problem solving
- Assertiveness
- Positive self-talk
- Stress and anger management
- Communication skills
- Skills for establishing and maintaining relationships
- Conflict resolution
- Time management
- Community living skills (Hungerford et al 2015; Meadows et al 2012).

An understanding of the types and levels of anxiety and defensive patterns of behaviour used in response to anxiety is basic to effective psychiatric nursing care. Hildegard Peplau was a nurse theorist whose conceptual model of anxiety provides a firm basis on which nurses can plan interventions for consumers experiencing anxiety. Nurses would benefit from reviewing the work of Peplau (1991) and other psychiatric nursing texts to enhance their knowledge of the relationship between anxiety and mental illness and the range of treatment options available.

## Care during a panic attack

Care during a panic attack can take the form of:

- Remaining with the person during the attack and speaking in a calm confident voice using short and simple sentences

- Ruling out that the person is not experiencing a cardiac incident
- Asking the person to take slow deep breaths and to breathe in and out through their nose. Place their hand on their diaphragm to focus their attention on their breathing and reduce the breath rate to 10 per minute until the anxiety recedes
- Explaining to the person to cup their hands around their mouth and breathe can assist in preventing fainting from hyperventilating.
- Following the panic attack, explaining to the person what they have experienced is a panic attack; reassure the person that they can get help to manage panic attacks
- Referring the person to their general practitioner for a full physical assessment to rule out a physical cause (Jakopac & Patel 2009).

In addition, strategies to help tolerate and decrease the effects of anxiety can be taught, although these address the effects rather than the cause of anxiety. These strategies include complementary therapies such as visualisation techniques, guided imagery, meditation and relaxation training.

## The consumer experiencing depression

Depression is an emotional state that most people experience at one time or another. It can manifest anywhere along a continuum from intermittent feelings of sadness to a persistent deep sense of unending despair accompanied by hallucinations and delusions (Hungerford et al 2015). Often at the onset of depression the mood begins with a feeling of sadness that may be described as 'feeling down in the dumps'. As depression worsens, sad feelings deepen until those affected feel gloomy and dejected much of the time. At this level of depression people may describe the experience with statements such as 'I have no joy in my life anymore' or 'I just feel unhappy'. They will often describe feeling no pleasure in undertaking previously pleasurable activities (such as going to the movies with friends)—this is known as anhedonia. For some people the depressed mood can deepen even further until there is a persistent feeling of utter desolation. Severely depressed people have a sense of hopelessness about the past and the present, and the future looks black and bleak. The heavy feelings of despondency, wretchedness and acute misery are relentless. People affected feel desperately low and worthless, and this experience is accompanied by a sense of despair so profound that they do not believe the feelings will ever lift (Elder et al 2013).

Feelings of sadness and even intense grief, such as might be felt at the death of a loved one, are normal reactions to the various losses encountered by most people during their lives. Sadness and depression in such cases may be transitory, with the person moving through a grieving process and recovering successfully after the loss. Sometimes recovery after a significant loss does not occur and the person moves into a level of persistent and severe depression that does not resolve without professional assistance. This would be termed dysfunctional grieving. In some cases sadness, moderate and severe depression can occur without the person affected being able to identify a particular trigger for the low mood. Depression caused by biochemical imbalance is an example of this (Elder et al 2013).

Feelings of depression are so common that depression is sometimes known as the 'common cold' of psychiatry. It can occur at any age, even in very small children. Children with parents diagnosed with a depressive disorder have a higher risk of experiencing depression than others, and certain events may predispose young people to develop depressive symptoms (Keltner et al 2011). These events include:

- Loss of parents through divorce
- Death of other individuals close to them (e.g. grandparents, siblings, other relatives or friends)
- Death of a loved pet
- Move to a new neighbourhood or town
- Academic difficulties or failure
- Physical illness or injury that entails a stay in hospital.

Depression has a wide range of signs and symptoms but even so some people are able to hide their depression from others. Clinical Interest Box 39.8 lists the common signs and symptoms of depression. For some people depression may also be accompanied by anxiety. Some people experience alternating moods of depression and elation that can be disruptive to their lives. The periods of elation may be accompanied by significant increase in goal-directed activity and insomnia. Such conditions are categorised as bipolar disorders, whereas mood disorders that have only the one dimension of depression without periods of elation are termed unipolar (Evans & Brown 2012; Videbeck 2013).

Care of a depressed consumer is directed towards first addressing immediate safety needs in those at risk of self-harm or suicide. Suicide is the deliberate act of inflicting harm to one's self where the intention is to die. Self-harm, on the other hand, is self-inflicted injury (such as cutting, scratching or burning) where there is no intention to die. This may require hospitalisation and frequent or constant observation of those so seriously depressed as to be actively contemplating suicide. Antidepressant medication, when necessary, is started immediately, but the symptomatic relief is not generally achieved for at least several days, and possibly up to 4 weeks after therapy starts. Other specific interventions include consumer, family, group, cognitive and behavioural psychotherapy (Keltner et al 2011; Evans & Brown 2012). The major goals are to lift the consumer's mood, improve self-esteem, identify and reduce the impact of any major identified stressors, promote the development of constructive coping mechanisms, assist the consumer to regain interest and motivation in life and also to address any concurrent problems associated with physical health. General care involves:

- Establishing and maintaining a trusting relationship
- Helping the person, when the acute phase is resolved, to recognise and express emotions (e.g. through verbal and non-verbal communication)
- Helping the consumer to set realistic, achievable goals

## CLINICAL INTEREST BOX 39.8 Signs and symptoms of depression

Signs and symptoms of depression vary according to the severity of the low mood but may include:

- Non-verbal cues (sad facial expression, crying, slumped posture, lack of eye content, mask-like facial features)
- Disturbed sleep patterns (e.g. insomnia or sleeping for much longer periods than usual)
- Self-criticism and expressions of guilt feelings
- Low self-esteem that may result in thoughts of self-harm or self-destruction
- Indecisiveness and poor concentration
- Psychomotor retardation or marked reduced mental or physical activity (slow dragging gait, slowed speech pattern and slow, flat, lifeless, colourless verbal responses, lack of concern and apathy about maintaining personal appearance)
- Psychomotor agitation (some people with depression experience significant anxiety that may manifest as restlessness, pacing or constant walking or constant purposeless movements such as pulling at hair or wringing of hands)
- Appetite disturbance—marked loss of weight or weight gain
- Loss of energy
- Loss of sexual libido
- Headaches, chest pains, gastrointestinal disturbances and other physical manifestations
- Increased consumption of substances such as nicotine, alcohol and illicit substances
- Anhedonia (inability to feel any pleasure when participating in activities that previously were pleasurable)
- Delusions and/or hallucinations.

Particular signs that may be associated with depression in children and adolescents include:

- Frequent, vague, non-specific physical complaints such as headaches, muscle aches, stomach aches or tiredness
- Frequent absences from school or poor performance in school
- Efforts to run away from home, or talk of this
- Outbursts of shouting, complaining, agitation, unexplained irritability or crying
- Complaints of being bored
- Lack of interest in playing with friends
- Reckless behaviour
- Extreme sensitivity to rejection or failure
- Increased irritability, hostility or anger
- Difficulty with relationships
- Substance misuse
- Fear of death.

*(Keltner et al 2011; National Institute of Mental Health 2011; Varcarolis & Halter 2010)*

- Encouraging the consumer to establish and maintain social contact and interpersonal relationships
- Encouraging visits by family or significant others, to reduce any feeling of isolation
- Promoting physical health and wellbeing (e.g. adequate exercise, sleep and nutrition)
- Providing information concerning measures that may reduce and help manage stress
- Identifying existing coping mechanisms and coping resources
- Promoting recovery
- Assisting the consumer to develop and enhance constructive coping mechanisms, including decision-making and problem-solving skills (Jakopac & Patel 2009; Hungerford et al 2015; Elder et al 2013).

Table 39.5 outlines nursing interventions and care for the consumer with depression.

People who are depressed are very vulnerable and this may be, in part, why they often withdraw and isolate themselves. This can make it very challenging for the nurse needing to establish effective communication. Clinical Interest Box 39.9 provides some strategies for promoting effective communication with consumers who have depression.

Depression is a major problem in older adults and may also be accompanied by excessive worry, ill-placed guilt and anxiety. Symptoms of depression in the older age group are relatively common but often go undetected and untreated. This may be because sadness is considered a normal response to the losses associated with ageing, such as physical decline, loss of social role and loss of a spouse, and it may not be recognised when normal sadness and grief has developed into clinical depression requiring treatment. It is important to be aware that men over the age of 85 years have the highest suicide rate in Australia; exceeding all other age groups and is more than three times the national average (ABS 2011). In addition, the complexities of physical illness, the side effects of medication and the symptoms of dementia may combine with symptoms of depression, making diagnosis of what is happening complex and difficult (Keltner et al 2011). It is very important for nurses working with older consumers, particularly those with dementia, to be alert for, and report, changes such as unusual expressions of sadness, voicing the

**TABLE 39.5 | Key nursing interventions and principles of care for consumers with depression**

| Action | Rationale |
|---|---|
| Accept consumers as they are and focus on their strengths | People with depression have low self-concept; this is the best approach to promote the return of a more positive sense of personal worth |
| Promote the consumer's own decision making; minimise dependency | Indecisiveness is a symptom of depression and can mean that consumers struggle to make even the most basic decisions. The nurse needs to move the consumer towards independent decision making that is part of mental health |
| Avoid presenting consumers with decisions to make when they are not yet ready to make decisions for themselves | At the height of a depressive illness it is best to simply present situations to the consumers that do not require a decision; for example, 'It's time to come for lunch', 'It's time to have your shower', 'Here is a cup of tea' |
| Respond to hostility or anger therapeutically | Expressions of anger are often part of a depressive illness, possibly because the person has developed a previous pattern of containing any such strong feelings. Understanding the dimensions of the illness helps the nurse to focus on the issue at hand and assist consumers to move towards more appropriate ways of expressing and dealing with their feelings |
| Spend time (brief but frequent) with withdrawn and isolative consumers, even when this feels uncomfortable | Withdrawn consumers remain aware of their surroundings and, even if they do not acknowledge the presence of the nurse or communicate in any way, they can be reassured by that presence. Spending time with the consumer communicates the consumer's worth as a person. It may be that the consumer will learn to be comfortable with the nurse and eventually initiate dialogue |
| Involve consumers in activities in which they can experience success | People can feel good about themselves in many different ways. Accomplishment is one way to develop a sense of self-worth |
| Avoid reinforcing hallucinations or delusions | Confronting these symptoms tends to reinforce them. The best approach is for the nurse to state his or her view of reality and to begin discussing real people, situations and events |

*(Adapted from Keltner et al 2011)*

wish to die, decrease in appetite, reduced enjoyment, loss of interest in activities or other symptoms that may indicate the presence of depression. Depression is not a normal stage of ageing. Clinical Interest Box 39.10 lists some issues relating to the mental health of older adults.

## The consumer experiencing feelings of anger and hostility

Anger is a feeling experienced by most people at certain times. It generally occurs in response to fear, confusion or

### CRITICAL THINKING EXERCISE 39.3

Jason is a 23-year-old man recently admitted to the acute inpatient unit. Jason is studying a law degree at university. However, recently he has been preoccupied with reading books on the occult and demonology in the library. Jason recently broke up with his girlfriend of 4 years, Megan, because he couldn't trust her anymore. Jason confronted his mother Pam recently and accused her of tampering with his food, because he could smell it rotting, and became threatening and hostile towards her. Pam took Jason to their GP and he suggested an assessment by a mental health team. During this assessment Jason revealed that he no longer trusts his best friend Joey because he 'communicates with the devil', and that, despite being a high-achieving student, is currently failing. Jason describes hearing the voice of a demon, who tells him who he can and cannot trust. Jason describes seeing this demon 'lurking in the shadows' at times and he is frightened of these experiences. On one occasion the demon told Jason to hurt Pam; on another he told him to kill himself. Jason describes actively thinking about ways he could kill his mother, and then himself.

The staff assessing Jason decide he should be admitted to the mental health ward. Jason is prescribed 5 mg of olanzapine; however, he refuses to take it, becoming distressed and frightened, claiming staff are trying to poison him. The psychiatrist who examines Jason has made a preliminary diagnosis of schizophrenia.

1. Define the terms hallucination and delusion and identify where these phenomena are expressed in Jason's case.
2. A risk assessment is an integral role of the mental health nurse. What risks does Jason present with?
3. Identify four (4) ways the mental health nurse can encourage Jason to be adherent with his medication.

## CLINICAL INTEREST BOX 39.9 Strategies for promoting effective communication with consumers who have depression

### Acceptance

Spend time with the consumer and accept the person without judgment. People who have depression are not always able to express feelings and may express them through behaviour that is unusual or even bizarre. The nurse should be careful not to make or imply any criticism of the consumer's behaviour because people with depression have low self-esteem and are particularly vulnerable to feelings of disapproval that may be interpreted as rejection.

### Openness and honesty

Because people with depression are less able than others to tolerate disappointment, the nurse should be truthful at all times and never make promises that for any reason might not be kept. Nor should the nurse offer false reassurance.

It is important for the nurse to develop a trusting relationship with the consumer and this will only be achieved with honesty. For example, a consumer may wish to share something private with the nurse but not want the nurse to tell anyone else about what is disclosed. The nurse builds trust by telling the consumer that significant information will need to be shared with other members of the healthcare team. The consumer learns to trust the nurse as a professional whose main concern is shown to be the consumer's own best interest.

### Empathy

Any attempts to cheer up a depressed consumer may be perceived as a failure to understand their feelings or difficulties. Inappropriate approaches such as this may cause the consumer to withdraw further from interactions and may increase their isolation and depression.

Empathy means facilitating the consumer to express feelings of pain and inner distress and to respond in a way that indicates recognition and understanding of that pain and distress.

### Tolerance

People with depression may be unable to make even the simplest decision (e.g. where to sit, what clothing to select and put on). The nurse needs to understand how low mood slows physical as well as mental responses and that the psychomotor retardation is part of the illness, not a deliberate act. It is impossible for consumers with depression to 'shake themselves out of it' and it is not therapeutic to try to badger people with depression into activity. This is likely to result in further feelings of guilt and inadequacy in the consumer. Tolerance is also required for consumers with depression who experience psychomotor agitation.

Underlying anxiety in the depressed consumer may also manifest as hyperactivity or anger and hostility that may be directed towards the nurse. Consumers sometimes shock themselves at the hostile and sometimes hateful things they say to others during periods of depression. It is a normal response for the nurse to feel some frustration and irritation or even anger towards consumers at times, but the nurse must be mindful that the consumer's behaviour is an outward reflection of inner anguish and that to be therapeutic they must remain patient. To assist in this the nurse must reflect on, and implement, the strategies needed to maintain personal mental wellbeing. This may include discussing feeling responses to consumers with a colleague.

*(Keltner et al 2011; Shives 2011)*

frustration. Anger often occurs in response to the anxiety a person feels when a threat is perceived. Most people have little difficulty in handling mild anger, which is experienced as annoyance and usually subsides quickly. Feelings of anger, disappointment and frustration may be expressed verbally or non-verbally; for example, by cursing or kicking a car when it won't start. When a person is very frustrated, such as when they are unable to attain an important goal, anger may become more intense. A person experiencing intense anger may try to disperse the unpleasant feeling through an angry outburst or an act of aggression. Occasionally a person may be so consumed by feelings of anger that they become violent and pose a threat to themselves and to others nearby.

Nurses may encounter anger in the course of providing nursing care; for example, a person whose health is disrupted becomes frustrated, and frustration can lead to anger. Sometimes people express their anger through verbal or physical abuse towards others, including staff members. Therefore it is important that nurses are aware of the reasons why a person may be angry, of their own responses to outbursts of angry feelings and of how to help a consumer to express anger in an appropriate manner. Anger may be the result of various stressors. Some of the factors that may cause anger or aggression in people who are in hospital for any reason include:

- A feeling of loss of control and/or independence, particularly evident when the consumer has no insight into their illness and is compulsorily (or involuntarily) detained
- A sense of isolation from family and familiar environment
- A feeling of loss of identity or individuality

## CLINICAL INTEREST BOX 39.10 Mental health issues in older adults

- The older person is vulnerable to emotional and mental stress from many losses, including the loss of a spouse, loss of social roles and resources, decreased income and loss of status and socialisation associated with paid employment
- Physical health problems such as chronic illness, disability, visual problems, falls and incontinence
- Issues with polypharmacy
- Disorders common in the older population include depression, paranoid reactions and dementias
- Depression is the most common emotional disorder in the older population
- Paranoia may be related to depression and/or neurological disorders. It is also associated with sensory deficits and loneliness
- Of the dementias, the Alzheimer's type is the most common non-reversible dementia
- The risk of suicide increases with age, with men aged 85 and over being particularly vulnerable
- Family carers of people with dementia are more likely than other family carers to experience emotional health problems such as stress, exhaustion and depression

*(Byrne & Neville 2010)*

- Feelings of fear and discomfort because of inadequate privacy
- Anxiety about the possible outcomes of illness (e.g. altered body image).

Some of the specific risk factors leading to a potential for aggression in consumers with mental illness have been identified (Elder et al 2013) as:

- A diagnosis of an illness with paranoid features (paranoia can lead to fears that induce aggressive acts aimed at defending against a perceived threat; for example, the belief that someone is plotting against you or trying to harm or kill you can lead to lashing out at that person defensively)
- Substance misuse
- Deterioration in family and/or social relationships
- A previous history of aggression or violence and declared threats of violence
- Developmental history of exposure to aggression and violence
- Non-adherence to a medication regimen
- Failure to learn to delay gratification of wants (e.g. extreme frustration when need is not met immediately)
- Failure to learn alternative strategies other than aggressive responses
- Unresolved conflicts
- Hostility to authority
- Denial of aggressive behaviour
- Lack of remorse.

Aggressive outbursts may occur when a person is unable to find a solution to a problem that is causing fear, confusion or frustration. Aggressive action may be directed towards the person or object perceived as the source of the frustration, or at other persons or objects in the vicinity. Displacement is a defence mechanism whereby a consumer discharges pent-up feelings, such as anger, on a person or object other than the one that aroused the feelings (Halter 2014). Approaches for dealing with anger and hostile behaviour in the mental healthcare environment are outlined in Table 39.6. Nurses may apply the principles of these approaches, when necessary and appropriate, in any healthcare setting.

Preventing aggression and violence is important for the wellbeing of consumers and others. Assertive behaviour is one constructive way of dealing with anger. To be assertive is to stand up for oneself while taking into account other people's interests and feelings. It takes time to develop the ability to be assertive when people are in the habit of being subservient or responding to situations they are unhappy with by being aggressive. It is within the role of MHNs to conduct training for consumers who will be helped by developing assertiveness skills.

## The consumer who is at risk of self-destructive behaviour

Self-destructive behaviour is that which results in physical harm and, sometimes, in the person's own death by suicide. Self-destructive behaviour includes self-mutilation and any form of suicidal activity.

### Self-mutilation/Self-harm

Deliberate self-mutilation results from overwhelming mental distress and is the deliberate destruction of body tissue usually without conscious intent of suicide (Hungerford et al 2015). Self-harm may occur once or it may become repetitive. It may or may not be impulsive. It is a behaviour associated with a range of mental health disorders (Elder et al 2013) including:

- Childhood and physical and sexual abuse
- Schizophrenia
- Drug-induced psychosis
- Borderline personality disorder
- Eating disorders
- Cognitive impairment disorders
- Obsessive–compulsive disorder
- Post-traumatic stress disorder.

Self-harm may involve skin cutting, severe skin scratching or burning, head banging, self-biting, eyeball pressing, tearing out hair, self-punching or inserting dangerous objects into body orifices such as the vagina or rectum. It may involve skin carving (words, designs, symbols), bone breaking or interfering with healing by picking at wounds. Very rarely, extremely serious acts of self-mutilation occur, such as eye enucleation or amputating fingers, toes or genital organs. Other behaviours that may be considered self-destructive include involvement in unsafe sex, irresponsible gambling or spending, substance misuse, driving recklessly and binge

**TABLE 39.6 | Approaches for dealing with anger and hostile behaviour in the mental healthcare environment**

| Action | Rationale |
|---|---|
| Accept the consumer but make it clear that certain behaviours are not acceptable | This is a non-judgmental approach that informs the consumer that they are accepted as a person but that certain aspects of their behaviour are not appropriate |
| Acknowledge the person's anger and their right to their feelings | This demonstrates respect and acceptance of the consumer |
| Allow expression of the anger in appropriate safe ways; for example, voicing angry feelings verbally, discharging anger in non-destructive acts (e.g. not damaging property or person) | Anger is self-limiting and it may be better to let it run its course than to forcibly try to stop an angry person. Attempting to stop the person's expression of anger can restimulate the aggressive feelings and lead to a continuance of displayed anger |
| Try to remain calm (self-talk and relaxation techniques such as deep breathing and muscle relaxation can help with this). Provide psychological containment by staying in the same calm 'gear' and avoiding any tendency to retaliate or placate | Retaliation or trying to placate an angry person can stimulate the consumer to higher levels of aggression. Consumers need their feelings to be acknowledged and understood; retaliation and appeasing do not achieve this |
| Be aware of your body language—try not to communicate threatening non-verbal signals (e.g. keep your hands in a low position) and avoid trying to touch a consumer who is agitated | Raised hands may be interpreted as a threatening gesture, particularly by consumers who are experiencing paranoia, confusion or disorientation and such a gesture may be interpreted as indicating a failure to understand the consumer's feelings and point of view<br>Touching a person who is agitated may be interpreted as threatening, and consumers who are paranoid may already be experiencing heightened fear |
| Do not try to defend the person or situation the consumer is feeling angry about | |
| Set limits and be firm and consistent in treatment approaches. Encourage the consumer to take control by raising awareness of options at times of angry feelings (e.g. time-out, walking/talking with nurse, medication). The consumer should also be aware of the outcomes if self-restraint is not demonstrated | A consumer at risk of aggressive outburst is helped to remain in control if limits on what is acceptable are clear and alternative options for dealing with feelings are provided; for example, exercise, informing and seeking help from a nurse or other therapist when feelings are surfacing |
| Later, when the consumer is calm, assist to explore the immediate cause of the anger and anything that precipitated the aggressive response | Recognition of triggers can assist with problem solving |
| Help the consumer engage in problem solving and exploring alternative ways of handling their feelings | Engaging the consumer in solving their own problems is empowering because it informs the consumer that they can take responsibility for their actions |
| Be supportive and provide positive feedback when the consumer controls hostile or aggressive behaviour | Positive reinforcement is a way of helping people to modify unwanted behaviour |
| Accept that some anger may be displaced or projected on to you | The defence mechanisms of displacement and projection serve to reduce the anxiety and the threat to self, caused by the intense emotions. Understanding this helps the nurse to avoid taking the hostility personally |

**TABLE 39.6 | Approaches for dealing with anger and hostile behaviour in the mental healthcare environment–cont'd**

| Action | Rationale |
|---|---|
| Don't take unnecessary risks. If a person's anger is not subsiding but is in danger of escalating into destructive or violent acts, take whatever action is necessary to protect yourself and others (e.g. remove yourself and others from the area, seek assistance from others) | Nurses have rights in relation to workplace safety. Apart from the risk of personal harm to the nurse or others, the consumer who causes harm can later feel devastated by what has happened. Such an occurrence can be extremely destructive to the person's self-esteem and to the therapeutic process |
| Debrief with colleagues after the incident and seek any additional support that you feel you require | Dealing with aggression is challenging and can be frightening. Debriefing is a way of relieving the associated stress and can serve to identify ways for nurses to reduce risks and improve responses in the future |

*(Shives 2011)*

eating (Elder et al 2013; Varcarolis & Halter 2010). The reason for self-mutilation is not totally clear but various explanations are possible. It may be:

- A maladaptive coping mechanism that raises low self-esteem by denying helplessness or powerlessness
- A self-punishing act that helps relieve unconscious feelings of guilt
- Risk-taking behaviour that, when overcome, raises self-esteem
- A way to reconnect to feeling real and alive, as opposed to feeling empty or feeling nothing
- A way of releasing tension or anger
- Using physical pain to create distraction from emotional pain
- An unspoken request for nurturing and love
- A way of manipulating others.

Nursing skills for helping consumers manage self-harming behaviour include:

- Adopting an empathic and non-judgmental attitude
- Demonstrating support and using active listening
- Encouraging the consumer to share their thoughts and feelings about self-harm
- Helping the consumer to identify personal triggers and stressors
- Exploring with the consumer adaptive ways to cope with uncomfortable feelings
- Gaining the consumer's agreement that they will contact a staff member if they experience negative or overwhelming thoughts concerning self-harm
- Demonstrating a sense of calm and safety for the consumer
- Staying with the consumer and providing support if they are distressed
- Telling the consumer that you will spend time with them when they need emotional support
- Encouraging the consumer to engage in their usual activities and self-care where possible
- Maintaining a safe environment—removing harmful substances or objects from the consumer and the area
- Selecting a room that is close to the nurses' station in order to keep the consumer safe
- Providing safer means to experience physical pain that do not result in disfigurement, such as holding ice to a location on the body the consumer wishes to cut or harm
- Following the policies and procedures of the setting regarding observation and medication (Elder et al 2013).

## Suicidal behaviour

Suicide is an action where the intention is to result in self-inflicted death, as opposed to self-harm where the intention is to hurt one's self but not die. Self-destructive behaviour may result from any stress a person perceives as overwhelming, and is commonly associated with low self-esteem. When the sense of self-worth is extremely low, self-destructive behaviour reaches its peak and it is at this point that the risk of suicidal behaviour is likely. Suicidal behaviour implies a loss of the ability to see oneself as being of any value or worth at all (Elder et al 2013). Some of the risk factors for suicide are identified in Table 39.7.

Risk assessment is a crucial intervention in estimating a person's intent to self-mutilate or end their own life, and a formal risk assessment should be conducted whenever a mental state examination is conducted. It should be noted that the successful use of an assessment tool involves the ability to establish effective open and honest communication with the consumer, and expertise in the art of therapeutic communication is perhaps the most important component of the mental health nurse's contribution to care (see Chapter 8).

The first priority in dealing with a person who is at risk of, or exhibits, self-destructive behaviour is to protect the person from harm. All dangerous or potentially dangerous objects that could be used in an act of self-harm must be

**TABLE 39.7 | Suicide risk factors**

| Variable | Risk categories |
|---|---|
| Age | Risk generally increases with age but also at particular risk are young men and elderly men |
| Marital status | Higher risk in single, widowed, separated and divorced people. The death of a loved one is a particular risk factor in the older population |
| Gender | More common in men than in women (more women attempt suicide, more males succeed) |
| Physical health | Those experiencing chronic, debilitating, progressive or life-threatening illness<br>Alcohol and drug misuse/addiction<br>Sleep disorder/deprivation |
| Psychological health | Low self-esteem<br>Depression<br>Feelings of hopelessness<br>Feelings of loneliness and abandonment ('nobody cares')<br>Experience of significant loss<br>Unrelenting and distressing hallucinations/delusions<br>Command hallucinations (auditory hallucinations instructing the person to self-harm)<br>Impulsiveness, hostility and aggression<br>Bereaved by suicide |
| Social health | Social isolation/exclusion or sense of alienation<br>Poor level of social supports<br>Conflict with supportive others<br>Social upheaval (e.g. divorce, accommodation changes)<br>Unemployment<br>Poverty and poor living conditions (e.g. homelessness) |
| History | Suicide attempts in previous 12 months<br>Family history of suicide<br>Expressed intent<br>Evidence of planning (e.g. has given away possessions, made a will, said goodbyes)<br>Evidence of preparation; that is, has the means available (e.g. has a gun, has the pills)<br>Early recovery phase in severe depression |
| Previous suicidal attempts | |

*(Adapted from Ryrie 2000; Muir-Cochrane et al 2014)*

removed from the consumer's environment. This includes knives and other sharp implements, matches, glass, phone chargers, items of clothing such as belts, scarves or stockings or anything else that may be used by the consumer to inflict self-harm. Other approaches for dealing with self-harm and suicidal behaviour are outlined in Table 39.8. While it takes time and experience to become an accomplished mental health nurse, and the care and management of at-risk consumers requires particular expertise, the principles of care, when necessary and appropriate, may be applied by others in any healthcare setting to protect consumers.

Deliberate self-harm and suicide are complex issues, and a simple and brief overview has been provided here. As people with depression and self-harming tendencies may be encountered in every area of nursing, it is recommended that nurses explore the issues further by accessing psychiatric or mental health nursing textbooks and state government policies. See, for example, *Working with the Suicidal Person* (Department of Health (Victoria) 2010).

## The consumer who experiences hyperactivity

Hyperactivity can be a manifestation of a variety of mental health disorders, caused by the misuse of certain substances such as cocaine and amphetamines (Elder et al 2013) but is particularly associated with bipolar disorders. Bipolar disorders are a group of mood disorders that manifest with periods of depression and mania. The hyperactivity associated with mania is quite different to the normal exuberant activity engaged in by most people at various times. Hypomania is a clinical syndrome similar to, but not as severe as, mania which is sometimes termed hypermania (Sadock et al 2015). Previously people who experienced the mood cycles associated with bipolar disorders were said to have a manic depressive illness.

Mania is characterised by excitability, optimism, marked hyperactivity, talkativeness and a decreased need for sleep. The symptoms vary in intensity. In the milder form, people

## TABLE 39.8 | Approaches for dealing with self-harm and suicidal behaviour in the mental healthcare environment

| Action | Rationale |
|---|---|
| Engage in an open exploration of suicidal ideas, including the frequency and intrusiveness of the thoughts, the planning and motivation | Open exploration is an essential component of identifying the level of risk of self-harm. Any statement that alludes to self-harm (e.g. a threat or innuendo made by the consumer that they are thinking about harming themself should be taken seriously) |
| Assess the risk factors | A formal risk assessment should be conducted whenever any risk of self-harm is detected. Risk-minimisation strategies appropriate to the level of risk identified should be put in place (e.g. close observation, removal of objects deemed unsafe, contractual agreement for the consumer to report to the nurse when thoughts of self-harm are likely to be acted on). Mental healthcare agencies usually have specific guidelines and policies for management of consumers at risk of self-harm |
| Be with consumers in a calm, accepting and empathic manner | Facilitates open and honest communication and the development of a therapeutic relationship |
| Engage in therapeutic conversation that facilitates the safe expression of distress and the identification of the underlying issues and concerns | Helps the consumer to identify the factors (stressors) responsible for wanting to commit acts of self-destruction and will inform as to the measures that are appropriate to facilitate the healing of mental anguish Therapeutic silence is also powerful. Often remaining quietly with the consumer without speaking is a powerful tool |
| Recognise the opportunity for learning, personal growth and positive change as a potential outcome of the consumer's present experience | Recognising that positive outcomes are possible stimulates a sense of hope in the nurse, which can be relayed to the consumer. Hope and realistic optimism facilitate recovery |
| Work collaboratively with at-risk consumers, their significant others and other health professionals in assessing needs and planning care | Appropriate interventions may involve different areas of professional expertise (e.g. recreational therapist, psychiatrist, dietitian, psychologist). The consumer's significant others need to be aware of the strategies required to maintain the consumer's safety, and their involvement can be supportive for the consumer |
| An appropriately qualified person should negotiate a risk-minimisation plan with the consumer and significant others | Risk-minimisation plans usually involve a contractual agreement, and this needs to be firm and clear. Nurses are advised to work with experienced staff in relation to these before attempting to implement them |
| Be clear about the consumer's responsibility for their own safety within the context of the plan | Consumers need to understand that, within the contractual arrangement, control of the situation is theirs. This is empowering, but consumers also need to feel supported in managing their feelings |
| The care plan must be clear to all staff working in the consumer's environment (see Nursing Care Plan 39.1 as an example) | It is a team responsibility to support and protect the consumers and facilitate the success of the contractual arrangement |
| Be clear about the availability of support when a person feels unsafe, and ensure the person understands the boundaries that apply | The consumer needs to be clear about who is available and when they can provide support, and the type of support that is possible. This ensures that the risk of inappropriate dependency on staff is reduced and the consumer's sense of responsibility in the situation is reinforced |
| Mobilise social support | Social support is important in maximising the consumer's coping abilities. It can also assist the consumer to increase self-esteem (e.g. by promoting relationships with others). For consumers who are at risk but living in the community, arrangements may be made for another person to 'keep the means' (e.g. the consumer's medication), and for people to visit the consumer during times of the day when they are likely to be on their own |
| Engage in problem solving with the consumer | Helps maximise the consumer's constructive coping strategies and develop others |
| The nurse must be aware of personal and team responsibilities and accountability in relation to caring for at-risk consumers. | Consumer safety depends on staff fulfilling responsibilities. Responsibilities include knowing which consumers are demonstrating an increasing risk of self-harm (e.g. increasing alienation), and which are showing signs of improvement (e.g. smiling, interacting with others). The nurse should be aware that signs of improvement can be misleading |

*(Hungerford et al 2015; Elder et al 2013)*

can appear to have excess energy, they may present as the 'life and soul of the party', be able to work long hours and be very productive in work and leisure activities. If the symptoms increase to the most severe level, people may experience serious impairment in judgment that allows them to behave in ways not usually in keeping with their personalities. For example, a normally shy and quiet woman may become loud, dress in bright and gaudy clothing and become overtly sexually provocative; a normally sensible and frugal young man may run up huge and unmanageable debts on his credit card, drive his car at outrageously dangerous speeds and yell obscenities out of the car window as he narrowly misses other vehicles and pedestrians. Such dangerous and life-threatening behaviours may be of no concern to the affected person if they have psychotic symptoms, because delusional thoughts may make them believe that they are indestructible; for example, the young man above may believe that he is immortal because he is a new god come to save the world. Common symptoms associated with mania are summarised in Table 39.9. People who are experiencing the severe form of mania may need to be admitted to an inpatient unit for their own protection and for the protection of others.

Treatment includes firm limit setting, cognitive therapy, counselling and medication. Lithium (a mood stabiliser) is one drug that is effective in treating the symptoms of acute mania and in reducing or preventing recurrence of the mood swings associated with bipolar disorders. However, lithium and other drugs often cause unwanted side effects and levels in the blood require strict monitoring to prevent lithium toxicity. In addition, some of the feelings of elation and mania are enjoyed, so consumers are understandably not always willing to take the medications that stop the feelings so drastically and they may seek alternative ways of controlling the illness. Nursing interventions vary according to the level of mania and include:

- Maintaining consumer's safety and the safety of others
- Maintaining the consumer's biological normality (e.g. meeting rest, nutrition, fluid and elimination needs)
- Facilitating activities of daily living (e.g. meeting hygiene needs)

**TABLE 39.9 | Common symptoms associated with mania**

| Type | Symptoms |
|---|---|
| Affective (mood) | Labile, elation or euphoria<br>Expansiveness<br>Humorousness (witty)<br>Inflated self-esteem<br>Intolerance of criticism<br>Lack of shame or guilt |
| Physiological | Dehydration<br>Inadequate nutrition<br>Weight loss<br>Reduced need for sleep |
| Cognitive | Ambitiousness<br>Denial of realistic dangers<br>Distractibility and poor attention span<br>Flight of ideas (jumping from one train of thought to another without pause)<br>Grandiosity (e.g. delusions of grandeur)<br>Illusions<br>Lack of judgment and impaired decision making (e.g. unable to evaluate realistic danger and consequences of actions)<br>Looseness of associations<br>Delusions |
| Behavioural | Irritability/argumentativeness/aggressiveness especially if thwarted in achieving what is desired<br>Excessive spending when unemployed or broke and other forms of irresponsibility<br>Grandiose acts that may involve excessive risk taking<br>Increased motor activity and pressure of speech (extreme rapidity)<br>Impulsiveness (e.g. making important financial decisions with little thought)<br>Poor or bizarre personal grooming<br>May wear bright and ornate clothing (reflect elevated mood)<br>Sexual provocativeness and sexual hyperactivity that is often promiscuous<br>Excessive involvement in pleasurable activities without regard for negative consequences (e.g. swimming in dangerous conditions, unprotected sexual activity with strangers) |

*(Sadock et al 2015; Videbeck 2013)*

- Helping the consumer to regain and maintain self-control
- Preserving the consumer's dignity when behaviour is out of character and when it will be a source of embarrassment or humiliation when functioning more normally
- Reducing the amount of stimulation to which the consumer is subjected
- Providing a structured daily program that allows opportunities to expend energy in set activities (e.g. physical activity such as using an exercise bike or walking may help to drain excess energy)
- Promoting sleep and rest (which may require sedatives such as temazepam).

The overall goals of care are to help the consumer establish constructive coping mechanisms and increase the consumer's satisfaction gained from interaction with the world (Elder et al 2013). To do this the mental health nurse must establish and maintain a trusting relationship with the consumer. Attempting to do this can be challenging and frustrating for the nurse, partly because particular unusual speech patterns are common in people experiencing episodes of mania that impact on the ability to communicate effectively, particularly when consumers are in the acute phase of mania. The speech patterns associated with mania are listed in Clinical Interest Box 39.11.

Some of the factors that present challenges to nurses in developing therapeutic relationships are that the consumer may:

- Have a brief attention span
- Find it difficult to be still, and need to be in perpetual motion
- Find it difficult to listen to others and constantly interrupt
- Appear unaware of verbal and non-verbal cues indicating that others wish to speak
- Continue with a constant stream of speech that is sometimes unintelligible
- Have confused thinking, with thoughts racing one after the other (this makes it difficult for the consumer to make connections between concepts and so when speaking they may jump rapidly from one subject to another)
- Have diminished awareness of personal space boundaries and tend to invade the 'intimate zone' of others
- Have little understanding of how overpowering, excessive and confrontational their interactions can feel to others
- Test the rules and limits set for the therapeutic environment
- Be insistent on having their own way and may attempt to manipulate people, including the nurse, in order to achieve this
- Frequently insult staff or others, use foul or sexually explicit language, taunt and annoy others
- Be seductive towards the nurse (among others) (Elder et al 2013; Hungerford et al 2015; Halter 2014).

Management includes setting clear limits on behaviour while being supportive but firm. Setting limits involves reinforcing that it is the behaviour and not the person that is rejected. For example, it is preferable to say, 'That sort of language is not accepted in this unit', rather than, 'You are so crude speaking like that.'

## CLINICAL INTEREST BOX 39.11 Examples of speech patterns associated with mania

| | |
|---|---|
| Pressured speech | Rapid and accelerated speech that continues without pauses between words or sentences. The flow of rapid talking continues without regard to others who may be attempting to answer, intervene or add something |
| Clang associations | The stringing together of words that rhyme without regard to their meaning. Words are chosen for their sound, not their meaning. |
| Circumstantiality | Use of long irrelevant descriptions when trying to describe a person, situation or event. The account may include vast amounts of irrelevant and unrelated information and may include lots of repetition |
| Loose associations | Lack of a logical relationship between thoughts and ideas that renders spoken communication vague, unfocused (waffly) and diffuse (longwinded) |
| Flight of ideas | A nearly continuous flow of accelerated speech characterised by abrupt verbal skipping from topic to topic, usually based on chance associations between words |
| Tangentiality | Constantly diverging in mid-conversation to different and unrelated topics. When describing a situation, frequently losing the train of thought, and not completing descriptions of anything |

*(Shives 2011; Sadock et al 2015; Videbeck 2013)*

The nurse at all times needs to remain calm, speak clearly and explain what is required simply and firmly but in a caring manner. Staff should be mindful of not mirroring manic behaviour, ensuring they take note of the tone and volume of their voice. All staff must be aware of the limits and rules set for the consumer's behaviour, which must be constantly reinforced to assist the consumer to regain control of their behaviour. It must be remembered that behaviours that appear manipulative, fault finding or exploitative of others' vulnerabilities are the outward expression of inner turmoil, distress and often serious emotional need. Such behaviour is the consumer's way of trying to gain a sense of control at a time when they have no control of most aspects of their life; not even their own thoughts or feelings (Halter 2014). Table 39.10 provides some approaches for dealing with hyperactivity associated with the manic phases of bipolar disorders, but the principles apply to consumers experiencing excessive or uncontrolled hyperactivity from any cause.

Bipolar disorders and any disorder in which hyperactivity is a serious problem can be potentially devastating for consumers and their families. It is an important part of the mental health nurse's role to ensure that everyone affected understands about the illness causing the behaviour, is aware of what can and cannot be done to control the illness and what services and supports are available to help them to cope.

### CRITICAL THINKING EXERCISE 39.4

Jane is a 19-year-old unemployed woman who was brought into the emergency department by her mother after taking an overdose of drugs from the family medicine cabinet. She was found by her mother in her bedroom unconscious. Following treatment in the emergency department she was transferred to the inpatient psychiatric unit. She has recently separated from her boyfriend and her father has left to live interstate with a new partner. Identify the risk factors for suicide. What are the specific risks factors for Jane? Outline the approaches for dealing with self-harm and suicide in the inpatient setting.

## Consumers experiencing confusion or disorientation

A person may become confused or disoriented for a variety of reasons, including as a result of delirium, dementia or from the toxic effects of alcohol and some prescribed and non-prescribed drugs. The effect in each case is a significant marked change in cognitive abilities from the consumer's previous level of functioning. Cognitive functioning includes the mental processes of memory, reasoning, judgment, orientation, problem solving, decision making, the acquisition of knowledge and the ability to use and comprehend language. Some causes of cognitive dysfunction are reversible, others are not. Delirium, for example, is a syndrome that involves a disturbance to a person's state of consciousness, which is accompanied by changes in cognition, almost always due to an identifiable cause that can in most cases be rectified. Dementia, on the other hand, is a progressive, irreversible and disabling condition in which changes in cognitive function are caused by gradually increasing, permanent damage to the brain. The focus here is on caring for those with progressive dementia.

Dementia is one of the most common causes of confusion and disorientation, with over 280 000 people in Australia currently identified as having the illness. It is a disorder normally associated with older consumers but, although the risk of dementia does increase with age, more than 16 000 of those identified as having dementia are under age 65 (Alzheimer's Australia 2011). Alzheimer's dementia (AD) is the most common form of the illness, but all types of dementia share similar symptoms and require similar interventions. Dementia is associated with high rates of diagnosed co-morbid mental illness in residents of aged care facilities (affecting up to 44% of dementia sufferers) and in Australia dementia is the second leading cause of death (ABS 2015; Australian Government Department of Social Services 2015). The symptoms depend on the sequence in which areas of the brain are damaged by the disease process, so the progression of symptoms varies in different people. Symptoms change and increase in severity over the duration of the illness, which in the case of AD can be 3–20 years, the average span being 7–10 years (Alzheimer's Australia nd). Symptoms include:

- Gradual memory loss
- Increasing loss of language and communication skills
- Progressive decline in ability to perform routine tasks despite having intact physical functioning (in the early stages of dementia this may mean difficulty with coordination when preparing a meal or when shopping and handling money, or when driving a car. Later this extends to include difficulty with tasks such as dressing, eating and bathing)
- Impaired judgment, abstract thinking
- Difficulty in concentrating and learning new information or skills
- Changes in behaviour (e.g. wandering, incessant walking, constant repetition of words, confabulation)
- Changes in personality and mood (up to two-thirds of people with AD have symptoms of depression, and about 20% exhibit aggression)
- Hallucinations and delusions (hallucinations are experienced by about 16% of people with AD, delusions by about 30% and they are often paranoid in nature)
- Loss of initiative
- Altered sleep–wake patterns
- Loss of bladder and bowel continence (usually later stage) (Access Economics 2003).

### Caring for the consumer with dementia

Care interventions for a consumer with dementia are dependent on the consumer's abilities, and the focus of care should be on what the consumer can still do rather on abilities lost.

**TABLE 39.10 | Approaches for dealing with hyperactivity associated with bipolar disorders (manic phase)**

| Action | Rationale |
|---|---|
| Use a firm and calm approach | This helps promote a therapeutic relationship and is reassuring for the consumer and provides structure and control for a consumer who is out of control |
| Use short concise explanations or statements | A short concentration span and confused thinking make it difficult for the consumer to absorb complex information |
| Remain neutral, avoid power struggles and value judgments | Avoids provoking hostility or combativeness. Consumers can use inconsistencies and value judgments as justification for arguing and escalating mania |
| Maintain a consistent approach (e.g. provide a consistent and structured environment and keep expectations the same) | This provides the framework that assists the consumers to regain a feeling of control. Clear and consistent limits and expectations minimise the potential for consumers to manipulate staff or annoy others |
| Firmly redirect energy into appropriate and constructive channels, provide an outlet for physical energy in a non-stimulating environment (e.g. use of a punching bag in a quiet area) | Helps in establishing constructive mechanisms for coping with excess energy. Can help release pent-up hostility and relieve muscle tension |
| Decrease environmental stimuli whenever possible (e.g, avoid loud music, noises, bright lights, people) | Limits distractions that can provoke agitation and escalate mania |
| Provide structured solitary activities—tasks that take minimal concentration are best. Avoid groups and stimulating activities | Solitary activities are best until distractibility is settled and the consumer is able to comfortably tolerate being part of a group |
| Spend one-on-one time with the consumer, especially when psychotic or anxious | Provides reassurance and gives the message that the consumer is a worthwhile person. As mania and hyperactivity settle, provides time for exploration of issues |
| Encourage frequent rest periods<br>Provide high-calorie fluids and finger foods frequently throughout the day<br>On a daily basis, monitor the consumer's sleep pattern, food and fluid intake and elimination pattern (constipation is a common problem) | It is important that the consumer's physical wellbeing is maintained during the time they are not concerned with it themselves |
| Provide the consumer and the family with explanations and written information about the illness and the treatment plan (it is particularly important that the consumer and family understand the information concerning medication) | Information is important to promote compliance with treatment regimens and minimise the risk of recurrence of symptoms |
| Ensure consumer and family or significant others understand how to access the supportive services in the community | Knowing about community supports includes information about accessing help in a crisis, which can be reassuring. Information about support groups and activities aimed at prevention are helpful in promoting coping mechanisms and recovery |

*(Adapted from Varcarolis & Halter 2010)*

General care interventions are listed in Table 39.11 and in Clinical Interest Box 39.12. (See Chapter 15 for more information.)

Reality orientation is a form of rehabilitation used to orientate confused or cognitively impaired consumers by promoting or maintaining their awareness of person, time and place. It is recognised as unrealistic to expect to orientate people in the later stages of dementia to present time reality, but some of the principles of reality orientation are appropriate and helpful (Elder et al 2013). Helpful aspects include:

- Calling the consumer by their preferred name every time they are approached

## TABLE 39.11 | Information for nurses and for consumers with dementia and their family carers

| Information that nurses need to know | Information that nurses need to give people with dementia and their family carers |
|---|---|
| • Short-term memory loss is a primary symptom in the early stages of dementia of the Alzheimer's type. Memory loss later becomes global and affects short- and long-term memory<br>• Certain medications, especially in combination, can cause increased confusion and agitation<br>• Safety in the home and in healthcare settings is a primary concern because consumers with dementia are at increased risk of falls and other injuries from the combination of sensory effects, memory loss and age-related factors<br>• Consumers may be unable to communicate pain or emotional distress; the nurse needs to assess consumers regularly and monitor closely for physical and mental concerns, including concurrent depression, which can exacerbate the symptoms of dementia<br>• Sundowning syndrome (evening agitation associated with a busy time of day and resulting from consumer fatigue) may lead to challenging behaviours. Planned activities for consumers are helpful in preventing agitated behaviour at this time<br>• A structured environment with minimal changes is critical because it reduces consumer anxiety, confusion and agitation<br>• Consumers with AD may occasionally confabulate (attempt to fill memory gaps with unrelated information), which is not considered lying<br>• Consumers who confabulate may need gentle validation of their sense of what is true, or they may be gently redirected to another topic because confronting them with reality may result in confusion and distress<br>• Intake of nutritional supplements, herbs and over-the-counter medications may interfere with the consumer's prescribed medications<br>• Consumers cared for at home may resist outside help and place undue demands and stress on the family carer<br>• Stressors that can provoke consumer anxiety or confusion should be identified and modified or avoided as much as possible (e.g. loud music, cluttered rooms)<br>• Potential elder abuse may be a result of family carer strain, and consumers and carers need to be evaluated if abuse is suspected. Carers need to be made aware of all available supports and respite services in the community to reduce strain when people with dementia are cared for at home<br>• Access current resources available on the internet and in the library | • Teach consumers (in the early stages of the illness) and their families about the disorder and explain the progression of the illness and prognosis so that expectations are realistic. Consumers with dementia (especially those with young-onset disease) can choose and plan what they want to do with their lives in light of their prognosis, and can deal with any legal matters while cognition allows (e.g. make a will, advance directives)<br>• Teach the family carers actions and precautions to reduce the consumer's risk for falls or other injury<br>• Instruct the family how to observe for non-verbal signs of pain and discomfort (e.g. groaning, cold clammy skin, holding body part, changed vital signs)<br>• Teach the family about sundowning syndrome and offer strategies to reduce fatigue, confusion and agitation (sometimes family carers themselves discover helpful strategies that they can pass on to professional carers, as the 24-hour/day care they provide often makes them experts in dementia management and care)<br>• Teach the family about changes in condition (e.g. exacerbation of confusion, signs of depression) that are signs of health problems separate to dementia. Ensure awareness of who to contact for help and advice<br>• Teach strategies that promote the consumer's existing memory and connectedness with others (e.g. validation, reminiscence, environmental cues, familiar songs, pictures, pets, etc.)<br>• Ensure awareness of correct medication regimen, possible side effects and importance of following the medical officer's directions for administration<br>• Ensure awareness of discussing use of non-prescribed drugs (e.g. herbal remedies) with the medical officer to avoid side effects when combined with prescribed medications<br>• Suggest that the consumer remain under care of one medical officer to provide consistent care and clear medication regimen. This avoids the risks of adverse drug interactions from incompatible medications and polypharmacy (multiple medications)<br>• Teach the family about confabulation and stress that it is not lying, and that it is best to validate the person's belief of what is true. Stress that it can be distressing to challenge the person's view of reality. For example, if the person says they had egg, bacon and mushrooms for breakfast, it is best not to contradict them even if you are certain that they only had porridge<br>• Teach to identify stressors (anxiety triggers) in the home environment, and offer realistic solutions<br>• Explain the benefits of outside help when the help comes from skilled and reliable carers who can bond with the person with dementia<br>• Encourage the family carer to take advantage of respite and other services that will reduce the strain of caring for someone with dementia. Encourage family members to share the caregiving responsibilities<br>• Stress the importance of 'time out' for the family carer to recharge personal batteries, and the importance of maintaining their own health. This includes attendance to preventive strategies such as routine health checks, mammograms and flu injections<br>• Inform family carers about how to access current information via the internet and libraries, and from agencies such as Alzheimer's Australia (there are Alzheimer's information centres in many areas of Australia and New Zealand, many of which offer consumer and family carer support groups, among other services. Many also offer educational programs for family and professional carers) |

*(Adapted from Fortinash & Holoday Worret 2011)*

## CLINICAL INTEREST BOX 39.12 Interventions appropriate for consumers experiencing confusion or disorientation

Appropriate care for the confused or disoriented consumer includes:

- A safe, consistent, pleasant and familiar environment
- Freedom from physical/emotional/spiritual pain
- A calm, relaxed, caring and non-challenging atmosphere
- A stable and familiar staff
- Staff who have appropriate expertise and are compassionate
- Skilled communicators (expertise in communicating with cognitively impaired consumers)
- Frequent and gentle touch
- Tactful use of humour
- Frequent contact and interaction with staff/family
- Contact with pets if desired (especially the consumer's own pets)
- Opportunities to socialise
- A structured individualised routine (as close to the consumer's familiar routine at home as is possible)
- The presence of the consumer's own familiar belongings (e.g. personal objects)
- Therapeutic activities/programs to promote cognitive stimulation (e.g. reminiscence therapy, music therapy)
- Nutritious diet/adequate hydration, including pleasurable snacks
- Adequate periods of rest and sleep
- High standard of hygiene/personal grooming
- Effective use of well-maintained visual/hearing/sensory aids
- Adequate daily exercise
- Access to a pleasant and safe outdoor area
- Maintenance of treatments ordered by the medical officer.

*(Adapted from Fortinash & Holoday Worret 2011)*

- Stating your name each time you start an interaction with the consumer
- Maintaining a normal day–night cycle; for example, opening curtains and blinds during the day and closing them at night and encouraging the consumer to dress in their own clothes during the day, rather than in nightwear
- Leaving the furniture and the consumer's belongings in the same place, as rearranging objects in the environment adds to confusion
- Encouraging the consumer to wear their spectacles and/or hearing aids, as not wearing them adds to sensory confusion
- Maintaining a routine and a sense of order in daily activities
- Ensuring that the environment is designed to minimise confusion; for example, using distinctive colours or pictures on bathroom or toilet doors to help the confused person identify these areas, and ensuring adequate lighting in all areas to minimise the effect of shadows that might confuse perceptions of what is seen
- Using a notice board to display information about the date and place that is consistently maintained to give residents an opportunity to remain orientated to dates, times and important events.

Consumers who have temporary confusion or who are in the early stages of dementia and are seeking to maintain orientation to time and place may benefit from the following interventions:

- Telling the person the date and time each morning and repeating the information as appropriate during the day
- Having the day and date displayed in large bold letters on a board and having the person change it accordingly each day
- Reminding the person of holidays, birthdays and other special events
- Providing cues to reinforce verbal information; for example, clocks with clear and large numbers, large calendars
- Discussing current affairs; for example, items in the newspaper or on television news.

A key to providing quality care is to find a way to connect with consumers who have dementia. This is different to simply communicating, which can be one sided, with the nurse talking and the consumer largely passive. Connecting involves the nurse or other carer having to develop skills and spend time and effort establishing connection. The use of validation therapy, reminiscence and remotivation therapy promotes connection and these therapies are highly appropriate for use with consumers who have dementia (Varcarolis & Halter 2010). (How to communicate effectively with consumers who have dementia and the use of appropriate therapies such as validation and reminiscence therapy are outlined in Chapter 8.) Recreational, occupational and complementary therapies can also be therapeutic in promoting cognitive, sensory and physical stimulation and can provide opportunities for staff to connect with consumers.

### Managing challenging behaviours in confused consumers

Many of the behaviours that people with dementia exhibit are a direct result of the illness and so need to be considered as 'normal' symptoms of the illness, rather than abnormal behaviours. Behaviours that fall into this category include aimless wandering, becoming lost, muddled actions and conversations, disturbances in sleep–wake cycles and, especially with some particular types of dementia (e.g. Pick's disease), loss of emotional control and aggressive reactions (Elder et al 2013). Other behaviours, such as unusual outbursts of physical or verbal aggression, dressing or disrobing publicly or refusing to bathe, eat or attend activities previously enjoyed, can be due to a range of influences that can exacerbate the normal effects of the illness. The reason for the

behaviour—the core of the problem—may be related to a variety of issues including:

- A change in the environment (e.g. too noisy, too busy, causing feelings of being overwhelmed)
- The person's physical condition (e.g. too hot or cold, clothing uncomfortable, pain or discomfort)
- Hallucinations or delusions (may create fear and anxiety)
- Provocation by another resident
- The way a particular staff member interacts with the person (e.g. being loud or bustling or rushing the person).

Whatever the consumer's behaviour, it is important for the nurse to respond quietly, calmly, confidently and kindly. This kind of response is often enough to modify the behaviour. The use of psychotropic medications for managing challenging behaviour is best avoided because these agents tend to have little effect on problem behaviour associated with dementia, particularly of the Alzheimer's type, and they may cause serious side effects more difficult to deal with than the behaviour itself (Shives 2011). When behaviour is not acceptable the nurse should firmly let the person know that this is the case, and behaviour that is appropriate should be praised.

Care by staff who fully understand the effects of the dementia illness and have appropriate expertise in communicating with confused people is important to the consumer's sense of wellbeing, and it is clearly evident that disruptive behaviour is less likely in residential care settings when the principles of dementia care management are followed (Elder et al 2013). The appropriate interventions for consumers with challenging behaviour are outlined in Clinical Interest Box 39.13.

It should be noted that, while many of these principles apply to caring for consumers who are confused or

## CLINICAL INTEREST BOX 39.13 Nursing responsibilities for managing challenging behaviour

- Maintain a calm environment and respond to the situation calmly
- Remain neutral, do not attribute blame, never 'tell off' in a patronising manner or punish in any way
- Avoid the use of restraints, including chemical restraints; in particular physical restraints tend to increase agitation and confusion
- Try to identify the cause
- Observe and keep a record of when the behaviour occurs, the type of behaviour, the consumer's mood and where and with whom the behaviour occurs: this helps to identify triggers for the behaviour that in many cases suggest how the cause can be eliminated
- Assess the person
- Is there a physical or emotional trigger for the behaviour? Is the consumer or resident unwell, in pain, overtired, overstimulated, bored, anxious, embarrassed or feeling ignored, misunderstood or patronised?
- Is the consumer or resident reacting to an unpleasant incident or is the behaviour associated with:
  - A change?
  - A disturbing memory?
  - A particular person or occurrence?
  - A situation or request that is culturally inappropriate?
  - Delusions or hallucinations?
  - The memory of a traumatic past experience stimulated by the current situation?
- Consider all the facts together. Ask:
  - Does the behaviour always happen in the same place or in similar surroundings?
  - Is it new behaviour?
  - How was this situation (e.g. daily shower) managed when the consumer lived at home?
  - Does it occur with a particular person in particular circumstances?
  - Is it connected with a particular staff member, relative, friend or other resident?
  - What does the consumer say, if anything, about the behaviour?
  - Can the family carer provide any insights into the behaviour?
- Use a team approach to problem solving
- It may take time and several different ideas may need to be implemented before certain problem behaviours are resolved. If one nurse finds a successful intervention, this should be documented appropriately and shared with all team members.

### Redirection

Redirection involves distracting the consumer from the situation causing the behaviour. For example, the nurse may distract the consumer who is upset and shouting at another resident without obvious cause by saying, 'I don't know what's wrong but I think we should get away from here—let's go for a walk outside.' The consumer who is jumping up from the meal table and upsetting other consumers by saying 'this food is bad, it tastes like poison' may be directed if

## CLINICAL INTEREST BOX 39.13 Nursing responsibilities for managing challenging behaviour—cont'd

the nurse responds, 'I don't think things are right, come with me, you can leave that food, let's go and find something else to eat' or 'You'd better leave that, let's get something else to eat later on—can you come and help me water the plants outside and then we'll eat later?'

### Triggers

The following example is an illustration of how identifying a trigger can help to reduce challenging behaviour and how different strategies may need to be tried until a successful way of stopping the behaviour is found.

Mrs Lamb, 72, who has dementia and is living in a residential care facility, was generally happily confused but on some days would be very agitated, pace about, bang on tables and sometimes swear and shout out abuse such as 'get away, you cow' at the top of her voice. On these days she would often start crying for no apparent reason and the staff found it difficult to console her or to establish what was upsetting her. On the last two occasions of being so upset, she became physically aggressive and even succeeded in biting one of the nurses.

After keeping a detailed record of when and where the behaviour occurred it was realised that it was on certain days of the week that corresponded with when a particular nurse was on duty. This was a surprise, as the nurse was respected for her compassion and skill in dementia care nursing, but it was soon confirmed that the challenging behaviour was definitely triggered by the nurse's presence. It was only after consulting with Mrs Lamb's sister that the cause became clear. The nurse bore a close resemblance to a next-door neighbour who had reversed her car over and killed Mrs Lamb's much adored Labrador dog over 40 years previously.

The problem was discussed at a team meeting. It was decided that the nurse should not be responsible for Mrs Lamb's personal care and that she should attempt to reinforce her own identity with Mrs Lamb. When the nurse next came on duty she wore her hair differently and made a point over the next few weeks of consistently introducing herself and showing Mrs Lamb her name badge. She managed to tell Mrs Lamb about herself; she even used photographs of her family, her home and her holidays to assist the process of trying to reinforce her real identity. This seemed to be effective on most occasions, although Mrs Lamb sometimes continued to respond with agitation and aggression towards the nurse she believed had killed her pet dog.

Not knowing what else to do as Mrs Lamb one day yelled at her 'get out, dangerous bitch' the nurse quickly said, 'I'm so sorry, I was so careless, I never meant to hurt your dog. I am so sorry, please forgive me.' With this, Mrs Lamb acknowledged the apology with a firm quick nod of the head, walked to her chair and with a sigh sat down. This seemed to settle what for Mrs Lamb may have been unfinished business. The nurse continued to use this approach whenever Mrs Lamb was agitated and eventually the agitation and aggressive response to the nurse stopped.

*(Videbeck 2013)*

disoriented from causes other than progressive dementia, the approach for reversible confusion or temporary disorientation may include strategies to assist the person with progressive dementia to remain orientated to reality.

Dementia is one of the most complex and disabling illnesses. It presents huge challenges to nurses and to the many family carers who tend loved ones with dementia at home. Table 39.11 provides a summary of some of the information that nurses need to know and some of the information that nurses need to teach to family carers.

Dementia care, while not always acknowledged as such, is a specialty area of nursing, requiring a high level of integrated skills. It is predominantly a disorder of the elderly, who often have multiple other concurrent health issues that the nurse must be knowledgeable about. Dementia consumers are often not able to explain their feelings or their needs; the nurse therefore needs high-level observation and communication skills to provide quality care. The nurse also needs to be able to support the family carers of people with dementia, who are often devastated by what has happened to their loved ones.

Though this section has briefly highlighted some of the many issues relating to dementia care it is recommended that nurses undertake specialist courses to enhance their knowledge and skills in this area. Organisations such as Alzheimer's Australia provide up-to-date information relevant to people with dementia, their families and health professionals. All caring needs to be undertaken with an understanding of the legal and ethical issues that relate to mental health nursing. The next section adds some specific points to the general legal and ethical principles impacting on mental health nursing.

## LEGAL AND ETHICAL ASPECTS OF MENTAL HEALTH NURSING

The provision of healthcare for consumers suffering from mental health disorders is governed by government mental health Acts. Each Australian state and territory has its own Act and these Acts are periodically revised. The nurse who is involved in mental health nursing has a responsibility to be aware of the relevant current Acts in the geographical area of their employment. Information about legal issues may also be accessed from government departments responsible for the health of the community such as the Department of Health and Human Services (Victoria) or its equivalent in other states and territories.

**TABLE 39.12 | Steps and questions in ethical decision making**

| Steps | Relevant questions |
|---|---|
| Gathering background information | Does an ethical dilemma exist?<br>What information is known?<br>What information is needed?<br>What is the context of the dilemma? |
| Identifying ethical components | What is the underlying issue?<br>Who is affected by this dilemma? |
| Clarification of agents | What are the rights of each involved party?<br>What are the obligations of each involved party?<br>Who should be involved in the decision making?<br>For whom is the decision being made?<br>What degree of consent is needed by the patient? |
| Exploration of options | What other options exist?<br>What is the purpose or intent of each option?<br>What are the potential consequences of each option? |
| Application of principles | What criteria should be used?<br>What ethical theories are subscribed to?<br>What scientific facts are relevant?<br>What is the nurse's philosophy of life and nursing? |
| Resolution into action | What are the social and legal constraints and ramifications?<br>What is the goal of the nurse's decision?<br>How can the resulting ethical choice be implemented?<br>How can the resulting ethical choice be evaluated? |

*(Stuart 2001:208)*

Mental health Acts provide guidelines and directions regarding the provision of mental healthcare (e.g. criteria for determining criteria for compulsory admission to hospital), and regulations and requirements regarding the periodic review of consumers suffering from mental illness. The information here is based on the law as it relates to mental health consumers in the state of Victoria but the principles apply to laws across Australia.

## Legal issues relating to informal and formal admission

Treatment in a mental healthcare facility or by a community mental healthcare team may take the form of informal or formal admission. Informal (voluntary) admission is when a consumer chooses to receive treatment and is the most preferred modality of treatment. Treatment may be at personal request or based on the advice of family or a health professional, and the consumer is able to withdraw from treatment or leave the healthcare facility whenever they choose.

Formal (compulsory) admission is when the request for admission comes from a source other than the mentally ill person, who is deemed incompetent to make an informed decision. A consumer may be referred for admission if they pose imminent danger to themself or others or if they require treatment but are too confused or disorganised to seek voluntary admission. The consumer is examined by a number of healthcare professionals during the process of compulsory admission to ensure that they meet appropriate admission criteria, and that they cannot be treated in a least-restrictive environment. Carers are also encouraged to take an active role in the process.

In a crisis situation it may be a team of professionals based in the community, such as a crisis assessment and treatment team (CATT), that is called to assist. The team can request formal (compulsory) admission for a consumer.

As soon as a consumer no longer meets all admission criteria they must be discharged from their compulsory status, or what is termed formal detention. There are strict guidelines governing who should review formal consumers and how often they should be reviewed. Consumers have the right to appeal their detainment as a community mental health patient or an inpatient in a facility. Nurses working in the mental health field need to have a thorough understating of the mental health Act that relates to their state or territory.

## Treatment orders and issues of consent

Mental health consumers who are admitted compulsorily to a mental health service are sometimes treated under a community treatment order (CTO) or while living in the community. The CTO may require that the person lives in a particular place to facilitate treatment; the restricted community treatment order (RCTO) may stipulate which psychiatrist will provide treatment, where and how often treatment will be applied and how long the order will last. It may also stipulate other specific conditions under which the consumer may remain in the community while receiving treatment. All formal consumers, whether treated in the community or in a hospital, are legally obliged to accept recommended treatment, and treatment can be enforced against the consumer's will if necessary. Even though this is the case it is in everyone's best interest for formal and informal consumers alike to be given all relevant information connected with any treatment, and informed consent should be gained whenever possible. The right of formal and informal consumers to seek a second opinion must be respected.

The mental health Acts in each state and territory have clear guidelines concerning issues such as informed consent to treatment, the way treatments may be implemented (e.g. electroconvulsive therapy) and the use of restraint, including the use of seclusion as a therapeutic measure. It is an offence to restrain or seclude someone if it is not conducted within the requirements of the mental health Act applicable to where

the practice occurs, and the mental health service can be prosecuted and fined if an offence is committed.

### Legal issues and electroconvulsive therapy

Electroconvulsive therapy (ECT) is a prescribed treatment and as such it is regulated under the different mental health Acts and regulations in each state. The use of ECT is indicated when the consumer has an increased risk of suicide, has not responded to psychotropic medication or has had an adverse reaction to medication. It is also indicated when the consumer has had a previous history of a good response to ECT (Henderson 2011).

ECT involves the consumer being given a light general anaesthetic and muscle relaxant medication. A regulated electrical current is passed through the brain until a seizure occurs (a therapeutic fit). This is sometimes referred to as shock treatment. A course of ECT involves a series of treatments. Informed consent must be gained whenever possible for any form of treatment, but there are some issues specific to ECT.

Further information about ECT and the law can be located in the mental health Act for the relevant state or territory. References and websites for accessing legal information are provided at the end of this chapter.

## ETHICAL ISSUES AND DILEMMAS

Ethical issues and dilemmas abound in the area of mental health nursing. It is sometimes a challenge to balance the consumer's right to autonomy, the rights of others and the legal concepts relevant to nursing care. Some of the areas that may give rise to ethical concerns include:

- Informed consent/refusal of treatment
- Seclusion and other forms of restraint
- Consumer confidentiality versus the need to prepare/warn/protect other parties
- Consumer autonomy (self-reliance and choice issues) as opposed to paternalism
- Boundary issues in the nurse–consumer relationship.

Within these areas are situations that may give rise to the nurse experiencing conflicting or troublesome feelings. For example, enforcing medication or treatment that is refused, or needing to restrain a consumer by enforced seclusion, may give rise to feelings of guilt, concern or distaste. Or the nurse may be torn between a consumer's right to confidentiality and the importance of informing a family carer about a consumer's diagnosis, such as HIV (human immunodeficiency virus) infection, or of the risk of violence if the consumer has voiced threats when they do not want their diagnosis, feelings or voiced intentions revealed.

It can also be discomforting and confusing trying to balance establishing and maintaining a trusting and helping relationship while maintaining the appropriate professional boundary with certain consumers, and this can cause ethical dilemmas, particularly for nurses new to psychiatric nursing (Elder et al 2013). Nurses must practise within professional codes of practice and the law, and consistently remain aware of the ethical principles of beneficence (do good), non-maleficence (do no harm), autonomy (consumer self-determination) and those of justice, fairness and equity when caring for consumers. Whenever ethical concerns arise where the decisions about what to do are not clear, nurses should raise the issues and discuss them openly with colleagues. Nurses should take certain steps and consider the answers to particular questions when faced with ethical dilemmas. These suggestions are listed in Table 39.12. Nurses considering a career in mental health nursing are advised to access further information concerning ethical issues in mental healthcare.

### DECISION-MAKING FRAMEWORK EXERCISE 39.1

You are an Enrolled Nurse working in the acute mental health ward when the nurse in charge goes on her dinner break. Before she leaves, she tells you that she has already pre-prepared and signed for the medications for two consumers who wanted to wait until after dinner to have them. She hands you the medication keys, and tells you the medications are on the bench in the treatment/medication room. You have seen many staff do this, but have never been asked to do this yourself. This nurse has been working in this ward for over 10 years.

Using the decision-making framework:

1. Do you administer the pre-prepared medication to the two consumers? Why? Why not?
2. Consider the legal requirements of medication preparation and dispensing; is it acceptable to dispense medication you have not prepared/seen prepared?
3. How would you approach this situation with the nurse?

## Summary

Many Enrolled Nurses (ENs) may wish to follow a career in the specialty area of mental health nursing, and those who remain in other fields may be required to assist in the care of consumers experiencing mental illness; for example, when they are being cared for in general hospitals or in residential care facilities.

There is no clear dividing line between mental health and mental illness; rather, mental wellbeing is represented on a continuum and no one is entirely mentally unhealthy or fully mentally healthy at all times. The ability to remain mentally healthy depends on a wide range of interrelating factors, including those that are physiological,

*Continued*

## Summary—cont'd

psychological and sociocultural. There are many theoretical models to explain the development of mental illness, on which MHNs base their clinical practice. These include the biological (medical) model, psychological/psychodynamic, social/interpersonal, cognitive–behavioural and stress vulnerability/adaptation models.

Mental illness can be diagnosed and formally classified according to the presenting symptoms. A diagnosis can guide treatment but also places a label on the person that can be a source of stigma, which can be one of the most difficult aspects of mental illness for consumers to cope with. It is a primary role of the MHN to educate the public about mental illness to reduce stigmatising attitudes, which are in part based on historical factors.

Mental health nurses, who work as members of a multidisciplinary team, develop nursing diagnoses and focus care on the feelings of consumers and the behavioural manifestations of mental distress that they display. The development of a trusting, helping relationship is essential to being able to work therapeutically with mentally unwell consumers and in promoting the healing process. Assisting consumers to develop constructive coping mechanisms is an important component of the therapeutic relationship, as is supporting effective rehabilitation of consumers living in the community, where currently most mental healthcare takes place.

This chapter has not provided detailed information about mental illness but it has provided a brief overview of some issues and suggestions appropriate to the care of consumers who are anxious, depressed, aggressive, self-destructive, hyperactive or confused. The nurse interested in working in the wonderfully challenging area of mental health nursing is advised to access more information about manifestations of mental anguish, models of care and the legal and ethical issues that relate to this dynamic field of nursing.

## Review Questions

1. Explain what is meant by mental health.
2. What is mental illness?
3. Identify four (4) attributes that can be considered indicators of mental health.
4. Identify four (4) groups of people in society that are at particular risk of developing a mental illness and why.
5. Identify four (4) early warning signs of mental illness in children, in pre-adolescents and in adults.
6. Explain the primary characteristics of thought disorders, mood disorders and behavioural disorders and give an example of each.
7. How can nurses reduce stigma about mental illness?
8. Define the terms hallucination, delusion and confabulation.
9. Define the following four (4) terms and indicate when they are experienced: akathisia, anhedonia, anxiety and apathy.
10. Identify five (5) ways of assisting a consumer experiencing a panic attack.
11. Outline four (4) strategies for promoting effective communication with consumers who have depression.
12. Identify ten (10) interventions necessary to provide quality care for people with dementia in an aged-care residential facility. Consider the environment, the staff and nursing care activities.

### NURSING CARE PLAN 39.1

**Assessment:** First episode psychosis
**Issue/s to be addressed:** Disturbed thought process
**Goal/s:** To develop trusting relationship with staff
To be adherent with medication regimen resulting in improvement in mental state
For mental state to improve

| Care/Actions | Rationale |
|---|---|
| Establish rapport/therapeutic relationship with Jason | Jason will approach staff when feeling distressed and staff will implement distraction techniques |
| Promote need for prescribed medication through psychoeducation | Psychotropic medications have demonstrated efficacy in reducing distress and agitation of psychosis |
| Frequent MSE | Changes in MSE may be indicative of medication adherence and efficacy in medication. Alternatively, decline in MSE may be indicative of non-adherence to medication regimen and/or poor response to specific medication. |

## NURSING CARE PLAN 39.1—CONT'D

**Evaluation**

Jason has developed a trusting rapport with his primary nurse and seeks out staff when distressed.
While at times Jason demonstrates a mistrust of medication, he has remained adherent and his mental state has improved.
Daily MSE has indicated an improvement in psychotic symptoms indicating response to medication.
**Assessment:** First episode psychosis
**Issue/s to be addressed:** Reduced nutritional intake
**Goal/s:** To develop trust with Jason so that he is comfortable taking food from staff
To demonstrate adequate hydration/nutrition

| Care/Actions | Rationale |
|---|---|
| Staff continue to engage with Jason and develop a trusting rapport<br>> Have someone Jason trusts bring in food<br>> Observe Jason preparing his own food<br>> Medication adherence | If Jason trusts staff he may feel more secure in eating food from the unit. By not 'forcing' Jason to eat unit food, this may help alleviate his paranoia. |
| Monitor hydration/nutrition through observation of hydration levels and weight, in addition to observing eating/drinking behaviours | To ensure that Jason remains hydrated and is eating regularly |

**Evaluation**

Jason has developed a good rapport with staff on the unit and his paranoia reduced significantly when a friend was permitted to bring in food, including non-perishable items.
Jason has remained well-hydrated and nourished.

CHAPTER 40

# Nursing care in rehabilitation

*Sally Moyle*

## KEY TERMS

adaptation
choice
community
decision making
education
empowerment
independence
person-centred goals
team

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Recognise the terminology used in rehabilitation nursing to describe the individual's level of functioning
- Explain the philosophy of rehabilitation
- Outline the functions of each member of the rehabilitation team
- Describe the process of adjustment to disability
- Recognise a person-centred approach to nursing care of the individual who requires rehabilitation
- Develop a plan of care for a person experiencing disability within the context of their environment
- Examine the effects of interactions between the individual, carers/family, health professionals and community context in the rehabilitation process
- Demonstrate problem-solving skills appropriate to the discipline by identifying potential issues involved in assessment and nursing care for a person with a disability

## CHAPTER FOCUS

Rehabilitation is a dynamic process which, to be effective, must occur as a collaborative process involving all members of the rehabilitation team, of which the individual is the most important. Effective rehabilitation enables the individual to achieve optimal physical, emotional, psychological, social and vocational potential to maintain dignity and self-respect. Rehabilitation empowers the individual to make informed choices about healthcare and achieve a level of wellness that is acceptable to that individual. The rehabilitation nurse provides care, and employs education and supportive strategies based on rehabilitation philosophy, goals and concepts. Rehabilitation is a process of functional improvement that involves the individual, family, community and healthcare provider. Optimal function is achieved when the uniqueness and wholeness of the individual is recognised. The focus of this chapter is to introduce the nurse to the processes of rehabilitation and the many facets of rehabilitation that can be practised in any care setting.

## LIVED EXPERIENCE

I am just glad he is alive. I didn't think when he first had his intracranial haemorrhage we were going to get this far. Do you know that he always used to bring me a cup of tea every morning before he went to work? Well, now it is my turn to look after him.

**Sharon, wife to Glen, 48, who suffered an intracranial haemorrhage 5 months previously**

Rehabilitation is a complex process with a range of dimensions including: motivation; adaptation to change; coping with stress; adjustment to altered circumstances, body capabilities and/or appearance; and regaining independence and wellness.

## AIMS AND CHARACTERISTICS OF REHABILITATION

The basic aim of rehabilitation nursing is to limit the effects of disability and impairment in individuals with particular conditions. It begins with immediate care to minimise the effects of damage and to prevent complications in the stage immediately after an accident or the onset of illness. It continues through the time individuals are receiving restorative care and it often necessitates helping them to adapt to a permanently changed situation and a new kind of life. Rehabilitation nursing includes a wide range of activities that include working collaboratively with other members of a rehabilitation team to:

- Retrain physically damaged individuals to walk again
- Retrain cognitively damaged individuals to communicate effectively orally or in writing
- Help individuals adapt to impairment in a way that enables them to care for their own needs, such as showering, dressing and eating and using ordinary toilet facilities
- Promote individuals' abilities to manage ordinary everyday modes of travel
- Teach individuals how to put on, remove and care for different types of prosthetic appliances (e.g. an artificial limb or eye)
- Provide support to the individual and help them adjust emotionally to their change in function (Australasian Rehabilitation Nurses' Association (ARNA) 2009; Jester 2007; Nathenson 2012; Tyrrell et al 2012).

The rehabilitation process comprises the following stages:

- Assessment
- Goal setting: short, medium and long term
- Development of a plan to achieve goals
- Evaluation of progress (Australasian Faculty of Rehabilitation Medicine 2011; Jester 2007).

Rehabilitation also takes place in the area of mental health nursing and includes minimising impairment in function and preventing relapse in individuals who experience recurrent problems with mental ill health. Clinical Interest Box 40.1 indicates the main characteristics of rehabilitation.

Rehabilitation services can be delivered using a number of models of care including multidisciplinary and interdisciplinary teams, inpatient, outpatient, domiciliary and community-based rehabilitation services. All models include, to a varying extent, a **team** of people comprising the individual, their family, allied health and nursing professionals and specialist rehabilitation doctors, working collaboratively to achieve the individual's goals.

### CLINICAL INTEREST BOX 40.1 What is rehabilitation?

At its core, rehabilitation is about:

- Maximising a person's abilities and independence
- Restoring lost function
- Preventing new or further functional loss
- Working with other healthcare professionals

## Categories of individuals requiring rehabilitation

A person may experience a disability of acute or chronic onset at any stage of the lifespan. Those conditions requiring rehabilitation can be categorised as follows:

- Acute onset (e.g. cerebrovascular accident, head injury, myocardial infarction)
- Gradual onset/relapsing course (e.g. multiple sclerosis, rheumatoid arthritis, motor neuron disease, Parkinson's disease)
- Acute onset/constant course (e.g. spinal cord injury, burns)
- Gradual onset/progressive course (e.g. heart failure, some cancers, HIV, respiratory conditions) (Chang & Johnson 2013; Farrell & Dempsey 2013; Frontera 2010; Jester 2007).

Rehabilitation services have four target groups:

- Individuals who cannot go home from hospital without a return of, or improvement in, function
- Individuals discharged after an acute admission requiring continuing care as an outpatient
- People living with congenital or acquired disability or progressive illness with the goal of preventing the need for hospitalisation
- People who are ageing and experiencing the functional losses associated with multiple chronic diseases (Royal Australian College of Physicians 2011).

Rehabilitation programs may be developed and implemented for an individual who is experiencing any of the conditions listed in Clinical Interest Box 40.2.

In many situations complete rehabilitation is achieved; but in others complete recovery of function is not possible and the individual faces a permanent disability or impairment (see Chapter 41 for definitions of these terms). When this happens, individuals must be helped to accept, adapt to and compensate for the existing or progressive impairment to establish an optimal level of **independence** and quality of life. Clinical Interest Box 40.3 provides an explanation of the term **adaptation**.

People involved in rehabilitation include children, adolescents, adults or older people; therefore, it is important for the nurse involved in rehabilitation nursing to apply relevant theoretical knowledge of the social, physical and psychological stages of development (Jester 2007).

## The meaning of habilitation and rehabilitation

Habilitation, rather than rehabilitation, is a term that refers to the process in which a person who is born with an impairment is helped to achieve optimal independence and function by learning new skills that empower them to make choices and have degrees of control. Long-term habilitation programs are necessary for individuals born with conditions such as spina bifida, Down syndrome or intellectual or physical impairment.

One function of rehabilitation is to address long-term problems such as chronic health problems and degenerative diseases. Although there may be no cure for such conditions, a rehabilitation program can improve the quality of life. In this sense rehabilitation is directed towards the maintenance of optimal function and prevention of complications, or towards retaining the greatest amount of function and independence that the individual desires for as long as possible.

Rehabilitation begins at the onset of illness or accident and continues until it is decided by the individual, in consultation with the rehabilitation team, that the optimal level for that particular individual has been attained. The rehabilitation process may extend over a period ranging from a few weeks to several months or years.

Rehabilitation programs are conducted in a variety of settings, including acute care hospitals, specific rehabilitation institutions, day clinics, outpatient settings, the home and in the **community** (Crisp & Taylor 2012; Hoeman 2008; Kent et al 2014).

### CLINICAL INTEREST BOX 40.2 Conditions frequently requiring rehabilitation

- Spinal cord injury
- Cancer
- Burns
- Joint replacement
- Brain injury
- Multiple sclerosis
- Guillain–Barré syndrome
- Heart failure
- Myocardial infarction
- Alzheimer's and other dementias
- Parkinson's disease
- Airway disease
- Organ transplantation
- Renal impairment
- Psychiatric or emotional disturbances

*(Chang & Johnson 2013; Farrell & Dempsey 2013; Frontera 2010)*

### CLINICAL INTEREST BOX 40.3 Explanation of adaptation

Adaptation implies the ability to adapt oneself or to modify behaviour and expectations in line with changing circumstances. Adaptation is a mechanism that affects the whole being—physically, socially and psychologically—and is a necessary process of normal life. However, in times of trauma or when facing disability, individuals may find it beyond their capabilities to adapt to circumstances without professional assistance. For a clearer understanding of adaptation it is recommended that the reader refer to Sister Callista Roy's work *The Roy Adaptation Model* first published in 1984.

## PHILOSOPHY OF REHABILITATION

A philosophy is a broad statement of basic related principles, concepts and beliefs. A philosophy of rehabilitation offers a framework from which the rehabilitation process can be developed. Although rehabilitation teams devise their own philosophy, philosophies of rehabilitation are generally based on the premise that rehabilitation recognises the worth and uniqueness of the person as a valuable human resource, and that rehabilitation programs must be a major integral component of care offered by health services. Rehabilitation necessitates the participation and coordination of all health team members through constant communication with the individual and significant others to develop a comprehensive rehabilitation plan acceptable to and agreed to by the individual. The individual receiving rehabilitation must be viewed as an active team member, and the process must actively involve the family and significant others in the individual's life. By doing this the rehabilitation process adopts a person-centred approach.

Rehabilitation is concerned with the whole person and includes the sociocultural aspects of the person's life, sexuality, family and home, job, vocation, religion and community role. Rehabilitation aims to achieve the highest level of empowerment and independence possible for the individual and is person-centred and goal focused (Bright et al 2012; Chang & Johnson 2013).

### Person-centred goals and empowerment

Goal setting can be seen as a way to give control back to individuals and make empowerment real. As individuals reach goals the nurse must help the individual to realise that their achievements are due to their own abilities. The nurse can guide the individual so that they are empowered in **decision making**, taking control and accepting that progress is due to their own effort. This knowledge will help them maintain the motivation to continue to strive for more independence. Person-centred goal planning in individuals with spinal cord injuries has been found to facilitate increases in independence and gains in physical, social and psychological functioning (Byrnes et al 2012).

In healthcare, **empowerment** is defined as an educational process designed to help individuals develop the knowledge, skills, attitudes and self-awareness required to effectively assume responsibility for their health-related decisions. Empowerment is an approach that aims to establish the individual's autonomy and self-control and enables groups or individuals to change after being given the skills, resources, opportunities and authority to do so (Chang & Johnson 2013; Fernandez et al 2012). Traditionally, individuals have been regarded as passive recipients of care, with healthcare providers being considered the experts. This view differs from the modern paradigm of empowerment in which the individual should become an expert in their own healthcare. This approach allows individuals to acquire skills and knowledge for improving their overall health status and focuses on health promotion, individuals' abilities rather than disabilities and wellness rather than illness.

A partnership between team members and the individual transfers power and builds on the person's self-esteem and self-worth. Often individuals in rehabilitation experience feelings of poor self-esteem and a sense of worthlessness. They can be grieving for what they perceive as a loss of independence and lifestyle. **Person-centred goals** can assist in identifying what is important to that individual. The individual may not always set the goals at the level the team believes they should be able to achieve. It is not an effective use of resources if therapists aim for the individual to walk 100 metres if the person only wants to walk around the house or only wants to be able to walk to the letterbox. The goals must be realistic and the individual must have a desire to reach them. One of the most effective ways the nurse can empower the individual is to offer **choice**. Asking the individual what they would 'normally' prefer to do, and then allowing it to happen, is a step towards empowerment. The rehabilitation nurse should include the individual's own beliefs, wishes and goals in the delivery of care therefore goal setting should be a collaborative process between the individual and the healthcare team (Byrnes et al 2012; Fernandez et al 2012; Hoeman 2008).

The importance of the individual feeling in control of what is happening, what is being planned and of decisions that affect their life cannot be emphasised strongly enough. Person-centred rehabilitation is precisely that—rehabilitation planned together with an individual and their carers, families and friends, around their goals, needs and existing circumstances. There is great skill involved in empowering the individual. This sense of control is facilitated when the individual is involved in determining their own rehabilitation goals.

It is important for nurses working in the area of rehabilitation to keep in mind that throughout the process of rehabilitation the individual and the family are often facing markedly changed circumstances and may be struggling to adapt to what has happened. This may also be a time when an individual's choices may not be guided by rehabilitation-orientated goals and can lead to ethical concerns regarding risk of harm to the individual versus maintaining the individual's autonomy (Gill et al 2014; Hunt & Ells 2011).

## ADJUSTMENT TO DISABILITY

The process of adjustment as it relates to disability is similar to that in dying. (See Chapter 38 for more information on loss, grief and dying.) Disability involves loss and is accompanied by an adjustment process as the individual and significant others learn to come to terms with the disability and its implications. The grieving process will gradually occur as the impairment increasingly impacts on the individual's level of function (Boer et al 2014). The individual may experience loss of:

- Sensation
- Skin integrity
- A body part
- Ability to walk

**PROGRESS NOTE EXAMPLE 40.1**

| | |
|---|---|
| 31/10/2015 1400 hrs | Nursing: Individual seen crying in room after home visit. Individual states feeling 'I just don't think that I'll be able to cope at home even though everyone says I'm doing OK'. Individual stated she 'needs full assistance with showering and how can she get that help when she lives alone'. Individual is currently receiving assistance with putting her shoes and socks on, otherwise she is independent with PADLs. Individual reassured by nursing staff and is currently not crying. Discussed with occupational therapist and occupational therapist will do a PADL assessment with individual tomorrow morning and determine any discharge needs. |

***J. Smith*** **(Smith), EN**

- Use of an arm
- Bowel and/or bladder control
- Sexual function
- Ability to speak, read, write and comprehend
- Memory
- Ability to relate to other people and the environment
- Self-image, sense of self-worth, self-esteem, sexuality
- Independence.

The person whose disability has only occurred recently generally experiences four stages in adjustment during the rehabilitation process:

1. Acute disorganisation. The individual may express feelings of extreme anxiety, fear and disbelief that such an event has occurred.
2. Assessment. The individual begins to assess what has happened and begins to recognise and identify changes in function and ability. They may experience anger, depression, denial and bargaining. The individual may hope for a spontaneous recovery or a medical miracle, and tends to resist activities designed to help regain function from impairment (Spiess et al 2014).
3. Mourning. The individual continues to experience anger and depression; however, there is generally a new awareness of the losses involved. The individual begins to accept the changed probable future and no longer denies or ignores the disability. Eventually the individual begins to participate more fully in the rehabilitation program.
4. Re-entry. The individual resolves the depression of the mourning process and begins to experience more positive feelings about self and the future. They recognise that the disability does in fact exist and are keen to find means to adapt their personal lifestyle to the disability.

It is important for nurses to understand that each person will have an individual timetable for adjusting and adapting to living with a disability. Thus, while some people adjust in a relatively short time, others will take much longer. There is no normal period of time before a person finally accepts and adjusts to a disability. It must not be forgotten that the family also goes through a process of grieving and adjustment including experiencing feelings of overwhelming shock, helplessness, denial, disbelief, sadness, anger and anxiety (Watermeyer & McKenzie 2014). The rehabilitation team plays an important role as it supports the individual and family during the process of adjustment and adaptation. Progress Note Example 40.1 displays documentation of an individual who is having difficulty adjusting and displays anxiety in relation to their change in independence and level of function.

**CRITICAL THINKING EXERCISE 40.1**

Discuss how a person may express their emotions when coming to terms with functional decline, especially coping with the change in level of function and how this may be affecting a rehabilitation program.

**CRITICAL THINKING EXERCISE 40.2**

Discuss implications for an individual's family when caring for someone with functional decline and why it is important to include them in the individual's care.

## THE REHABILITATION TEAM

Effective rehabilitation involves person-centred care planning with the individual, family or significant others and the whole healthcare team. The special needs of the individual determine the fields of expertise that are represented in the rehabilitation team. An interprofessional team is required and consists of members from various disciplines, each with a vital role to play. Clinical Interest Box 40.4 identifies some of the people who might be included in a rehabilitation team. Which team members are included depends on the specific needs of the individual; for example, a non-English-speaking person would need an interpreter to be included.

### Members of the rehabilitation team

#### The individual

It is essential that the individual who requires rehabilitation be viewed as the pivotal team member. The other team members must help motivate the individual to be actively involved in the rehabilitation process, however slow it may be. Unless the individual is encouraged, a lack of motivation and cooperation with prescribed therapy may result. It is important that each small achievement is positively reinforced (e.g. recognised, praised or rewarded). At all stages of rehabilitation, the rest of the team must consider the individual's strengths and weaknesses and the social and cultural

## CLINICAL INTEREST BOX 40.4 Members of the rehabilitation team

- The individual
- The individual's family/friend(s) or significant other(s)
- Nurse
- Case manager
- Counsellor (possibly an expert in grief and loss counselling)
- Physiotherapist
- Occupational therapist
- Speech therapist
- Social worker
- Dietitian
- Podiatrist
- Prosthetist/orthotist
- Psychiatrist
- Psychologist
- Chaplain or other religious/spiritual support person
- Teacher/educator (essential for children undergoing long-term rehabilitation)
- Medical officer (often the team's clinical director)

*(Crisp & Taylor 2012; Farrell & Dempsey 2013; Nathenson 2012)*

influences that affect adjustment to disability (ARNA 2004). The team must be aware of how the individual perceives the illness and the impact of the disability that has occurred.

A disturbance of an individual's body image—for example, paralysis resulting from a cerebrovascular accident—is difficult to accept. The initial reaction is usually one of shock, followed by denial. As the individual gradually realises what has happened and that life may never be the same again, they may experience depression, anger or guilt (Umphred et al 2013). Self-esteem and self-worth are threatened (see Chapter 38). While there is inevitable dependency initially, the overall aim of rehabilitation is to help the individual regain optimal quality of life. The motivation of the individual is crucial, and it is essential that the individual be regarded as the most important team member, who must be encouraged to participate actively in all aspects of the rehabilitation process. The individual must be involved in planning the personal rehabilitation program with the team. The individual must learn in detail about the disability that has been experienced and ways of accomplishing the desired goals. The team must inform the individual as to what options are available so that the person can choose the best options for a successful outcome (Byrnes et al 2012).

### The family or friends

The family, or significant others, are recognised as a potential support system for the individual. Members of the family are evaluated to determine their ability to help with the rehabilitation process. All families, or significant others, cannot contribute in the same way or to the same degree. In some instances the individual can return home and receive excellent care and support, while in other situations the family may be unable or unwilling to help care for the person. As each situation presents different problems, individual evaluation is essential.

The family, or significant others, need to understand and/or be involved with the rehabilitative goals that the individual develops with the team, and the methods selected to meet these goals. Partners, family members or supportive friends need to understand that their greatest contribution may be to allow the individual to be as independent as possible. This may be difficult for them at times, as their natural instinct may be to assist and 'do for' their loved one. In addition, those supporting the individual can be instructed in how to assist with specific therapy, thus enabling them to feel that they are playing a vital role in rehabilitation.

It is important to understand that when illness or disability occurs, family life is interrupted and altered. The effects of illness have significant implications for the family as well as for the individual. Plans for the rehabilitation process should, therefore, also address the needs of the family as well as those of the individual (Lawrence & Kinn 2013). The nurse and the team must remember that a spouse or partner can become depressed if their loved one faces permanent lifestyle changes. It is important to inform the spouse or significant other that this is a normal reaction and encourage the person to seek assistance from a medical officer or team psychologist. Another concern with family occurs when ageing carers assisting relatives with disabilities in the home environment themselves become ill and are no longer able to provide care for their dependent relatives. People who have been cared for by their loved ones in the community for many years are sometimes suddenly faced with a crisis because that carer has become ill. This often limits the amount of support that the carer has for transition back into the community, and placement of the individual they cared for may be an issue if the carer cannot resume a level of functioning that enables a return to the role of carer.

### The nurse

Rehabilitation nursing is a speciality area of practice requiring specialised knowledge, skills and attitudes.

The skills of the rehabilitation nurse include:

- Communication
- Listening
- Facilitating
- Enabling
- Coordination
- Leading
- Collaboration
- Empowerment
- Liaison
- Advocation
- Educating
- Planning.

The goal of rehabilitation nursing is to assist people with disability and chronic illness to attain maximal functional ability, maintain optimal health, prevent and minimise disability and adapt to an altered lifestyle (ARNA 2009; Chang

& Johnson 2013). Goals of rehabilitation nursing include maximising:

- Potential
- Learning
- Ability
- Quality of life
- Family-centred care
- Wellness
- Culturally competent care
- Community reintegration.

Nurses are in a prime position to promote these things because they spend more time with the individual than any other member of the rehabilitation team, and therefore play a pivotal role in assessing, planning, implementing and evaluating care. A nursing assessment includes an evaluation of the extent to which the individual's physical and psychosocial needs are met.

In rehabilitation, a Registered Nurse (RN) makes a nursing assessment and develops a nursing care plan to meet the needs of the individual, taking into account the person's goals, both short and long term. An Enrolled Nurse (EN) provides care under the direction of the Registered Nurse. In many settings, nursing is the only component of the rehabilitation team represented throughout the entire 24 hours of each day. Nurses are therefore responsible for reinforcing the health education of other team members, such as the physiotherapist and occupational therapist, throughout this time, so that there is continuity of the rehabilitation program. The rehabilitation nurse's role includes preventing complications that would impede the restoration of optimal functioning; therefore, attention to potential problems as well as actual problems is necessary (ARNA 2004).

The effective rehabilitation nurse understands the short and long-term goals of the individual and the rehabilitation program. The nurse has a pivotal role in the multidisciplinary team and is aware of the need to liaise and communicate closely with all team members to achieve coordinated and effective outcomes for the individual. This often means that the nurse's role needs to be flexible and amenable to change. The nurse requires a full understanding of the role and function of each team member and needs to recognise when to refer to the expertise of others as the individual's needs indicate.

Individuals react and respond in various ways to personal health conditions and the rehabilitation program. The nurse must be able to assess accurately, monitor and educate the individuals and their significant others throughout the process, so that the individual's goals and the rehabilitation goals can be achieved successfully. The nurse works in a partnership with the individual, assisting them to make informed choices and have control over the process. At times the nurse might find it difficult to empower the individual, especially if they are despondent and in the early stages of denial. It is essential that the nurse takes time to build rapport and trust. Advocacy for the person is vital for this trust to develop. The nurse should be responsive to the individual's rights and be able to advocate for the individual in team discussions. The nurse's role involves being an educator, not only for the individual but also for the family, carers and other staff. This **education** will involve teaching rehabilitative techniques, preventing complications and promoting a healthy lifestyle. The nurse will act as a resource for information and clarification and know when to call in other professionals to assist.

Many clinical skills are employed when working as a rehabilitation nurse. Depending on the individual person, skills employed may include pain and continence management, preventing pressure areas, wound management and behaviour management. While the rehabilitation nurse needs to acquire excellent general nursing knowledge, there may be a necessity to refer to more advanced trained rehabilitation nurses specialising in neurological, orthopaedic, cardiac/pulmonary, oncology, renal, gerontic or paediatric rehabilitation nursing. The rehabilitation nursing team members between them commonly have a skill mix that meets the needs of the individual (Buzio & Pryor 2012).

Rehabilitation nursing takes place in any specialty or clinical environment where the aim is to maximise independence and minimise the impact of disability in individuals with particular impairments. Therefore, many nurses, including those who have not specialised in rehabilitation nursing, are involved in the rehabilitation process. However, should a nurse choose to make rehabilitation nursing a career focus, there are many different specialty areas of rehabilitation nursing, including orthopaedics, burns, spinal injury, head injury, amputation, cardiac and stroke rehabilitation (Farrell & Dempsey 2013).

## The case manager

The case manager can be of any discipline. It is fast becoming a very popular role for the rehabilitation nurse with advanced training. The case manager develops a formal, written, comprehensive needs assessment that includes a formal review of evaluations performed by other members of the rehabilitation team. The case manager assists the individual and the service provider in planning and program development that meets the individual's needs as identified and prioritised in the assessment. The case manager's role and function will vary depending on the practice setting. The case manager may be employed in an institutional setting such as a hospital or rehabilitation facility, or they may work in the insurance industry, such as the Transport Accident Commission or a health insurance organisation.

## The physiotherapist

Physiotherapists evaluate the individual's physical capabilities and limitations in a collaborative assessment process. The physiotherapist administers therapies designed to correct or minimise deformity, increase strength and mobility or alleviate discomfort or pain (Mulligan 2011). The physiotherapist has a person-centred approach. Treatments include the use of specific exercises, heat, cold, hydrotherapy and electrophysical therapy. A physiotherapist is also involved in educating the individual and their family or significant others and other team members in correct methods of positioning, transferring

and mobilising so that what is taught in therapy sessions can be carried over to day-to-day activities and reinforced by the nurse.

Physiotherapy will help with weak or tight muscles, stiff joints, poor coordination, balance, stair practice, walking and general fitness along with everyday functional activities such as rolling in bed, sitting, standing up and reaching forward/using hands.

### The occupational therapist

Occupational therapists are concerned with assisting the individual to achieve independent performance in the activities of daily living. They also assess the need for, and provide, adaptive devices, for example aids such as specially designed cutlery or making a splint for someone's hand so they can grasp their cutlery to feed themselves.

The occupational therapist usually assesses the individual's home in preparation for transition back into the community. This is done in conjunction with the individual and family on the pre-discharge home visit. Home modifications may be required to an individual's home to ensure the individual's safety and enhance their ability to mobilise and function as independently as possible despite any physical limitations. Equipment may need to be provided to ensure that the home environment is safe and conducive to the individual's independence level. Modifications may be minor, such as installation of a handrail, or major, such as structural alterations to enlarge space in a toilet and bathroom if a wheelchair or lifting machine needs to be accommodated. The occupational therapist may also be involved in teaching someone with memory problems strategies so that, for instance, they can remember to purchase everything they need at the supermarket (Chang & Johnson 2013).

### The speech pathologist/therapist

Speech pathologists, otherwise referred to as speech therapists, are also involved in the individual's goal-setting process. They are concerned with assessing, diagnosing and treating aphasia which encompasses communication and language disorders, such as the formation and perception of speech, the ability to articulate words and to understand and initiate speech, retraining reading and writing skills following a stroke or teaching someone how to speak after a traumatic brain injury (Chang & Johnson 2013). As part of the rehabilitation process a speech therapist may be required to assist a person to relearn communication skills. Communication deficits present a real problem for affected individuals, and much reassurance and counselling are often required. The individual who cannot speak may feel hopeless and frustrated. Often, depending on the area of brain affected by a cerebrovascular accident, the individual can understand fully but cannot articulate. Technical devices may need to be used to assist the individual to communicate with others. If both areas of the speech centre are damaged, global aphasia may occur, in which the person cannot speak or understand the spoken word. How to empower this individual is a very real challenge.

## CLINICAL INTEREST BOX 40.5 Videofluoroscopy—a diagnostic test to identify dysphagia

Videofluoroscopy is a modified barium swallow conducted by the speech pathologist and radiologist to determine the extent of dysphagia and to identify if the individual is at risk of aspiration. The test allows for the viewing of the oral cavity, laryngopharynx and cervical oesophagus. The person swallows small amounts of a liquid puree or solid mixed with barium. As the individual manipulates the bolus in the oral cavity and swallows, the fluoroscopic study is recorded on videotape. Videotaping of the swallowing study allows clinicians to have repeated viewing and slow-motion analysis.

*(Argolo et al 2013)*

A speech pathologist may also be involved in the management of an individual with dysphagia in which their swallowing abilities are impaired; for example, after a cerebrovascular accident. The speech pathologist liaises closely with the nurse, dietitian and family to achieve safe swallowing strategies for the individual. In consultation with the individual, a videofluoroscopy may be required to ascertain the extent of the swallowing deficit (see Clinical Interest Box 40.5). Often the individual and family will resist the strategy of thickened fluids to prevent aspiration; therefore, in-depth education and counselling are required so that informed choices, including a full understanding of the risks, can be made. Ultimately it is the individual's choice as to whether treatment strategies are followed.

### The social worker

Social workers are concerned with counselling and assisting individuals and their families who are experiencing personal problems as a result of illness or injury. A social worker acts as an advocate by liaising with existing community groups and resources, and assists the individual and the family to deal with social, domestic, financial and emotional implications of the illness or condition. The social worker engages in discharge planning and often accompanies the occupational therapist and individual on the pre-discharge home visit. The social worker communicates with the community services that may be required to assist the individual when discharged home or, if alternative placement is required, the social worker would assist in this process (Barber et al 2015).

Social workers assist individuals and their carers to deal with the emotional impact of illness, traumatic injury and disability and the adjustment to hospitalisation. Social workers help individuals and carers to adjust to life changes and challenges, deal with grief and loss, explore emotions, thoughts and behaviour, improve relationships and plan for the future.

Social workers provide counselling to individuals and families, assist individuals with financial, accommodation, legal and other problems, run groups to provide support

for carers, participate in discharge planning and link individuals to community support services for assistance post discharge.

### The dietitian

Dietitians are concerned with assessing nutritional needs and planning ways to meet those needs (Chang & Johnson 2013). As part of the rehabilitation process, the individual may require specific dietary restrictions or modifications, and a dietitian collaborates closely with the individual to plan an appropriate diet. The dietitian also plays an important role in ensuring that all those involved with the individual's care understand the importance of a specific diet for the person's recovery. Nutritional screening is also important for persons over the age of 65.

### The podiatrist

Podiatrists are concerned with assessing, preventing and treating disorders of the feet. As part of the rehabilitation process, an individual may be required to relearn how to ambulate; for example, after a cerebrovascular accident. In order to mobilise, the feet must be in good condition, with no skin lesions or nail disorders, and the podiatrist plays an important role in maintaining the health and integrity of the skin and toenails. In collaboration with the individual, the podiatrist determines appropriate footwear for safe mobilisation.

### The prosthetist/orthotist

Prosthetists are concerned with assessing an individual's need for prosthesis, such as an artificial limb. After assessment, a prosthetist designs and supplies an appropriate prosthesis. Generally a temporary prosthesis is provided and trialled before a permanent one is supplied. Modifications to an existing prosthesis may be made by a prosthetist who also checks at regular intervals to ensure that the prosthesis is meeting the individual's needs. Some individuals may need to be fitted with splints or braces to correct deformities or provide added support. Such mechanical devices are called orthoses, and include braces for the neck, arm or leg. These assist with mobilisation and improve the quality of life for individuals (Farrell & Dempsey 2013).

### The psychiatrist and psychologist

If the individual is experiencing a psychiatric or emotional problem, either a psychiatrist or a psychologist is generally involved in the rehabilitation process. A psychiatrist is concerned with the causes, prevention and treatment of mental, emotional and behavioural disorders. A clinical psychologist is concerned with the causes, prevention and treatment of individual social problems especially in regard to the interaction between the individual and the physical and social environment. A psychiatrist, clinical psychologist or neuropsychologist may be involved in the rehabilitation of an individual who is depressed as a result of the implications of the disability, or if behavioural problems result from the condition. The psychologist can also assist the rehabilitation team with strategies to manage individuals who have behavioural disturbances that impact on the day-to-day rehabilitation process. These disciplines can also assist the family or significant others if problems of coping and adaptation are identified. Depression can be common in the individual undergoing rehabilitation, especially individuals who have been hospitalised for a prolonged period of time; family members are also vulnerable to depression (Turner 2012).

### The clinical director (medical officer)

The clinical director is commonly a medical officer specialising in rehabilitation medicine and often the first member of the team to encounter the individual as a response to a referral for rehabilitation intervention. The medical officer is responsible for the medical and/or surgical management of the person and oversees the treatment that involves meeting the physical, emotional and social needs of the individual (Chang & Johnson 2013). These needs must be satisfied to successfully restore the individual's quality of life to maximum potential. The medical officer collaborates with all members of the team and is usually the team leader. They assess the individual's health status regularly and explain the diagnosis and prognosis to the individual and relatives. The medical officer often takes on the role of chairing the case conferences and other meetings, such as team and family meetings. Regular ward rounds are conducted by the medical officer, who also has an active educative role with team members, particularly for more junior medical members of the team.

## Case conferences and team meetings

These meetings are held at regular intervals and are the forum at which team members discuss the progress and problems of every individual who is undertaking rehabilitation. During these meetings the individual's short and long-term goals are discussed, with each member being aware of, and respecting, the roles of others in accomplishing these goals. Goals must be re-evaluated regularly with the individual, so that the individual and therapists can determine whether they are realistic and/or whether they have been accomplished. All goals should be set with specific time frames. Specific therapy goals are also set at these meetings. These therapy goals are compatible with the individual's goals but are usually broken up into smaller attainable sequences, with time frames; for example, John will stand for 3 minutes, with the aid of the tilt table, three times tomorrow; John will increase time on the tilt table in increments of 2–3 minutes until standing for 10 minutes three times a day.

Each team member explains to the other members the procedures and techniques to be carried out. The proceedings are documented in terms that are meaningful and valid for all persons concerned. The individual and/or family may or may not be present at the case conference, depending on the time limitations of the meeting and the individual healthcare facility's policy. Quite often a designated team member meets with the individual and family before or after the meeting to discuss and inform and assist in the decision-making process. Family conferences can be conducted aside from the case conference, when more time can be given to the concerns of the individual and their family.

## THE PROCESS OF REHABILITATION

The rehabilitation process involves assessing the individual's rehabilitation potential, planning and implementing an appropriate program and continuous evaluation of progress (Australasian Faculty of Rehabilitation Medicine 2011; Jester 2007).

### Assessment of rehabilitation potential

Assessment of the individual and a realistic evaluation of their rehabilitation potential is the first step towards planning a program. Assessment involves determining the individual's:

- Expected level of functional ability
- Readiness to participate
- Knowledge level
- Ability to understand expectations and instructions
- Self-efficacy
- Self-esteem
- Energy levels
- Priorities at any point in time (ARNA 2009).

In some instances assessment can be a relatively simple process, while in others it is more complicated. For example, it is comparatively easy to assess the rehabilitation potential of a healthy young adult with a fractured femur, while it is more difficult to make an assessment in an elderly person with diabetes who has experienced a cerebrovascular accident.

Assessment may take the form of observation, listening, interview, physical exam and consultation with other team members and/or family.

Assessment of each individual must take into account:

- The nature of the disability. Some conditions affect only isolated areas of the body, while others exert widespread effect. Some disorders cause progressive and diverse impairment of function
- The overall condition of the individual and their ability to cope with a rehabilitation program. There may be other existing conditions that could influence the choice of rehabilitation measures; for example, chronic conditions such as arthritis or emphysema may restrict the person's ability to engage in active exercise
- The motivation of the individual and the understanding of the situation. The individual's motivation should stem from a realistic acceptance of the situation and should not be the result of over-optimism or a refusal to acknowledge limitations
- The individual's home environment and the ability of the family or significant others to be supportive.

Physical and psychological assessment of the individual is performed to evaluate functional state, so that a suitable program involving both short- and long-term goals can be set (Farrell & Dempsey 2013). Assessment includes evaluating muscle function, range of joint motion, body alignment and posture, neurological function, cardiopulmonary function, mood and cognition. The assessment should identify both the abilities and the limitations of activities of daily living and mobility.

### CLINICAL INTEREST BOX 40.6 Ten variables assessed in the Barthel Index

1. Feeding
2. Bathing
3. Grooming
4. Dressing
5. Bowels
6. Bladder
7. Toilet use
8. Transfers
9. Mobility
10. Stairs

### CASE STUDY 40.1

**Jill's experience**

Jill, aged 35, was diagnosed with multiple sclerosis (MS) 3 years ago. She is married to David and has a 6-year-old daughter. She continues to work 2 days a week as an administration officer. Recently she fell and fractured her arm and needed to stay in hospital for rehabilitation. The nurse on night duty found Jill in the day room, unable to sleep. When she asked her what was keeping her awake she said 'nothing' but proceeded to cry.

What are some strategies the nurse could use to facilitate Jill discussing her feelings?

A number of tests can be used to assess functional ability and activities of daily living and include the Functional Independence Measure (FIM) and the Barthel Index. The FIM is an 18-item assessment used to measure the individual's ability to perform activities of daily living (ADLs) related to self-care, elimination, locomotion, transfers, communication and cognition. The Barthel Index measures the individual's ability to perform in relation to 10 domains of motor function (see Clinical Interest Box 40.6).

Assessment of concerns/alterations to sexual function should also be taken into consideration (see Case Study 40.1).

### Determining short- and long-term goals

Short-term goals of a rehabilitation program are those that may be achieved in a short period of time. For example, activities such as achieving a standing position, moving from a bed to a chair, managing meals independently, tying shoelaces or formulating a sentence may be set as short-term goals. Long-term goals are those that are expected to take much longer to accomplish and depend on success in achieving the short-term goals. These may include activities such as walking, managing to climb stairs, independence in the activities of daily living or returning to employment. An example of the use of goals within a plan of care to assist the individual in improving their health and level of function can be found in Nursing Care Plan 40.1.

## NURSING CARE PLAN 40.1

**Assessment:** Mr Smith has Parkinson's disease and needs full assistance with ADLs and all mobility. He is experiencing dysphagia and is on a soft diet. Sometimes in the morning when he is having breakfast in bed he experiences some trouble swallowing and often coughs. He is incontinent of urine and faeces and wears an incontinence pad. His skin around his groin is starting to become red and excoriated. He is only able to sit out of bed in his chair for short periods during the day due to fatigue and finds that when he sits out in the morning he is often too tired to sit out in the afternoon.
**Issue/s to be addressed:** His dysphagia and coughing, especially at breakfast.
His incontinence and consequent skin excoriation.
Fatigue management.
**Goal/s:** Mr Smith will not cough with his breakfast.
Mr Smith's skin will be intact and healthy, especially in his groin area.
Mr Smith will sit out of bed for 4 hours a day in increments of up to 1 hour. This will include in the afternoon.

| Care/Actions | Rationale |
|---|---|
| Mr Smith will sit out of bed for breakfast | To decrease the risk of aspiration when eating and to help with the motion of swallowing |
| Mr Smith will be toileted every 2 hours and skin care attended to his groin at this time | To decrease incontinence episodes and to protect his skin from breaking down |
| Mr Smith will sit out of bed for each meal, including morning and afternoon tea | This will give Mr Smith a timetable of sitting out of bed and ensure that he is resting between these times to assist with fatigue management |

**Evaluation**
Mr Smith will not cough with breakfast or with any meal.
Mr Smith's groin and skin integrity will remain intact.
Mr Smith will sit out of bed each day for a minimum of 4 hours.

*(Chang & Johnson 2013; Crisp & Taylor 2012)*

The value of setting goals is that both the individual and the team know what they are aiming for and will be able to identify when they have achieved a specific goal. As mentioned earlier, the individual and family assist in the development of the goals and this assists in empowering the individual and providing a degree of control. If realistic goals are to be set the entire rehabilitation team must be involved in the planning process and must meet frequently to re-evaluate the situation.

It may be difficult for an individual to maintain a high level of motivation and they may think that little progress is being made and that the set goals are unattainable. They may view the rehabilitation program as tedious, boring, exhausting or painful. As a result, they may become depressed and discouraged. The nurse may help by:

- Being empathic about the situation, which involves trying to understand how the person is feeling
- Emphasising what progress has been made and expressing honest confidence in the person's ability to make further progress
- Spending as much time as possible with the person, particularly during activities in which active encouragement is required
- Ensuring that the individual does not become overtired or attempt to exceed the limits prescribed. Encourage the individual to take one day at a time. Some days will be better than others
- Encouraging the individual to concentrate on achieving one goal at a time. An over-ambitious program may result in frustration and despair
- Encouraging the individual to express feelings. A relationship can be established by listening to the individual. This creates a sense of trust so that the person feels able to express concerns and feelings to the nurse (see Chapter 8).

**CRITICAL THINKING EXERCISE 40.3**

Discuss ways that may help someone regain empowerment during a time-limited rehabilitation phase.

# PLANNING AND IMPLEMENTATION

## Nursing aspects of rehabilitation

Based on goals set, a collaborative plan of action needs to be developed. The nursing activities involved will depend on many factors such as the individual's age, degree of independence and type of impairment. The overall purpose of rehabilitation is restoration of the individual to optimal functioning,

or to assist the individual to adjust to a disability after an illness or injury. As a member of the rehabilitation team, the nurse provides support and assists the individual to meet personal physical and psychological needs. Nursing care may include care of the skin, hygiene, nutritional care, continence, sexual health, activities of daily living, wound management, medication administration, mobility and transfers.

Regardless of the specific impairment, the philosophy and aims of rehabilitation remain the same. The nurse plays a key role in assisting the person to carry out the activities of daily living and must be aware that the ultimate aim is to achieve the goals that the individual has developed with the team. The achievement of personal goals that the individual has developed is one of the most important aspects of their rehabilitation.

For example, in a program developed for a person who has experienced a cerebrovascular accident and subsequent hemiplegia, one specific long-term goal may be that the person is able to dress themselves. For that goal to be achieved, short-term goals will be set, such as 'The person is able to sit up in a chair'. The occupational therapist will be involved in teaching dressing and undressing techniques, and the nurse should understand the techniques the person is using so that the teaching of the occupational therapist can be reinforced in day-to-day activity (see Case Study 40.2).

Continuity of care is vital for effective rehabilitation outcomes. The individual's day should be planned to maximise the rehabilitation process. It is also important that the nurse working with the individual is aware of the plan, and works with them to achieve their goals. There is a tendency to 'get the work done' and, rather than allowing the time for the individual to wash and dress themself, the nurse does it for them because it is quicker than supporting them to do it themselves. It is destructive to the rehabilitation process for the nurse to take over when an individual is attempting to dress themselves; for example, doing up the buttons on a shirt when a person is making slow progress may save the busy nurse time, but it undermines the importance of the individual's efforts and may deter them from trying in the future.

One important nursing function is to prevent the complications of immobility (Crisp & Taylor 2012; Farrell & Dempsey 2013; Kalisch et al 2014) which include:

- Decubitus ulcers
- Contractures
- Footdrop
- Venous stasis
- Pulmonary stasis
- Urinary stasis
- Constipation
- Postural hypotension
- Subluxation of a hemiplegic shoulder
- Psychological consequences such as boredom or depression.

(See Chapter 28 for more information concerning mobility.)

## Evaluation

Progress towards achieving goals needs to be reviewed regularly, and is a collaborative approach between the individual, family and all the team members. Evaluation of progress may take the form of individual self-reporting, physical measurements such as timed walking, range-of-joint movements, quality-of-life indices and team reports based on observation and interaction with the person. Based on this evaluation the individual's goals and action plan should be reviewed and amended as required.

## Aids to daily living

There are numerous devices to help a person with a disability perform the activities of daily living. Such devices are invaluable, as they make a degree of independence possible. For example, there are long-handled shoe horns to promote independence with dressing (Figure 40.1), long-handled brushes to promote independence with hygiene (Figure 40.2) and devices to promote independence with meals (Figure 40.3) and drinking (Figure 40.4). In addition to aids assisting with activities of daily living, aids are also available to assist with recreational and vocational activities such as sport wheelchairs, postural support devices including Hi-Lo seating and modifications to commonly used items such as footwear, electronic equipment and work spaces. Nurses should be familiar with the full range of aids available and should be capable of teaching the individual and their family the correct way to use them. A range of available aids is listed in Clinical Interest Box 40.7.

In Australia there are centres for independent living that provide a wide range of aids to assist with the tasks of daily living. A variety of community services is available to assist persons with disabilities to remain at home, including community health centres, day hospitals and day centres, drop-in

### CASE STUDY 40.2

Roger, an 88-year-old, lives by himself and has fallen over while gardening. He fractured his hip and required surgery. He was admitted to the rehabilitation unit 7 days after surgery for a reconditioning program.

He is on a combination of antihypertensive and cardiac medications. He requires the administration of aperients to keep his bowel actions regular. He suffers from occasional urinary incontinence and uses a pad at night. He is able to walk with a frame, and requires assistance with transfers, dressing his lower body and applying his anti-embolic stockings. He progressed well with his therapy and after a home visit identified modifications required for his bathroom which were attended to. He was ready to be discharged home 2 weeks after admission.

1. Outline the nursing plan of care you may be involved in for Roger.
2. List the rehabilitation team members involved in Roger's care and explain why they are included.
3. What education might Roger require before discharge?

**Figure 40.1** Long-handled shoe horn

*(Patterson Medical USA)*

centres, elderly/senior citizens clubs, self-help groups, home nursing services, home meal services and sheltered workshops. Nurses should be aware of the state/territory-specific social welfare services and agencies, most of which can be found in the telephone directory or through an internet search for community services in Australia.

## CULTURALLY RELEVANT CARE

Outcomes, interactions and responses are influenced by social and cultural factors. In rehabilitation, nurses can bridge cultural barriers to facilitate and improve outcomes. Family members or significant others are also interviewed to obtain accurate information as to pre-morbid functional status, personal interests, cultural considerations and discharge plans affecting the rehabilitation admission.

For those individuals from cultures different to that of the nurse, the nurse needs to take into consideration cultural influences—of their own and of the individual—on participation and decision-making. An Australian study that focused on the difficulties arising from cross-cultural care found that communication barriers were often a major

**Figure 40.4** Aids to promote independence with drinking

Tumbler with a special cut out for the nose allows the individual to drink without tipping the head back

*(Patterson Medical USA)*

## CLINICAL INTEREST BOX 40.7 Aids to independent living

- Suction devices fitted to kitchen utensils, backs of nail brushes, etc, for the benefit of a person with the use of only one hand
- Boards with spikes to hold fruit or vegetables to be peeled, or bread to be buttered
- Face washers in the shape of a mitten, with a pocket to hold the soap
- Long-handled tongs for a person who is unable to pick items up by bending or stooping
- Dressing sticks with one end covered by foam rubber to grip the sleeve or shoulder of a garment, making it easier to don and remove
- Various devices to enable socks and stockings to be put on
- Overlapping adhesive fastenings (e.g. Velcro) on clothing for people unable to manage other conventional types of fastenings
- Long-handled shoe horns to make bending or stooping unnecessary (Figure 40.1)
- Elastic shoelaces, which do not have to be untied when shoes are removed
- Cuffs which, when placed over the hand, hold a pencil, toothbrush or razor
- Easy-to-turn tap fittings
- Raised toilet seats
- Chairs with an ejector seat, which rises as the occupant leans forward
- Ramps to replace stairways
- Hand grips in bathroom and toilet areas
- Long-handled brushes to enable individuals to perform their own hygiene activities (Figure 40.2)
- Low-level fittings for occupants of wheelchairs (e.g. sinks, stoves, mirrors, light switches)
- Eating and drinking aids (Figures 40.3 and 40.4)
- Walking aids

factor contributing to non-adherence and non-participation in services and self-management strategies and, furthermore, these individuals were also disadvantaged in accessing health services (Haghshenas & Davidson 2011). See Chapter 10 for further information on culturally appropriate care.

While 65 years of age is traditionally used as the point where the term 'older aged' may be applied, in the non-Indigenous community, Indigenous people would regard a person over 45 years as an older person requiring aged-care services. The Indigenous population experiences significantly greater morbidity and premature mortality compared with non-Indigenous people (Ward et al 2014; Waugh & Mackenzie 2011). This is a result of, among other things, the increased prevalence of chronic conditions such as cardiovascular disease, diabetes, kidney disease, chronic respiratory disease and cancer. Chapter 11 gives the reader further understanding of Indigenous issues.

## DISCHARGE PLANNING

Discharge planning prepares the individual for the transition to another setting, such as from hospital to home. It is the link between hospitals, community-based services, organisations, families and carers. The elements of the discharge planning process should begin on the day of admission. The overall goal of discharge planning is to promote continuous healthcare services to meet the individual's needs (see Chapter 21). Effective discharge planning can decrease the chances that a person is readmitted to the hospital, can help identify care issues and needs and enable appropriate care plans to be developed.

Although discharge planning is a significant part of a person's overall care plan, frequently there is a lack of consistency in both the process and the quality of discharge planning across the healthcare system.

An effective discharge plan depends on the resources available to the individual who is being rehabilitated. Available resources include:

- The family or significant others—the individual's support systems
- Home care nursing
- Social and counselling agencies
- Volunteer community services
- Support and special interest groups; for example, those dealing with multiple sclerosis, diabetes, cancer, heart conditions, arthritis
- Medical supplies and equipment
- Adaptation of the home environment for safety and optimal independence.

The individual and the nurse, together with other team members, assist in coordinating and developing the discharge plan, using the steps of the nursing process to achieve the final plan. A discharge planner or continuing care coordinator is sometimes part of the hospital staff and functions as a consultant for the discharge planning process within a health facility, providing education and support to hospital staff in the development and implementation of discharge plans.

### CRITICAL THINKING EXERCISE 40.4

Discuss the possible roles and functions of the nurse in planning for discharge for an individual during inpatient rehabilitation.

### CRITICAL THINKING EXERCISE 40.5

Describe three (3) community services or other resources that could help to facilitate a successful community re-entry for a person post discharge from inpatient rehabilitation.

## Summary

Rehabilitation is a dynamic process in which individuals are helped to achieve optimal quality of life by increased function and independence, within the limits of their disability. A disability is any physical, mental, emotional or social impairment that limits a person's ability to carry out an activity in the usual manner.

Effective rehabilitation involves the individual, family or significant others and professional members of the healthcare team. As part of the rehabilitation team, the nurse plays a vital role in helping the individual to meet physical and psychological needs as independently as possible. The rehabilitation process empowers the individual to make informed decisions and choices about treatment modalities, care regimens and lifestyle options.

### DECISION-MAKING FRAMEWORK EXERCISE 40.1

You are working as an Enrolled Nurse within an orthopaedic rehabilitation ward and have been allocated 14 individuals to care for with a Registered Nurse under the organisational team nursing policy. This is your second week as an Enrolled Nurse and you have never worked in the healthcare system before. The Registered Nurse allocates you both seven individuals each. At the commencement of your shift all of your individuals are medically stable. During your shift you notice the health status one of your individuals declining. They have had a total hip replacement 5 days ago and are complaining of feeling lethargic, dizzy and generally unwell. You perform a set of observations on them and find they have a temperature of 38.8°C, their blood pressure is 88/60, heart rate is 109, oxygen saturation level is 96% and respiration rate is 20.

You report these findings to the Registered Nurse you are working with and state that you are unsure what to do as you have not had experience with individuals who are unstable before. You state that you do not know what to do next and do not feel confident providing care to this individual. The Registered Nurse tells you that this can often happen to individuals undertaking orthopaedic rehabilitation and asks you to decide on a plan of action and report back to her. You feel unsure of what you need to do and are worried about the individual's current health status.

Using the decision-making framework:

1. What would you do following this discussion with the Registered Nurse?
2. When you do not feel confident providing care for your individual, what should you do?
3. Who is accountable for the provision of nursing care when working within a team nursing model?

## Review Questions

1. What are the main goals of a rehabilitation program?
2. What are the stages of the rehabilitation process?
3. List three (3) methods of assessment the nurse could be involved in when a rehabilitation program is being planned for an individual who has experienced hemiplegia as a result of a cerebrovascular accident (stroke).
4. List three (3) ways a rehabilitation nurse can assist in empowering the individual who has lost the ability to speak but can understand.
5. List three (3) areas of health education that might be helpful for the rehabilitation nurse to provide for an older person who has recently been diagnosed with Parkinson's disease.
6. List four (4) roles within the rehabilitation team that the nurse may undertake.
7. List four (4) settings in which the rehabilitation nurse may function, and identify six (6) types of illness, condition or injury that individuals might experience in which rehabilitation would be essential.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing care: chronic illness and disability

*Vicki Blair Drury*

CHAPTER 41

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Describe how chronic diseases and disability are defined
- Identify factors that lead to an increase in long-term conditions
- Critically examine contemporary models of care for long-term conditions
- Apply a self-management approach to the management of individuals with long-term conditions and/or disability
- Identify factors that lead to disability
- Apply an understanding of normalisation and inclusion to the management of individuals with disabilities
- Acknowledge the important role family/carers play in supporting people with disabilities or chronic diseases
- Identify health promotion strategies that serve to reduce the incidence of disability and chronic diseases in society
- Identify the importance of educational supports and strategies that serve to reduce the impact of having a disability or chronic disease, including the benefits of early intervention

## KEY TERMS

chronic disease
disability
equity and access
health promotion
impairment
inclusion
independence
normalisation
self-management
social role valorisation (SRV)

## CHAPTER FOCUS

Chronic illness and disability affect people across the lifespan irrespective of race, gender or cultural group. However, some conditions are more prevalent in some cultures or races than others. Socioeconomic factors and education have been found to influence illness and mortality (Meara et al 2008) with socioeconomic inequalities evident for most of the chronic diseases (Glover et al 2004). Globally, ageing populations significantly affect the increase in chronic disease. Chronic diseases are now the leading causes of illness, disability and death in many countries (Mathers & Loncar 2006; Schmidt et al 2011; Wang et al 2005). Chronic disease, also known as long-term conditions, encompasses a broad spectrum of diseases. Comorbidity (i.e. the coexistence of two or more diseases together) is a common feature of chronic disease. Additionally, comorbid chronic diseases often share similar risk factors which act together to affect individual health status (Australian Institute of Health and Welfare 2014).

Although chronic disease and disability are often discussed together, not all people with chronic disease have a disability and not all people with a disability have a chronic disease. While chronic disease is often classified according to major disease groups and risk factors, disability is categorised according to severity.

Chronic disease is defined as a disease that lasts more than 3 months and for which there is no cure. Disability is considered to be a condition that in some way affects a person's ability to carry out day-to-day activities.

This chapter outlines the classification and causative factors of chronic diseases and disabilities. Models of care focus on normalisation and facilitating **independence** through individual empowerment. The theme throughout is the need for nurses and other allied health professionals to recognise and promote the importance of successful inclusion and acceptance into the community and to work towards improving the quality of life for all people with disabilities.

## LIVED EXPERIENCE

### Arthur's story

Arthur, 75, cares for his wife, Meg, who has motor neuron disease. Arthur retired from work and with family support moved to Queensland about 5 years ago where it was felt the climate would help Meg's condition. At first it was a hard move as his family returned to Melbourne and Arthur had to cope on his own. He has gradually adjusted, with the help of service providers, to manage Meg's condition, which has deteriorated; she is now paralysed and can only move her head. Swallowing food and drinking is becoming a real issue with concerns around Meg choking. She is no longer continent. Arthur sponge bathes her every weekday, assists her with toileting and all meals (which he prepares himself) and takes her out in her wheelchair, though this is getting harder to do.

Arthur admits to getting very tired at times but has no regrets—he feels the role of carer has improved him as a person. 'I am a different person because of caring for Meg; we have been blessed with three lovely children, nine fantastic grandchildren and now the great-grandchildren are on the way. We have had over 50 years of marriage,' he says. 'It's shown up different areas of my life that needed changing, like my impatience and quick temper. I've had to change and this has been hard. I think I'm a much more caring person, I can put myself in other people's situations, which I didn't always do before.'

When Arthur and Meg were offered more professional assistance with Meg's hygiene and meals, Arthur at first declined, although Meg expressed concern for him. Arthur responded, 'I want to do it; I feel I am repaying Meg for all the times I wasn't there for her and the kids in the early part of our marriage ... and I feel good because I do things for her I never thought I'd be able to do, and I've earned her love and respect and the respect of my kids now.'

**Arthur, age 75**

## CHRONIC DISEASE

Confusion often surrounds chronic diseases due to numerous definitions being used in the literature. **Chronic diseases** are also called long-term conditions, non-communicable diseases or lifestyle diseases in the literature. These definitions do not appropriately define chronic disease as some may be due to communicable factors such as cervical cancer and others are determined more by environmental factors rather than behavioural or lifestyle factors (World Health Organization (WHO) 2005). However, chronic diseases generally extend for a long period, progress slowly and have no cure. The Australian Institute of Health and Welfare (2012b:2) defines chronic diseases as being characterised by 'complex causality, multiple risk factors, long latency periods; prolonged course of illness and functional impairment or disability'. This definition clearly illustrates the complexity of chronic diseases.

WHO (2005) asserts that chronic diseases often start at a young age but take many years to evolve and that they require a long-term and systematic approach to management. Examples of chronic diseases include high blood pressure, heart disease, chronic obstructive pulmonary disease, diabetes, macular degeneration, glaucoma, tinnitus, some cancers, Parkinson's disease, Crohn's disease, epilepsy, schizophrenia, bipolar affective disorder, systemic lupus erythematosis and arthritis.

## PREVALENCE, CLASSIFICATION AND CAUSES OF CHRONIC DISEASES

WHO emphasises that chronic disease is now the leading cause of death globally even in countries where infectious diseases are widespread (WHO 2005). Eighty per cent of all deaths in middle- and low-income countries are now attributable to chronic diseases which are largely preventable (WHO 2005). Chronic disease impacts on the individual, the community and the country. Chronic diseases cause premature death, decreased quality of life and place financial burdens on families and communities. The impact of chronic disease globally is significant. It is estimated that unless countries unify and take action more than 388 million people will die from chronic disease in the next decade (WHO 2005). The impact of these deaths, many of them premature, on families, communities and countries will be significant.

Chronic diseases are often classified according to disease types with cardiovascular diseases (mainly heart disease and stroke), cancer, chronic respiratory diseases and diabetes being the main classifications. However, visual and hearing impairments and genetic diseases also account for a significant portion of the global disease burden (WHO 2005).

The causes of many chronic diseases are well known and reported widely in various media from medical literature to daily newspapers. The three most significant modifiable factors influencing chronic diseases are poor nutrition, lack of exercise and tobacco use. These factors affect blood pressure, lipid control, blood glucose and body mass index and, combined with non-modifiable risk factors of age and heredity, explain why there has been a global increase in chronic diseases (Figure 41.1) (WHO 2005).

## CONCEPTUAL MODELS OF CHRONIC CARE

Several models of care have been developed that focus on a broader framework integrating individual, community and organisational goals to manage chronic diseases. The most significant of these is the Chronic Care Model (CCM) developed by Wagner in 2001 (Bodenheimer et al 2002). This model remains the foundation of most chronic disease models today and identifies individuals' empowerment, self-management support and organising community and organisational resources to meet the individuals' needs as the key principles required to improve chronic disease management. Despite evidence that the model remains effective (Adams et al 2007; Coleman et al 2009; Tsai et al 2005) it was identified that it excluded health promotion and health prevention strategies which were viewed as integral to effective sustainable chronic disease management (Barr et al 2003). Expanded models of this framework have therefore evolved that include social determinants of health and the inclusion of health prevention strategies (Barr et al 2003; Epping-Jordan et al 2004).

WHO asserts that governments must take action to meet the increasing burden of chronic diseases and provide guidelines that countries can use to improve health service delivery and management of chronic diseases (WHO 2002). In 2002, WHO joined with the MacColl Institute to adapt the Chronic Care Model to a more globally appropriate model. The resultant framework was the Innovative Care for Chronic Conditions Model (see Figure 41.2) which focused on improving care for people with chronic conditions at three levels:

1. the macro level concerning policies and the environment
2. the meso level involving organisations and the community
3. the micro level comprising individuals and their families (Epping-Jordan et al 2004).

While each level of this framework is important, the macro level is essential for the development of programs and providing leadership at both the meso and micro levels. It is at this level that partnerships are developed and human and material resources are provided for the sustainability of programs (Sharma 2013). At the meso level it is essential to improve continuation of holistic care and facilitate healthcare and community organisations working together. At the micro level individuals need to be empowered and become active participants in their own care. Healthcare staff need to be informed and take on a supportive and educative role in care. Chronic disease self-management acknowledges that the person with a chronic disease must cope not only with the disease and the effects of the disease but also the impact on their quality of life (Drury & Aoun 2014). See Clinical

*(World Health Organization 2005)*

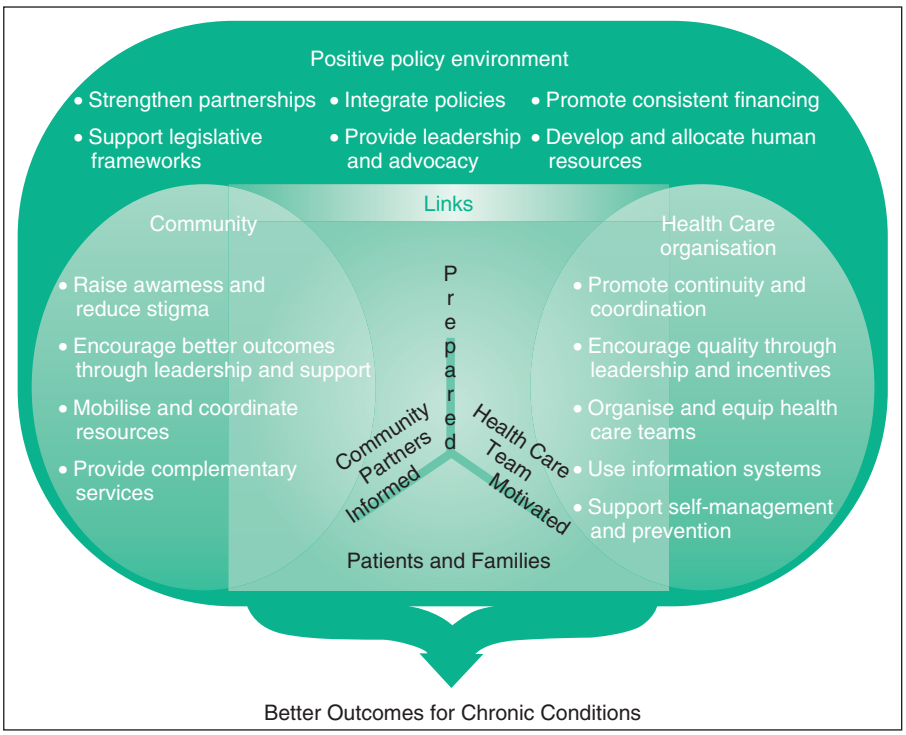

**Figure 41.2** Innovative Care for Chronic Conditions Model *(WHO 2002)*

Interest Boxes 41.1 and 41.2 for examples of adjustments and adaptations individuals with chronic disease face.

## DISABILITY

Historically the term **disability** was medically or diagnostically focused; however, over time this has evolved to one that is functionally focused, thus making an important distinction between two concepts—functional limitation and disability. Disability thus becomes something that occurs outside of a person, rather than something a person has. The functional limitation is influenced by numerous factors such as the environment, functional ability, age and life experiences. This new definition views disability as a matter of degree: the person is more or less disabled based on the intersection between the individual, their functional abilities and the many types of environments with which they interact.

WHO defines disabilities as 'an umbrella term, covering impairments, activity limitations and participation restrictions. An **impairment** is a problem in body function or structure; an activity limitation is a difficulty encountered by an individual in executing a task or action; while a participation restriction is a problem experienced by an individual in involvement in life situations' (WHO 2015).

## PREVALENCE AND CAUSES OF DISABILITIES

WHO estimates that around 15% of the world population has some form of disability with 2% having severe disabilities (WHO 2015). Mont (2007) asserts that disability and poverty are interwoven due to the impact poverty has on nutritional status, access to health services, living and working conditions and sanitation while, conversely, disabled people are often forced into poverty due to the challenges they encounter accessing education, health services and social activities. The global ageing population and the increase rise in chronic disease will further increase the number of people living with disabilities.

## CLASSIFICATIONS OF DISABILITY

Classifying disability is complex. Although it is acknowledged that all people with disabilities do not have the same desires nor confront the same challenges, policy makers and clinicians need a system of classification that enables the organisation of disabilities into categories, enabling the application of universal codes. These codes are then used for a range of purposes including tracking prevalence of disabilities, reimbursement of costs and assisting with making decisions about services. In Australia, disabilities are categorised according to the type and cause (Table 41.1), and according to the level of restriction incurred (Table 41.2). In addition, disabilities are described according to whether limitations or restrictions are sensory, physical, psychological or intellectual (Table 41.3) (Australian Bureau of Statistics 2009). Multiple or complex disabilities generally refer to the coexistence of two or more conditions; for example a physical and intellectual disability. In addition it has been found that many people with disabilities have comorbid chronic diseases (Fried et al 2004).

## CLINICAL INTEREST BOX 41.1 Phases of adjustment to living with a chronic disease

**Crisis phase**

- Sense of dismay and urgency to find treatment
- May use drugs and/or alcohol to cope
- Seek alternative interventions
- Blame self or others
- Fear and anxiety
- The goal of this phase is for the person to regain a sense of control. The healthcare team assists the person to manage physical and psychological symptoms and offers support. The healthcare team must help the person turn negative thoughts into positive thoughts and empower them to regain control.

**The stabilisation phase**

- Acute phase of the illness has passed and there is an awareness that this is now a chronic condition
- Friends and family may retreat
- Feelings of isolation and helplessness
- The goal of this phase is for the person to restructure their life. The healthcare team assists the person to understand what they can do and helps them achieve their goals.

**The reconstruction phase**

- Coming to terms with the chronic disease
- Learning to live with the consequences of the disease
- Heightened sense of control and empowerment
- Renewed sense of self.

**The integration phase**

- Accepting that the disease has provided positive life experiences
- Sense of pride in achievements.

*(Jason et al 1999; Fennell 2003)*

## CLINICAL INTEREST BOX 41.2 Adjustments and adaptations to living with a chronic disease

- Loss of roles
- Changes to health status
- Loss of identity
- Lifestyle changes
- Financial adjustments

*(Chang & Johnson 2014)*

## TABLE 41.1 | Classification of disability according to type and cause

| Type | Cause | Example |
|---|---|---|
| Inherited | Genetically transmitted | Down syndrome, spina bifida, muscular dystrophy |
| Congenital | Due to infection during pregnancy or injury to the fetus during or soon after birth | Cerebral palsy or a hearing impairment due to the mother being in contact with rubella during pregnancy |
| Acquired | Due to accidental or intentional injury | Brain injury due to trauma or fetal alcohol syndrome from maternal excess consumption of alcohol during pregnancy |
| Unknown origin | Cause unspecified | Some types of intellectual and behavioural disorders and some mental health conditions |

*(ABS 2009; 2012)*

## TABLE 41.2 | Classification of disability according to restriction

| Level of restriction | Example |
|---|---|
| Profound | A person is unable to perform self-care, mobility and/or communication tasks, or always needs assistance |
| Severe | A person sometimes needs assistance with self-care, mobility or communication |
| Moderate | A person does not need assistance, but has difficulty with self-care, mobility or communication |
| Mild | A person has no difficulty with self-care, mobility or communication, but uses aids or equipment |

*(ABS 2009; 2012)*

## The unique meaning of disability

Disability is a subjective experience. An injury to the leg that results in permanent inability to bend the knee or stand for long periods of time might be a serious anxiety-provoking disability for a person working as a nurse or a tradesperson. The impact of the same disability on an elderly person who lives alone and spends most of their time watching television and rarely going out of the house may be quite different. Many people learn to adapt so well with their disability that it becomes inconsequential. These people often say that they can do everything an able-bodied person can do; they just do it differently! A disability places a restriction or functional limitation on the person.

A disability, therefore, is not something that a person has but, instead, something that occurs outside of the person; the person has a functional limitation.

**TABLE 41.3 | Classification of disability according to area affected**

| Type | Example |
|---|---|
| Sensory | Visual impairment<br>Hearing loss |
| Physical | Arthritis<br>Paralysis due to spinal cord injury<br>Acute pain |
| Psychological | Schizophrenia<br>Dementia<br>Depression |
| Intellectual | Intelligence quotient or IQ score below 70 |

*(ABS 2009; 2012)*

## CONCEPTUAL MODELS OF DISABILITY

Conceptual models of disability have struggled for years with whether disability should be viewed through a medical lens or a social lens. In isolation neither of these models provided an adequate framework for supporting people with disabilities. In 2001 WHO endorsed the International Classification of Functioning, Disability and Health (ICF) which provides a framework for measuring health and disability at both individual and population levels. The new ICF definition of disability, referred to as the biopsychosocial model, evolves from the medical and social model and incorporates the idea that anyone might become disabled (WHO 2007). This new framework views disability not as something that a person has but as a functional limitation that occurs outside of the person. Disability occurs as a result of the interaction between a person, their functional ability and the environment. Therefore, a disability may be minimised by designing environments to accommodate varying functional abilities and providing individualised solutions.

In 2014 WHO global disability action plan 2014–2021 'Better health for all people with disability' was adopted by the World Health Assembly. This action plan, based on recommendations from WHO and the World Bank report on disability, has three aims:

*(i) to remove barriers and improve access to health services and programmes; (ii) to strengthen and extend rehabilitation, habilitation, assistive technology, assistance and support services, and community-based rehabilitation; and (iii) to strengthen collection of relevant and internationally comparable data on disability and support research on disability and related services.*

**(WHO 2014)**

### Adjustment

Adjustment to a disability is dependent on numerous factors, and most people also transition through a number of phases before accepting their disability (see Clinical Interest Box 41.3).

It is important to recognise that adjustment to disability may be short and relatively uncomplicated, but commonly it can be a long and difficult process involving extensive rehabilitation and a process of grieving (see Chapter 40). While individuals respond differently, it is helpful to recognise that in the initial period after illness or accident, when individuals are first facing disability, they may be extremely stressed. This stress may result in behaviours that the person does not usually display, including:

- Hostility or anger at themselves, their families or primary carers and the professional staff who aim to support them
- Rebelliousness (e.g. refusing care, refusing to get up or shower)
- Refusal to socialise, shunning visitors, even close family and friends (this may be due to embarrassment at changed appearance or abilities, or fear of rejection)
- Depersonalisation (avoiding or disowning self or parts of self, which may be demonstrated by a refusal to acknowledge, talk about or look at an altered body part such as a stoma, a stump or a burned area)
- Refusal to participate in activities (Thomas 1999). See Table 41.4.

**CLINICAL INTEREST BOX 41.3**
**Phases in adjusting to a disability**

**Shock**
- Feeling emotionless
- Sense of unreality

**Denial**
- A coping mechanism that allows the individual time to adjust
- This is not happening

**Anger**
- Withdrawal
- Isolation
- Hostility
- Self blame
- Grieve for loss of roles or changes to self-image

**PAcceptance**
- Does not mean the individual is happy with the status quo
- Accepts the disability
- Takes back control over life
- May benefit from speaking to others in similar situations

*(Cohen & Napolitano 2007)*

### Providing care for individuals and their families

Nurses may provide care for individuals with disabilities and their carers in any setting in which care is provided. These include:

- The person's own home
- Community houses
- Day or drop-in centres
- Day clinics
- Residential care facilities
- General hospitals

**TABLE 41.4 | Factors affecting adjustment to disability**

| Factors | Example |
|---|---|
| Length of time with disability | The longer a person has a disability the more likely they are to accept the limitation and adjust to the consequences of the disability (Chao et al 2010) |
| Amount and quality of support | Good social support is associated with better functioning (Müller et al 2012) |
| Acceptance of disability | Acceptance allows individuals to move into a phase of adjustment and reintegration (Cohen & Napolitano 2007) |
| Degree of impairment | The greater the impairment the more difficult the adjustment and acceptance |
| Emotional reactivity | Personal beliefs promote adaptation (Townend et al 2010) |
| Attitudes and behaviours of others | Stigma and non-acceptance by others affects the confidence and self-esteem of the person with a disability and may prevent acceptance of the disability (McLaughlin et al 2004) |
| Finding positive meaning in disability | Looking for a positive meaning in the negative experiences enhances positive coping (Dunn 2014) |
| Access and affordability of health services | Access to affordable service provision ensures better outcomes (Andrews et al 2001) |

- Rehabilitation units
- Schools or preschools
- Obstetric units (neonates born with a disability)
- Respite care accommodation.

Nurses may encounter individuals with a disability who are hospitalised for totally unrelated reasons; for example, a person who has epilepsy but is hospitalised because they need an appendectomy. Others may be in care to provide respite for a family carer (e.g. a person with multiple sclerosis or perhaps dementia) and some may have only just acquired the disability (e.g. hemiplegia as a result of a cerebrovascular accident or a spinal cord injury due to road trauma). This means that nurses need to adapt the ways they communicate with and respond to individuals according to the type of disability and the specific circumstances. Clinical Interest Box 41.4 provides some guidelines to aid the nurse caring for individuals with disabilities. Sometimes people with disabilities demonstrate behaviour that even experienced nurses find challenging to manage. There are often complexities involved in managing challenging behaviours—now more commonly known as behaviours of concern, and it is recommended that nurses refer to texts that deal specifically with this issue to enhance their knowledge and expertise. Chapter 39 provides some information on managing challenging behaviours.

## The move to community-based service provision

Historically people with disabilities were institutionalised, segregated from society and from their local communities and denied the rights of access to services and opportunities available to the rest of the population. People who entered institutional care facilities often remained there for their entire lives.

Australia went through a process of deinstitutionalisation in the mid-1980s. Although the process of deinstitutionalisation had started in the 1970s, it was with the release of the Richmond report in 1983 (Richmond 1983; Molony & Taplin 1988) that the process began in earnest. Richmond's recommendations included a government-funded system of community support underpinned by acute hospital services (if needed) and accommodation services. The findings from this report changed the provision of both mental healthcare and disability service provision, initially in NSW

### CLINICAL INTEREST BOX 41.4 Suggestions to aid relationships between nurses and individuals with disabilities

**Keep in mind that:**

- In many cases the individual and the family carer will know more about the disability than the nurse
- The person with a disability is the same as anyone else, just with particular needs associated with that disability
- Many difficulties that the person faces are likely to be more to do with societal attitudes than the disability itself
- It is best to concentrate on what the person can do rather than on the things they are unable to do
- It is best to let the person guide how and at what pace things should be done
- Self-responsibility should be handed over to people with disabilities as soon as they are ready

*Continued*

## CLINICAL INTEREST BOX 41.4 Suggestions to aid relationships between nurses and individuals with disabilities—cont'd

**When communicating:**

- Adapt your pace of communication to suit the other person and, when communication ability is impaired, allow time for responses
- Speak directly to the person—do not use another person (e.g. family carer) as a go-between
- Monitor how much input into the conversation the person with the disability has—be careful that you don't dominate the conversation
- Take the person's lead, pick up on what the person may prefer to talk about, or finds interesting or important. Be alert to signals and act on them; for example, in a person whose speech is impaired, eye movement towards an object may indicate that the object is wanted
- Ask the person what help is required; avoid automatically doing things for the person; do not insist on helping and do not assist without asking first
- Ask if unsure of how to behave towards the person; for example, if the person has an arm missing or has uncontrolled limb movements, how do they prefer you to place meals or other objects?
- Respond with understanding and goodwill if the person knocks something over or spills something; for example, a glass of water. Humour can also be helpful and, when used effectively, can minimise embarrassment
- Do not be overly concerned if you say something that feels inappropriate; for example, saying 'Do you want to hop into the shower now?' to a person who has a right leg amputation. Having a disability does not remove a person's sense of humour, and humour can relieve discomfort for both nurse and an individual
- Whatever the disability, always use age-appropriate language; for example, speak to the adult person with intellectual or cognitive impairment in the same manner as you would any other adult (Chapter 34 provides more information on communicating with people who have hearing, visual or cognitive impairment)

**Caring for people in wheelchairs:**

- Do not assume that the person in a wheelchair needs assistance
- Do not try to move the person or wheelchair without first gaining permission
- Do not hold on to the wheelchair unnecessarily. It is part of the person's body space and the person cannot step away from you
- Ensure you are familiar with how a wheelchair is pushed and manoeuvred before taking a person in a wheelchair out and about. This includes knowing how to get it up and down steps, how to tip it backwards, how to use the brake and how the armrests are removed (never lift a wheelchair by the arm rests—most are removable) and how it folds up. It is a useful exercise to practise pushing and manoeuvring a wheelchair with a person who does not have a disability sitting in it

**Promoting confidence:**

- Reinforce that people with disabilities have the same rights as other people in their community and in society as a whole
- Reinforce that they have the right to have a say in all decision making that concerns their lives, their treatment and their general wellbeing
- Reinforce that it is appropriate to be assertive and persistent in defending their rights, and to be firm but polite when defending their rights to things such as access, independence or privacy

**Encourage people with disabilities to:**

- Feel comfortable about asking for assistance when needed and avoid apologising for what they cannot do
- Feel comfortable in communicating in whatever way is appropriate for them, and about having to repeat things that are not understood or about asking other people to repeat or re-explain things that are unclear
- Understand that many people have little knowledge of disabilities (e.g. the realities of cerebral palsy), and be tolerant of and polite to people who are unsure of how to respond to them in social situations, or who offer help that is not needed
- Be prepared for times when they may feel anxious or depressed. Reinforce that such feelings are common and that help is available should they need it
- Try to create opportunities to instigate the person's contact with positive role models or others who have a similar disability. For example, it may be encouraging to a person who has recently become visually impaired to talk with a person who has adapted successfully to vision impairment. It may be helpful for people who are hearing impaired to meet with deaf people communicating avidly with sign language.

*(Ferris-Taylor 2003; Gething 1997)*

**TABLE 41.5 | National organisations in Australia concerned with the rights of people with disabilities**

| Organisation | Role |
|---|---|
| Australian Human Rights and Equal Opportunities Commission (HREOC) | A commission established in 1986 with specific objectives: to eliminate discrimination against people with disabilities and to promote acceptance and inclusion of people with disabilities into the community |
| Disability Services Australia | Range of services, including daytime activity programs and support with accommodation to help bridge the gap between school and adult life |
| Australian Council for Rehabilitation of the Disabled (ACROD) | National industry association for disability services, influencing government legislation and funding to promote quality services for people with disabilities |
| Action for Carers and Employment (ACE) | National body representing the many state and territory organisations that provide employment assistance and support to people with disabilities in the regular workforce |
| Australian Institute of Sport (AIS) | Activities include a program to coach elite athletes with disabilities |
| Australian Sports Commission | Promotes active lifestyle for all Australians, including those with disabilities. Activities include an education program to train teachers and community leaders to run sports and other outdoor events suitable for people with disabilities |
| Australian Sport and Recreation Association for People with an Intellectual Disability (AUSRAPID) | National sporting body that promotes equal access to sport and recreational programs for people with intellectual disabilities |
| Other organisations that promote inclusion in sporting activities include Australian Blind Sports Federation, Australian Deaf Sports Federation, Australian Sport and Recreation Federation, Disabled Wintersports Australia, Riding for the Disabled Association of Australia, Wheelchair Sports Australia | |

*(Australian Government 2015)*

and then throughout Australia. Subsequently other services such as foster care for children were also influenced by the findings.

During this process the asylum network was dismantled. The goal of deinstitutionalisation was not only to assist people with disabilities move into the community but also to develop new services to meet the changed needs thus created. For example, dispersed housing in the community has been shown to be a preferable alternative to large-scale institutions for improving the quality of life for people with disabilities (Queensland Government 2013). The process of deinstitutionalisation now forms the basis of the provision of care for people with disabilities. For people with disabilities, being part of the community is essential to their wellbeing and to improving their quality of life. Unfortunately, the process was not always smooth, particularly for people with severe and profound levels of intellectual disabilities or those with severe behaviours of concern (Bigby & Fyffe 2010; Clement & Bigby 2009) and while there is some contestation over the success of deinstitutionalisation there is also a significant body of evidence supporting the positive outcomes in relation to improved quality of life and independence (Cooper & Picton 2000; Milton 2006).

In Australia, despite the development of a national strategy to achieve **equity and access** for disabled persons, the systems available today continue to be 'fragmented, inequitable and under-resourced' (Queensland Government 2013:iii). Table 41.5 lists some of the national organisations in Australia that work to address issues concerning the rights of people with disabilities.

## THE PHILOSOPHY OF INCLUSION AND NORMALISATION

The concept of **normalisation** for people with disabilities is not new and has been discussed by governments and organisations for more than 30 years. The principle of normalisation stems from the work of Bengt Nirje (1969) and was further defined by Wolf Wolfensberger (1972; 1992) and identifies a basic philosophy that socially valued roles for people with disabilities should be supported and defended because their social roles as individuals are at risk of being devalued. Intrinsic to the concept of normalisation is the belief that all people are capable of growth and development (Brown & Smith 2012). Normalisation is not concerned with making everyone normal; rather the goals are to provide equitable access and services for people with disabilities. Wolfensberger asserts that normalisation should instead be called **social role valorisation (SRV)** as this is more inclusive and values the social roles held by an individual with a disability (Wolfensberger 2004). The key principle underpinning SRV is that if a person holds valued social roles, that person is more likely to receive from society the good things in life that are available to that society: these include home and family; friendship; being accorded

## CLINICAL INTEREST BOX 41.5 Implementation of normalisation and inclusion principles

### Education

Significantly increased integration of children with disabilities into mainstream schools.

### Arts, sports and recreation

Being inclusive in arts, sports or recreation is about providing a range of options to cater for people of all ages and abilities in the most appropriate manner possible. It is more than including people with disability in regular sport activities: it includes ensuring that an individual chooses to participate in a range of opportunities that take into account:

- their functional ability
- the sport in which they are participating
- the opportunities within their local environment
- their personal preferences.

Drama groups such as RAWCUS have provided ongoing opportunities for people with disabilities to fully participate in all areas of theatre production including international arts festivals (in 2008) as well as working with organisations such as the Melbourne Symphony Orchestra (in 2007).

### Employment

Access to employment has improved as a result of stipulated requirements and government schemes

Employers are required to modify workplaces to facilitate the employment of people with disabilities (e.g. purchasing special equipment, provide for wheelchair access) unless doing so causes unjustifiable hardship to the business

Government funding is available to assist with modifications to some business workplaces

Advertisements for jobs must not discriminate against or exclude a person with a disability from applying for the position provided that they have the ability to do the work.

### Transport

The Disability Standards for Accessible Public Transport 2002 (Transport Standards) are mandatory standards in Australia and are further supported by state legislation such as the Disability Services Act 2006 (Queensland). The Transport Standards cover premises and infrastructure and apply to public transport operators including bus, coach, train, taxi and aviation companies.

### Access to buildings

The Building Code of Australia stipulates that buildings must be designed to facilitate access and meet the needs of people with a range of disabilities. Requirements include:

- Doorways wide enough for people using wheelchairs
- Appropriate toilet space and facilities
- Minimum lighting to meet needs of visually impaired people and those who communicate by sign language or lip-reading.

### Entertainment

Captioning: in 1982 the Australian Captioning Centre was established to provide captioning services for hearing impaired people. Captioning on film or television provides written on-screen messages about what is being said and what sound effects or music are happening. Australian legislation requires that captions are provided for news, current affairs and prime-time television programs. In 2001 captioning was introduced in major cinemas around the country, but at the time of writing not all films were yet captioned.

dignity, respect and acceptance; a sense of belonging; an education; the development and exercise of one's capacities; a voice in the affairs of one's community and society; opportunities to participate; a decent material standard of living; at least a normative place to live; and opportunities for work and self-support. Clinical Interest Box 41.5 provides some examples of how the philosophical principles of **inclusion** and normalisation have been, or are still to be, implemented. (See Case Study 41.1.)

## CONTINUING CHALLENGES

Despite the many changes that have occurred in the past three decades there is still stigma attached to both chronic illness and disability. The more profound and obvious the disease or disability, the more significant the social barriers are (Willett & Deegan 2001). Many such barriers may impact significantly on the way people with disabilities perceive and feel about themselves (Green et al 2005).

## CASE STUDY 41.1

Grace is 42 years old. She was born with a brain injury as a result of birth trauma. Her parents have been her primary carers since birth. Grace requires a high level of physical assistance. For example, every day of her life her father has lifted her from her bed in the morning and carried her to a recliner chair in the lounge and later returned her to bed the same way. Each day her mother has prepared the food and assisted Grace with her meals. Because of the difficulties Grace has with chewing and swallowing her food, mealtimes have always been a lengthy process. Personal care routines such as showering and dressing are provided by her parents. Sometimes Grace resists and yells out. Grace is incontinent of urine and her parents fit her with disposable pads every morning and change them frequently during the day. They take care of the pressure areas that sometimes develop.

After leaving her special developmental school at 17 years Grace began attending a day centre 3 days each week. She was taken there in a community bus specially designed to accommodate her wheelchair. Activity at the centre revolved mostly around the staff meeting the hygiene, toileting, medication, mobility and nutritional needs of the two dozen or more people with severe or profound disabilities who also attended. The staff reported that Grace spent a lot of her time there simply dozing.

On the days she is at home Grace has many things surrounding her that give her pleasure. She has a box containing many different pieces of material. She enjoys the feel of the different textures, especially the velvet and silk. Other times she holds on to colourful toys and, although she has a profoundly limited vocabulary, she is able to express her pleasure in her favourite television programs and music. Grace also enjoys being with her mother in the kitchen and sitting on the outside veranda watching people walk past the house. Many of the neighbours greet her cheerfully.

Grace's parents have been anxious for some time about their future ability to care for her, but now Grace's mother has fallen and fractured her hip. Her father is exhausted and cannot manage to care for Grace alone. Grace has been admitted to a residential care unit, where most of the residents are elderly and have dementia. There is nowhere else available at the moment.

1. What might Grace's mother and father be feeling about this situation? What could be done to help them?
2. What might be the impact of this move on Grace? How might she be feeling? How can staff help ease the transition to her new accommodation and situation?
3. What other supports could you refer both Grace and her parents to?
4. What are Grace's rights? What are the risks of those rights being infringed?
5. What can staff do to ensure that her rights are not infringed?
6. How can staff create a stimulating and pleasurable environment for Grace?
7. What does social role valorisation or normalisation mean to Grace?

It is essential if these challenges are to be overcome that the first step is in educating healthcare professionals so that they can:

- Influence the physical and social environments in which people with disabilities live and work
- Educate the public so that people with disabilities are included
- Advocate to governments, service providers or councils for changes in the way current services are provided and suggest affordable improvements that provide easy access.

# APPROACHES TO MANAGEMENT OF INDIVIDUALS WITH CHRONIC CONDITIONS OR DISABILITIES

## Assessment

Assessment of the individual is integral to the development of effective nursing care plans. People with chronic conditions and/or disabilities should always be assessed holistically placing the person at the centre of the assessment. An example of a nursing care plan for an individual with chronic obstructive pulmonary disease has been provided as well as an example of an entry into progress notes (see Nursing Care Plan 41.1 and Progress Note Example 41.1).

A multidisciplinary approach to assessment is generally required. Depending on the age and type of disability the person is experiencing, assessment may involve a range of professionals including but not limited to teacher, doctors, occupational therapists, speech pathologists, social workers, psychologists and nurses.

The purpose of assessment is to identify the abilities, strengths and specific needs of an individual so that appropriate care may be planned. The overarching goal is to ensure support that allows the person to live life as near as possible to the way they desire. The assessment process should consider all aspects of the person's life including:

- Physical needs
- Health and medical needs
- Financial support
- Spiritual and emotional support needs
- Cultural needs
- Learning needs
- Behavioural support needs
- Need for meaningful work
- Recreation and leisure needs
- Transport issues

## NURSING CARE PLAN 41.1

Mr Smith is a 75-year-old man with chronic obstructive pulmonary disease. He lives at home with his wife but his breathlessness prevents him from exercising or actively participating in social activities. He has been showering and dressing himself and he has a motorised mobility aid for mobility. Due to an exacerbation of his condition and a chest infection he has been admitted to hospital. The Registered Nurse asks you, the Enrolled Nurse, to assist Mr Smith with showering and dressing and to evaluate his ability to perform this activity. Mr Smith tells you that he has been washing with a bowl for the past few weeks as his breathlessness has made it too difficult to shower.
**Assessment:** Impaired home maintenance related to intolerance to activity, decreased strength/endurance
**Issue/s to be addressed:** Able to perform activities of daily living—showering and dressing at home with assistance
**Goal/s:** Home evaluation by occupational therapist for home modifications such as rails; purchase of suitable chair for the shower; contact home nursing service and organise nursing assistance with showering and dressing.

| Care/Actions | Rationale |
|---|---|
| Educate Mr Smith on how to pace activities | Increased knowledge will lead to a change in behaviour |
| Assess the ability to perform the ADL | Mr Smith may only need assistance with some aspects of the ADL |
| Slow the speed that tasks are performed | Decreases activity intolerance |
| Stop and rest when tired or breathless | Decreases activity intolerance and allows for tasks to be performed using less energy |
| Pace your activities | Prevents fatigue |
| Sit on a chair or stool in the shower and when performing grooming activities such as shaving. Assess whether other assistive devices are needed | Use of assistive devices and chairs increases independence |
| Limit the use of products that may affect your lungs such as spray deodorants—use non-spray products instead | Some products may cause exacerbations of breathlessness |
| Assess the need for home care on discharge | Home care may maintain independence and help Mr Smith stay in his own environment for longer periods |

**Evaluation**

Mr Smith will be able to verbalise the understanding of appropriate measures to decrease breathlessness and fatigue when performing activities of daily living.

## PROGRESS NOTE EXAMPLE 41.1

| | |
|---|---|
| 21/10/2015<br>1500 hrs | Nursing: Mr Smith has had a comfortable day and was able to carry out all ADLs independently. He required one PRN dose of Ventolin this shift prior to lunch. His IV remains patent and the insertion site is free from signs of infection or extravasation. Mrs Smith came to visit and has asked to meet with the team prior to his planned discharged home in a few days. Mr Smith's treating team and medical officer have been informed of this request.<br>***K. Marter*** **(Marter) EN** |

- Accommodation needs
- Support networks (family and community)
- Impact of the person's environment.

The team may assess the individual using a variety of methods, such as observation, interviewing and testing. A checklist may be used to help identify activities that can be performed independently by the individual, and those for which assistance is required. When assessment is complete the team, collaboratively with the individual or family carer, can plan the care to be implemented following the principles of person-centred planning.

The extensive types of disability, and the fact that many individuals will have multiple disabilities, means that after the assessment process nurses may determine a broad range of nursing diagnoses for each person. Clinical Interest Box 41.6 identifies some common issues that need to be considered for a nursing assessment of individuals with disabilities. The list is by no means exhaustive and not in any particular sequence. The degree of relevance and nursing response will vary with each person and each situation.

## Planning and implementing care

Using the information obtained from the assessment process, a care plan or treatment plan is developed to meet the individual's needs. Central to development of a program is the concept of helping the individual to achieve as much independence as possible (Table 41.6). The aim of professional support is to facilitate the person living as independently as possible and assisting them to engage in activities that enhance their quality of life while encouraging them to develop effective interpersonal relationships and make informed choices.

## CLINICAL INTEREST BOX 41.6 Nursing considerations related to the needs of individuals with chronic disease or disabilities

**Psychological needs**

- Impaired adjustment
- Ineffective individual coping
- Self-concept disturbance (incorporating body image/self-esteem/role performance/personal identity)
- Hopelessness
- Powerlessness
- Altered sexuality pattern
- Impaired social interaction

**Physical needs**

- Impaired physical mobility
- Impaired verbal communication
- Self-care deficit (incorporating hygiene/dressing and grooming/toileting)
- Sleep pattern disturbance
- Altered patterns of elimination (incorporating urinary/bowel)
- Potential for impaired tissue integrity
- Potential for falls/injury

*(Lubkin & Larsen 2006)*

## Evaluation

Evaluation must be performed continuously to assess progress in achieving the goals of care. Continuous evaluation is also needed to identify whether there are potential risks that have not been considered previously and to confirm that safe, holistic care is maintained.

## Person-centred care

Person-centred care views individuals and their significant others as equal partners in the planning and provision of services. Unlike other models of care, this model places the person at the centre of their own care and also considers the needs of the caregiver (Cambridge & Carnaby 2005). The concept of person-centred care originates from the counselling approach developed by Rogers in the late 1940s. Rogers (1951) believed that all people have a personal responsibility and choice in decisions and that no one should make decisions for another person. Rather than give advice, the role of the clinician is to maintain an 'attitude of positive regard'; that is, be non-judgmental and supportive. More recently the inclusion of other strategies such as motivational interviewing have strengthened this model. Clinical Interest Box 41.7 outlines the principles of person-centred care and Table 41.7 provides a list of some of the core skills and knowledge required by nurses to support individuals to self-manage.

## TABLE 41.6 | Stages in the development of a care plan for a person with a disability or chronic disease

| Stage | Action |
|---|---|
| Identify a person's capabilities | What are the person's strengths and weaknesses?<br>What do they need assistance with?<br>Focus on what the person can do rather than what they cannot do |
| Establish common goals | Assist the person to set SMART goals:<br>• Specific<br>• Measureable<br>• Achievable<br>• Realistic<br>• Timely<br>Set small goals to develop a sense of achievement<br>Ensure family and significant others are aware of the goals |
| Identify and prioritise skills that need to be developed | What skills does the person need?<br>What resources are needed?<br>How can the family/significant others assist? |
| Determine the most effective teaching strategies | How will the person learn the new skills?<br>Experientially?<br>Practically?<br>Vicariously? |
| Determine the most effective interventions to meet social, educational and other needs | What does the person want to achieve?<br>How can this be achieved? |

## CLINICAL INTEREST BOX 41.7 Principles of person-centred care

- Develop a rapport and get to know the person and caregiver
- Responsibility and decision making is shared
- Individual's preferences are respected
- Provision of accurate and easy-to-understand information so that individuals can make informed choices
- Care is co-ordinated and integrated, working seamlessly to improve a person's outcomes
- The environment supports staff in the provision of person-centred care

*(Victorian Department of Human Services 2006)*

**TABLE 41.7 | Core knowledge and skills essential for healthcare professionals to provide self-management support**

| Skill | Ability |
|---|---|
| Assessment skills | Able to assess:<br>• Readiness for change<br>• Risk factors<br>• Support systems<br>• Self-management ability<br>• Strengths and weaknesses |
| Behaviour change skills | • Motivational interviewing techniques<br>• Understanding models of behaviour change<br>• Able to assist the individual with goal setting, problem solving and developing action plans |
| Organisational skills | • Able to work in multidisciplinary teams<br>• Applies evidence to practice<br>• Sound knowledge of community resources |

**TABLE 41.8 | Phases in the stages of change model**

| Phase | Description |
|---|---|
| Pre-contemplation | The individual does not intend to change behaviour within the next 6 months. In this phase the individual lacks motivation but also may lack the knowledge and skills to make any changes |
| Contemplation | During this phase the individual is considering making changes within the next 6 months; however, they are hampered by ambivalence and tend to focus on the barriers and challenges that will be encountered rather than the positive effects |
| Preparation | The individual is preparing to take action within the next month and has usually developed a plan and may already have initiated some actions |
| Action | The individual is actively taking action to modify and change behaviour. Relapse is a real concern at this stage and ongoing support is essential |
| Maintenance | The individual has made the changes and the risk of relapse is decreasing as time goes on. At this point the individual will usually state they are confident they can continue the new behaviour |

## Motivational interviewing and assessing readiness to change behaviour

In a model of care where the person is regarded as being an equal it is essential that the clinician does not 'tell a person what to do'. As previously mentioned, the role of the clinician is to support the person while encouraging the person to explore issues preventing behaviour change. Prochaska and DiClemente's model of behaviour change describes a process of behaviour change which occurs over time with individuals moving through five stages, from pre-contemplation to maintenance (Table 41.8) (Prochaska & DiClemente 1986). This model is a useful way of identifying whether a person is ready and motivated to modify or change behaviours (Norcross et al 2011).

Prior to moving to discuss a plan of action planning and interventions, the clinician should ascertain the individual's readiness to change. If the individual is not in the preparation or action phase then motivational interviewing strategies may be used to explore reasons preventing change.

### Motivational interviewing

Motivational interviewing (MI) strategies have become the 'gold standard' communication methods of working with individuals who are reticent to make changes considered necessary for optimal health (Britt et al 2004). Based on the principle that most people do not enter into relationships with clinicians motivated to make changes or modify their behaviour, the role of the clinician therefore is to assist the individual to explore their ambivalence about making the behaviour change (Drury & Aoun 2014). There are four phases in MI:

1. Engaging
2. Guiding
3. Evoking
4. Planning (Drury & Aoun 2014; Miller & Rollnick 2012; Rubak et al 2005).

See Table 41.9 for more detail.

Motivational interviewing may take a number of sessions and a considerable amount of time. Unfortunately in the real world clinicians do not always have unlimited time nor do individuals always return for appointments. Therefore it may be more useful to use brief motivational interviewing strategies as these are designed to be used in a single session of approximately 45 minutes. Using the same communication strategy as that used in MI the clinician works through seven stages to encourage the individual to explore ambivalence (Rollnick et al 1992):

1. Build rapport—establish a therapeutic relationship and encourage the individual to openly share. Be non-judgmental and empathetic. This may help you to understand whether the person plans to make any

**TABLE 41.9 | Phases in motivational interviewing**

| Phase | Clinician's role |
|---|---|
| Engaging | Assess the individual's stage of change using OARS:<br>• Open-ended questions<br>• Affirmations<br>• Reflective listening<br>• Summarise the discussion |
| Guiding | Explore the attitudes and values held by the individual<br>Encourage the individual to identify costs and benefits of changing or not changing behaviour<br>Assist with goal planning and set goals that are measurable and achievable in a short space of time |
| Evoking | At this stage the individual is motivated to change behaviour<br>Ask the individual to identify reasons for making the change and then reinforce the change with these statements<br>Affirm all positive action<br>Encourage the individual to reflect on the change |
| Planning | Identify and set measurable and achievable goals |

changes and where they are in the stages of change model
2. Open the discussion—allow the person to discuss their concerns by inviting them to tell their story. Use open-ended questions and probing to elicit further information
3. A typical day—ask the person to describe a typical day to you from the time they get up in the morning. This often helps the individual identify and explore issues that are a problem or triggers for behaviours that need changing
4. The good things and the less good things—encourage the person to talk about the good things and the less good things. The terminology here is important as speaking of the less good things rather than concerns allows the person to identify problem areas without feeling that these behaviours are being labelled as problematic. Use open-ended questions to probe further and affirmation when the person identifies good coping skills.
5. Provide information—avoid giving advice. Ask if the person would like information about specific issues and provide it if wanted. Use reflective listening and paraphrase to ensure you heard the correct message
6. The future and the present—this strategy can be used if the person is concerned about a particular behaviour. Ask the person how they would like things to be different in the future
7. Explore concerns—this essential step is where you listen to the person and facilitate them thinking about changing behaviour.

A goal-directed and focused type of counselling approach, both MI and brief MI require training and practice. It is essential that any clinicians using this approach have received appropriate training from a qualified person and receive adequate supervision while they become proficient in its use (Madson et al 2009). Referral to clinicians trained in MI should be organised if ability to provide competent MI counselling is outside the clinician's scope of practice.

## Self-management for individuals with chronic diseases and/or disability

The origins of self-management of chronic disease are in Lorig's seminal work with arthritis sufferers in the USA in the 1970s. **Self-management** is a theory-based approach to healthcare that recognises the central role played by the individual in health promotion, disease prevention and successful management of illness. It is the ability to manage the disease process, the emotional consequences of living with the disease and the changes that occur to daily living as a consequence of the disease. Evidence in the literature shows that education programs incorporating self-management skills can enhance health outcomes (Bodenheimer et al 2002). Self-management is both a process whereby training is provided to people with chronic illness and an outcome which indicates when people with chronic health problems achieve the skills and knowledge to manage the medical, emotional and role aspects of their illness (McGowan 2005).

Previous development of many self-management programs has focused on the major chronic illnesses existing in industrialised societies; for example, arthritis, diabetes, chronic obstructive pulmonary disease and heart disease. In more recent times, however, there has been a move to facilitate self-management principles into programs for people with disabilities with evidence suggesting statistically significant positive outcomes (Drury et al 2012; Girdler 2006). Disease self-management programs can be delivered to groups or individuals by health professionals or lay people, via face-to-face format or interactive technology such as the internet or telephone. Each of these methods of delivery requires healthcare professionals to learn new skills and refine existing skills (Mensing & Norris 2003).

Integral to self-management is the support and advocacy provided by healthcare professionals that empower the individuals to make informed choices and actively participate in the management of their disease or disability. This involves a partnership between the person and the healthcare provider where the person is the manager of the daily consequences of the disease and the healthcare professional is the coach (Drury & Aoun 2014). This model is similar in principle to person-centred care whereby the healthcare professionals share information with the person and caregivers, understand the

person's values and goals and help them to create a care plan that meets their goals. Holland et al (2010) suggests that self-management support involves three steps:

1. Defining the issues or problems
2. Setting goals and developing problem-solving strategies
3. Active sustained follow-up.

The main difference in this model is that the person is acknowledged as being the expert in managing their disease and the healthcare professional is the expert in the disease and disease process. Thus the person takes an active role in determining care and setting goals. Bodenheimer et al (2002) described the role of the healthcare professional as providing support to the person by assisting them to make informed choices, set their own goals and develop problem-solving skills.

Experts in self-management programs suggest that core knowledge and skills essential for healthcare professionals to provide self-management support can be centred on assessment and behaviour change skills and organisational strategies (see Table 41.7) (Australian Government Department of Health and Ageing & Flinders University 2009).

Establishing a rapport with the person and eliciting information about their challenges and successes are components of effective self-management support (Battersby et al 2008; Harvey et al 2008; Lorig 2000; Packer et al 2008; Vancouver Coastal Health 2008). Assessing the individual for readiness to change and exploring the consequences of current behaviour and any ambivalence towards change are the first steps in self-management support (Drury & Aoun 2014).

Ambivalence is at the core of change and it is essential to acknowledge that not all people are ready or willing to change. The role of the healthcare professional is not to tell the individual they must change but rather help them explore their ambivalence and behaviours, provide information and help them understand their lifestyle and concerns in the hope that they will become intrinsically motivated to make changes. The interpersonal relationship that develops must provide the individual with a safe and supportive place to do this.

### CRITICAL THINKING EXERCISE 41.1

Maria is a 45-year-old overweight woman diagnosed 5 years ago with non-insulin-dependent diabetes. She is a stay-at-home mother with three teenage children and a husband who works shift work. Initially treatment was with an oral hypoglycaemic agent and diet; however, this was poorly adhered to and her blood glucose levels escalated. On examination she has a small ulcerated area on the side of her foot. She appears anxious but in a hurry and tells you she has to get home as the children are due home from school. She tells you she feels like a failure and is ashamed of having diabetes. As the nurse in the clinic you realise you have limited time to effectively explore her issues with her.

What brief motivational interviewing strategies might you use that could get Maria to consider the consequences of her behaviour?

## Provision of services

The federal, state and territory governments in Australia fund a range of services for people with disabilities and their family carers, including:

- Family support services such as respite care and community-based respite care
- Domiciliary support, such as help with cleaning, house and garden maintenance and Meals on Wheels
- Personal care support
- Home modification and provision of equipment
- Independent-living skills programs
- Pre-vocational training, vocational placement and employment support
- Social support, including recreational and culturally specific activities
- Community-based accommodation and support; for example, support available to people with a disability living at home or in other accommodation in the community
- Counselling in the areas of sexuality
- Education and training for carers, individuals and their families
- Behaviour management programs and specialised training in this area
- Specialist assistance from professionals such as psychiatrists, psychologists, speech therapists and occupational therapists
- Case management (both short and long term), providing individual support, advocacy and monitoring
- A person's disability allowance
- Carer's allowance (small regular financial payment to assist with additional expenses).

These services aim to assist people with disabilities to achieve as much independence as possible by promoting and supporting family and community acceptance and involvement, by providing sufficient support services and by offering a range of accommodation options.

As highlighted earlier, there is now much greater acceptance of the importance of family living and of participation in community life than previously. The wellbeing and the quality of life of people with disabilities depends on recognition and acknowledgement of their rights, promotion of community acceptance and the implementation of programs that appropriately promote education, provide training for employment, develop independent skills in activities of daily living and promote enjoyment of life. Professional support is primarily directed towards enabling a person with a disability to achieve as much independence as possible, through interventions and by providing support that promotes independent living and vocational capacities. Planning and implementation of appropriate educational and vocational programs is performed on an individual basis and takes into account any associated physical, sensory or emotional effects of the disabilities.

Basic principles that should guide the provision of services include:

- A collaborative approach between health professionals: the individual and the family should be consulted to decide what is needed, what will be of most help and how that help should be implemented for maximum benefit
- Identification of the individual's and family's strengths and capabilities
- Recognition and validation of emotions, needs and concerns.

These principles should be kept in mind when assessing, planning, implementing and evaluating care.

## CAREGIVERS OF PEOPLE WITH CHRONIC DISEASE OR DISABILITY

Family and carers of people with chronic disease and/or disabilities are often expected to provide care and support 24 hours a day. Unlike nurses, family carers do not get breaks between shifts or get to go home after finishing their work. Even when respite is available, the responsibility is permanent, 7 days a week, often lifelong and often falling primarily on one family member (Starke 2011).

For many the responsibility begins with the birth of a child with a chronic disease such as cystic fibrosis or a disability such as a hearing impairment. Parents in this situation are faced with an unplanned lifetime of giving full-time care that interferes with their ability to give as much time as they would like to their other children or to conduct their lives as previously planned. They are faced with coping with the situation as they deal with the grief associated with lost expectations about their baby and the future. For others it begins at the stage of life when caring responsibilities are expected to reduce; for example, the parent caring for an adolescent offspring who has an acquired brain injury or has developed serious mental illness. Caregiving responsibilities may also begin in older age when a spouse develops a chronic disease such as chronic obstructive pulmonary disease or dementia.

Families caring for adolescents face particular challenges impacting on daily life: internal factors such as changing family roles and relationships and external factors such as service discontinuity, where forfeiting of a desired option may be necessary. Also, teenagers with intellectual disabilities (ID) have significantly more health problems than the rest of the population and many encounter difficulties accessing the services they need (Bhaumik et al 2011). Challenges such as these mean that family routine in the adolescent years is dynamic rather than static. Families use multiple strategies to accommodate these challenges, which are underpinned by their beliefs, values and resources. Professionals working with families caring for an adolescent with disability need to be aware of these in order to support families effectively to sustain a meaningful family routine during the adolescent years (Schneider et al 2006). Some professionals find the families they support considering or actually relinquishing the care of the person to the state (Nankervis et al 2011). The professional must ensure the family has an understanding of the ramifications of this decision.

### The impact of caring: lifestyle changes and loss

Whenever the carer role begins, it is often associated with great lifestyle changes and many losses, including:

- Loss of the ability to continue with a career or paid employment
- Loss of income and financial security
- Loss of status and socialisation that often accompanies a paid work position
- Lost hopes and dreams of what the future will bring
- Loss of freedom and socialisation
- Loss of a normal or expected relationship (e.g. loss of companionship or a sexual partner when physical and cognitive functioning are profoundly affected) (Funnell 1998).

Despite the seriousness of their situation, many people caring for family members with disabilities gain pleasure, a sense of satisfaction and feelings of personal fulfilment from the role they have undertaken.

The grief associated with loss cannot be ignored and one of the greatest and most difficult challenges confronting people with long-term conditions or disabilities is coming to terms with the loss. Often, despite the losses being significant, the grief surrounding them will largely go unnoticed. The person themselves may not be aware that they are grieving as they struggle to manage the complexities of their new life. Although it is acknowledged that people experience loss in unique and individual ways, the common responses to loss identified by Kübler-Ross in her seminal work are applicable to the loss and grief experienced in chronic illness and disability (Kübler-Ross 1969). These stages are denial, anger, bargaining, depression and acceptance. These stages help us understand where a person may be in relation to accepting and living with their chronic illness or disability but they are not prescriptive; that is, not everyone experiences all stages and the stages are not always linear. Grief and loss is a unique experience. Individuals experiencing these emotions need support from a range of health professionals. To help the person move forward and develop positive coping strategies professional counselling may be critical at this time. Referral to a general practitioner, a psychologist or a counsellor should all be considered at this stage.

### Support for primary (family) carers

It is essential that nurses and other professionals acknowledge and credit family carers as having the primary caregiving role, and carefully assess how to best enable and facilitate their ongoing coping abilities. Some family carers prefer to cope independently; some prefer a regular visit from a nurse or other team member; others may view such visits or other interventions as an invasion of privacy (Starke 2011). Some simply need the reassurance of having a contact to call when information or assistance is needed. Others need a significant amount of support when supporting people with complex health needs or in managing challenging behaviours (Thompson et al 2007). The amount and type of support may vary

in terms of its frequency or intensity but whenever and whatever services are implemented they should be determined in collaboration with the primary carer. There are key times when additional services or support may be needed. These include:

- At the time of diagnosis or identification of a disability
- During the care of a preschool child with a disability
- When educational needs and the person's potential need to be determined or reviewed
- Before transition from child to adult services or from adult to aged care services
- When the person is unwell
- When the primary carer is unwell
- When the person's general functioning declines and care needs increase (Wake 2003).

The opportunity for primary carers to take short-term breaks through the use of respite services should be integrated into care planning. Even though such breaks do not resolve the stresses and strains of full-time caring, they may have a positive influence on the ability of the primary carer to continue the carer role in the long term. However, some family carers feel guilty about putting a dependent loved one into respite care, and choose not to take much-needed breaks. Even so, demand for respite services sometimes exceeds supply (Nankervis et al 2011).

One of the significant issues facing primary carers is what will happen to the dependent loved one if they should get sick or die. This is particularly worrying for parents who have spent a lifetime caring for dependent children with limited service support. As resources and services experience higher demand with shrinking budgets, families often carry the added burden of planning for ongoing care, in particular in the area of accommodation, because of the ongoing shortage of appropriate accommodation for people with disabilities.

Whenever possible, individuals, families and carers need to develop a plan in advance to ease this worry, but this can be a complicated matter. The current shortage of suitable accommodation options for young people already results in young people with disabilities living in aged care facilities. This situation is not likely to improve in the near future. In future years the current older generation of family carers will need to relinquish care of adult children with disabilities and thus demand for appropriate accommodation and care will increase significantly. There is a very real possibility that, unless action is taken now, many people with disabilities will be left without a suitable home and without appropriate care and support. It is essential that professionals such as nurses continue to advocate for appropriate resources for people with disabilities. In addition, based on the assessment of the family needs made by the nurse, grief counselling for the family and caregivers may help relieve caregiver burden and compassion fatigue.

Caring for people with profound or multiple disabilities is challenging. The nurse needs to make an informed assessment of needs, plan sensitive and timely interventions and demonstrate respect for the individual. It is also of vital importance the nurse acknowledges and shows empathy for the role of the primary carer. These attributes are at the heart of excellent nursing care for people with disabilities.

## HEALTH PROMOTION: DISABILITY PREVENTION

While much can be done to improve the lives of people with disabilities, it is equally as important to minimise disability in the community as much as possible. Several **health promotion** strategies have been implemented with the aim of reducing the number of people who are born with or acquire a disability (see Clinical Interest Box 41.8).

Prevention of disability needs to be a priority. Currently there are an estimated 4.2 million people in Australia (18.5% of the population) who live with one or more limitations to functioning (Australian Institute of Health and Welfare 2012a). It is difficult to determine exactly how many of these disabilities were preventable; however, it is known that many of these injuries occur in preventable situations such as traffic accidents, or are sporting injuries, or are due to the misuse of illicit substances.

Many of these causes of acquired brain damage, and some other congenital or acquired disabilities, could be minimised by health and safety education programs and/or programs

### CLINICAL INTEREST BOX 41.8 Strategies for health promotion/ disability prevention

- Vaccinations: promoted to prevent serious illness that can lead to a range of impairments; for example, vaccination against the rubella virus is important because maternal rubella in the early stages of pregnancy can cause congenital abnormalities
- Road safety campaigns and 'Swim Safe Stay Safe' campaigns: aimed to reduce the number of disabilities caused by road, diving and near-drowning accidents
- Safe sex campaigns: aimed to reduce the incidence of AIDS and other disabling disorders
- Safety in the workplace and safety in the home programs: aimed to reduce avoidable injuries to employees, children and adults
- Anti-smoking campaigns: aimed to reduce the physical impairment caused by damage to the lungs and other organs by smoking
- Education of pregnant mothers about the dangers of smoking to the unborn infant: aimed to reduce the risk of brain damage and intellectual disabilities in children. Education programs for pregnant mothers have also focused on the importance of healthy nutrition and the elimination of alcohol and other drugs
- 'SunSmart' campaigns: aimed to reduce disability caused by skin cancer

that promote and support a healthy lifestyle. An important role for nurses, particularly those working in community settings, is the prevention of additional illness in people with disabilities by ensuring their ongoing access to routine health screens. This is sometimes difficult, perhaps due to a physical disability preventing a person achieving the correct position for a particular health screen, such as a mammogram or a Papanicolaou test (Pap smear), or a person with an intellectual disability giving consent for these procedures. This does not mean that health screening should be put in the 'too hard basket'. Consultation between medical officers, radiographers, physiotherapists, nurses and especially the person with the disability is needed to establish a way in which tests can be successfully managed.

## ABUSE AND ADVOCACY

Unfortunately despite all the information and support available for caregivers, people with disabilities and chronic diseases are still subject to abuse, neglect, exploitation and risk. There are legislative frameworks such as the International Convention on the Rights of Persons with a Disability and the Disability Discrimination Act that exist to protect these people against abuse. As healthcare professionals it is our responsibility to know and understand the legislation we work under. It is also essential that people with disabilities understand their own rights. If you have concerns regarding a person in your care you should refer the issue to a more experienced staff member.

## Summary

Chronic disease and disabilities are becoming more common as societies globally confront the challenges of ageing populations. The impact of a chronic disease and/or disability on an individual's life may vary from mild to profound. Experiences are subjective and the meaning of impairment is unique to each person.

Although the focus of service provision for people with chronic diseases and/or disabilities has shifted from institutionalised and acute care to community-based primary care, allowing many to live independently or semi-independently in their own environments, there is still a long way to go before service provision meets need.

The philosophy of person-centred care where the person is supported to self-manage and provided with the resources and support to make informed choices means that nurses and other healthcare professionals must take on the role of support and advocate. This support role provides advice, assessment and access, empowering people to take control.

In this chapter we have provided a brief overview of chronic disease and disability focusing on normalisation and individual empowerment.

### DECISION-MAKING FRAMEWORK EXERCISE 41.1

You are the EN allocated to care for Mr Smith. During a conversation he voices his concerns regarding the future for himself and his wife due to his illness. He is worried his condition is getting worse and he doesn't know how his wife would cope if he was to die. He asks you for advice and wants to know if you can talk to his wife too.

1. How would you approach this scenario?
2. What suggestions could you make to allay Mr Smith's fears and support him?

## Review Questions

1. Identify the ways in which disabilities may be classified.
2. Define the terms medical model, social model and biopsychosocial model of disability.
3. Define the levels of restrictions that are used to categorise the assistance needs of people with disabilities.
4. Explain what is meant by the terms 'social role valorisation' and normalisation.
5. Identify the nursing considerations related to caring for a person with chronic condition.
6. Identify actions that can help prevent chronic conditions.
7. List the principles of person-centred care.

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing in the acute care environment

*Michelle Hall*

CHAPTER 42

## LEARNING OUTCOMES

After the completion of this chapter, and with further reading, students should be able to:

- Define the key terms
- Discuss the increased scope of practice for Enrolled Nurses and the impact this has on clinical practice
- Identify the impact of acute health problems on the individual and family
- Describe nursing interventions to support healthcare of individuals with acute health problems
- Demonstrate critical thinking and problem-solving approaches in undertaking individual care
- Develop nursing care plans for the individual with acute health problems
- Understand the use of clinical pathways

## KEY TERMS

acute renal failure
cellulitis
clinical pathway
deep vein thrombosis (DVT)
diverticulitis
Guillain–Barré syndrome
pulmonary embolism (PE)
scope of practice
sepsis

## CHAPTER FOCUS

Traditionally, Enrolled Nurses (ENs) worked in the aged care setting. With increasing scope of practice, ENs are now moving into new clinical areas. Enrolled Nurses now work in nearly all nursing disciplines and have become valued, skilled members of the team. However, increasing the scope of practice of ENs has not been without problems. Working in the acute care environment brings new challenges for the Enrolled Nurse; these are explored in this chapter.

Also explored in this chapter are clinical pathways. An understanding of clinical pathways is critical for all nurses and as the scope of practice expands for ENs it is of utmost importance that the EN develops an understanding of these crucial tools for practice.

## LIVED EXPERIENCE

I work in a busy diagnostic imaging department. One day an individual was brought down to the nuclear medicine department for a VQ with a suspected PE; she had had an emergency caesarean the day before and was clinically obese. We placed her on the table and put an oxygen saturation monitor on her, which was protocol. She was already on 2 L of oxygen via nasal prongs as she was having dyspnoea and desaturation. As we commenced the scan her oxygen saturation started to decrease; she was experiencing more dyspnoea but the doctors present did not want to stop the scan. The Registered Nurse (RN) asked me to increase her oxygen to 4 L and I tried to comfort her, while asking the nuclear medicine technologist to call another nurse from my department for assistance. She arrived and went to get the crash cart. All the while the individual's oxygen saturations were decreasing: she was becoming tachycardic and tachypnoeic. The doctors present, who were radiologists, not the woman's treating unit, refused to allow us to make a medical emergency team (MET) call. As the individual's condition continued to decline in front of us, the RN and I decided to override the doctors and make a MET call. As soon as she left the room to make the call, the individual went into cardiac arrest. We commenced CPR immediately and called a code blue. The team arrived and took over. The individual was transferred to the ICU but passed away 2 days later. What I learnt from that experience is to trust your instincts: make the MET call early—better to call it and not need it. If the MET call had been made earlier the individual might have survived.

**Laura Spence, EN**

# SCOPE OF PRACTICE

The healthcare system is under increasing pressure due to an ageing population, an increase in chronic diseases and advancing medical technologies (Parkinson & Parker 2013). In every health setting there is a shortage of nurses, which is due in part to an ageing workforce and an increased demand by nurses and other health professionals to work part time (Graham & Duffield 2010). In order to overcome this shortage, the traditional roles of both Registered Nurses (RN) and ENs are developing rapidly. The RN role has traditionally been viewed as that of the assessor, planner and evaluator of care, while the EN worked under the direct supervision of the RN (Eagar et al 2010). But in recent years both the RN and the EN **scope of practice** have been expanded. This includes the creation of the nurse practitioner role for RNs and the ability for ENs to now administer medications, including via the intravenous route (be aware that this is different in each state and territory). This increase in scope of practice has been met with resistance from both inside and outside the nursing profession. ENs report feeling undervalued and that the expanded scope of practice is not supported within the profession itself (Jacob et al 2014). Both RNs and ENs agree that there is a lack of role definition, leading to confusion and uncertainty regarding roles (Change & Handcock 2003 cited in Phillips et al 2014). The National Safety and Quality Health Service (NSQHS) Standards have attempted to address this issue, stating that 'individuals with delegated responsibilities are supported to understand and perform their roles and responsibilities' (Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012:16). The aim of the Standards is to improve individual safety and quality of care provided. Hospitals, in accordance with the NSQHS Standards, should provide staff with professional development that supports improvements within scope of practice (ACSQHC 2012).

All nurses must work within their scope of practice and as an active member of the interdisciplinary healthcare team. In recent years the importance of team work in the acute care setting has been emphasised. Effective teams can lead to better outcomes for individuals receiving care in health organisations and fewer medical errors. Communication is the key for effective team work (Bajnok et al 2012; McKinlay & Pullon 2014). Refer to Chapter 8 for more information regarding communication in the healthcare setting.

# WHERE IS ACUTE CARE DELIVERED?

## Hospital care

Acute care is defined as any care that is provided in 'a hospital or other healthcare facility providing healthcare services to individuals for short periods of acute illness, injury or recovery' (ACSQHC 2012:7). When discussing acute care most people will automatically assume care takes place in a hospital and in many cases this is where care commences. For many individuals suffering an acute illness their first encounter with healthcare will be in the emergency room. In 2013–14, 7.2 million people presented to public hospital emergency departments. From these, 2 million people were admitted to hospital (Australian Institute of Health and Welfare (AIHW) 2014). Once admitted to a hospital varied outcomes can result. For some individuals their condition will be treated and they will be discharged home, with or without outpatient follow-up. Others will require admission to hospital and may require surgery, admission to an intensive care unit (ICU) or high-dependency unit (HDU) before reaching a ward. (For more information regarding care of the individual requiring surgery see Chapter 43.)

To improve quality of care, improve health and lower financial cost it is essential the individual transitions effectively through the healthcare system (Vecchio 2013). This is regardless of where primary care occurs.

ICUs care for critically ill or injured individuals who have various illnesses (O'Connor 2010). The care is usually one nurse to every individual and involves invasive monitoring and care and treatments not available on general wards (Martin et al 2010). In 2006, there were 181 intensive care units in private and public hospitals in Australia and New Zealand (Martin et al 2010). In Australia the majority of ICUs are classified as general; however, as outlined in Table 42.1, ICUs can be classified by type.

**TABLE 42.1 | Classifications of ICUs**

| Type | Description |
|---|---|
| General ICU | Those that care for both medical and surgical individuals |
| Combined ICU | Combined ICUs where an ICU is combined with an HDU and/or coronary care unit |
| Paediatric ICU | Specialises in care of paediatrics |
| Neonatal ICU | Specialises in care of neonates |
| Speciality ICU | Examples are cardiothoracic, neurological or oncology |

*(Martin et al 2010)*

HDUs provide a level of care between ICU and the general wards (Gould et al 2010). Most hospitals will also have high-dependency units, either as stand-alone wards or, more commonly, dedicated rooms on each ward. HDUs work as a step down from ICU for those individuals who no longer require the invasive monitoring of an ICU but are not yet ready for a general medical or surgical ward. The aim of HDUs is to reduce the workload of ICUs by reducing the incidence of ICU admissions (Gould et al 2010).

The majority of individuals with an acute illness will spend some time in a hospital on a general ward. Although referred to as general, the majority of wards in hospitals are specialised. The specialties include respiratory, cardiovascular, cardiopulmonary, neurological, burns, oncology, haematology, gastrointestinal, renal, trauma, surgery and paediatrics. When an individual is admitted to acute care, the aim is always to allocate a bed on the most appropriate ward; however, with bed shortages this is not always possible.

## Home care

For some individuals care in the home is appropriate, even during an acute illness. Post-acute care providers are essential to assist hospitals in reducing unnecessary hospital admission (Butcher 2013). In some Australian states this can be delivered via the Hospital in The Home (HITH) service or Royal District Nursing Service (RDNS). In both cases, delivery of care is in the individual's home instead of hospital. HITH was introduced in some states of Australia in 1994 (Department of Health, Victoria 2014). When an individual is treated under HITH the individual is regarded as an inpatient of the hospital and remains under the care of the home unit doctor of the hospital (Department of Health, Victoria 2014). Individuals admitted to HITH receive the same treatment they would receive if they were to remain an inpatient but have the benefit of being at home; this has been shown to result in better outcomes, such as reduced risk of hospital-acquired infection (Department of Health, Victoria 2014).

Many hospitals have now introduced HITH due to the cost benefits and the enhanced ability to better manage beds as individuals can be discharged earlier (Department of Health, Victoria 2014). To be eligible for HITH the individual must be clinically stable, have appropriate home support, live in a suitable environment, be willing to be treated by the HITH team and be suitable for treatment at home (Department of Health, Victoria 2014). The most common reasons for referral to HITH include intravenous antibiotics for cellulitis, genitourinary tract or respiratory tract infection, anticoagulation therapy and chemotherapy (Department of Health, Victoria 2014).

The Royal District Nursing Service (RDNS) was first introduced to Australia in 1885 (RDNS 2011). The RDNS differs from HITH in that the individual will not be considered an inpatient of a hospital. It is an independent, not-for-profit organisation that funds its service from state government funding in some states of Australia, and individual fees, donations, sponsorship, corporate partnership and fundraising (RDNS 2011). Nurses working in the home care setting have

to be prepared for the unexpected and be able to provide care in unconventional settings, sometimes at the kitchen table (Skott & Lundgren 2009).

## IMPACT OF ACUTE ILLNESS

### The individual

No matter where an individual is admitted they are the centre of care (Ferguson et al 2013). Acute illness can occur suddenly and have devastating and long-term consequences. Once the individual is diagnosed with an acute illness, there can be an increase in subsequent hospitalisations, which may be due to complications or ongoing manifestations of the initial illness (Williams et al 2010). This, of course, negatively impacts on an individual's quality of life. While they are in hospital it is important for them to be involved and engaged in their own care. Participating in making healthcare decisions and receiving education regarding their current condition encourage the individual to take on responsibility for their own health during their course of stay and on discharge (Ferguson et al 2013). Involving the individual in decisions related to their care is included in the NSQHS Standards. Individuals must be respected and engaged in the care they receive. The Standards state that hospitals must start 'implementing processes to enable partnership with patients in decisions about their care, including informed consent to treatment' (ACSQHC 2012). The NSQHS Standards emphasise the importance of including the individual in all aspects of care.

Adequate communication during hospital admission is essential. Communication is extremely important to ill individuals and assists in developing a therapeutic relationship (Ferguson et al 2013). Refer to Chapter 8.

Once discharged after an acute illness many individuals will have ongoing physical and psychological issues related to their hospital admission. These issues can be related to the stress that an acute illness causes. When diagnosed with an acute illness individuals have to deal with being in a foreign environment, the illness itself, physical or traumatic injury, feelings of mortality, fear, pain and the unknown impact this illness will have, not only on their own life but also the lives of their loved ones (Kelly & McKinley 2010). Post-discharge individuals may report fatigue, weakness, ongoing pain, sleep difficulties, nightmares and flashbacks which can all lead to mood changes and impact on the individual's ability to cope with their new-found lifestyle (Kelly & McKinley 2010). After an acute illness individuals may find that their role and responsibilities in the family have altered; they may be more dependent on others, which is a big adjustment to make and which can lead to feelings of resentment (Kelly & McKinley 2010). See Case Study 42.1.

### The family

When the nurse is caring for an acutely ill individual, they must take care to include the family. Family members play a critical role in the care of an individual. For most cultures family is central to caregiving—illness is a family affair. Family members as non-formal, untrained caregivers are an important part of the healthcare team. Family members can assist with the care of an ill individual in many ways. From assisting with activities of daily life (ADLs) to running errands, family members can assist nurses caring for their loved one (Bhalla et al 2014).

It is essential to develop a relationship based on trust with both the individual and their family. To do this the nurse must actively listen to the individual and involve the individual and family in care planning. Encouraging family presence can also build a trusting relationship (Mastro et al 2014). Involving the individual and family in care recognises the knowledge and expertise that the individual and family may have regarding their illness (Ewart et al 2014). It is important to remember that with chronic illness often the individual and family will be more knowledgeable than the nurse. Communication is essential when individuals are admitted to hospital. Effective communication can reduce complaints from both the individual and family members (Ewart et al 2014).

The family of an acutely ill individual should not be expected to take on all the care the individual requires (Ewart

### CASE STUDY 42.1

**Rebecca's acute care experience**

About 2 years ago Rebecca started experiencing intense headaches which culminated one day in her passing out at work. She worked as a nurse and her nurse unit manager put her in a wheelchair and took her around to the emergency department of the hospital that she worked in. This was the beginning of 2 months of being admitted and discharged from hospital five times. She had all the tests done—MRI, CT, blood test and even a lumbar puncture—but no doctor could tell Rebecca why her head felt like it was going to explode. When admitted to the wards, she felt that once the nurses realised that they were caring for a fellow nurse, they treated her differently from other individuals. Treatments didn't get explained as it was assumed that she understood what was happening. No one explained to her the reasoning behind all the tests she was having. For Rebecca, one of the scariest experiences was when she had a drug reaction; she thought she was going to die.

On her last admission one of the nurses looking after her suggested she see an osteopath and get her back and neck looked at. Rebecca took her advice and achieved some relief. Two years on and what started as an acute episode has turned into a chronic pain issue. Rebecca has had to change jobs and work part time as the chronic pain causes her constant exhaustion. This has had a major impact on her life and she has had to modify her lifestyle to manage the pain she experiences every day.

What impact may Rebecca's illness have on her life?

et al 2014). The family should be used in conjunction with nursing staff, not instead of. Additionally family members should not be made to feel guilty if they cannot or do not wish to take part in care (Ewart et al 2014). For those family members who wish to assist with the care of a loved one the physical and emotional toll must be recognised (Bhalla et al 2014).

Historically, nurses and medical officers have not been good at predicting what the family needs and therefore the family's needs may not be met (Davidson 2009). When an individual is unexpectedly admitted to hospital, the family may display physical, emotional and behavioural responses to situations based on personal coping mechanisms and feelings for the ill relative (Vandall-Walker 2010). It is a highly stressful time characterised by feelings of fear and anxiety caused by disruptions and changes to family relations (Davidson 2009). To help families during this time of high stress it is important to communicate expected healthcare outcomes and to keep open the lines of communication. Families reported less satisfaction with the care their loved one received when there was a lack of communication from both nursing and medical staff (Davidson 2009).

For the family of an acutely ill individual the journey really only continues once the individual has been discharged home. For many families this means taking on the care of the individual with or without the help of community-based services. Roles in the family can be reversed, with children becoming the carer. There can be financial hardship, which adds to the stress that carers face. Studies show that partners who become carers are exhausted, excessively overprotective, burdened, anxious and suffer from the effects of ill health (Dougherty & Thompson 2009). On a more positive note, stress for the family and individual is at its greatest at time of discharge and will decline over time (Dougherty & Thompson 2009). See Case Study 42.2.

### CRITICAL THINKING EXERCISE 42.1

You are looking after an individual who has been admitted post a myocardial infarct. He is recovering post coronary artery bypass graft surgery. The individual is the main income earner in his family and has three young children at home.

1. Identify physical issues for this individual.
2. Identify psychological issues for this individual.
3. List appropriate ongoing care including allied healthcare that this individual will require.

### CASE STUDY 42.2

**Rebecca's acute care experience: the family's perspective**

When Rebecca started experiencing headaches I thought nothing of it; she has suffered from migraines since a young age. Then suddenly they escalated and she had to be admitted to hospital multiple times. I cannot explain the sense of helplessness I felt as her mother. I felt I should have been able to make it all better. It was very frustrating that the doctors could not give us any answers; they didn't listen to her when she said it wasn't a migraine. One of the worst moments for me was receiving a phone call from my sister who was visiting Rebecca when she had the drug reaction. My sister thought Rebecca was going to die. Another moment that stands out for me was being ordered from her room as nurses rushed in. No one told me what was going on. I found out later she had been given too much morphine and had a dangerously low respiratory rate. Two years on and I am proud of how Rebecca deals with the pain; most people have no idea that she has pain every day. It is lucky that I am a casual worker so I can take time off when Rebecca needs to be taken to hospital; I don't know what would happen if I had to work full time.

**Lisa, mother of Rebecca**

What impact will Rebecca's illness have on her family?

## ACUTE DISORDERS

The following acute disorders are ones that have not been covered in other chapters.

### Cellulitis

**Cellulitis** is an acute, localised bacterial infection of the dermis and subcutaneous tissue. Cellulitis is an umbrella term used for any acute non-necrotising dermis and hypodermis infections. Cellulitis in more severe forms can include tissue necrosis (Lasschuit et al 2014). Individuals with ulcers or wounds are more at risk of developing cellulitis due to bacteria being able to enter the skin (Nazarko 2012). One-third of people diagnosed with cellulitis are misdiagnosed, resulting in unnecessary exposure to antibiotics. Common disorders misdiagnosed as cellulitis include vascular eczema, lymphoedema and lipodermatosclerosis (Nazarko 2013). Refer to Chapter 29 for more information on skin integrity and wound care.

#### Clinical manifestations

Clinical manifestations of cellulitis include localised swelling, redness and pain. The skin can be red, hot and tender to touch. Often there is a distinct border between normal and affected skin. It is good practice to mark this border with a permanent marker to enable you to observe the spread of infection. Up to 40% of individuals diagnosed with cellulitis will also develop systemic signs of infection such as fever, chills, vomiting, malaise and sweating. Cellulitis commonly develops in the lower extremities with only one limb affected. It is rare for an individual to develop cellulitis in both legs. The individual may also present with enlarged lymph glands in the groin and lymphangitis (Lasschuit et al 2014; Nazarko 2012).

## CLINICAL INTEREST BOX 42.1 Risk factors in the development of cellulitis

- Venous insufficiency or stasis
- Lymphoedema
- Surgery
- Diabetes mellitus
- Malnutrition
- Substance abuse
- Presence of another infection
- Compromised immune system
- Trauma
- Intravenous drug use
- Radical mastectomy with axillary dissection

*(Farrell & Dempsey 2013)*

### Risk factors

Risk factors for developing cellulitis involve both systemic and local factors. Systemic risk factors of cellulitis include: obesity, diabetes, cancer, hepatic cirrhosis and past history of cellulitis. Local factors that increase the risk of developing cellulitis include: chronic limb oedema, surgical resection of lymph nodes, saphenous venectomy and acute or chronic skin breaks. Skin disruption may be caused by trauma, ulceration, dermatitis or toe web intertrigo (Lasschuit et al 2014). Human and insect bites have a high risk of causing cellulitis (Eron 2009). (See Clinical Interest Box 42.1.)

### Pathophysiology

Cellulitis usually occurs due to a break or lesion on the skin that allows microorganisms to invade the body. In some cases there is no identifiable skin break or lesion (Nazarko 2012). The most common bacterial infections that cause cellulitis include: β-haemolytic streptococci, mainly the *Streptococcus pyogenes* group followed by *S. aureus* and occasionally Gram-negative bacilli (Lasschuit et al 2014). The cellulitis infection can spread due to the production of a substance known as hyaluronidase (spreading factor). This substance is produced by the causative agent and breaks down fibrin networks and other barriers that normally localise infection (LeMone et al 2013). Complications of cellulitis can include subcutaneous abscesses, sepsis, post and streptococcal nephritis and, in extreme cases, death (Nazarko 2013).

### Medical management

The medical management of cellulitis when the infection is mild includes treatment with oral antibiotics, including an antibiotic that is effective against *Streptococcus* species and *S. aureus.* Antibiotics such as dicloxacillin/flucloxacillin, cephalexin or clindamycin should be considered.

For severe cases and those which do not respond to oral antibiotics within 48 hours treatment should include intravenous antibiotic. On average individuals diagnosed with cellulitis will require 3.5 days of intravenous antibiotics.

The decision to change from intravenous to oral antibiotics will be made based on the individual's clinical condition. For most individuals oral antibiotics will need to be continued for 1 to 2 weeks (Lasschuit et al 2014; Nazarko 2012). Non-steroidal anti-inflammatory drugs can also be prescribed to reduce pain and inflammation (Napierkowski 2013).

### Nursing care

When caring for the individual with cellulitis the nurse should instruct the individual to elevate the affected area above the heart (Farrell & Dempsey 2013). Warm, moist packs should be applied to the area every 2 to 4 hours; care must be taken in individuals with decreased sensory perception to ensure burns do not occur (Farrell & Dempsey 2013). Cellulitis can result in damage to the lymphatic system which can cause chronic oedema or lymphoedema (Riches & Keeley 2012).

### Individual education

Individual education for cellulitis has an emphasis on prevention of future episodes (Farrell & Dempsey 2013). Refer to Chapter 6 for more information on providing education to individuals.

## Venous thromboembolism

Venous thromboembolism (VTE) is an umbrella term that includes both deep vein thrombosis (DVT) and pulmonary embolism (PE) (Harvey et al 2013; Donner & Johnson 2014). VTE is a common medical complication, causing significant mortality and morbidity (Rajasekhare & Steiff 2013; Kahn 2009 cited in Donner & Johnson 2014). It is commonly asymptomatic and misdiagnosed (Abdou et al 2011). It is estimated that VTE will occur in 10–40% of all individuals admitted to hospital on general medical wards, and 40–60% of all individuals who undergo major orthopaedic surgery (Duff et al 2013). In Australia it is estimated that 17 000 new cases of VTE are diagnosed each year (Skinner 2013). Refer to Chapter 19 for more information on venous thromboembolism assessment.

### Risk factors

VTE risk factors include advancing age (those over 75 years old), cancer (history of or current), past history of VTE, obesity, varicose veins, hormone therapy, chronic heart failure and bed rest. Medical conditions that increase the risk of developing VTE include congestive heart failure, severe respiratory disease, acute medical illness that leads to immobility, active cancer, previous VTE and admission to critical care units. Individuals who have undergone hip or knee surgeries, trauma or major injury are also at risk of developing VTE (Abdou et al 2011).

### Deep vein thrombosis

**Deep vein thrombosis (DVT)** is a thrombosis in the deep veins of the body, usually involving the lower extremities (Donner & Johnson 2014; Streiff et al 2014). Most DVTs occur in the distal veins of the calf. They can extend proximally into the veins in and above the knee (Donner &

Johnson 2014). DVT is a leading factor in preventable hospital mortalities. When a DVT occurs in a lower extremity mortality rates are 13–21%. This rises to 48% when the DVT has occurred in an upper extremity. In 20% of individuals who develop a DVT, the thrombus will detach from the site, migrating in the blood stream to the lungs, causing a PE (Meguid 2011; Streiff et al 2014).

## Clinical manifestations

A diagnosis of DVT can be difficult to make as the clinical manifestations can be similar to other diseases such as cellulitis. Clinical manifestations of a DVT may include unilateral oedema, pain, localised warmth and erythema (Meguid 2011). When an individual presents with these symptoms a Wells score will be obtained. This score rates the likelihood that the symptoms are the result of a DVT based on past medical history and physical examination (Meetoo 2013). (For information on prevention of DVTs see Chapter 28.)

## Risk factors

Risk factors, including pathological factors, associated with DVT are shown in Clinical Interest Boxes 42.2 and 42.3. It is estimated that individuals over 40 who are admitted to hospital will have two or more risk factors for developing a DVT (Meguid 2011; Donner & Johnson 2014).

## Pathophysiology

A thrombosis can develop when there are changes in the vessel walls, changes in blood flow or changes in blood composition. These three conditions are known as Virchow's triad. Changes in blood flow are usually a result of immobility. Changes in blood composition are in the form of hypercoagulability which can be due to inflammation, malignancy or tissue damage. DVTs most often occur in the lower extremities (Meguid 2011; Meetoo 2013; Streiff et al 2014).

## Diagnostic tests

If a DVT is suspected, a blood test known as the D-dimer can be performed. This detects fibrin breakdown that is present in the blood post thrombus formation. The test is used for negative predictability only, meaning that a negative result indicates no DVT, while a positive will result in further tests being carried out (Walter et al 2014). If a positive D-dimer occurs the individual may then be sent for an ultrasound—the most appropriate and accurate test for diagnosing a DVT (Zierler 2004 cited in Donner & Johnson 2014). When sending an individual for ultrasound to determine the presence of a DVT the nurse must ensure that the individual can change their own position and be able to tolerate the pressure used during the scan as this can be quite firm. It is also important to alert the diagnostic imaging department if the individual has a wound or cast which may impact on the technician's ability to complete the scan (Zierler 2004 cited in Donner & Johnson 2014).

## Medical management

Prevention of DVT is crucial. To achieve this:

- Early ambulation post surgery is required
- Individuals should be advised to stay hydrated, wear lose clothing and exercise their calf muscles (Meguid 2011).

Once the diagnosis of DVT is made, treatment needs to commence immediately. Traditionally individuals were put on bed rest as the assumption was that movement would dislodge the thrombus and lead to a pulmonary embolism (Anderson et al 2009). The current treatment regimen includes a combination of anticoagulation therapy and thrombolytic therapy with the aim of preventing the thrombus from growing or fragmenting (Scarvelis & Wells cited in Donner & Johnson 2014).

### CLINICAL INTEREST BOX 42.2 Risk factors associated with DVT

- Surgery
- Increased age
- Family history
- Thrombophilia
- Cancer
- Myocardial infarct
- Ischaemic cerebrovascular accident
- Chronic obstructive pulmonary disease
- Heart or respiratory failure
- Pregnancy
- Hormone therapy including the oral contraceptive pill and hormone replacement therapy
- Acute inflammation disorders
- Obesity
- Bed rest
- Immobilisation of extremities
- Varicose veins
- Trauma
- Central access catheters

*(mayoclinic.org/diseases-conditions/deep-vein-thrombosis/basics/risk-factors/con-20031922; Crisp et al 2013)*

### CLINICAL INTEREST BOX 42.3 Pathological risk factors associated with DVT

- Previous DVT
- Inherited hypercoagulable states
- Cancer
- Sepsis
- Obesity
- Nephritic syndrome
- Polycythaemia vera
- Myeloproliferative disorders
- Vitamin deficiencies
- Heparin-induced thrombocytopenia
- Acute myocardial infarction
- Neurological disease causing paralysis

*(Meguid 2011)*

Individuals with a DVT will usually be commenced on a dual therapy treatment plan with:

- Parenteral or oral anticoagulants, usually in the form of vitamin K antagonist (VKA)
- Low molecular weight heparin (LMWH).

These should be commenced as soon as possible after diagnosis.

It is important to note that LMWH is porcine-derived and therefore some people may refuse its use based on religious or cultural grounds (Donner & Johnson 2014). One-third of all individuals diagnosed with a DVT will go on to develop post-thrombotic syndrome (Kahn 2009 cited in Donner & Johnson 2014). Post-thrombotic syndrome is usually caused by venous reflux and venous hypertension. These complications are a result of damage by the DVT to valves in the leg. These valves usually aid in the return of blood to the heart. This is a significant complication that affects the individual's quality of life, causing ongoing pain, heaviness and swelling in the affected leg (Kearon 2003 cited in Donner & Johnson 2014). Between 5% and 10% of individuals will develop severe post-thrombotic syndrome which can lead to venous leg ulcers (Kahn 2009 cited in Donner & Johnson 2014).

### Nursing care

When caring for the individual with a DVT the nurse must monitor the individual for potential complications of treatment such as bleeding and thrombocytopenia. The nurse should also maintain individual comfort by elevating the affected extremity, applying compression stockings and administering analgesia; these all help to increase circulation (Farrell & Dempsey 2013). The affected leg should be assessed every shift for signs of skin breakdown to enable early intervention. The individual must also be monitored for signs of PE (see below) (LeMone et al 2013). Gradual compression stockings should be used when an individual is diagnosed with a proximal DVT. These stockings exert pressure on the limbs, reducing the risk of fluid seeping from superficial veins into surrounding tissue. Gradual compression stockings have been found to reduce the risk of developing post-thrombotic syndrome from 54.0% to 25.2% (Donner & Johnson 2014).

### Individual education

Prior to discharge inform the individual that they need to report any unusual bleeding to their doctor. For women, menstrual bleeding may be slightly increased: they should contact their doctor if it increases significantly. Men should shave with an electric razor to reduce the risk of cuts, and soft-bristle toothbrushes should be used. Contact sports should be avoided while taking anticoagulation drugs (LeMone et al 2013). The effectiveness of VKAs can be impacted by many factors including diet, alcohol consumption, other medications and gastric issues (Glee 2011 cited in Donner & Johnson 2014).

## Pulmonary embolism

**Pulmonary embolism (PE)** is a major cause of mortality and morbidity (Walter et al 2014). Between 5% and 10% of all hospital deaths are caused by PE (Abdou et al 2011). Ten per cent of PEs will cause death within 1 hour of symptom development (Meguid 2011). PEs are the leading cause of preventable hospital deaths each year. They are the third most common cause of vascular death (after myocardial infarction and stroke). DVT is the cause of 95% of PEs (Walter et al 2014). The risk factors associated with the development of a PE are very similar to those for a DVT (see Clinical Interest Box 42.2). Refer to Chapter 25 for more information on respiratory assessments.

### Clinical manifestations

The clinical manifestations of PE may include chest pain, chest wall tenderness, palpitations, back and shoulder pain, upper abdominal pain, syncope, haemoptysis, dyspnoea and painful respirations (Skinner 2013).

### Pathophysiology

PE involves obstruction of a section of the pulmonary artery tree by a thrombus or embolism (Sheares 2011). This thrombus or embolism forms in the venous system or right side of the heart (Farrell & Dempsey 2013) and commonly originates in the leg or pelvic vein (Sheares 2011).

### Diagnostic tests

Diagnosis of PE can be difficult because of the non-specific symptoms that are manifested (Walter et al 2014). If the clinical manifestations indicate the possibility of PE (Skinner 2013), a D-dimer test may be ordered; if this test is positive more investigations are required to confirm the diagnosis (Walter et al 2014). Table 42.2 outlines investigations for diagnosis of PE.

In recent years the computed tomography pulmonary angiogram (CTPA) has replaced pulmonary angiograms in the diagnosis of PEs.

### Medical management

The best treatment for individuals at risk of developing a PE is prevention (Farrell & Dempsey 2013). Many hospitals now require all individuals to have a risk assessment performed on admission. Those deemed at high risk for DVT or PE are commenced on a prophylaxis regimen, such as enoxaparin (Duff et al 2013). This is usually given twice a day subcutaneously and may continue even after discharge (Rogers 2010). Once a diagnosis of PE is made the individual will be classified as either high or low risk for developing complications.

High-risk individuals are those who are haemodynamically unstable. Haemodynamically instability occurs when the PE causes vasoconstriction and reduces cardiopulmonary function. Treatment of PE will depend on the individual's risk for complications. For haemodynamically unstable individuals treatment aims to restore pulmonary arterial flow. This is achieved by using thrombolytic therapy with such medications as:

- Streptokinase
- Urokinase
- Recombinant tissue plasminogen.

**TABLE 42.2 | Investigations for diagnosis of pulmonary embolism**

| Investigation | Rationale |
|---|---|
| Chest x-ray | May be normal but may also show atelectasis, pleural effusion, hypovascularity or peripheral lobe infarcts |
| Arterial blood gases | May show that the individual has hypoxaemia and hypocapnia or they may be normal |
| Ventilation-perfusion scan (VQ scan) | A ventilation-perfusion scan involves injection via an intravenous line and inhalation by the individual of a contrast agent. The lungs are scanned at different angles and a comparison made of the percentage of ventilation and perfusion in each area; a hypoperfused area indicates the presence of a PE |
| Pulmonary angiogram | Allows for direct visualisation of a thrombus or embolism in a pulmonary artery branch and so is the most accurate diagnostic test for PE. However, while pulmonary angiogram is considered the most accurate, it is not cost effective or easily performed |
| Computed tomography pulmonary angiogram (CTPA) | CTPA has replaced pulmonary angiograms in the diagnosis of PEs. This type of CT evaluates slices as narrow as 1.0 mm, allowing for accurate visualisation of a PE by enabling visualisation of the pulmonary arteries. The main disadvantages of the CTPA are that the individual must be transferred to a diagnostic imaging department as the CT is not portable and the individual must be injected with contrast, which can cause allergic reactions and is contraindicated in individuals with renal impairment and those taking metformin |

*(Skinner 2013; Walter et al 2014)*

**TABLE 42.3 | Emergency management of pulmonary embolism**

| Management | Rationale |
|---|---|
| Nasal oxygen | Relieves hypoxaemia and respiratory distress |
| Insertion of intravenous lines | Prepares for medication administration |
| ECG | Provides continuous monitoring for arrhythmias and right ventricular failure |
| Medications | May include digoxin glycosides, diuretics, enoxaparin, heparin and anti-arrhythmic agents. Sedatives may be administered to relieve anxiety |
| Blood tests | Include serum electrolytes, full blood count, haematocrit and arterial blood gases |
| Indwelling urinary catheter | Inserted to monitor fluid output |
| Mechanical ventilation | Used if the clinical assessment and investigations warrant it |

*(Farrell & Dempsey 2013)*

The medications are given intravenously, meaning they will have systemic effects on the individual. This increases the risk of adverse bleeding events. Thrombolytic therapy is recommended to run over 2 hours to reduce the risk of adverse bleeding events (Walter et al 2014). This is a medical emergency which will cause death in 50% of individuals who develop it (Walter et al 2014). See Table 42.3 for emergency management of PE.

For haemodynamically stable individuals with PE treatment involves the provision of a VKA, usually in the form of warfarin. This is used in conjunction with a LMWH. Heparin should be commenced first. VKA therapy can begin on the first or second day of heparin administration and both therapies should continue for 5 days. During this time the individual's international normalised ratio (INR) is monitored. INR has target range of between 2.0 and 3.0. The individual will need to remain on VKA treatment for around 3 months (Walter et al 2014). See Table 42.4 for considerations for the treatment of PE in special populations.

## Nursing care

The management of a PE depends on the severity of the individual's condition. The nurse initiates interventions aimed at improving respiratory and vascular status; these interventions include oxygen therapy and elevation of lower extremities (Farrell & Dempsey 2013). Anti-embolic stockings or intermittent pneumatic leg compression devices may be used to decrease venous status (Donner & Johnson 2014). When caring for the individual with a PE the nurse must monitor for signs of bleeding and only essential venepunctures are performed. The individual's pain and anxiety must be managed, with medication if necessary. Vital signs should be monitored every 2 hours, increasing when deterioration is noted (Farrell & Dempsey 2013).

## Individual education

The individual will require education regarding adherence to medication regimens. This will include anticoagulants therapy

**TABLE 42.4 | Considerations in special populations for the treatment of PE**

| Type | Risk | Treatment |
|---|---|---|
| Incidental PE (asymptomtic patients). Most are small and located in segmental and subsegmental vessels | Unknown due to location | Controversial, particularly if cardiopulmonary reserve is satisfactory and there is no evidence of concomitant DVT |
| Subsegmental PE | No increased risk of adverse outcomes when isolated subsegemental emboli are detected | Risk of bleeding due to anticoagulation may outweigh benefit<br>No clear guidelines<br>Most will be treated |
| Perioperative management of anticoagulation in individuals with PE | Conventional treatment may not be an option due to risk of bleeding during surgery | VAK should be stopped 2–3 days prior to procedure when moderate risk of bleeding, 5 days when high risk<br>Should be commenced 12–24 hours postoperatively providing haemostasis is maintained |
| PE in pregnancy | Leading cause of pregnancy-related mortality in the developed world<br>Diagnosis is difficult due to overlap of symptoms with those of pregnancy and the need to limit radiation exposure | VKA, especially warfarin, are teratogenic and can cause congenital abnormalities<br>LMWH or UFH both do not cross the placental barrier. Both can cause maternal haemorrhage, heparin-induced thrombocytopenia and heparin-induced osteopenia |
| PE and cancer | VTE affects approximately 15% of all cancer patients<br>Second leading cause of death in cancer patients | LWMH treatment is recommended as it is considered safer than VKA<br>Recommended long-term use of LMWH to decrease reoccurrence |

*(Walter et al 2014)*

education (see 'Individual education' for DVT above) and information regarding follow-up appointments and blood tests (LeMone et al 2013).

### CRITICAL THINKING EXERCISE 42.2

You receive handover from the morning nurse on one of the individuals you are caring for who is expected to be discharged this afternoon. The individual is a 39-year-old female admitted with a DVT who has responded well with treatment and will be transferred to HITH care. The nurse handing over to you reports that this morning the individual complained of slight back and shoulder tip pain which was resolved with paracetamol. All paper work has been completed and the individual is waiting for her discharge medications before she can leave. When you enter the individual's room, you find her pale and complaining of dyspnoea and chest pain.

1. What is your first action going to be?
2. What do you think has happened?
3. What sign did the morning nurse miss?
4. What diagnostic tests need to be done?

## Diverticulitis

It is estimated that up to 40% of people over the age of 60 have diverticulosis, a disease where pouches, known as diverticula, develop in the bowel wall, usually in the sigmoid colon (Tadlock et al 2013). **Diverticulitis** occurs when there is infection or inflammation of the diverticula (Reddy & Longo 2013).

### Clinical manifestations

Individuals with diverticulitis will present with left lower quadrant abdominal pain, abdominal tenderness, increased white blood cells counts and fever (Wolf 2012).

### Risk factors

The risk of developing diverticulitis increases with age. Other risk factors include reduced fibre intake and increased red meat consumption (Wolf 2012).

### Pathophysiology

Diverticula usually develop at a weak spot in the muscle wall, allowing the inner layer of the wall to balloon outwards. For the majority of people with diverticulosis, the diverticula cause no problems; however, some will go on to develop diverticulitis. Diverticulitis occurs when diverticula are either eroded by pressure or faecal matter becomes trapped, leading to infection (Tadlock et al 2013). The damage can range from mild to severe. Perforation can occur, allowing bowel matter to leak into the abdomen causing abscess formation (Reddy & Longo 2013). The pathophysiology for this happening for

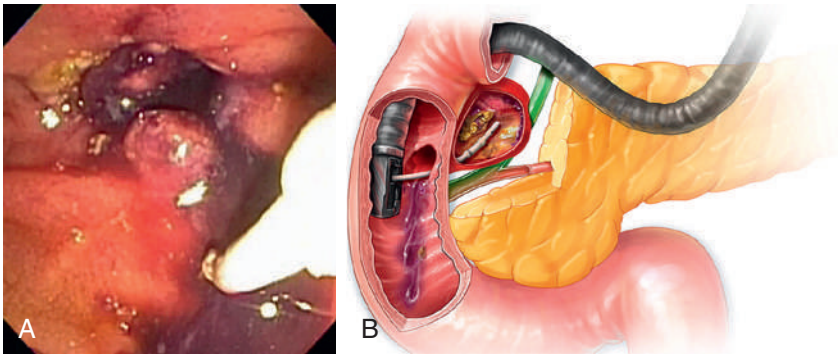

**Figure 42.1** Treating diverticulitis with endoscopic therapy
*(Salah & Faigel 2014)*

some and not all people with diverticulosis is not known but research suggests that chronic inflammation may be the cause (Lipman 2011).

Figure 42.1 shows how diverticulitis is treated with endoscopic therapy.

### Diagnostic tests

For individuals presenting with signs and symptoms as outlined above, diagnosis of diverticulitis is achieved via abdominal CT with contrast, as it will enable visualisation of infection, as well as any perforations and abscesses.

### Medical management

Treatment of diverticulitis involves broad-spectrum antibiotics, usually metronidazole and ciprofloxacin, and a liquid diet. For some individuals who develop an abscess that fails to respond to antibiotic therapy a drain tube may need to be inserted into the abdomen to drain the infected fluid. For some individuals who suffer repeat attacks, surgery to remove the affected area of bowel may be the only option as bowel function can be permanently diminished due to scarring, narrowing and loss of normal contractions (Tadlock et al 2013; Reddy & Longo 2013; Wolf 2012).

### Nursing care

As the individual with diverticulitis is at risk for bowel perforation, vital signs must be monitored 4 hourly or more frequently if clinically required. The abdomen should be assessed at the same time, measuring girth, auscultating bowel sounds and palpating for tenderness. Any changes must be immediately reported to the doctor as they may indicate spread of infection. The individual will rest in bed with limited activity to promote healing. Pain relief is paramount so the individual should be assessed frequently for pain (LeMone et al 2013).

### Individual education

On discharge individuals need education on diet. A high-fibre diet is required to reduce complications. The individual may benefit from a consultation with a nutritionist or dietitian, for which the nurse can make a referral (LeMone et al 2013).

## Guillain–Barré syndrome

**Guillain–Barré syndrome** (GBS) is a rare acute inflammatory autoimmune disorder that is characterised by rapid and progressive neuromuscular paralysis. Guillain–Barré syndrome often occurs after an individual has had an infection in their body. In severe cases, Guillain–Barré syndrome can cause paralysis of the respiratory nerves, leading to ICU admission (Hsieh et al 2013). The pathophysiology of GBS is demyelination of nerves, most commonly peripheral nerves, by antiganglioside antibodies which attack the Schwann cells of the myelin sheath. This causes diminished nerve conduction which results in severe weakness and often paralysis (Zhang et al 2013).

Individuals with GBS will initially complain of decreased function, weakness and decreased sensation in their arms and legs, with or without pain. This rapidly develops into muscle weakness, commencing distally then travelling to proximal with decreased reflexes and sensations. Individuals with GBS will also show abnormalities in their cerebrospinal fluid and nerve conduction studies (Derksen et al 2014). For some individuals the disease progression will stop there; they will experience difficulty walking but will be able to be discharged to home. Others will progress to total paralysis. It is estimated about 30% of individuals with GBS will require mechanical ventilation because of respiratory dysfunction and up to 13% will die from the syndrome. The most common causes of death from GBS are respiratory failure, pneumonia, cardiac arrest and autonomic dysfunction.

Treatment of GBS is supportive. Individuals diagnosed with GBS may be treated with IVIg or plasma exchange therapy (van den Berg et al 2013). Over time the Schwann cells will re-myelinate and most individuals can expect a full recovery (Schub et al 2011). Post recovery many individuals will suffer from ongoing severe fatigue (Drenthen et al 2013). When assessing the individual with GBS the nurse should monitor airway and breathing, refer to speech pathology, maintain the individual as nil by mouth until otherwise ordered, ensure adequate analgesia, perform pressure area care and take steps to reassure the individual.

## Acute kidney injury

**Acute kidney injury** (AKI), previously known as **acute renal failure**, is defined as a rapid decline in kidney function causing a rise in serum creatinine and/or blood urea nitrogen levels with or without a decrease in urine output. The decrease in renal function can be over hours to days (Bellomo et al 2012; Obermüller et al 2014; Tolwani 2012). It can be a common complication in critical areas with as many as 35% of all critically ill individuals developing AKI (Berry & Clatworthy 2012). For the majority of cases of AKI there is an underlying problem which, if identified and treated early, can prevent the development of AKI. The most common causes of AKI are sepsis, acute tubular necrosis and prerenal stasis. AKI can also be a result of urinary tract infections and hydronephrosis (Podoll et al 2013). Acute tubular necrosis is often caused by a reduction of systemic blood pressure or renal blood flow (Berry & Clatworthy 2012) and results in ischaemia or nephrotoxic injury to the tubules (Tolwani 2012).

### Clinical manifestations

AKI is typically asymptomatic until kidney function has declined significantly (Bellomo et al 2012). AKI can have effects on other body systems such as the cardiovascular, respiratory, hepatic and neurological systems (Lameire et al 2012). The individual can rapidly become critically ill, showing symptoms of lethargy, nausea, vomiting and diarrhoea. The individual may exhibit signs and symptoms of dehydration, their breath may smell of urine, they may complain of a headache and muscle twitching and may even develop seizures (Farrell & Dempsey 2013).

### Risk factors

Individuals at risk of developing AKI include those with diabetes mellitus, cardiovascular disease, chronic liver disease, cancer and anyone who has undergone complex surgery. Some medications are also known to be nephrotoxic. These include iodine- and gadolinium-based contrast mediums used in diagnosis procedures (Lameire et al 2012) and medications such as cisplatin and aminoglycosides. It is important to identify any potential nephrotoxic medications to discontinue their use. Around 20% of AKI cases are caused by medications. In hospitalised individuals sepsis is the most common cause of AKI (Bellomo et al 2012).

### Pathophysiology

ARF can be classified into three categories: prerenal failure, intrarenal failure and postrenal failure (Lameire et al 2012).

- Prerenal failure is the result of hypoperfusion of the kidneys. Hypoperfusion of the kidneys leads to a decrease in the glomerular filtration rate. Renal hypoperfusion may be the result of volume depletion from hypotension, hypovolaemia or cardiac insufficiency and significant renal vascular stenosis or thrombosis (Lameire et al 2012) (Figure 42.2)
- Intrarenal failure results when there is damage to glomerulus, vessels or kidney tubules. This is most often due to prolonged prerenal causes (Figure 42.3), infections and toxins that result in inflammation or injury (Yaklin 2011)
- Postrenal failure is caused by obstruction, which may be a result of renal calculi, strictures, thrombosis, benign prostate hypertrophy, malignancies and pregnancy (Figure 42.4). The obstruction causes pressure to increase in the kidney resulting in injury to the kidney (Lameire et al 2012).

### Diagnostic tests

Diagnosis of AKI is based on the individual's history, clinical presentation and kidney function. When an individual is suspected of having AKI there are many investigations that may be ordered. These include:

- Urinalysis
- Blood tests (including urea, creatinine and electrolytes, full blood examination, coagulation status, virology for hepatitis B and C and HIV)
- Renal ultrasounds
- CT, MRI
- Renal biopsy (Bellomo et al 2012; Lameire et al 2012; Podoll et al 2013).

The individual with AKI will have a decreased glomerular filtration rate, increased serum creatinine and may or may not have oliguria (Obermüller et al 2014).

### Medical management

The investigations required depend on the individual and the results of the health assessment (Murphy & Byrne 2010). Once a diagnosis is made the medical aim is to:

- Restore chemical balance
- Prevent complications to allow the kidney to repair itself.

There is no specific pharmacological management for AKI. Many traditional treatments with medications have now been found to be ineffective in the treatment of AKI. This includes the use of dopamine and loop diuretics (Negi & Shigematsu 2012). If there is a known cause it is treated and eliminated. For some individuals dialysis is required (see Chapter 31). In critically ill individuals with AKI requiring dialysis mortality is 40–70%. The individual with AKI may require:

- Fluid resuscitation
- Oxygen support
- Haemoglobin replacement (Bellomo et al 2012).

When providing fluid replacement therapy the individual must be monitored via a fluid balance chart and vital signs for fluid overload. Timely reversal of known causes of prerenal and postrenal failure can lead to recovery with no ongoing effects. If the cause of AKI is not promptly reversed permanent kidney damage can result (Lameire et al 2012), potentially leading to chronic renal failure (Bellomo et al 2012).

### Nursing care

When caring for an individual with AKI the nurse needs to closely monitor fluid balance. This can be done by commencing the individual on a strict fluid balance and daily weighing

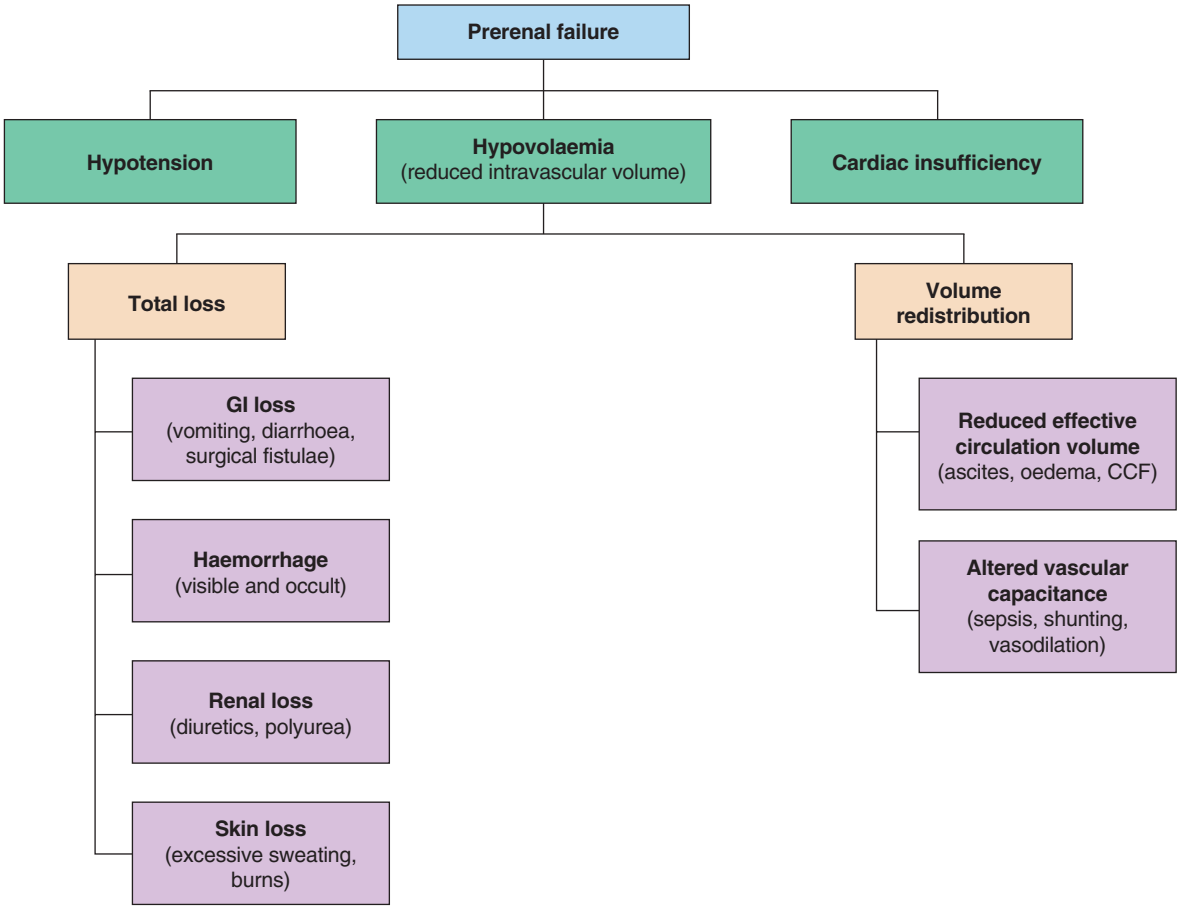

**Figure 42.2** Causes of prerenal failure
*(Blakeley 2008)*

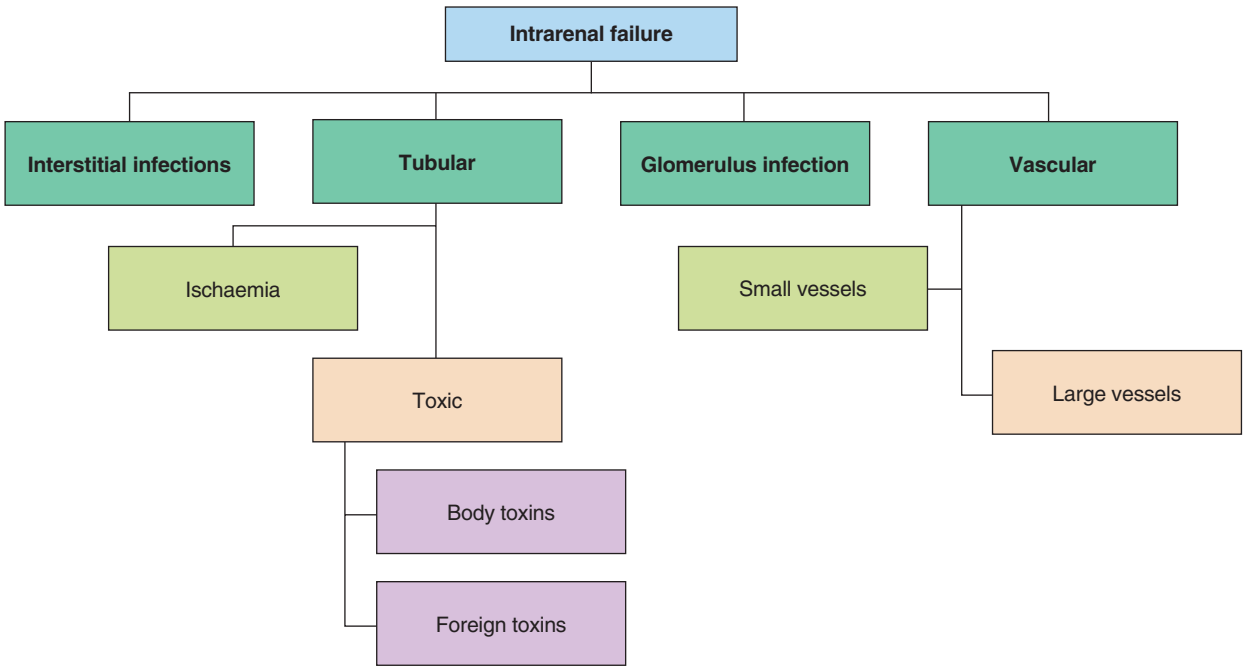

**Figure 42.3** Causes of intrarenal failure
*(Blakeley 2008)*

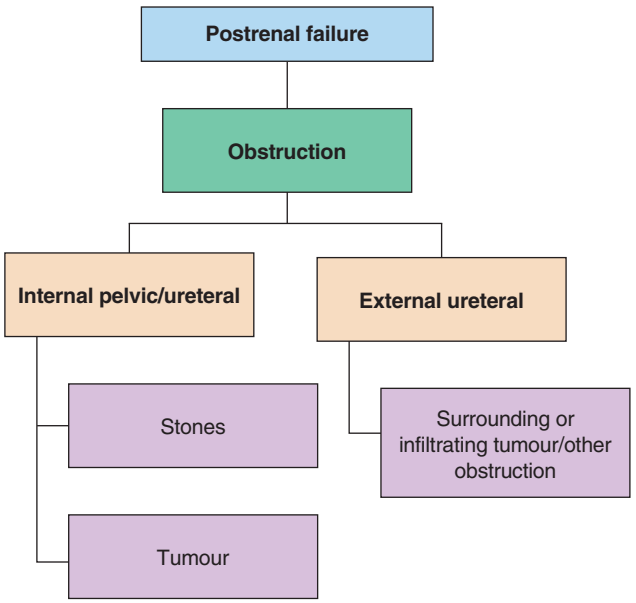

**Figure 42.4** Causes of postrenal failure

*(Blakeley 2008)*

regimen, ensuring that the individual is weighed at the same time on the same scales and in the same clothes every time. The nurse should also monitor the individual for signs of oedema and any difficulty in breathing (Lameire et al 2012). Individuals with AKI are at increased risk of infection and skin breakdown; therefore, the nurse should ensure asepsis when caring for these individuals and meticulous skin care to prevent skin breakdown (Farrell & Dempsey 2013).

### Individual education

The individual with AKI needs education to identify complications of fluid volume excess such as increased weight or oedema. Educate to avoid nephrotoxic agents for at least 1 year post ARF. The individual will need to avoid stress and infection (LeMone et al 2013). (See Table 42.5.)

**TABLE 42.5 | Differences between acute renal failure and chronic renal failure**

| | Acute renal failure | Chronic renal failure |
|---|---|---|
| Health history | Recent presentation of acute illness | Long duration<br>History of kidney disease or a history of a causative factor |
| Clinical examination | Hypotension, oedema/fluid overload | Generally not diagnosed until substantial kidney damage has occurred<br>Anaemia, cachexia and grey colouration of the skin may be present |
| Creatinine<br>Calcium<br>Haemoglobin | Increased values<br>Usually normal<br>May be normal or low | Stable measurements<br>Low in untreated disease<br>Will show chronic anaemia |
| Renal ultrasound | Often normal<br>When due to obstruction, hydronephrosis may be evident | May show scars from reflux nephropathy<br>Kidneys may be enlarged when the individual has diabetes, amyloidosis, chronic hydronephrosis or polycystic kidney disease |

*(betterhealth.vic.gov.au/bhcv2/bhcarticles.nsf/pages/Kidney_failure; Crisp et al 2013)*

## Sepsis

**Sepsis** is a life-threatening condition caused by a systemic inflammatory response to infection (Miller 2014). Severe sepsis can occur when organ dysfunction or disuse hypoperfusion results from the sepsis infection (Dellinger et al 2013). When sepsis occurs the body's response to infection causes damage to tissues and organs which can lead to shock, multiple organ failure and death. Early detection of sepsis is crucial to enable treatment to commence and decrease the risk of severe sepsis and septic shock. All healthcare professionals play a role in the early detection of sepsis (Daniels & Robson 2013). Recognising the deteriorating individual is included in the National Safety and Quality Health Service Standards. The Standards state that healthcare professionals must adopt 'processes to support the early identification, early intervention and appropriate management of patients at increased risk of harm' (ACSQHC 2012:18). Mortality from sepsis remains high—30% of individuals diagnosed with sepsis will die within 1 month and 50% within 6 months (Buck 2014). For a diagnosis of sepsis to be made the individual must have a known infection and systemic inflammatory reaction syndrome (SIRS) (see Clinical Interest Box 42.4).

Sepsis can be caused by many different infections. The most common infections that lead to sepsis are urinary tract infections and pneumonia. While the majority of infections that lead to sepsis are bacterial infections, fungal infections can also be the cause (Daniels & Robson 2013). Refer to Chapter 7 for more information on infection control.

### Clinical manifestations

Clinical manifestations include fever, peripheral oedema, hypotension, tachycardia, tachypnoea, severely altered mental state and hot flushed skin (Daniels & Robson 2013).

### Risk factors

Risk factors for the development of sepsis include cauterisation, invasive devices, certain surgery, urinary tract

## CLINICAL INTEREST BOX 42.4 SIRS

For a diagnosis of systemic inflammatory response syndrome (SIRS) to be made the individual must display two or more of the following:

- Temperature >38°C or <36°C
- Heart rate >90/min
- Respiration rate >20/min

SIRS can be present without an infection; however, sepsis can only be diagnosed when SIRS and an infection are present

*(Adapted with permission from Schub & Schub 2011b. © 2011, EBSCO Publishing, Inc)*

**TABLE 42.6 | Signs of organ failure**

| Body system | Clinical manifestation |
|---|---|
| Neurological | Decreased mental alertness |
| Urinary | Acute oliguria |
| Endocrine/ metabolic | Hyperglycaemic without the presence of diabetes |
| Respiratory | Tachypnoea, hypoxaemia |
| Gastrointestinal | Paralytic ileus, no bowel sounds |
| Circulatory system | Decreased cardiac output, decreased perfusion/BP |

infections, appendicitis, diverticulitis, Crohn's disease, cholecystitis, renal disease, prostatitis, meningitis and complicated obstetric delivery (Schub & Schub 2011a). Older adults, children and immunosuppressed individuals are at an increased risk of sepsis progressing to severe sepsis and septic shock (Schub & Schub 2011b).

## Pathophysiology

Sepsis develops when the body is unable to contain a localised infection, enabling the infective agent to enter the bloodstream. The associated SIRS can impair the clotting cascade, causing systemic inflammation, vasodilation and capillary leakage which contribute to hypotension and can lead to organ failure (Whitehead 2010). Sepsis can develop into severe sepsis. Severe sepsis involves all the clinical features of sepsis but has the added complication of organ dysfunction (Dellacroce 2009) (see Table 42.6). When an individual is diagnosed with severe sepsis there is a 30–35% chance of death (Whitehead 2010).

One of the major complications of severe sepsis is hypotension. When an individual remains hypotensive in spite of adequate fluid resuscitation, the individual has progressed into septic shock (Dellacroce 2009). Septic shock is a life-threatening condition, with 1400 people worldwide dying each day (Gerber 2010). After diagnosis of septic shock, 30% of individuals will die within the first month and 50% within 6 months (Gerber 2010).

## CASE STUDY 42.3

**Septic shock**

Melissa, a 26-year-old female with acute myeloid leukaemia, was admitted to the ward. She had undergone a bone marrow transplant, which had yet to take and she was neutropenic. She started spiking temperatures of 38°C or more. As per protocol the medical officer ordered blood cultures every time this happened, which kept coming back negative. This continued for 2 days before she deteriorated very suddenly and was taken to the ICU in septic shock. A chest x-ray showed she had developed a fungal infection in the left lower lobe of her lung, and this was suspected as the causative agent. The medical officers made the decision to remove the affected lobe of lung to remove the source of infection. The individual spent over a month in the ICU before returning to the ward and another 4 months on the ward before she could be discharged.

What are some ongoing issues that you can identify that Melissa may face?

## Diagnostic tests

It is recommended that all individuals at risk of developing sepsis have routine screening to enable early intervention and treatment if infection occurs. This can lead to improved clinical outcomes for individuals diagnosed with sepsis. Early identification can also decrease the risk of sepsis progressing to severe sepsis, which has worse outcomes for individuals. As soon as sepsis is suspected blood cultures should be taken, ideally prior to the commencement of antimicrobial therapy (refer to Clinical Skill 42.1: Venepuncture). Blood cultures should be taken prior to the commencement of antimicrobial therapy only when this will not lead to a delay in the commencement of treatment. Both aerobic and anaerobic blood culture collection bottles must be used. Ideally two sets of blood cultures should be obtained prior to the commencement of antibiotic therapy. The blood cultures can be taken at the same time if drawn from two different sites (percutaneously and all vascular access devices). The cultures should be taken from all lumens of central and peripheral lines. Obtaining blood cultures prior to commencement of antibiotics is important to confirm infectious agents.

Once confirmation of infection has occurred antibiotic therapy can be scaled back to enable a more targeted approach. It is important to note that in as many as 50% of individuals diagnosed with sepsis and severe sepsis blood cultures will be negative. This is more likely to occur when antimicrobial treatment has commenced. For the majority of individuals who have negative blood cultures, the sepsis and severe sepsis will be caused by bacteria or fungi. Cultures from other sites including urine, cerebrospinal fluid, wounds, respiratory

## CLINICAL SKILL 42.1 Venepuncture

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Disposable gloves<br>Tourniquet<br>Vacutainer access device/2–23 g needle and syringe/ butterfly 21–23 g with Vacutainer attachment<br>Pathology test tubes<br>Sharps container<br>Alcowipes<br>Gauze square or cotton ball<br>Tape<br>Pathology form and pen |

| **Skill activity** | **Rationale** |
|---|---|
| Perform hand hygiene<br>Explain procedure to the individual<br>Verify individual's identity against the pathology form | Prevents cross-infection<br>Reduces anxiety/apprehension and gains individual's trust and cooperation<br>Reinforces consent of individual |
| Collect equipment | Ensures all equipment ready for procedure |
| Place tourniquet about 15 cm above intended puncture site (above the elbow or wrist joint) and clip ends together and tighten firmly, so that two fingers can fit under comfortably<br>Palpate the distal pulse to ensure the artery not occluded | Helps to distend vein<br>Prevents discomfort due to tourniquet being too tight<br>Helps prevent complications |
| Locate the vein by palpating using the index and middle fingers of your non-dominant hand<br>Ask the individual to open and close their hand to increase dilation of the vein<br>Once the vein is located, release tourniquet<br>Perform hand hygiene and don gloves<br>Reapply tourniquet | Palpating for the vein enables assessment of the vein through touch (bouncy and full of blood)<br>Facilitates filling of the vein and distension<br>Facilitates refill of the vein<br>Prevents cross-infection |
| Cleanse the area with an alcowipe and wait 30 seconds for the area to dry<br>Insert the needle tip into the vein by stabilising the vein, stretching the skin taut<br>The needle should be parallel to the vein and above it with the angle of insertion approximately 15–30 degrees<br>Once the tip of the needle is in the vein attach the tubes one by one to the Vacutainer (or gently pull plunger back on syringe) and fill each tube with blood<br>Releasing of the tourniquet may be required for certain blood tests to prevent haemolysis | Prevents the introduction of microorganisms and ensures proper antiseptic preparation of skin<br>Enables the smooth entry into the vein and prevents the vein from moving around<br>Going in too deep can lead to puncturing the vein through and causing a haematoma<br>Haemolysis can interfere with an accurate result |
| Once the required tubes are filled and the tourniquet released, support the insertion site with the gauze or cotton ball (do not push down) and withdraw the needle<br>Apply pressure to the puncture site and ask the individual to continue putting pressure on the site if able | Prevents discomfort to the site<br>Prevents excessive bleeding and a haematoma from forming |
| Label and sign the tubes of blood and verify the individual's details<br>Sign the pathology form and place form and tubes in the required pathology bag | Abides by organisational guidelines and ensures the correct results for the correct individual<br>Enables proper transporting of tubes |
| Check the puncture site to ensure the bleeding has stopped and change the gauze/cotton ball if required and apply tape<br>Inform individual to notify you if any further bleeding, pain at the site or a haematoma forms | Prevents complications from the procedure |

| CLINICAL SKILL 42.1 Venepuncture—cont'd | |
|---|---|
| Dispose of the equipment in the appropriate waste receptacle ensuring the sharps are placed in the sharps container<br>Perform hand hygiene | Abides by infection prevention policies and procedures<br>Prevents needlestick injury<br>Prevents cross-infection |
| Send blood specimens to pathology in a timely manner<br>Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical officer | Ensures blood tests are as fresh as possible for accurate results<br>Appropriate care can be planned and implemented |
| *(Crisp & Taylor 2013; Phillips & Gorski 2014; Centers for Disease Control and Prevention 2011; Tollefson et al 2012)* | |

secretions or other sources of body fluid which may harbour infection should be obtained prior to commencement of antibiotics only if doing so will not cause significant delay in antibiotic administration.

Diagnostic imaging studies should also be performed in order to detect a potential source of the infection. Once a source of infection has been identified a sample should be obtained for a more targeted treatment regimen. In addition the source of infection can be drained which improves the likelihood that treatments will work (Dellinger et al 2013).

## Medical management

The European Society of Critical Medicine in conjunction with the International Sepsis Forum and the Society of Critical Care Medicine have developed 'The Surviving Sepsis Campaign' (Surviving Sepsis 2015). The aim of the campaign is to decrease mortality and morbidity associated with sepsis by providing health professionals with guidelines for the early recognition and treatment of sepsis (Kent & Fields 2012).

Treatment of sepsis should begin within the first hour of diagnosis. Treatment includes commencing broad-spectrum antibiotics and/or antifungal agents within 1 hour of diagnosis.

Once the causative pathogen has been identified antimicrobials must be reassessed to provide a more targeted approach to treatment. Antimicrobials must be assessed daily to ensure the individual is responding to treatment and to determine when medications can be reduced. This is essential to decrease the likelihood that the affected individual will develop resistance to or toxicity from the treatment. Antimicrobial treatment will typically be required for 7–10 days. Some individuals will require longer antimicrobial treatment if they are not responding adequately (Dellinger et al 2013).

Oxygen therapy should be commenced at high doses to stabilise oxygen saturations (Steen 2009). Studies have shown that there is no difference in individual outcomes when fluid resuscitation is performed with colloid solutions in comparison with crystalloids (normal saline).

Fluid resuscitation for individuals with sepsis or severe sepsis should be commenced using crystalloids within 1 hour of diagnosis (Guidet et al 2012) (refer to Clinical Skill 42.2: Central venous access device management). The aim is to maintain blood pressure greater than >100 systolic blood pressure (SBP). When crystalloids are not adequate to maintain the individual's blood pressure albumin should be commenced (Delaney et al 2011). In some cases fluid resuscitation will not be enough to maintain the individual's blood pressure. When this occurs additional medications will be required to cause vasopressin. The first-line drug for vasopressin is noradrenaline with the aim of achieving a mean arterial pressure of 65 mmHg. If noradrenaline is not enough to maintain blood pressure, adrenaline can be given. For certain individuals (those with no bradycardia or who have a low risk of tachyarrhythmias) dopamine may be used as an alternative to noradrenaline (De Backer et al 2012). Any individual who requires vasopressors in order to maintain blood pressure will require an arterial line (Dellinger et al 2013). See Table 42.7 for supportive therapies used in severe sepsis and Clinical Interest Box 42.5 for central venous access device information.

### DECISION-MAKING FRAMEWORK EXERCISE 42.1

You are performing a ward round with the RN you have been allocated to work with. One of the individuals under your care has an IV medication due to be given. The individual has a CVC which is being used to give IV medications. You are new to this ward and have never cared for a CVC line or given medications via one. While you have the required knowledge to give the medication you do not have the confidence to do so. The RN you are working with insists that hospital policy is that you, as an EN, can administer medications via a CVC. You have not had time to look up the policy.

Using the decision-making framework, determine if you are able to give this medication.

## CLINICAL SKILL 42.2 Central venous access device management: dressing, removal and medication administration

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Sterile gloves<br>Disposable gloves<br>Sterile dressing pack<br>Occlusive dressing<br>Chlorhexidine in alcohol solution 70%<br>Sterile bungs/caps<br>Stabilisation device<br>Extra sterile gauze squares<br>Suture remover<br>Specimen container<br>Waste bag |

Refer to Clinical Skill 24.7 Administration of intravenous medications: infusion and bolus (p 600) for medication administration

| **Skill activity** | **Rationale** |
|---|---|
| Perform hand hygiene<br>Explain procedure to the individual<br>Verify individual's identity<br>Check organisation's policies and procedures | Prevents cross-infection<br>Reduces anxiety/apprehension and gains individual's trust and cooperation<br>Reinforces consent of individual<br>Abides by organisation's policies and procedures |
| Collect equipment | Ensures all equipment ready for procedure |
| Open a sterile dressing pack and place any additional equipment within easy reach | Prevents cross-infection<br>Prevents the introduction of microorganisms |
| **Dressing change**<br>Don disposable gloves and gently peel back old dressing towards the insertion site, anchoring the catheter<br>Remove stabilisation device (if PICC line)<br>Inspect for signs of infection<br>Measure length of catheter from the insertion site to the tip | Prevents cross-infection<br>Prevents the dislodgement of the catheter<br>Used generally on PICC lines<br>Assesses for complications, which may need further management<br>Identifies external catheter migration |
| Remove gloves, perform hand hygiene (as per policy) and don sterile gloves<br>Cleanse skin with chlorhexidine in alcohol solution and ensure catheter is cleaned also with the solution<br>Wait for alcohol to dry<br>Place stabilisation device onto skin in the correct place (if PICC line)<br>Apply occlusive dressing over the catheter insertion site including the stabilisation device (if PICC line)<br>Note: If changing bungs/caps on the central line refer to policy and procedure | Prevents the introduction of microorganisms and ensures asepsis<br>Prevents cross-contamination<br>Ensures full antisepsis has been achieved<br>Secures the catheter to prevent dislodgement<br>An occlusive dressing allows the area to breathe by preventing moisture under the dressing, preventing infection<br>Allows monitoring for any signs of infection |
| **Catheter removal**<br>Confirm medical order for removal of central catheter<br>Position the individual in a supine position<br>Don disposable gloves and gently peel back old dressing towards the insertion site, anchoring the catheter<br>Remove stabilisation device (if PICC line)<br>Inspect for signs of infection | Abides by legal and organisation guidelines<br>Reduces the risk for air embolism during catheter removal<br>Prevents cross-infection<br>Prevents the dislodgement of the catheter<br>Used generally on PICC lines<br>Assesses for complications, which may need further management |

## CLINICAL SKILL 42.2 Central venous access device management: dressing, removal and medication administration—cont'd

| | |
|---|---|
| Remove gloves, perform hand hygiene (as per policy) and don sterile gloves<br>Cleanse skin with chlorhexidine in alcohol solution and ensure catheter is cleaned also with the solution<br>Wait for alcohol to dry<br>Remove any sutures<br>Ask the patient to perform the Valsalva manoeuvre (breathing in and out a couple of times and then inhaling and holding)<br>Place a piece of sterile gauze over the insertion site and gently remove the catheter from the vein in one smooth motion, leaving the gauze in situ once removed<br>Place the tip of the catheter on the sterile field of the dressing tray<br>Check the site for any bleeding or exudate and place a piece of sterile gauze over the site covering it with an occlusive dressing<br>Note: If the tip is to be sent to pathology, cut the tip with sterile scissors and place tip in a sterile specimen container<br>Sign and label container and complete the pathology form correctly | Prevents the introduction of microorganisms and ensures asepsis<br>Prevents cross-contamination<br>Ensures full antisepsis has been achieved<br>Reduces the risk of air embolism during catheter removal<br>Do not force catheter, as it may break apart. If any resistance, stop the procedure, cover with a sterile dressing and inform the nurse in charge/doctor<br>Reduces the risk of contamination<br>Prevents post-removal air embolism and the introduction of microorganisms<br>The doctor may want to test for any microorganisms |
| Place individual into a comfortable position and ask the individual to inform you of any difficulty breathing, pain or oozing from the site<br>Dispose of equipment in the correct waste receptacle and perform hand hygiene | Promotes comfort<br>Prevents complications<br>Abides by infection prevention policies and procedures<br>Prevents cross-infection |
| Monitor individual for any adverse effects<br>Report and document all relevant information correctly in the healthcare record. Communicate abnormal findings to the Registered Nurse/medical office | Appropriate care can be planned and implemented |

*(Crisp & Taylor 2013; Phillips & Gorski 2014; Centers for Disease Control and Prevention 2011; Tollefson et al 2012)*

## CLINICAL INTEREST BOX 42.5 Central venous access device (CVAD) management

For individuals with severe illness CVADs are essential for their treatment (Johansson et al 2013). CVADs are small, flexible tubes that are inserted into the superior vena cava (Chong et al 2012). They are inserted to provide long-term vascular access and can be used for blood sampling, total parenteral nutrition, chemotherapy and long-term antibiotics (Nayeemuddin et al 2013).

As with any procedure, insertion of a CVAD has associated risk factors including arterial puncture and infection (Nayeemduddin et al 2013). Once inserted the main risks are to patency of the tube (Bolton 2013) and catheter migration (Gabriel 2013). To prevent tube blockage it is important to flush the tube adequately after access (refer to hospital policy). To decrease the risk of catheter migration it is essential that the CVAD is secured appropriately (Gabriel 2013). The CVAD site must be monitored regularly for signs of infection.

There are three main types of CVADs: PICC lines, tunnelled CVCs and implantable ports.

Each hospital will have different policies and procedures regarding the care of CVADs. As an EN it is important that you understand your scope of practice with CVADs. Some hospitals will not allow ENs to care for individuals with CVADs. Other hospitals will allow an EN to care for an individual with a CVAD but not manage the CVAD and others will allow the EN all responsibility for the CVAD. Hospital policy will also differ on which types of CVADs ENs can manage.

Refer to Chapter 24 for more information on medication administration.

**TABLE 42.7 | Supportive therapies for severe sepsis**

| Therapy | Rationale |
|---|---|
| Blood product administration | Red blood cell administration required when haemoglobin <7.0 g/dL<br>Fresh frozen plasma and antithrombin therapies NOT to be used<br>Platelets to be used prophylactically when results are <10 000/mm$^2$ |
| Immunoglobulins | Not recommended for use |
| Mechanical ventilation for sepsis-induced acute respiratory distress syndrome (ARDS) | Individual will be cared for in the ICU<br>Head of the bed should be elevated to 30–45 degrees to decrease the risk of aspiration |
| Sedation, analgesia and neuromuscular blockade | Sedation should be kept to a minimum for mechanically ventilated individuals<br>Neuromuscular blocking agents should not be used in individuals without ARDS |
| Glucose control | Insulin to be commenced based on blood glucose levels<br>Blood glucose levels to be taken every 1–2 hours until stabilised |
| Renal replacement therapy | When renal failure has occurred haemodialysis will be required |
| DVT prophylaxis | Daily clexane or other preventative medication injections are required<br>TED stocking to be applied if possible |
| Stress ulcer prophylaxis | Administration of a proton pump inhibitor for individuals with known risk |
| Nutrition | Oral or enteral feeding as tolerated<br>Low dose feeding in the first week<br>Intravenous glucose and enteral nutrition is recommended rather than using total parenteral nutrition (TPN) |

*(Dellinger et al 2013)*

### Nursing care

The best treatment for sepsis is prevention, which all nurses must aim to achieve by being diligent with handwashing and the use of aseptic technique and standard and additional precautions. Goals of care should be discussed with both the affected individual and their family. Many individuals with multiple organ failure will not survive. In some cases the involvement of the palliative care team is required (Dellinger et al 2013).

## CLINICAL PATHWAYS

A **clinical pathway** is best described as a multidisciplinary, locally approved plan of care for an individual based on guidelines and, wherever possible, evidenced for a particular individual group (Duffy et al 2011).

The clinical pathway was introduced in the 1980s in the US to meet the needs of healthcare professionals and improve quality of care for individuals (Duffy et al 2011). The main aim is to encourage standardisation of care for all individuals (Neuman et al 2009) with similar requirements throughout a specific time frame by providing clinical standards and expected outcomes (D'Entermont 2009; Neuman et al 2009).

The development of clinical pathways combines an evidence-based approach with local policy and procedure and current practice to develop a process map which in turn is developed into a pathway. The pathway enables less variation and more transparency in individual care (Baker et al 2012). In Australia, The National Safety and Quality Health Service Standards recommend the use of clinical pathways. They recommend that clinical pathways are developed using best practice guidelines (ACSQHC 2012).

Clinical pathways are most advantageous when individual outcomes are predictable, thus ensuring that the individual receives relevant clinical interventions and assessments (Allen et al 2009). While clinical pathways cannot be used for all individuals, in 80% of cases a clinical pathway is indicated (Duffy et al 2011). Pathways provide a daily care plan for the individual, and include guidelines on assessment, treatment, activities of daily living, nutrition, education, referrals to be made and discharge planning (D'Entermont 2009). An example care plan has been provided in Nursing Care Plan 42.1.

## NURSING CARE PLAN 42.1

**Assessment:** Imbalanced nutrition, less than body requires related to ongoing nausea and vomiting, anorexia and dietary restrictions
**Issue/s to be addressed:** Weight loss
**Goal/s:** To stabilise individual's weight within 1 month

| Care/Actions | Rationale |
|---|---|
| Commence food chart | To monitor individual's nutritional intake |
| Commence daily weight | To monitor individual's weight |
| Provide anti-emetic medication 30 minutes prior to meals | To prevent nausea and vomiting during meals |
| Refer to nutritionist | To advise individual on dietary requirements |
| Encourage small, frequent meals | To increase calorie intake throughout the day |
| Encourage high-energy drinks | To increase calorie intake throughout the day |

**Evaluation**

After 1 month the individual's weight should have stabilised.

## PROGRESS NOTE EXAMPLE 42.1

| | |
|---|---|
| 09/06/2015<br>1430 hrs | Nursing: Individual is day 3 of 7 for antibiotic treatment for right lower leg cellulitis. Individual is alert and orientated. Pain 4/10 in right lower leg. Analgesics provided as per medication chart, nil further complaints of pain. Temp 37.0, HR 78, BP 126/78. Right lower leg remains swollen, nil further progression of cellulitis—refer to wound chart. Individual showered with minimal assistance this am. Tolerating FWD and fluids. All medications provided as per medication chart. Individual currently sitting out of bed with right leg elevated. For physio and OT review tomorrow.<br>***F. Daly* (Daly) EN** |

The novice nurse can find pathways especially helpful by providing a guide as to what is expected of the individual on any given day (D'Entermont 2009). However, it is not just the novice nurse who benefits from clinical pathways; even the most experienced nurse will encounter individual conditions they are unfamiliar with and the pathway will enable them to provide the most appropriate care for these individuals.

Clinical pathways can form all or part of the individual's medical records (Duffy et al 2011). At the end of a shift, providing there has been no variation from the pathway, the nurse responsible for the individual's care signs off that all expected outcomes and interventions have been met. When a variation from the plan has occurred the nurse is expected to document this in the individual's progress notes. An example of an entry into progress notes has been provided in Progress Note Example 42.1.

Studies have shown that clinical pathways improve individual outcomes, promote decision making and may lead to shorter hospital stays and reductions in readmission (Allen et al 2009). Shorter hospital stays are achieved as clinical pathways act as an organisational device by encouraging proactive interventions and the use of relevant resources for the individual (Allen et al 2009). However, not all individuals are appropriate for clinical pathways. Clinical pathways are not effective when care needs to be flexible, such as with the care of the individual post cerebrovascular accident (Allen et al 2009). Clinical pathways can never replace professional clinical judgment (D'Entermont 2009).

## Summary

This chapter has presented some common and not-so-common conditions the Enrolled Nurse may encounter when working in the acute, aged or community care sectors. It has explored the area of acute care provided in venues other than hospitals and presented an introduction to clinical pathways. There are many acute conditions the Enrolled Nurse will come across, in various settings, and this introduction, along with further reading, provides a general introduction to a broad range of conditions that may be seen in acute settings.

## Review Questions

1. You suspect your individual had cellulitis. What are the common sites the infection originates from?
2. What are the two (2) conditions that are included under the term venous thromboembolism?
3. Identify the major risk factors associated with the development of a DVT.
4. What does a positive D-dimer test indicate?
5. Outline the treatment of an individual who has been diagnosed with a pulmonary embolism.
6. Describe diverticulitis.
7. List the clinical manifestations of diverticulitis.
8. What is a preceding factor for the development of Guillain–Barré syndrome?
9. Explain the pathophysiology of Guillain–Barré syndrome.
10. Provide a cause of each stage of acute renal failure.
11. What two (2) conditions must be present for a diagnosis of sepsis?
12. Where are the common sites that a sepsis infection originates?
13. Define the term clinical pathway.
14. What is the main aim of clinical pathways?
15. For what individuals are clinical pathways most appropriate?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER
43

# Nursing in the perioperative care environment

*Karen Stilo*

## KEY TERMS

anaesthesia
intraoperative
perioperative
postoperative
preoperative
surgery

## LEARNING OUTCOMES

At the completion of this chapter, and with further reading, students should be able to:

- Define the key terms
- Describe the nature of the operative experience and outline the phases it entails
- Describe the individual care roles of the perioperative nurse
- Describe the general physiological, psychological and local responses to surgical intervention
- Describe the various classifications of surgical procedures
- Define informed consent and discuss the role of the nurse in ensuring consent
- Assist in planning and implementing preoperative and postoperative nursing care for the individual who requires surgical intervention

## CHAPTER FOCUS

Perioperative nursing encompasses the care of an individual who is undergoing a surgical procedure. Care takes place from the time the decision is made to have surgery, through to recovery from the procedure. Throughout the perioperative period it is essential that there is a flexible multidisciplinary team approach to ensure continuity of individual care from admission, throughout the surgical experience to recovery at home. It is important for the nurse to be familiar with the types of surgery an individual is likely to undergo in order to plan and implement adequate and individualised care and to provide appropriate psychological support. 'The care encompasses safe and effective management in collaboration with other healthcare team members; the nurse also safeguards the individual's integrity by acting as an advocate for individuals during their perioperative experience' (Hamlin et al 2009).

This chapter provides an overview of the perioperative period, which comprises the preoperative, intraoperative and postoperative phases as well as the specific physiological and psychological support that each phase requires.

## LIVED EXPERIENCE

I remember feeling very nervous and scared for my daughter, Emily (4 years old), when she had to have her tonsils removed. When we arrived at the operating theatre from the ward I expected to have to leave her there, and I was dreading the upset that would cause us both. The nurse in the waiting area was very kind and understanding; she explained everything and got me dressed in a white covering, shoe covers and a cap, which made Emily laugh. I was allowed to stay with Emily in the actual operating room right up until she was asleep, and was called from the ward as soon as she was in recovery. My face was the first she saw when she woke up. This made a scary situation so much easier for Emily and for me; they even put an IV wrapped in a bandage on Emily's teddy bear!

**Brooke 2015**

# PERIOPERATIVE CARE

The individual's experience of **perioperative** care is divided into three phases. Both Registered Nurses (RNs) and Enrolled Nurses (ENs) may work in any or all of the roles during the phases described below. These phases are fully described later in this chapter:

1. Preoperative phase
2. Intraoperative phase
3. Postoperative phase.

Perioperative nurses are RNs and ENs who fulfil the roles of circulating nurse (scout), instrument nurse (scrub), anaesthetic and postanaesthesia recovery nurse (see Table 43.1). The responsibilities of these nurses are specialised and multifaceted. The principal aim is to ensure that holistic, clinically effective, evidence-based care and support is given to the individual throughout their perioperative experience. The perioperative nurse provides this care alongside other members of the multidisciplinary team, in an environment that is challenging, changing and fast paced. The nurse acts as the individual's advocate and provides continued and effective communication with the individual, their significant others and the surgical team. The nurse undertakes efficient assessment and intervention, maintains accountability for their own practice, documents care and emphasises individual safety in all phases (Crisp et al 2013; Hamlin et al 2009).

In Australia professional standards, guidelines and policy statements for perioperative nursing are set by the Australian College of Operating Room Nurses (ACORN). ACORN's ongoing focus is the improvement, standardisation, education and support of perioperative nursing care (Hamlin et al 2009).

# SURGERY

Undergoing surgery is an experience that is unique to the individual; a person faces numerous stressors when confronting surgery. The anticipation of having a surgical procedure may incite fear and anxiety. Some individuals associate having surgery with pain, disfigurement, loss of independence and even death. It is important for the perioperative nurse to quickly establish rapport with individuals, listening to them so that their concerns are heard and relieved. What individuals all have in common is the fact that in the perioperative environment they are at their most vulnerable and reliant on the skills and knowledge of the multidisciplinary team to achieve an optimal outcome.

## The purpose of surgery

**Surgery** is performed for a variety of reasons:

- Diagnostic—surgical exploration that allows the surgeon to confirm a diagnosis; tissue may be removed for further diagnostic testing
- Ablative—excision or removal of a diseased body part
- Constructive—restores lost or reduced function resulting from congenital abnormalities
- Reconstructive—restores appearance or function to tissues that are traumatised or malfunctioning

**TABLE 43.1 | Role responsibilities of the perioperative nurse**

| | |
|---|---|
| Anaesthetic nurse | • Collaborate and assist the anaesthetist during preparation, induction, maintenance and emergence phases of the anaesthetic<br>• Anticipate and provide equipment/supplies for routine and emergency anaesthetic procedures<br>• Assist the individual to maintain a clear airway<br>• Individual assessment and monitoring<br>• Assessment/documentation of fluid balance<br>• Assist with individual transfer and positioning before and after surgery<br>• Individual advocate, especially when anaesthetised<br>• Evaluate effectiveness of planned care<br>• Collaborate with PACU staff to provide individual care |
| Circulating (scout) nurse | • Anticipate the needs of the surgical team before/during surgery<br>• Monitor any breach in aseptic technique and initiate corrective action<br>• Perform the surgical count with the instrument nurse<br>• Correct handling and labelling of surgically removed human tissue and implanted items<br>• Advocate for the anaesthetised individual<br>• Documentation of intraoperative nursing care |
| Instrument (scrub) nurse | • Prepare the instruments and equipment needed in the operation<br>• Anticipate the needs of the surgical team before/during surgery<br>• Adhere to and maintain aseptic technique throughout the procedure<br>• Monitor any breach in aseptic technique and initiate corrective action<br>• Perform the surgical count with the circulating nurse<br>• Correct handling of surgically removed human tissue and implanted items<br>• Documentation of intraoperative nursing care |
| Postanaesthetic nurse | • Individual assessment and airway management<br>• Individual observation and monitoring<br>• Perform resuscitation<br>• Management of acute pain, nausea and vomiting<br>• Management of the individual's fluid balance<br>• Documentation of nursing care during the immediate postoperative period<br>• Prompt acting on and reporting of aberrant changes in the individual's condition to anaesthetist/surgeon<br>• Provision of a comprehensive individual handover to the nurse caring for the individual in the receiving unit |

*(Hamlin et al 2009)*

- Cosmetic—performed to improve the individual's personal appearance
- Palliative—alleviates or reduces the intensity of disease symptoms; will not cure the disease (Crisp et al 2013).

## Classifications of surgery

Surgery is classified under the descriptors of risk and urgency. The classification of the surgery for each individual may change during the course of the disorder, depending on the time lapse between identification of the need for surgery, any increase in symptoms and the time surgery occurs (see Table 43.2).

## Responses to surgical intervention

There is a degree of risk with any surgical procedure. Various factors and conditions increase an individual's risk during surgery. Knowledge of the risk factors allows the nurse to appropriately plan individual care. Some of these risk factors include:

- Age—very young and very old people are at risk during surgery due to their physiological status being immature or declining (see Table 43.3)
- Nutrition—the need for adequate nutrition is intensified by surgery; normal tissue repair and resistance to infection is dependent on sufficient nutrients
- Obesity—the bariatric (obese) individual is at an increased surgical risk due to reduced ventilatory and cardiac function. Diabetes, hypertension, coronary artery disease and congestive heart failure are common in the bariatric population. They are also susceptible to wound infections and poor wound healing due to the structure of fatty tissue which contains deficient blood supply
- Fluid and electrolyte balance—the body responds to surgery as a form of trauma: the more extensive the surgery the more severe the stress. The degree of fluid and electrolyte imbalance is influenced by the severity of the stress response evoked.

### Physiological responses

In response to surgical invasion, the body mobilises defences to maintain homeostasis. Most of these mechanisms are

**TABLE 43.2 | Classifications of surgery**

| | | |
|---|---|---|
| Risk | Major | Increased degree of risk if complicated or prolonged<br>Vital organs involved<br>Potential for large blood loss<br>Postoperative complications more likely |
| | Minor | Usually involving small amount of risk<br>Fewer complications likely |
| Urgency | Emergency | Surgery to preserve the individual's life, body part or body function |
| | Elective | Category 1: urgent cases, surgery within 30 days for a condition that could quickly deteriorate<br>Category 2: semi-urgent, surgery within 90 days for conditions of pain, dysfunction or disability unlikely to deteriorate quickly to an emergency<br>Category 3: non-urgent, surgery within 180 days for conditions causing minimal pain, dysfunction or disability and which do not have the potential to become an emergency |

*(Adapted from Department of Human Services 2009). © State of Victoria)*

generally favourable to survival and healing. If, however, the mechanisms are prolonged or uncontrolled, they may contribute to the development of complications. Table 43.4 outlines the physiological responses to the stress of surgery.

### Local responses to tissue injury

After injury, local inflammatory reactions occur to promote healing. A surgical incision, even though created under sterile and controlled conditions, still constitutes injury or insult. The inflammatory response begins with the creation of a surgical wound, and the normal sequence of tissue replacement and wound healing must occur to ensure tissue recovery. The physiology of wound healing involves a specific sequence of events and is discussed in Chapter 29, as are influences on healing and the specific care of wounds.

### Psychological responses

As a result of psychological stress related to surgical intervention, the individual may experience changes in mood and/or behaviour, including:

- Anxiety, which may be related to the procedure itself, or to associated factors, including changed social circumstances, loss of independence or privacy, separation from family/support people, financial hardship or prolonged recovery time
- Depression
- Fear of anticipated pain, concern of mutilation or decreased function, dread of death, panic of waking up under anaesthetic
- Grief associated with loss of health or a body part, self-image change, altered function or presence of a scar
- Anger
- Impaired judgment
- Reduced willpower
- Inability to concentrate and/or remember
- Intolerance of noise and other stimuli
- Emotional unpredictability
- Aimless non-productive activities.

See Table 43.6 (p 1247) for information about medications with special implications for the surgical client.

## PREOPERATIVE CARE

The **preoperative** phase begins when surgical intervention is first considered, and ends when the individual is transferred to the operating table. This phase may be of short duration if the individual is taken directly to an operating room from the emergency department or transferred soon after admission to a surgical unit. The duration depends on a number of factors, such as the amount of time required to prepare the individual adequately for surgery. The preoperative phase may begin with the individual as an outpatient in a designated pre-admission clinic, where preoperative investigations are undertaken prior to the individual's procedure. In Australia it is now common practice for an individual, depending on the type of surgery to be performed, to be admitted for same-day surgery. In this instance the individual is admitted in the early or late morning depending on the time of the operation or procedure. The individual is prepared for and undergoes surgery, is recovered from the anaesthetic, is cared for in the day surgery unit (DSU) after the procedure and is discharged home on the same day. Individuals undergoing surgery who will require inpatient care are also, in most cases, admitted through the DSU as a day of surgery admission (DOSA). DOSA individuals are taken to theatre from the DSU and are taken to the ward from the recovery room. DOSA individuals require comprehensive preparation and teaching about home recovery. Follow up at home (often by telephone) must be available for continuity of care to occur. Day-stay surgery is suitable for less complex surgical procedures or invasive techniques for which some anaesthesia is required (e.g. endoscopy). These units are staffed by both RNs and ENs.

Day surgery is now well established throughout Australia, in both the public and the private sectors. Currently up to 60% of all procedures are undertaken as day patient procedures. At present, day surgery is widely practised in over 240 freestanding day surgery centres. Many large public hospitals and over 320 private hospitals around Australia have designated DSUs in place (Australian Day Surgery Council 2004).

## TABLE 43.3 | Physiological factors that place older adults at risk during surgery

| Alterations | Risks | Nursing implications |
|---|---|---|
| **Cardiovascular system** | | |
| Degenerative change in myocardium and valves | Reduced cardiac reserve | Assess baseline vital signs<br>Recognise the longer time period required for heart rate to return to normal following stress on the heart, and evaluate the occurrence of tachycardia accordingly |
| Rigidity of arterial walls and reduction in sympathetic and parasympathetic innervation to heart | Alterations predispose individual to postoperative haemorrhage and rise in systolic and diastolic blood pressure | Maintain adequate fluid balance to minimise stress to the heart<br>Ensure blood pressure level is adequate to meet circulatory demands |
| Increase in calcium and cholesterol deposits within small arteries; thickened arterial walls | Predispose individual to clot formation in lower extremities | Instruct individual in techniques for performing leg exercises and proper turning<br>Apply elastic stockings, sequential compression devices (SCDs)<br>Administer anticoagulants as prescribed by healthcare provider<br>Provide education regarding effects, side effects and dietary considerations |
| **Integumentary system** | | |
| Decreased subcutaneous tissue and increased fragility of skin | Prone to pressure ulcers and skin tears | Assess skin every 4 hours; pad all bony prominences during surgery<br>Turn or reposition at least every 2 hours |
| **Pulmonary system** | | |
| Decreased respiratory muscle strength and cough reflex (Thomas & Adcock 2014) | Increased risk for atelectasis | Instruct individual in proper technique for coughing, deep breathing and use of spirometer. Ensure adequate pain control to allow for participation in exercises. |
| Reduced range of movement in diaphragm | Residual capacity (volume of air left in lung after normal breath) increased, reducing amount of new air brought into lungs with each inspiration | When possible, have individual ambulate and sit in chair frequently |
| Stiffened lung tissue and enlarged air spaces | Blood oxygenation reduced | Obtain baseline oxygen saturation; measure throughout perioperative period |
| **Renal system** | | |
| Decreased renal function, with reduced blood flow to kidneys | Increased risk of shock when blood loss occurs; increased risk for fluid and electrolyte imbalance (Thomas & Adcock 2014) | For individuals hospitalised before surgery, determine baseline urinary output for 24 hours |
| Reduced glomerular filtration rate and excretory times | Limits ability to eliminate drugs or toxic substances | Assess for adverse response to drugs |
| Reduced bladder capacity | Increases the risk for urgency, incontinence and urinary tract infections (Thomas & Adcock 2014) (sensation of need to void often does not occur until bladder is filled) | Instruct individual to notify nurse immediately when sensation of bladder fullness develops<br>Keep call light and bedpan within easy reach<br>Toilet every 2 hours or more frequently if indicated |

**TABLE 43.3 | Physiological factors that place older adults at risk during surgery—cont'd**

| Alterations | Risks | Nursing implications |
|---|---|---|
| **Neurological system** | | |
| Sensory losses, including reduced tactile sense and increased pain tolerance | Decreased ability to respond to early warning signs of surgical complications | Inspect bony prominences for signs of pressure that individual is unable to sense<br>Orient individual to surrounding environment<br>Observe for non-verbal signs of pain |
| Blunted febrile response during infection (Thomas & Adcock 2014) | Increased risk of undiagnosed infection | Ensure careful, close monitoring of patient temperature; provide warm blankets; monitor heart function; warm intravenous fluids (Thomas & Adcock 2014). |
| Decreased reaction time | Confusion and delirium after anaesthesia; increased risk for falls | Allow adequate time to respond, process information and perform tasks. Perform fall risk screening and institute fall precautions. Screen for delirium with validated tools. Orient frequently to reality and surroundings |
| **Metabolic system** | | |
| Lower basal metabolic rate | Reduced total oxygen consumption | Ensure adequate nutritional intake when diet is resumed, but avoid intake of excess calories |
| Reduced number of red blood cells and haemoglobin levels | Ability to carry adequate oxygen to tissues is reduced | Administer necessary blood products<br>Monitor blood test results and oxygen saturation |
| Change in total amounts of body potassium and water volume | Greater risk for fluid or electrolyte imbalance occurs | Monitor electrolyte levels, and supplement as necessary<br>Cardiac monitoring (telemetry) as needed |

*(Potter & Perry 2013:1259)*

The advantages to the individual and their relatives include considerable reduction in cross-infection risk compared with individuals who remain in hospital; decreased risk of thromboembolism associated with early ambulation; less anxiety for the individual as an overnight stay in hospital is avoided, particularly in the case of children for whom minimal separation from parents is beneficial, and for the older individual who may become disoriented when subjected to unfamiliar surroundings for extended periods of time. The individual will have a quicker return to normal activities with less time off work and less stress for their relatives, saving time, travel and in some cases the need for accommodation to visit an inpatient in hospital (Australian Day Surgery Council 2004; Timmins & McCabe 2009).

Another trend is that overall length of stay in hospital after surgical procedures is decreasing. With this practice of earlier discharge comes the implication that individuals may go home with complex medical and nursing needs and will require suitable follow up with visiting nurses, or involvement in a 'Hospital in the Home' or a 'Rehabilitation in the Home' program. See also Chapter 40.

The overall aim of preoperative preparation is to ensure that the individual is in the best physical and psychological condition possible before undergoing surgery. It is essential to gather appropriate data concerning the individual's health status through the taking of baseline observations and a detailed and accurate nursing history. Nursing assessment is based on the data collected and includes the identification of actual and potential problems that may be faced by the individual throughout any phases of the perioperative period. Although certain aspects of preoperative preparation are similar for most surgical procedures, other factors are specific, depending on the individual's condition and the type of operation to be performed. (See Nursing Care Plan 43.1.)

Preoperative preparation generally consists of:

- Providing information
- Teaching activities (e.g. deep breathing and coughing techniques and leg exercises)
- Examination of the individual by the anaesthetist and surgeon
- Performing laboratory tests and diagnostic studies
- Gaining the individual's informed consent

**TABLE 43.4 | Physiological responses to the stress of surgery**

| Response | Purpose |
|---|---|
| Increased peripheral vasoconstriction and blood coagulation | Prevents excessive blood and fluid loss |
| Increased rate and strength of heart beat, and dilation of the coronary arteries | Maintains cardiac perfusion and oxygenation |
| Increased reabsorption of sodium ions from the kidneys, causing retention of sodium and water | Maintains blood volume, blood pressure and cardiac output |
| Decreased peristalsis in the gastrointestinal tract | Reduces metabolic activity which is non-essential in the short-term emergency |
| Relaxation of smooth muscle that promotes dilation of the bronchioles | Improves gas exchange and tissue oxygenation |
| Increased breakdown of protein | Increases the availability of amino acids for repair of tissues |
| Proliferation of connective tissue | Promotes wound healing |
| Increased circulation of glucose and mobilisation of stored fat | Provides required energy |
| Increased basal metabolic rate | Provides required energy and nutrients for the tissues |

## NURSING CARE PLAN 43.1

**Scenario:** Thea, 36 years old, is a recent arrival in Australia from Yemen. She is booked for a cone biopsy of the cervix due to a Pap smear result showing moderate changes. When she arrived it was apparent that she was severely distressed and fearful. With careful questioning it became clear that Thea believed she was having a much more invasive surgery that would result in her feeling she would no longer be a functioning woman.
**Assessment:** Preoperative emotional/psychological assessment
**Issue/s to be addressed:** Anxiety, fear of surgery related to misinformation/misunderstanding and cultural issues
**Goal/s:** Individual to verbalise reduced anxiety, a clear understanding of, and acceptance/informed consent to, the surgical procedure

| Care/Actions: | Rationale: |
|---|---|
| Encourage individual to verbalise cause of anxiety<br>Explain and describe in simple terms the exact nature of the surgical procedure using diagrams if required | To ensure the understanding of the nurse assessing her in the waiting area<br>To enhance communication and aid in the understanding and informed consent of the individual |

**Evaluation**
Preoperatively with follow up in PACU.

- Preparation of the individual both psychologically and physically.

## Providing information

Initial assessment of each individual's knowledge base should be undertaken, even if the person's past surgical experiences are extensive. The individual needs to be informed about all pre- and postoperative procedures and care because knowledge and understanding promote feelings of being in control, and a sense of control helps to relieve anxiety. The information given to individuals and, as appropriate, to their significant others should include:

- Preoperative procedures to be performed and the reasons for them; for example, restriction of food and fluids, cessation of smoking or preparation of the operation site
- Immediate preparation; for example, insertion of an intravenous (IV) cannula, the administration of pre-medication and the induction of anaesthesia, and what sensations may be experienced

- Details of the recovery phase in the postanaesthetic care unit (PACU) before returning to the ICU, HDU, DSU or the ward
- Postoperative situations to be expected; for example, the presence of an IV infusion or wound drain, and why these are necessary
- Postoperative activities; for example, deep breathing and coughing, early mobilisation and why they are important
- Anticipated pain or discomfort, and options for how this will be managed
- Any additional information specific to the operation to be performed.

The information must be provided in such a way that the individual can understand it, and it should be repeated if necessary. This is essential, as anxiety about hospitalisation and/or the surgical procedure may influence the individual's ability to process and retain information. The most helpful teaching program is designed so that all individuals receive the same information.

## Teaching activities

Preoperative teaching (see Clinical Interest Box 43.1) can help to reduce anxiety and stress, and teaching specific activities that the individual can undertake to promote their own recovery gives them a positive role to play. In some cases the individual may visit a specialty postoperative area; that is, an intensive care unit (ICU) as familiarity with environments that will be encountered during or after surgery may help reduce the stress associated with the surgical experience.

### CLINICAL INTEREST BOX 43.1 Teaching activities

- Deep breathing and coughing techniques to facilitate gas exchange and expectoration of accumulated mucus. The individual assumes a sitting position and takes several deep breaths followed by a short breath and cough. Alternatively, the individual may be taught to take a deep breath, hold it for 2–3 seconds then cough several times while exhaling. The individual will be taught to support any wounds with hands, or by splinting with a pillow, to reduce pain and facilitate deep breathing
- Leg exercises performed to stimulate blood circulation and enhance venous return to reduce the risk of a DVT. The individual is instructed how to bend the knees and contract the hamstring and quadricep muscles, then to dorsiflex and plantarflex the feet (see Chapter 28)
- Moving and changing position helps to prevent complications such as skin breakdown and DVT. The individual will be informed of any special equipment, or techniques that will be required for movement, and of any restrictions to movement

### CRITICAL THINKING EXERCISE 43.1

Identify the preoperative information and teaching you would provide for an individual who is having endoscopic surgery to remove his gallbladder (cholecystectomy).

## Physical examination

The anaesthetist and a medical officer each perform a thorough physical examination of the individual. The anaesthetist pays particular attention to the individual's cardiovascular and respiratory systems to evaluate the general level of function and to identify any problems that may cause difficulty during induction or maintenance of anaesthesia, such as an upper airway abnormality, which may make placement of an endotracheal tube difficult, or a spinal condition which may hinder regional anaesthesia. Loose or prosthetic teeth will be identified and noted on the admission chart. The anaesthetist also evaluates possible sites for peripheral or central venous cannulation. After assessing the individual, the anaesthetist may prescribe any preoperative medications deemed necessary to be administered prior to surgery.

## Laboratory tests and diagnostic studies

Laboratory tests and diagnostic studies help detect any risk factors or possible issues. Specific tests and studies performed depend on the individual's condition and on the nature and complexity of the operation. Ideally, diagnostic tests are carried out with sufficient time before the scheduled procedure to allow for correction of any detected problems.
Tests can include, but are not limited to:

- Blood type and cross-match, for procedures in which significant blood loss is anticipated or possible
- Arterial blood gas and pH, to check respiratory function and oxygenation
- Blood urea nitrogen, to check renal function
- Full blood examination (FBE)
- Prothrombin and/or plasma thromboplastin time, clotting factors, especially if the individual has been on anticoagulant therapy
- Serum electrolytes, including sodium and potassium levels
- Liver function studies
- Chest x-ray
- Electrocardiogram
- Pulmonary function studies
- Urinalysis.

## Medical history

Individuals will present at the ward for admission, with varied health and illness backgrounds. Some may have chronic illness, others a recent diagnosis that may or may not be related to the reason for this surgical admission. Many existing disorders will have an impact on the individual's recovery

**TABLE 43.5 | Medical conditions that increase the risks of surgery**

| Type of condition | Reason for risk |
|---|---|
| Bleeding disorders (thrombocytopenia, haemophilia) | Increase risk of haemorrhaging during and after surgery |
| Diabetes mellitus | Increases susceptibility to infection and impairs wound healing from altered glucose metabolism and associated circulatory impairment. Stress of surgery often causes increase in blood glucose levels |
| Heart disease (recent myocardial infarction, arrhythmias, congestive heart failure) and peripheral vascular disease | Stress of surgery causes increased demands on myocardium to maintain cardiac output. General anaesthetic agents depress cardiac function |
| Obstructive sleep apnoea | Administration of opioids increases risk of airway obstruction postoperatively. Individuals will desaturate as revealed by drop in $O_2$ saturation by pulse oximetry |
| Upper respiratory infection | Increases risk of respiratory complications during anaesthesia (e.g. pneumonia and spasm of laryngeal muscles) |
| Liver disease | Alters metabolism and elimination of drugs administered during surgery and impairs wound healing and clotting time because of alterations in protein metabolism |
| Fever | Predisposes individual to fluid and electrolyte imbalances and may indicate underlying infection |
| Chronic respiratory disease (emphysema, bronchitis, asthma) | Reduces individual's means to compensate for acid–base alterations. Anaesthetic agents reduce respiratory function, increasing risk for severe hypoventilation |
| Immunological disorders (leukaemia, acquired immune deficiency syndrome (AIDS), bone marrow depression and use of chemotherapeutic drugs or immunosuppressive agents) | Increase risk of infection and delayed wound healing after surgery |
| Abuse of street drugs | Persons abusing drugs sometimes have underlying disease (HIV, hepatitis) that affects healing |
| Chronic pain | Regular use of pain medications often results in higher tolerance. Increased doses of analgesics are sometimes necessary to achieve postoperative pain control |

*(Potter & Perry 2013:1258)*

from surgery, and surgery may have an impact on the severity or management of the existing disorder. See Table 43.5 for an outline of common medical conditions that may increase the risk of surgery. The nurse needs to be aware of the potential challenges to an optimal recovery for these individuals, in order to plan and implement effective care in all phases of the perioperative experience. The nurse also needs to be aware of the effect that the individual's medications for these medical problems may have on their ability to cope with the stresses of surgery and recovery. See Table 43.6.

## Informed consent

Before an operation is performed, the individual must give informed consent which should be freely given without coercion. Informed consent involves the surgeon providing the individual with enough information to understand the nature and consequences of the proposed procedure and informing the individual about the facts and possible risks relating to the surgery concerned, in terms that ensures understanding by the individual. The individual then consents, in writing, to have the operation. The surgeon and the individual must both sign a consent form, an important part of the documentation process that formalises the individual's agreement to undergo surgery. The nurse is not responsible for obtaining the individual's consent, but the nursing role includes checking that informed consent has been obtained and making appropriate notifications if this is found not to be the case. In some agencies, nurses are asked to witness

**TABLE 43.6 | Medications with special implications for the individual undergoing surgery**

| Drug class | Effects during surgery |
|---|---|
| Antibiotics | Antibiotics potentiate (enhance action of) anaesthetic agents. If taken within 2 weeks before surgery, aminoglycosides (gentamicin, tobramycin, neomycin) may cause mild respiratory depression from depressed neuromuscular transmission |
| Antiarrhythmics | Antiarrhythmics (e.g. beta-blockers such as metoprolol (Lopressor)) can reduce cardiac contractility and impair cardiac conduction during anaesthesia |
| Anticoagulants | Anticoagulants, such as warfarin (Coumadin), alter normal clotting factors and thus increase risk of haemorrhaging. Discontinue at least 48 hours before surgery. Aspirin is a commonly used medication that alters clotting mechanisms |
| Anticonvulsants | Long-term use of certain anticonvulsants (e.g. phenytoin (Dilantin) and phenobarbitone) alters metabolism of anaesthetic agents |
| Antihypertensives | Antihypertensives, such as beta-blockers and calcium channel blockers, interact with anaesthetic agents to cause bradycardia, hypotension and impaired circulation. They inhibit synthesis and storage of noradrenaline in sympathetic nerve endings |
| Corticosteroids | With prolonged use, corticosteroids, such as prednisone, cause adrenal atrophy, which reduces the body's ability to withstand stress. Before and during surgery, dosages are often temporarily increased |
| Insulin | Individuals' need for insulin changes after surgery. Stress response and intravenous (IV) administration of glucose solutions often increase dosage requirements after surgery. Decreased nutritional intake often decreases dosage requirements |
| Diuretics | Diuretics such as furosemide (Lasix) potentiate electrolyte imbalances (particularly potassium) after surgery |
| Non-steroidal anti-inflammatory drugs (NSAIDs) | NSAIDs (e.g. ibuprofen) inhibit platelet aggregation and prolong bleeding time, increasing susceptibility to postoperative bleeding |
| Herbal therapies: ginger, ginkgo, ginseng | These herbal therapies have the ability to affect platelet activity and increase susceptibility to postoperative bleeding. Ginseng is reported to increase hypoglycaemia with insulin therapy |

*(Potter & Perry 2013)*

consent forms, but the act of witnessing only verifies that this is the person who signed the consent, and that it was given voluntarily. It does not relate to the individual's actual knowledge or understanding of the procedure. (More information on informed consent is provided in Chapter 2.)

## Psychological preparation

To minimise anxiety and prepare the individual psychologically for the proposed procedure, the nurse must ensure that all relevant information is provided. People generally experience anxiety when they are facing the unknown, and anxiety is usually reduced somewhat when accurate and relevant information is supplied. The nurse must ensure that the individual and the significant others are given opportunities to ask questions and to express any concerns they may have. It is important for the nurse to recognise that procedures that seem relatively minor or routine may not appear that way to individuals or to their significant others. The prospect of any surgical intervention raises many fears about body image alteration, loss of control, pain or even the possibility of death. Some of the many factors that the individual may be worried about include:

- What will happen while they are unconscious
- Whether the surgeon will start the operation before the anaesthetic is effective
- Fear of experiencing severe pain
- Length of hospital stay
- Who will care for their family or pets
- How long it will be before it is possible to return to work.

The family or significant others may also be worried, especially if the diagnosis is questionable or the outcome of the surgery is difficult to determine. If they choose to remain in the hospital while the operation is being performed, the

nurse should ensure that they know where the waiting area is located and where they can obtain refreshments. If they prefer to remain at home they should be given an indication of what the notification process is; for example, if the surgeon will contact them after the procedure and at what time, and whom and when they can call to obtain information.

### Providing cultural safety

Providing healthcare, not only for individuals but for members of minority ethnic groups whose care is defined and influenced by social disadvantage, is a concept defined as cultural safety (Hamlin et al 2009).

The traditional values and religious beliefs of members of Indigenous groups in Australia and New Zealand are emphasised in the literature on this concept, also referred to as cultural competence. An example of this is outlined by Hamlin and colleagues (2009) in a case study on a Māori individual's wish to have an amputated limb returned to him and his family for burial, rather than sent for destruction as is the usual practice.

This requirement is not unique to Māori people, so nurses and other healthcare members in the perioperative environment need to be mindful of the policy and procedure for similar cases and be aware that there is usually a system in place for meeting most of the traditional beliefs of many cultures. 'It is important that nurses display cultural competency in their professional practice' (Kralik & van Loon 2011). This competency can be evidenced by a sensitivity to varied beliefs and values in all areas of healthcare and a willingness to accommodate these wherever possible.

Another example is the requirement for modesty in Muslim women. There are various degrees of dress requirements while in the presence of males other than family members, with some women adopting robes that cover all but the eyes, others allowing only the face to be visible, while most keep limbs covered. 'The requirement for modesty can affect healthcare as some patients may be reluctant to expose their bodies for examination or to expose areas not directly affected' (Queensland Health and Islamic Council of Queensland 2010).

With knowledge of the likely traditional or religious beliefs affecting some individuals, and some forethought, most of these beliefs can be accommodated in the perioperative environment. The responsibility for arranging any accommodations lies with all the stakeholders, from the individual to the ward staff and those working in the operating room. Case Study 43.1 provides an example of how traditional or religious beliefs should be accommodated.

### CASE STUDY 43.1 CULTURAL CASE STUDY

A Muslim woman was admitted to the holding bay of a public hospital prior to undergoing an elective gastroscopy/colonoscopy for diagnostic purposes. She arrived wearing a head covering over her hospital issue gown and a long-sleeved gown over that.

The ward staff indicated that she was unwilling to expose her hair or her limbs in public.

The perioperative nurse was happy for the individual to wear her scarf as long as she wore a paper cap over the top to which the individual was agreeable.

The (female) anaesthetist was able to reassure the individual that she would insert an IV access for the sedation into the back of her hand and therefore not expose her arms. The individual agreed that, should an emergency occur, she consented to exposure of other areas, like her chest, to allow resuscitation.

Problems occurred when the individual realised that she would have to expose her genital area to both the male scout nurse and the male gastroenterologist for the purposes of the colonoscopy. She stated that she expected that female staff only would be present in the theatre.

A female scout nurse was available from another theatre; however, the male gastroenterologist was the only one present on the day. The individual refused the procedure and was discharged to return another time when staffing could be arranged to suit.

1. Could this situation have been avoided? How?
2. Was the situation handled appropriately? If not, explain why not.
3. Identify some interventions that could be made to improve cultural understanding in the perioperative environment and better prepare patients and staff for the perioperative experience.

## Physical preparation

Ideal surgical conditions include an individual who is haemodynamically stable, with no current clinical infection, and with well-controlled pre-existing medical conditions. Depending on the individual's condition and the type of operation to be performed, specific measures may be implemented to minimise or eliminate any identified risks. For example, an individual with breathing problems may be required to undergo active therapy such as incentive spirometry (inhalation into a specially designed spirometer, to achieve maximum inspiratory capacity and reduce risk of pulmonary consolidation) or elimination of pulmonary secretions by postural drainage (the use of positioning to drain secretions from specific segments of the lungs). An individual with dehydration or poor nutritional status may be admitted for some time before surgery so that fluid and nutritional deficiencies may be corrected. A specific diet may be prescribed, such as low fibre before bowel surgery. A person with potential for infection may be administered prophylactic antibiotics prior to the operation. Other preoperative measures may include comprehensive preparation of the gastrointestinal tract and preparation of the skin (see Table 43.7).

Physical preparation may also include cessation or modification of certain medication administration; for example, aspirin and other anticoagulant drugs. Cessation of smoking should also be encouraged.

**TABLE 43.7 | Physical preparation for surgery**

| Preparation type | Method and rationale |
|---|---|
| Gastrointestinal | Fasting: to empty the stomach and prevent aspiration of stomach contents during anaesthesia. Individuals undergoing procedures under local anaesthetic may still be requested to fast in case a general anaesthetic needs to be used. Long-term fasting (over more than 6 hours) will ensure a clear operative view of the internal bowel for open and endoscopic procedures. Fasting status of individual ensured by nurse |
| | Bowel cleansing: orally taken preparations (Picolax, Fleet) will ensure the bowel is clear for gastrointestinal and some gynaecological procedures. Reduces contamination in open bowel procedures and allows clear view for colonoscopy and sigmoidoscopy. Bowel preparation undertaken by individuals at home prior to admission unless an inpatient where the nurse will ensure application of preparation |
| | Enema: may be required for individuals suffering from depressed gastrointestinal activity to prevent postoperative constipation |
| Skin | Shower: individuals will be requested to shower before surgery; the nurse will ensure this for inpatient as part of the surgical preparation. Some surgeons require that the shower be performed using antibacterial preparations |
| | Removal of hair: clipping, razoring or shaving of hair near the operative site is done as near as possible to the time of surgery, usually in the operating room, to prevent bacterial colonisation due to possible skin scratches. Some authorities state that, unless hair is thick enough to interfere with the surgery, it is preferable to leave it intact. Hair removal is performed by the surgeon, the technician or the nurse |
| | Antiseptic prep: when individual is anaesthetised, and prior to draping, the operative site and beyond is painted with an antiseptic skin preparation of the surgeon's choice. Skin preps may have an aqueous or alcoholic base and are applied by the scrub nurse or the surgeon using sterile gauze pads |
| Medication | Individual's own: the surgeon or anaesthetist may have temporarily discontinued some or all medications, or adjusted dosages. Otherwise, medications should be given as normal with a minimal amount of water |
| | Preoperative: some medications may be ordered for some individuals. These may be to reduce anxiety (rarely prescribed), reduce secretions (salivary, gastric, bronchial), open airways (pre-anaesthetic for COPD individuals) or to provide local constriction of vessels for haemostasis (ENT cases). The nurse needs to be alert to any medications, such as sedation, that should not be given prior to giving instruction to individual, or gaining consent |

*(Rothrock 2015)*

## Preparation of the individual immediately prior to surgery

Although preparation during the 1–2 hours preceding an operation may vary slightly depending on the individual and type of operation, preparation generally involves various standard procedures. These include:

- Measuring and documenting height and weight. Knowledge of the individual's weight (mass) enables drug dosages based on body weight to be calculated accurately. It is also useful for comparison as progress is monitored postoperatively, especially in relation to assessment of fluid balance status
- Measuring and documenting vital signs. Any deviation from previous results must be reported immediately and documented, as abnormalities may result in postponement of the operation. These preoperative measurements serve as a baseline for comparison as the individual's progress is monitored postoperatively
- Urinalysis, which is generally performed and documented. Any abnormalities must be reported immediately. As the kidneys excrete most drugs from the body, any sign of kidney dysfunction is significant
- Ensuring that the individual is not wearing any nail polish, lipstick, talcum powder or other cosmetics that could interfere with assessment of skin colour (pallor and cyanosis) or circulatory and oxygen saturation status
- Ensuring that jewellery, hairpins, prosthetic devices, spectacles, contact lenses or hearing aids are removed

and stored safely. Spectacles and hearing aids are usually worn to the operating room then removed and kept for the individual in recovery. Each healthcare agency has its own policy regarding the wearing of wedding rings and earrings; for example, these may be left on and secured in position with adhesive tape. This is to prevent loss of the jewellery or damage to the individual if jewellery is caught or dislodged in the course of the surgery

- Whether any dentures or plates are left in the individual's mouth depends largely on the anaesthetist's instructions. Usually dentures are left in situ, but partial plates or bridges are removed before surgery, as they may be dislodged during endotracheal intubation. It is important to check the presence of any loose teeth for the same reason.
- Attending to general hygiene and comfort needs by ensuring that appropriate clothing is worn and assisting the individual to dress if necessary. Generally a plain cotton open-back gown with tie-tapes is worn. A disposable paper cap is also worn to cover the individual's hair, and some facilities also provide disposable paper undergarments worn under the gown.
- Checking that the individual's identification bands (usually two) are correct and in situ. In some agencies a red identification band is worn if the individual has any known allergies. It is also important to check all documents that will accompany the individual to the operating room.

### Documentation

Each healthcare facility has its own preoperative forms and checklist. Usually, these checklists will require checking by the ward nurse, the operating room receiving nurse (holding bay or anaesthetic nurse) and the PACU (recovery room) nurse.

Included for checking on these lists are the other documents that are necessary to remain with the individual such as consent form, x-rays, medication charts, postoperative orders and others. See Clinical Interest Box 43.2 for an example of such a checklist and Clinical Interest Box 43.3 for information about paediatric individuals in the preoperative environment.

## INTRAOPERATIVE PHASE

Perioperative nurses undertake a variety of roles within the operating suite. These include circulating (scout) nurse, instrument (scrub) nurse, anaesthetic nurse and recovery room (PACU) nurse (see Table 43.1). The circulating nurse is responsible for the documentation and management of all accountable items opened onto the sterile field. The scout supports the instrument nurse by being aware of the requirements of the surgical team and makes certain all supplies are deposited on to the surgical field aseptically. The circulating nurse performs the surgical count with the instrument nurse, and undertakes other responsibilities including individual positioning, individual safety issues, specimen collection, provision of equipment and being the communication link between theatre staff and those outside. The role of circulating or instrument nurse may be undertaken by an EN or RN. The instrument nurse is the one who assumes primary responsibility and accountability for all items used during the surgical procedure. The instrument nurse sets up all sterile instruments and supplies, and hands instruments to the operating team anticipating their needs. Nursing practices and interventions in the **intraoperative** phase also include establishing personal contact and supporting the individual emotionally in the highly technical environment of the operating room. Protocols relating to the promotion of individual safety are another area of paramount importance, as during surgery, and particularly under anaesthesia, individuals are unable to protect themselves from many sources of possible harm.

All personnel who enter the theatre complex wear clean scrub outfits, hair covers and shoe covers, with additional sterile gowns, gloves, masks and eye protection during procedures. Strict surgical asepsis is mandatory throughout the surgical area, and all persons in the operating room must be alert to possible contamination of sterile items. Staff must consider their responsibilities in relation to the spread of infection and restrict or modify working if they have an upper respiratory or skin infection (ACORN 2014). (See Chapter 22 for further information on the control and prevention of infection, surgical scrub and surgical asepsis.)

Anaesthetic and PACU nurses are often referred to as perianaesthesia nurses. The anaesthetic nurse provides primary support to the anaesthetist and the individual immediately prior to the surgical procedure by carrying out individual assessment and preparation, assists the anaesthetist during intubation and the administration of the anaesthetic, helps during the operation and assists with waking the individual from the anaesthetic. The anaesthetic nurse works under the direct supervision of the anaesthetist and is responsible for the preparation of the required equipment, monitoring and pharmacology. Immediately following the procedure the individual is transferred to the PACU where they are cared for by the PACU/recovery room nurse. The PACU nurse is responsible for airway assessment and management, individual observations, identification and prompt correct action in case of surgical or anaesthetic complications. Postoperative pain and nausea management, accurate documentation of care and administration of medication as ordered are also roles of the PACU nurse. All these roles work collaboratively, with the individual roles dependent upon each other to work as a multidisciplinary team that aims to provide evidence-based best practice and optimal individual outcomes (ACORN 2014).

The anaesthetic nurse will notify the DSU or the ward that theatre is ready for the individual. The individual is brought to a preoperative holding bay or anaesthetic room where it is identified that they are the correct individual, any allergies are highlighted, fasting status is determined and the consent form is checked. The anaesthetist will insert an intravenous (IV) cannula and may give the individual some

## CLINICAL INTEREST BOX 43.3 Preoperative preparation of a child

- Young children are usually placed first, where appropriate, on the surgical list for the day, to prevent extended fasting and added anxiety
- Children need to be informed as to what is happening, in lay terms, to the level of the child's understanding
- Children are encouraged to bring a favourite toy with them to theatre to alleviate some anxiety; the toy may be used to explain procedures and/or have a dressing applied to the same site as the child's area for surgery
- Waiting time in the holding bay should be as brief as possible
- One parent or guardian is encouraged to accompany the child into the theatre to provide support until anaesthetised
- Where possible, if a child is traumatised by the prospect of IV insertion, the child may initially receive a gas induction, with IV insertion done when unconscious
- To alleviate distress it is helpful to have a parent or guardian waiting to be called to PACU to be present when the child wakes
- Young children and babies can usually have food or drink as soon as they are awake after a minor procedure. A distressed baby will usually settle well with a bottle upon awakening
- Children should be recovered in PACU in an area precluding a view of other, adult individuals who may have had major surgeries

medication to relax them; they are then transferred into the operating room and onto the operating table. ECG, blood pressure and oxygen saturation monitoring is applied, the individual is positioned, padding to prevent injury to nerves and to minimise pressure over bony prominences is strategically placed and safety straps secured to maintain the individual's position. Draping and preparation for surgery commences, ensuring the correct operation site is prepared.

It is important that the individual is correctly positioned according to the procedure being performed. Surgical positioning is an activity commonly performed by the technician, anaesthetic nurse, circulating nurse and, often, the surgeon and anaesthetist to ensure that the position is appropriate for the procedure and safe for the individual. Common positions used for surgery with potential risks outlined are illustrated in Table 43.8.

## Induction of anaesthesia

In most cases, an operative procedure requires some degree and type of **anaesthesia**, but not all procedures require a full general anaesthetic. There are different means by which anaesthesia can be achieved. Factors influencing the choice of anaesthetic include the nature of the surgery (length and complexity of operation), the individual's status (pre-existing medical conditions), anatomical and physiological conditions and, to some degree, individual preference. Anaesthetics can be classified as general anaesthetics, regional anaesthetics and local anaesthetics.

### General anaesthetic

General anaesthesia promotes unconsciousness, absence of sensation, loss of reflexes and muscle relaxation. Administration is primarily by IV injection, inhalation or a combination of both. The four components of general anaesthesia are amnesia, analgesia, muscle relaxation and unconsciousness. Ventilation during general anaesthetic is separated into spontaneous or controlled. Individuals whose ventilation is controlled have usually been administered muscle relaxants.

The three phases of general anaesthetic are induction, maintenance and emergence:

1. Induction—begins when the anaesthetic agents are administered and ends when the individual is ready for positioning, prepping or incision. Intubation occurs during this phase
2. Maintenance—continues from the end point of induction until the procedure is nearly complete. This

## TABLE 43.8 | Common positions for surgery

| Position | Possible surgical procedures/rationale | Pressure risks and other health and safety concerns |
|---|---|---|
| Supine  | Open and laparoscopic, abdominal, renal and pelvic surgery<br>Upper and lower limb surgery<br>Thoracic surgery<br>Allows clear, safe access for surgeon and anaesthetist | Back of head, elbows, sacrum, heels need gel pads to prevent pressure injury<br>Risk of overextension of arms at axilla with potential for nerve damage |
| Lateral  | Thoracic surgery<br>Lower limb surgery<br>Spinal surgery<br>Dorsal and buttock surgery<br>Allows clear, safe access for seated surgeon | Elbows, hip, knees and ankles. Gel pads required, with pillow/gel pad placed between knees. Padded back support and padded straps required to keep in position.<br>Risk of movement/fall if not secured properly, risk of injury from metal supports if not padded/covered |
| Reverse Trendelenberg  | ENT and head and neck surgery<br>Breast surgery<br>Allows clear, safe access for surgeon and anaesthetist<br>Head up tilt provides best view for surgeon, arms may be taped to the sides for better access | Back of head, elbows, sacrum, heels need gel pads to prevent pressure injury<br>Foot support or raised legs to prevent slide<br>Risk of overextension of arms at axilla with potential for nerve damage<br>Anaesthetic (BP) implications with head raised for long periods |
| Trendelenberg  | Open and laparoscopic lower abdominal and pelvic surgery<br>Allows clear, safe access for surgeon and anaesthetist<br>Uses gravity to help clear the area of upper abdominal organs and structures | Back of head, elbows, sacrum, heels need gel pads to prevent pressure injury<br>Shoulder support to prevent slide<br>Risk of overextension of arms at axilla with potential for nerve damage<br>Anaesthetic (BP) implications with lowered head and compressed diaphragm |
| Prone  | Spinal surgery<br>Dorsal and buttock surgery<br>Lower limb surgery<br>Allows clear access for surgeon | Head/face, elbows, hips, knees, feet need gel pads as in diagram to cushion and allow for expansion of chest<br>Implications for anaesthetist with access to airway<br>Care to be taken to ensure ventral body parts are correctly placed |

*(Bouyer-Ferullo 2013)*

phase is sustained with titrated doses or continuous infusion of IV drugs, or inhalation of anaesthetic gas
3. Emergence—begins when the individual starts to emerge from anaesthesia and ceases when the individual is ready to be transferred from the operating room to PACU. Extubation is usually carried out during emergence.

### Regional anaesthetic

Regional anaesthesia is a form of local anaesthesia; it results in loss of sensation to an area by blocking the conduction of nerve impulses to and from specific sites in the body. The anaesthetist injects an anaesthetic agent around nerves, thereby anaesthetising the area those nerves supply. The effect is dependent on the type of nerve concerned. Sensory (pain) nerves are more readily blocked than motor nerves, so some movement may remain. With these methods of anaesthesia the individual is often awake during the procedure, but the area targeted for surgery is without sensation.

With regional anaesthesia there is no loss of consciousness; therefore, considerations should be made for the fact that the individual can still feel pressure and hear sound. The nurse must be sensitive that the environment is quiet and therapeutic, with no unnecessary conversation about the individual, their diagnosis or the procedure being performed. Dependent on the operation being performed the anaesthetist may administer mild sedation to relieve anxiety or dull the individual's awareness of their surroundings. Regional anaesthesia is administered by infiltration and local application, including:

- Spinal (intrathecal) anaesthesia: an injection of local anaesthetic into the cerebrospinal fluid (CSF) within the subarachnoid space at the lumbar level. The extent of anaesthesia can be from the xiphoid process down to the feet. Spinal anaesthesia is frequently used for surgical obstetrics, lower extremity, lower pelvic and lower abdominal procedures
- Epidural anaesthesia: local anaesthetic is injected into the epidural space, via an inserted catheter allowing a continuous infusion or intermittent boluses to be delivered. Epidural anaesthesia is frequently used in obstetric procedures and for postoperative pain relief
- Caudal block anaesthesia: injection of a local anaesthetic into the caudal (sacral) portion of the spinal canal
- Peripheral nerve block anaesthesia: injection of a local anaesthetic into a specific site, such as the brachial plexus, to block a group of sensory nerve fibres.

### Local infiltration

Local infiltration anaesthesia is the injection of an anaesthetic solution into the tissues at the incision site. Loss of sensation occurs at a targeted site; for example, a skin lesion or a wound requiring sutures. Local anaesthesia is commonly used for minor procedures in DSUs or consultants' surgeries. Surgeons may infiltrate local anaesthetic to an operative area to enhance postoperative pain relief.

Anaesthetic agents may also be applied topically, as a cream, spray or drops applied to the skin or mucous membranes. Common local anaesthetic agents for infiltration, injection or for topical use include lignocaine, bupivacaine and procaine (Crisp et al 2013).

## Safe surgery

### Universal protocol

To ensure that individuals receive the correct operation on the correct site at all times, checkpoints and checklists are in place. The World Health Organization has adopted a three-step process called the Universal Protocol to be used to prevent error (WHO 2009) (see Clinical Interest Box 43.4).

### Count protocol

The counting of surgical instruments and other accountable items is a practice that has changed vastly in fairly recent times. While some agencies may have variations on a theme, it is desirable that they follow the guidelines set out in the ACORN Standards. *Standard S3: Counting of Accountable Items Used during Surgery* (2014) sets out step-by-step procedures related to counting items and dealing with incorrect count situations. Included in this standard are recommendations that those who document the addition of an item, or insertion of an item, are also responsible for ensuring the removal, or out-counting of said item. It also recommends that, in the event of an incorrect count, the individual remain in theatre, under anaesthesia if possible, until the count is correct. This may need to be determined with the use of x-ray to either confirm or totally disprove the presence of an accountable item left in the individual. This standard, along with agency-led protocols, is designed to prevent scenarios such as those set out in Critical Thinking Exercises 43.2 and 43.3.

# POSTOPERATIVE CARE

After completion of the operation the individual is transferred to PACU, which is located within the operating theatre complex. The individual is accompanied by the anaesthetist who will hand over to the PACU nurse the individual's general condition, the operation performed, the type of anaesthesia used for the procedure and any complications encountered during the surgery and anaesthesia. Immediate assessment of the individual's airway, heart rate, respirations, temperature and oxygen saturations are performed and recorded and blood loss is noted. Once these initial observations have been made it is essential to systematically assess the individual, either head to toe or by systems: central nervous system (CNS), cardiovascular system (CVS), respiratory system (Resp), gastrointestinal tract (GIT), urinary function, wounds, drain tubes, fluid management, skin integrity and pallor. The individual is not transferred back to the ward until fully awake, conscious and alert, motor and sensory functions have begun to return, vital signs are stable, pain is controlled and there are no immediate complications from the anaesthetic or surgery. A verbal handover is given by

## CLINICAL INTEREST BOX 43.4 Safe surgery

| | |
|---|---|
| **Step 1** | **Verification**<br>Consists of verifying the correct individual, site and procedure at every stage from the time a decision is made to operate to the time the individual undergoes the operation |
| **Step 2** | **Marking**<br>The Universal Protocol states that the site or sites to be operated on must be marked. This is particularly important in case of laterality, multiple structures (e.g. fingers, toes, ribs) and multiple levels (e.g. vertebral column) |
| **Step 3** | **Time out**<br>The 'time out or 'surgical pause' is a brief pause before the incision to confirm the individual, the procedure and the site of operation. It is also an opportunity to ensure that the individual is correctly positioned and that any necessary implants or special equipment are available.<br>The Joint Commission stipulates that all team members be actively involved in this process. Any concerns or inconsistencies must be clarified at this stage. The checks during the time out must be documented, potentially in the form of a checklist, but the Universal Protocol leaves the design and delivery to individual organisations |

recovery room staff to day surgery or ward staff receiving the individual, including any allergies, anaesthetic, analgesic and antiemetic drugs administered, details of the procedure, postoperative orders, as well as any other information relating to the individual's condition.

## Preparation of the individual's day surgery or ward environment

While an individual is in the operating suite, the day surgery or ward nurse prepares the individual's bed area ready for their return. As discussed earlier, in many agencies it is common practice for individuals to be transferred to theatre on their beds. The remaining linen, including the top bedclothes, are folded into a pack and stored in the bed area, which enables them to be unfolded over the individual quickly and with minimal disruption on return to the ward. Generally, one pillow is placed at the head of the bed, and the remaining pillows are placed in a convenient location in the room (see Chapter 23 for more information on making an operation or surgical bed). If the individual is a day surgery individual they will return to the DSU on a trolley. The

## CRITICAL THINKING EXERCISE 43.2

An individual who underwent a septoplasty procedure had a throat pack inserted by the anaesthetist which was documented on the intraoperative count record by the nursing staff. The anaesthetist did not record that the throat pack was inserted. The pack was not documented as being removed at the final count. Neither the instrument nurse nor the circulating nurse checked to confirm removal.

When the individual arrived in the postanaesthetic recovery unit the anaesthetist was questioned by the circulating nurse as to whether he had remembered to remove the throat pack—he had not. The individual was checked immediately. The individual was questioned by the anaesthetist as to whether they felt any discomfort in the throat and replied that no discomfort was felt. When a visual check was done there were no signs indicating the presence of the pack. The individual had no respiratory distress at this time and was quite comfortable. The situation was explained fully to the individual and their family. The individual had their throat x-rayed but no pack was observed, so an upper abdominal x-ray was ordered and it revealed the pack in the individual's stomach. The pack was removed via gastroscopy (Department of Human Services 2008a). What procedure was not followed to allow this event to occur? Whose responsibility was it to ensure removal of the pack was documented? Whose responsibility was it to check the documentation before the individual was sent to PACU?

## CRITICAL THINKING EXERCISE 43.3

An individual underwent a laparotomy for ulcerative colitis surgery. During the skin closure it was identified by the instrument nurse that an artery forcep was missing. The nurse told the circulating nurse and other members of the surgical team. A thorough search of the operating room environment failed to find the instrument. Subsequently an x-ray was taken in the postanaesthetic recovery unit where the artery forcep was revealed in the abdominal cavity. The individual was returned to the operating room where the artery forcep was retrieved (Department of Human Services 2008b). What procedure was not followed in this scenario? Whose responsibility was it to ensure that the forcep was accounted for before removal of the individual to PACU? Is it ideal that an individual be returned to theatre after reaching PACU? If not why not?

furniture in the room should be arranged to provide easy access for equipment; for example, the bed may be positioned away from the wall, and the over-bed table and locker should be positioned away from the bedside. The equipment required in the room will depend on the type of operation that was performed, but generally includes:

- Oxygen and suction apparatus
- IV therapy pole

### CASE STUDY 43.2 ELECTIVE HYSTERECTOMY

Mrs Jones, 45, is an elective category 3 individual who is to undergo an open hysterectomy. The surgery has been recommended as she has suffered with increasing blood loss and a lowering of Hb over the past 2 years, due to fibroids in the uterus.

She will return to the ward with an IDC in situ and a PCA (patient-controlled analgesia) unit.

1. What is the longest time Mrs Jones should have waited for her surgery?
2. What effect could an extended wait have on her health status?
3. Describe some fears or anxiety Mrs Jones may have in regard to her surgery.
4. Identify a psychological issue Mrs Jones could face in regard to body image, self-esteem.
5. What are likely to be the problems and potential problems for Mrs Jones immediately on return to the ward?
6. What nursing interventions could be implemented to prevent or reduce these problems?

- Postoperative assessment forms (e.g. a chart for frequent observations)
- Equipment for assessing the individual's vital signs
- Covered emesis bowl
- Hangers or holders for drainage bags.

Case Study 43.2 explores a scenario of preparation for post-surgical care.

### CRITICAL THINKING EXERCISE 43.4

You are asked to prepare a room for the return of an individual from surgery after an abdominal hysterectomy. The individual will have IV therapy and may have a urinary catheter and a wound drain in situ.

1. What supplies do you need?
2. How would you arrange the room?
3. When the individual returns to the ward, how often will you need to take vital signs?

What else will you assess? How often will you conduct these other assessments?

## Immediate general postoperative care and assessment

When individuals are transferred back to the DSU or the ward, an appropriate position is selected depending on their condition and the type of operation. Initially, this is often a lateral position, to promote a clear airway while the individual is still recovering from the anaesthetic (see Chapter 23). The upper bedclothes are placed over the individual to promote maintenance of body temperature and comfort. If an IV infusion is in progress, the bag of solution is suspended on a pole or stand, and the infusion is assessed to determine whether it is flowing at the prescribed rate. The individual's arm, in which the IV cannula is inserted, is positioned so that there is no obstruction to the tubing. Any drainage bags, such as urinary or wound-drainage bags, are placed in a holder or hanger and positioned to facilitate drainage by gravity.

Early postoperative assessment of the individual involves monitoring and reporting (see Chapter 19):

- Level of consciousness—although some drowsiness and disorientation is normal after a general anaesthetic, it should be possible to rouse the individual by verbal stimuli or touch. Orientation to person, place and time gradually return. Inability to rouse the individual should be reported immediately. After local or regional anaesthesia it is important to monitor for the return of normal sensation and movement to the anaesthetised area. Generalised restlessness should also be reported as it may be due to a change in the level of consciousness or may be associated with pain, discomfort, respiratory difficulties or haemorrhage. It is important during the early postoperative phase that details of the individual's condition and diagnosis should not be inappropriately discussed as the individual may be able to hear, even if not fully awake
- Colour—report any significant changes to the individual skin colour (extremely pale or cyanosed)
- Vital signs—any deviation from previous readings of temperature, pulse, respirations, oxygen saturation or blood pressure is reported immediately. If ordered, oxygen therapy is administered and monitored
- Presence of discomfort or pain—as individuals recover from the effects of anaesthetic, they may begin to feel pain. The level of pain experienced may vary according to the type of anaesthesia used; for example, after a spinal anaesthetic the operative area may still feel relatively numb until several hours after the procedure. The presence of any discomfort or pain must be assessed and reported immediately so that appropriate pain-relieving measures can be implemented
- Wound dressing—in the immediate postoperative period, assessing for haemorrhage is a major responsibility of the nurse. Both the dressing and the bed linen under the individual should be checked for evidence of haemorrhage; an increase in blood staining on the dressing, or a sudden increase of blood in a drainage tube or bag, must be reported immediately. Body cavities that have had a surgical pack inserted (nasal or vaginal packs) also require close observation
- Urinary catheters—if the individual has an indwelling catheter, the nurse must monitor the urinary output carefully. Absence of, or decreased amount of, urinary output must be reported; similarly, any unexpected presence of blood in the urine needs to be documented and reported.

See Table 43.9 for a quick reference guide to immediate care. Progress Notes Example 43.1 also shows how an entry in progress notes may be documented.

**TABLE 43.9 | Immediate general postoperative care and assessment**

| | |
|---|---|
| ABC | Level of consciousness |
| | Recovery position or semi-Fowler's unless otherwise ordered |
| | Airway support—check laryngeal mask in situ/Guedel airway |
| | Oxygen applied via LMA or Hudson mask |
| | Note colour, warmth of skin |
| | Document on arrival then at 10-minute intervals |
| Vital signs | Automatic monitoring, BP, HR, $O_2$ sats, ECG |
| | Temperature—require warm air blanket? |
| | Note reportable rates (on anaesthetic chart or postop orders) |
| | Document on arrival then at 10-minute intervals |
| Wound/s | Dressing dry and intact |
| | Change/support dressing as required |
| | Document on arrival then at 10-minute intervals |
| Drains | Wound drainage, amount, consistency |
| | Tubes unkinked, bottle attached to bed |
| | Patency of drain bottles/on suction? |
| | Indwelling urinary catheter—amount and colour |
| | IDC tube unkinked, bag attached to bed |
| | Document on arrival then at 10-minute intervals |

| | Pain assessment/scale |
| | Ensure adequate analgesia orders |
| | Position to enhance comfort |
| | Document on arrival and when required for change |

*(Hamlin et al 2009)*

## Subsequent postoperative care

The overall aim of the **postoperative** nursing phase is the return of the individual to an optimal level of functioning and independence. Postoperative care is directed towards assisting the individual to meet specific needs for oxygenation and circulation of blood, comfort, nutrition and fluids, elimination, movement and exercise, hygiene, psychological support, protection and safety. Nursing Care Plan 43.2 identifies the importance of continuously assessing vital signs and the need for early frequent detection of postoperative complications.

## PROGRESS NOTES EXAMPLE 43.1

| | |
|---|---|
| 25/06/15<br>1430 hrs | Nursing: Mr Sheerhan returned to the ward at 1345 post R TKR. IV in situ L hand, IDC in situ, on morphine infusion at 1 mg per hour. Dressing dry and intact. Mr Sheerhan was alert and orientated. Observations within normal limits. Pain score after arrival was 7/10. Phone order for bolus IV morphine gained via Dr Williams, who will review client at 1500 and write up phone order. Bolus administered at 1415 as per medication order. Mr Sheerhan's pain score was 4/10 at time of writing.<br>***M. Smithson*** **(Smithson) EN** |

## NURSING CARE PLAN 43.2

**Scenario:** Mary White, an 85-year-old woman, has returned to the ward post surgery for a Right Total Knee Replacement (TKR). An ex-smoker who occasionally suffers with bronchitis, she is an otherwise fit and well individual.
**Assessment:** Postoperatively
**Issue/s to be addressed:** Respiratory depression related to anaesthesia and subsequent narcotic pain relief
Pain due to surgical wound/incision
Potential for wound infection due to surgical incision
**Goal/s:** Early detection of hypoventilation
Pain to be of a level acceptable to the individual
Prevent infection and promote wound healing

| Care/Actions | Rationale |
|---|---|
| Record respiratory rate (specify) and maintain clear airway | Early detection of respiratory depression, ensures unobstructed airway |
| Position individual in accordance with postoperative orders/needs | Enables optimum chest expansion |
| Perform pain assessment on return to ward and at regular intervals (e.g. each time vital signs are recorded) | Timely detection of potential need for any PRN pain relief |
| Report unrelieved pain to RN and monitor effects of analgesics administered | Identifies any potential need for revision of medication type or dose |
| Assist individual to a more comfortable position | Appropriate positioning enhances general comfort and reduces pain |
| Dressing to remain intact until (specify date) | Reduces the potential for contamination in the early healing stages |
| Redressing to be performed as ordered using aseptic technique | |
| Observe wound for signs of infection. Report indications of infection promptly | Early detection of signs of infection allows for prompt medical intervention |
| Monitor temperature 4/24 and report elevation promptly | Increased temperature can indicate an infection |

**Evaluation**

Every 30 minutes for 4 hours then as general observations and as required.
With observations and as required.
At first dressing change and at dressing changes thereafter, with general observations.

### Assessing respiratory and circulatory needs

In the initial postoperative period, the frequency with which the individual's vital signs are monitored depends on their condition. Generally, vital signs are assessed and documented every 30 minutes for the first 4 hours, then 1 hourly for 4 hours, then every 2–4 hours if the condition is satisfactory. If the individual's condition is unstable, observations may be monitored more frequently for a longer period of time. (See Chapter 20 for the early warning signs indicating a deteriorating individual.) Assessment is also made of colour and breathing to observe for the signs of any respiratory tract complications. Mucus secretions can accumulate, leading to pneumonia, bronchitis or atelectasis. Throughout the postoperative recovery, the individual is also at risk of thrombophlebitis and pulmonary embolus. During this period deep breathing, coughing and, if possible, leg exercises and early ambulation are encouraged to decrease the possibility of the above complications occurring. See Clinical Skill 43.1 on pre- and postoperative exercises.

### Comfort needs

Individual comfort can be promoted by ensuring that a suitable position is assumed. Unless contraindicated, the individual is encouraged and assisted to assume a semi-upright position. This position promotes adequate lung expansion, and assists urinary or wound drainage by gravity. Pillows are

## CLINICAL SKILL 43.1 Pre- and postoperative exercises

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Pillow/rolled towel<br>Tissues<br>Rubbish bin |

| **Skill activity** | **Rationale** |
|---|---|
| Provide health education pre- and postoperatively to individuals regarding early mobilisation, repositioning, lung expansion exercises, secretion clearance techniques and limb exercises by effective communication skills and demonstration. | |
| **Deep breathing (D/B)** | Improves pulmonary function<br>Prevents pneumonia, atelectasis and other post-operative complications<br>Uses the diaphragm and abdominal muscles to fully ventilate the lungs<br>Normal breathing pattern can change and become shallower after chest or abdominal surgery, after general anaesthesia or when an individual is inactive |
| Assess normal breathing pattern | Note depth, rate, volume for baseline data |
| Assess individual's risk of postoperative complications by reviewing individual's history, past medical history, history of respiratory diseases, vascular disease, previous thrombosis, medications, history of occupation and smoking and any complications previously from anaesthetic | General anaesthetic (GA) predisposes individuals to respiratory problems due to lungs not being inflated fully; cough reflex is suppressed during surgery, thus secretions collect within airway passage. Post-surgery a decrease in lung volume requires a greater effort to cough. Inadequate lung expansion has potential for common complications such as pneumonia/atelectasis.<br>If individual has known history of respiratory disease it is more likely that complications may occur<br>Smoking damages cilia and increases mucus secretions<br>GA and immobilisation result in decreased contraction in lower extremities which promotes venous status |
| Assess individual's ability to cough/huff/D/B, observing movement of shoulders and chest wall or use of accessory muscles | Reveals maximum potential for chest expansion and ability to cough/huff/D/B<br>Serves as baseline data to perform activity |
| Explain the importance to recovery and physiological benefits of postoperative exercises to individual/significant others | Information allows individual to understand why they are important and allows individual to 'take charge' of information |
| Demonstrate to individual/significant others and instruct individual how to attend to exercises | |
| **Deep breathing (diaphragmatic breathing)**<br>Assist/instruct individual into comfortable semi-Fowler's to Fowler's sitting position or to stand | Upright position facilitates diaphragmatic excursion |
| Stand or sit facing the individual, close enough so individual can hear and see you | Allows individual to observe breathing exercises |

*Continued*

| CLINICAL SKILL 43.1 Pre- and postoperative exercises—cont'd | |
|---|---|
| Instruct individual to place palms of hands across from each other, down and along lower borders of rib cage, place tips of 3rd finger lightly together | Position of hands allows individual to feel chest and abdomen move as the diaphragm descends |
| Demonstrate to individual and watch individual do same | Ascertain individual is giving you their full attention<br>Allows individual to observe breathing exercises |
| Instruct individual to take a slow deep breath inhaling through the nose, instructing individual to feel middle fingers separate during inhalation | Slow deep breath prevents hyperventilation<br>Inhaling through nose warms and humidifies air |
| Demonstrate and watch individual attend to this step | Allows individual to observe breathing exercises |
| Explain to individual they should feel normal downward motion of diaphragm during inspiration<br>Explain that abdominal organs descend and chest wall expands | Explanation and demonstration focus on normal ventilatory movement of chest wall. Individual has understanding of how diaphragmatic breathing occurs and feels |
| Watch the individual is not using chest and shoulder muscles | Using ancillary shoulder muscle and chest muscles increases energy expenditure |
| Instruct individual to hold slow deep breath for 2–3 seconds and slowly exhale through the mouth | Allows for gradual expulsion of air |
| Explain middle fingertips will touch as chest wall contracts | Individual has understanding of expansion of lungs and how it feels |
| Repeat whole process together | Allows individual to observe slow rhythmic breathing patterns |
| Instruct individual to practise so they can be observed | Repetition of exercises re-enforces learning and correct techniques |
| Instruct individual these exercises will need to be attended to post surgery 10 times 2/24 | Regular deep breathing prevents postoperative complications |
| **Controlled coughing**<br>Maintain upright position<br>Nurse to demonstrate skill<br>Demonstrate/instruct individual on placing pillow/rolled-up towel over wound/invasive devices with the palm of hand with gentle pressure<br>Take 2 slow deep breaths in through the nose, hold for 2–3 seconds and exhale through the mouth on the third breath instead of exhaling cough from bottom of lungs. Ensuring cough is deep and not clearing the throat. Repeat. Inspect expectoration and record | Slow expulsion of air frequently initiates the coughing reflex, which facilitates expectoration of mucus and prevents hyperventilation<br>Clearing throat does not remove mucus from deep in airways<br>Coughing uses abdominal and accessory respiratory muscles<br>Splinting supports the incision and surrounding tissues and reduces pain during coughing |
| **Leg exercises** | |
| **Leg exercises**<br>Observe individuals closely for respiratory difficulty, chest pain and general discomfort<br>Decreased muscle mass, degenerative changes in joints and degenerative tissue changes can result in limited range of motion | Maintains blood circulation<br>Stimulates blood circulation, thereby preventing thrombophlebitis and thrombus formation<br>Exercise offers the potential to improve circulation, wound healing outcomes and functional and emotional wellbeing<br>Physical activity reduces the risk of falls and injuries |
| Expose the individual's legs by untucking the sheets at the foot of the bed and folding the sheets to the middle of the bed | Folding sheets back halfway exposes individual's legs to perform exercises, but maintains privacy |

## CLINICAL SKILL 43.1 Pre- and postoperative exercises—cont'd

| | |
|---|---|
| **Calf pumping**<br>Dorsiflexion and hyperextension of ankles<br>Have the individual:<br>1. Flex ankles and raise toes toward head, stretching posterior calf<br>2. Hold for a count of 2<br>3. Relax<br>4. Repeat 5 times then proceed to other foot<br>Perform every hour | Calf muscle pump improves venous return<br>The calf muscle pump is the primary mechanism to return blood from the lower limbs to the heart. During exercise, the calf muscles (gastrocnemius and soleus) contract and compress the intramuscular and deep veins, raising venous pressure and propelling blood in the deep venous system to flow towards the heart, while the one-way valve function prevents reflux, thereby preventing blood from pooling. When the gastrocnemius and soleus muscles contract, they expel more than 60% of venous blood into the large popliteal vein |
| **Foot circles**<br>Have the individual:<br>1. Point the toe and raise the leg slightly off the bed<br>2. Use the great toe to trace a circle in the air, first to the right and then to the left<br>3. Repeat 5 times and then proceed to the other foot<br>Perform every hour | Moving the ankle joint assists the calf muscles to pump venous blood back up to the heart |
| **Leg lifts**<br>Have the individual:<br>1. Lie on back or in a semi-sitting position, and raise the leg off the bed<br>2. Hold for count of 5<br>3. Lower leg to the bed<br>4. Repeat 5 times then proceed to other leg<br>Perform every hour | Stimulates blood circulation by contracting the hamstring and quadriceps muscles<br>Helps prevent circulatory problems, such as thrombophlebitis, by facilitating venous return to the heart. Also decreases postoperative 'gas pains' |
| **Quad exercise**<br>Have the individual:<br>1. Lie in a comfortable position<br>2. Press knee into the bed, relax, repeat<br>3. Press knee into the bed, lift leg straight, off the bed, hold, gently lower leg, repeat | Stimulates blood circulation by contracting the hamstring and quadriceps muscles<br>Helps prevent circulatory problems, such as thrombophlebitis, by facilitating venous return to the heart. Also decreases postoperative 'gas pains' |
| While the individual is performing the exercises, assess the person for signs of exertion or discomfort | Assessment alerts nurse if exercise activity needs to be stopped |
| At the completion of the exercises, assist the individual to a position of comfort and replace the covers | Repositioning promotes comfort |
| Return the bed to a low position, ensure the wheels are locked | Repositioning bed promotes individual safety and prevents falls |
| Place the call light within reach. | Call light facilitates communication |
| **Repositioning/ turning in bed** | Turning periodically and alternately facilitates better inflation of the uppermost segments of the lungs |
| Instruct an individual who has right-sided incision to turn to the left side of the bed as follows:<br>Flex the knees<br>Splint the wound/invasive devices by holding the left arm and hand or a small pillow or folded towel over the site | Minimises pressure against the incision and reduces pain |
| Instruct individual to assume supine position, place left hand over incision/invasive devices<br>Keep the left leg straight, flex the right knee over the left leg, hold onto the bed rail with right hand and pull as you roll towards left side | Puts less pressure on the side with the pain/incision |

*Continued*

| CLINICAL SKILL 43.1 Pre- and postoperative exercises—cont'd | |
|---|---|
| Special aids such as a trapeze are available on most beds; these should be taught to individual as required | Specific medical procedures may require the use of aids |
| Document the exercises performed, the number of repetitions, reports of pain or discomfort, any observations of physiological intolerance to the activity<br>Record date and time of procedure<br>Include description of secretions and amount expectorated | Informs all healthcare professionals and allows for planning and implementation of care; provides data for instructional follow up |
| *(Ali et al 2012; Brasher et al 2003; Cassidy et al 2013; Clarke et al 1996; Hunt 2006; O'Brien et al 2012; Rebeiro et al 2014; Rice & Johnson 1984; Australian Commission on Safety and Quality In Health Care (ACSQHC) 2012)* | |

arranged to provide adequate support without restricting movement. If the individual is unable to move independently, the nurse must assist the individual to change position every 2 to 4 hours. Regular administration of analgesia and assessment of pain levels, the prevention of nausea, tension on the surgical wound and bladder distension will all help to provide individual comfort. With adequate comfort and pain relief the individual is able to rest and perform postoperative activities and exercises, all of which act to enhance recovery.

## Nutritional and fluid needs

Because of the effects of stress and general anaesthesia on the gastrointestinal tract, in the initial postoperative period the individual may experience nausea and/or vomiting and be unable to tolerate oral fluids or food. Food and fluids are generally withheld until normal gastrointestinal functioning has returned, as made evident by the presence of bowel sounds and the passing of flatus. Until this has occurred, the individual receives fluids and nutrients intravenously. In some instances eating and drinking are contraindicated for an extended period, or the individual may require extensive nutritive therapy to rebuild tissue after the trauma of surgery. In such cases, hyperalimentation using parenteral nutrition may be indicated (Chapter 30). Depending on the procedure and anaesthetic used, some individuals may be able to tolerate sips of fluid within a short time. If sips of fluid are tolerated and there are no contraindications, individuals progress to free fluids, then to a normal diet. Day surgery individuals are encouraged to eat and drink once they are fully awake and can tolerate sips of water.

## Elimination needs

Generally, early ambulation and the intake of adequate fluids stimulates micturition. Some individuals may experience difficulty in passing urine; for example, due to pain or the embarrassment or difficulty of having to use a bedpan or urinal. It is important to observe urinary output on an ongoing basis. If retention of urine or inadequate emptying of the bladder occurs, it may be necessary for the individual to have a urinary catheter inserted. The need for catheter insertion is based on data collected using bladder scanning techniques, and medical orders following consultation. To re-establish normal bowel function the individual is encouraged to ambulate as soon as possible and to consume adequate fluids and dietary fibre, although, as described above, oral fluids and food are initially withheld until normal intestinal peristalsis returns.

## Movement and exercise needs

Postoperative exercises are started soon after the individual's return to the ward. The nurse should encourage deep breathing and coughing and leg exercises to be performed at 2- to 4-hourly intervals. These exercises are best continued until the individual is fully ambulant. Mobility and activity are gradually increased as the person's condition improves. Initially, postural hypotension and dizziness may be experienced when getting out of bed. Allowing the individual to gradually raise their head position, then sit on the edge of the bed and dangle their legs, then after a few minutes assisting them to get out of bed slowly, generally reduces these symptoms (Christensen & Kockrow 2010). The individual should be encouraged to ambulate a little more each day and should be informed of the benefits of ambulation.

Ambulation:

- Facilitates deep breathing and thus prevents respiratory complications
- Stimulates the circulation of blood, thus preventing vascular complications
- Improves muscle tone and strength
- Aids in the elimination of waste from the bladder and bowel
- Reduces the risk of skin breakdown and decubitus ulcer formation
- Improves morale.

See Clinical Skill 43.1 on pre- and postoperative exercises.

## Hygiene needs

Until the individual is able to fully attend to their own personal hygiene needs, the nurse assists. Once the individual has recovered from the major effects of the anaesthetic, the face and hands are washed, hair is brushed and mouth care provided. The individual is assisted to get dressed into their own nightwear, and any soiled or damp bed linen is changed. In the initial postoperative period when the individual is not having any oral fluids, frequent mouth care should be

provided preventing dryness, soreness or cracking of the tongue and lips. When able, the individual is encouraged to resume responsibility for personal hygiene needs. The nurse may be required to assist with a shower or bath and should be available to supervise activities to promote safety.

### Psychological needs

Psychological support is provided by keeping the individual informed, allowing expression of concerns about progress, change of body image and impact of surgery on lifestyle, and by encouraging visits from family and friends. Self-esteem is enhanced with increasing independence and should be encouraged—by allowing resumption of responsibility for own personal care, without endangering safety or recovery, the individual may feel more empowered. Whenever possible, the individual should be given a choice in care and in timing of activities and events. It is important that the individual understands the expected time-scale to full recovery and how any problems will be managed should they arise. All procedures and activities and their rationales should be fully explained. The nurse may need to help the individual and significant others to develop effective coping strategies. Coping methods may include:

- Obtaining additional information to deal with a situation more effectively
- Trying out various ways of solving a problem, to see which one is most helpful
- Talking over a problem with someone who has been in a similar situation
- Engaging in an activity that is relaxing and of interest, such as reading or listening to music.

### Protection and safety needs

In the postoperative period the nurse must implement measures to protect the individual from hazards in the environment. This is essential both initially, when conscious state may still be compromised and the ability to respond is diminished, and later, when changes in function may require individual adjustments when carrying out activities of daily living.

## Wound care

Care of a surgical wound is directed towards promoting healing and preventing infection. Chapter 29 provides in-depth information on general wound healing and management; in this chapter we discuss specific wound management for surgical wounds.

Wounds are described as healing by first, second or third intention:

- First intention healing occurs when wound edges are brought together; for example, a sutured surgical incision. Granulation tissue is not obvious
- Second intention healing occurs when wound edges cannot be brought together; for example, a gaping wound. Granulation tissue fills in the wound until re-epithelialisation takes place and a large scar results
- Third intention healing occurs when wound closure is delayed for a few days so that an infected or contaminated wound can be debrided. Closure of contaminated wounds is usually delayed until all layers of wound tissue appear healthy, usually within 4–10 days.

### Influences on wound healing

Healing is governed not only by the condition of a wound itself, but also by factors intrinsic to the individual, pertaining to the health status of the individual. External factors may also contribute to delayed wound healing, or failure of a suture line. Table 43.10 sets out some internal and external factors that create risk for optimal, timely wound healing.

Wound healing generally takes place within 7–10 days, although the time for normal healing depends on several factors:

- The extent of tissue damage
- The amount of stress and tension placed at the incision
- The extent to which the wound edges have been approximated
- The individual's age and general condition.

**TABLE 43.10 | Influences on wound healing**

| Influencing factor | Intrinsic/internal | Extrinsic/external |
|---|---|---|
| Position of wound | Stoma site draining bowel contents<br>Perianal proximity<br>Incision in area of movement (e.g. joint) | Excessive strain on the incision resulting from inappropriate or over-activity |
| Condition of wound | Infection, pus or dead tissue present will inhibit complete healing | Dressing treatment, hygiene measures |
| Nutritional status | Lack of adequate intake of required nutrients, including vitamins, and adequate hydration will delay or prevent complete healing | |
| Blood circulation | Poor circulation reduces the supply of oxygen and nutrients necessary for healing to the site | Restrictive dressings, plaster casts, positioning of wound site |
| Immune status | Advanced age, autoimmune disorders or drugs, other disorders (e.g. diabetes) | Proximity to other contagious individuals<br>Infection control measures |

*(Crisp et al 2013; Marieb & Hoehn 2012)*

## Promotion of healing

To promote healing, a range of general measures may be implemented. These include:

- Maintenance of adequate nutritional status. Provision of a diet that contains adequate kilojoules, protein, vitamins C and A, iron and zinc
- Promoting adequate oxygenation of the tissues. Deep breathing and coughing exercises and early ambulation to promote full lung expansion will enhance oxygenation of the blood
- Encouraging adequate blood circulation to the area, promoting transport of substances required for healing and combating infection. Adequate blood volume can be maintained by ensuring sufficient fluid intake and a suitable level of exercise and mobility can stimulate circulation
- Restricting movement of the area in the early stages of healing. If strain is placed on a wound, the newly formed granulation tissue may tear. The surgical wound area should be stabilised, rested and supported.

## Wound management

(See Chapter 29.) Surgical wounds are covered with specific dressings when the individual returns to the ward. These dressings are usually left intact until the individual is reviewed by the surgeon. If leakage appears on the original dressing it is important to reinforce the dressing and report and document the leakage immediately. If wound drainage is present and copious and potential exists for skin excoriation, a drainage bag or pouch may be placed over the wound to protect the skin. Before application of the pouch, an adhesive skin barrier such as a pectin wafer is placed on the surrounding skin. The pouch is placed over the draining area and secured to the barrier using gentle digital pressure. The principles of application and care relevant to a wound drainage pouch are similar to those that apply to stomal appliances. Several factors must be considered in the selection of surgical dressings, such as the individual's skin condition, allergies, the type and site of the wound, the amount of wound exudate and the availability of various dressings.

## Dressing changes

In relation to a closed surgical wound, when and how often dressings are changed depends on the surgeon's orders, the healthcare facility's protocol and on the type of dressing used. The ideal surgical wound has edges that are well approximated and secured, and tissue layers that have also been appropriately sutured. Often an adhesive film dressing with a central non-adherent pad (Airstrip, Cutifilm) will be used to cover a sutured incision. The individual's apprehension may be high at the time of initial dressing removal, and may be related to the size and appearance of the wound and issues concerning scarring. The nurse needs to provide appropriate support at this time. Once the original dressing has been removed and the wound inspected, it may be ordered that the wound remains uncovered, or perhaps that wound edges be given simple reinforcement and support with hypoallergenic strips of paper tape (Steristrips). If a dressing is to be changed, sterile equipment and aseptic techniques are used to prevent cross-infection, even though the wound has been surgically closed (see Chapter 29).

## Drainage tubes

At the time of the operation, the surgeon may place a drainage tube through a separate 'stab' incision near the principal wound. A drainage tube acts to promote healing by providing an exit for blood, serum and debris that may otherwise accumulate and result in postoperative swelling, pain or infection and abscess formation. The type of drainage tube inserted depends on the site and extent of the wound. A drainage system may be covered with an adhesive collection bag (i.e. non-suction drain), may be connected to intermittent suction or may be a self-contained disposable drainage system that supplies its own vacuum suction.

When a non-suction drainage tube (e.g. Penrose or Yates drain) is inserted, a sterile safety pin is usually passed through the tubing just above skin level to prevent the drainage from slipping back into the incision. A gauze dressing is placed between the pin and the skin. Alternatively, the drainage tube may be secured in position by one or two sutures. An absorbent dressing may be placed over the drainage tube to collect exudate, or a pouch or bag may be applied to the surrounding skin for drainage collection.

A closed-wound drainage system consists of tubing sutured at the skin edge and connected to a vacuum suction unit (e.g. Survac, Redivac, Provac, Exudrain). The unit is always positioned below wound level to promote drainage by gravity. There should be no kinks in the system or excessive tension on the tubing. Using standard infection-control precautions, the container is emptied as necessary. The vacuum in the container needs to be re-established each time the container is emptied, following the manufacturer's instructions. An absorbent dressing may be used to protect the drain exit site. While the system is in situ, it is important to observe both the system and the individual. Although it is important to observe the amount and nature of the drainage, it is also important to observe the individual's pain levels in relation to the drainage tube and the skin condition surrounding the tube, and to monitor the individual's temperature for early signs of infection. (See Clinical Interest Box 43.5.)

It is the nurse's role to observe and note the location of any drainage tubes, the character of drainage and, if there is a collection device, to measure and document the volume of the drainage. Any sudden change in the amount of drainage, or leakage at the tube entry site, should be reported, as this may indicate a blockage in the drainage tube or bleeding (Crisp et al 2013). Individual education regarding the drainage system and its workings is essential. The length of time a drain tube remains in situ depends on several factors, such as the nature of the surgery, the anatomical area involved and the amount of drainage. It is expected that initial drainage is bloodstained (perhaps heavily), and that over subsequent days the drainage will become lighter and more serous.

## CLINICAL INTEREST BOX 43.5 Common surgical drain tubes

| Common surgical drain tubes | Nursing implications |
|---|---|
| Jackson-Pratt® Wound Drainage<br> <br>*(Courtesy of Cardinal Health. © 2007 Cardinal Health. All rights reserved)* | Soft, squared tubing with holes; is totally inserted into wound<br>Bulb that creates a gentle suction when squeezed before opening clamp<br>Ensure suction is not lost; re-apply by clamping off tubing, detach, squeeze bulb, hold, then re-attach before unclamping tubing<br>Usually secured by a suture, except in some orthopaedic cases<br>Do not twist drain when removing—it is not round within the wound, despite the shape of the external tubing |
| Survac<br> <br>*(© Surimex)* | Pre-vacuumed bottle with tubing that then attaches to a semi-rigid, perforated tube that is inserted into the wound<br>A trocar is often used to insert the inner tubing, which is then usually sutured in place at the skin<br>Ensure suction is present by observing the green, concertina button on the top of the bottle; this should be depressed when patent<br>Lost suction can be re-established using clamps and wall suction |
| Penrose drain<br>  | Very pliable, soft drain relying on passive, non-suction drainage<br>Sometimes sutured as well as secured with a safety pin. Check carefully to identify the presence of a suture<br>Drains into an absorbent dressing or wound drainage bag |

Prior to removal of a non-suction drainage tube the nurse may be asked to rotate and shorten it a small amount each day for several days, preventing the body tissues becoming adhered to the tube, and to promote healing from beneath to the skin surface. The technique for shortening a tube should follow the employing agency's procedure manual. Suction drain tubes are removed without prior shortening. Removal of a drain tube involves removing all retaining sutures, rotating the tube, then steadily and gently withdrawing it, minimising discomfort. If the tube is attached to a suction device, the nurse must discontinue suction before removal of the tube, as per agency policy or manufacturer's directions. Generally, suction is discontinued to avoid damaging the tissues as the tube is being withdrawn, and to decrease pain. The amount of total drainage postoperatively must be documented on the individual's fluid balance chart and the time of removal should also be recorded.

### Sutures and clips

When surgery has been completed, the operative area is closed in separate layers, that is, organ, muscle, fat and skin. The wound edges are approximated and held together by sutures, clips or staples. Usually a single line of sutures or clips is sufficient for skin closure. In some instances, tension (large, reinforced) sutures are also required to ensure closure and to provide additional support for the wound. Suturing methods include intermittent and continuous. With intermittent (interrupted) suturing, the surgeon ties and cuts each individual suture. Continuous suturing is a series of sutures with only two knots; one at the beginning and one at the end

of the suture line. The manner in which the suture crosses and penetrates the skin determines the method of removal (see Chapter 29).

When healing has progressed well, sutures, clips and staples are removed, usually within 7–10 days after insertion. However, this is dependent on the area of the body involved and the vascularity of the area. The wound is checked for union of the edges before sutures or clips are removed. Sometimes alternate sutures or clips are removed one day, and those remaining removed the next day. The most important principle in suture removal is never to pull the visible portion of a suture through underlying tissue, as pulling the exposed portion of the suture through tissues may lead to infection. It is also important to ensure that all sutures have been removed, and that there is no opportunity for retention of suture material. The nurse may be required to perform this procedure if it is within the specified role and function and institutional policy permits.

Sutures are generally removed using a disposable sterile blade or stitch-cutter, and staples or clips are removed using a sterile staple extractor/remover. It is easiest to lift the suture at the knot, raise it up off the skin, and cut the suture as close to the skin as possible. Ensure safety with the stitch-cutter by cutting away from the individual and pulling out the suture to the side opposite to where it was cut. Supporting the skin edges with forceps may be appropriate. It is not always necessary to cleanse or swab the suture line before suture removal. This is indicated if there is dried blood or exudate present or if sutures are hard to see. Cleansing the incision gently with gauze swabs and normal saline may be necessary after suture removal if oozing has occurred as a result of the removal. Agency guidelines and standard precautions should always be followed when undertaking such procedures.

## Postoperative discomforts and potential complications

During the postoperative period the nurse must assess the individual for the manifestations of various discomforts associated with surgical intervention and potential complications. The nursing care plan should include any actual and potential problems, the goals, objectives or expected outcomes of the planned interventions and nursing measures to prevent, minimise or manage them. The nurse must know how to prevent complications and recognise the onset of discomforts or complications. Any manifestations or changes must be reported immediately. Table 43.11 lists some postoperative discomforts and potential problems.

### CRITICAL THINKING EXERCISE 43.5

Mrs Marcello, an otherwise well 83-year-old woman, is admitted after a fall for repair of a fractured hip. Outline the possible postoperative complications that might be seen in the older individual undergoing this type of surgery and what you, as an EN, can do to help minimise the risks of complications occurring with Mrs Marcello. Identify the discomforts and difficulties Mrs Marcello is likely to experience in the first 24 hours after surgery, and outline the nursing interventions you will implement to assist her.

## Preparation for discharge

Discharge planning commences in the preoperative phase and is continually reviewed throughout the postoperative period until the individual is discharged from the healthcare facility. The nursing care plan during this time is developed and implemented with the ultimate goal of returning the individual to an optimal level of functioning and independence. Before discharge the person and/or their significant others should understand how to meet any specific postoperative needs (see Chapter 21). The nurse may be required to demonstrate any techniques that are to be performed at home, such as dressing changes.

The nurse must ensure that the person knows how to care for any wound that is present, whether there are any dietary or activity restrictions, whether any special exercise program is to be followed and if and how prescribed medications are to be administered. The person should be informed of the date and time to visit the surgeon for a postoperative check. It may be necessary to notify the domiciliary nursing service if the individual requires ongoing assistance; for example, wound care.

The day surgery individual is discharged once they have fully woken from anaesthetic, have tolerated diet and fluids and have voided. They are discharged into the care of a friend or family member, as they are unable to drive, drink alcohol or be left alone for the next 24-hour period. The DSU nurse will contact the individual the next day to follow up on their progress and answer any concerns they may have.

## TABLE 43.11 | Postoperative discomforts and potential problems

| Condition | Manifestations | Causes | Prevention | Management |
|---|---|---|---|---|
| Nausea and/or vomiting | Pale, cool, damp skin. Sensation leading to the urge to vomit<br>Vomiting | Effects of anaesthetic agents, inadequate preoperative preparation, apprehension, sensitivity to medications | Adequate preoperative preparation (e.g. fasting; withholding oral fluids and food until gastrointestinal function has returned) | Withholding oral fluids and food, administering anti-emetic medications, promotion of physical and psychological comfort |
| Abdominal distension | Sharp abdominal pains, swollen abdomen, inability to pass flatus | Increased production of gas in the intestines and reduced peristalsis, causing stasis of the bowel contents | Early ambulation | Encouraging ambulation; passage of a rectal tube to release flatus |
| Paralytic ileus | Abdominal pain and/or distension, no passage of flatus, nausea and vomiting | Absence of intestinal peristalsis related to the trauma of surgery, especially handling during bowel surgery | Withholding oral fluids and food until normal gastrointestinal function has returned | Insertion of nasogastric tube and aspiration of gastric contents; withholding of all oral fluids and food; administration of fluids intravenously; early mobility as able |
| Urinary retention | Suprapubic discomfort or pain, suprapubic distension, inability to void; bladder ultrasound confirms urinary volume | Pain, micturition reflex depressed by anaesthetic agents (especially spinal or epidural), anxiety or fear of pain | Early ambulation, relief of anxiety and pain | Encourage increasing ambulation; assistance to assume a natural voiding position; providing sensory stimulation (e.g. the sound of running water); ensure adequate fluid intake; catheterisation if other measures fail |
| Constipation | Abdominal discomfort and distension, 'gas' pains, nausea | Disruption of normal diet; reduced mobility; reduced fluid intake; depressive effects of anaesthetic agents and/or medications, especially narcotics, including codeine | Early ambulation, return to diet high in fibre as soon as possible, ensure adequate fluid intake | Increase dietary fibre and fluid intake, encourage increasing ambulation, administration of stool softeners or rectal suppositories if necessary |
| Pain | Restlessness, 'guarding' the wound, verbal expression of pain, pale damp skin, rapid pulse | Tissue trauma, anxiety | Provide adequate analgesia, promote physical and psychological comfort | Provide psychological support; promote physical comfort (e.g. positioning); administer adequate analgesic medications |

*Continued*

**TABLE 43.11 | Postoperative discomforts and potential problems—cont'd**

| Condition | Manifestations | Causes | Prevention | Management |
|---|---|---|---|---|
| Shock | Hypotension; weak rapid pulse; restlessness; pale, cool damp skin; diminished urinary output | Reduction in the volume of circulating blood, physiological reaction to trauma | Avoid and relieve pain and fear, prevent reduction of circulating blood volume | Restoration of blood volume to normal, relieve pain and/or anxiety, administer oxygen, administer prescribed medications, maintain normal body temperature, place the individual in the recumbent position, possibly elevate feet |
| Haemorrhage (a): reactionary | Bleeding (obvious or concealed) within the first 24 hours after surgery; manifestations of shock | Dislodgement of clots from the cut ends of small blood vessels, or displacement of a ligature from a large blood vessel, as the blood pressure returns to normal | | Arrest the bleeding. Combat shock. Individual may need to return to the operating room to have the haemorrhage arrested |
| Haemorrhage (b): secondary | Bleeding that occurs 7–10 days after the operation | Infection that weakens blood clots or erodes blood vessel walls | Prevent infection | Treat infection, arrest the bleeding, combat shock |
| Hypoxia | Tachycardia, tachypnoea, pallor or cyanosis, lethargy and decreased responsiveness, confusion, agitation | Ventilations depressed by anaesthetic agents or medications, resulting in poor oxygenation of the blood, airway obstruction | Maintain a clear airway, promote adequate lung ventilation, administer oxygen if necessary, monitor vital signs frequently | Promote adequate oxygenation and tissue perfusion |
| Atelectasis (lung collapse) | Diminished breath sounds, increasing dyspnoea, pyrexia | Collapse of a portion of the lung due to obstruction of part of the bronchial tree (e.g. a plug of mucus or inhaled secretions or vomitus) | Maintain a clear airway, encourage regular deep breathing and coughing exercises, early ambulation | Promote adequate lung expansion, administer oxygen if necessary, administer prescribed medications |
| Pneumonia | Dyspnoea and cyanosis, pyrexia, tachycardia, limited chest expansion on the affected side(s) | Accumulation of secretions in the lung(s) | Maintain a clear airway, encourage regular deep breathing and coughing exercises, incentive spirometry, early ambulation | Promote adequate lung expansion, administer oxygen if necessary, administer prescribed medications |

**TABLE 43.11 | Postoperative discomforts and potential problems—cont'd**

| Condition | Manifestations | Causes | Prevention | Management |
|---|---|---|---|---|
| Thrombophlebitis | Calf tenderness; pain in the leg, perhaps increased when the foot is dorsiflexed; oedema and inflammation of the leg; pyrexia | Venous stasis related to inadequate mobility, reduced volume of circulating blood or damage to the veins by pressure or injury | Encourage leg and foot exercises; early ambulation, and use of anti-embolic stockings; avoid pressure on back of legs (i.e. no crossing legs); administration of prescribed anticoagulants; ensure adequate fluid intake | Anticoagulant therapy, bed rest with legs elevated, anti-embolic stockings applied, perhaps administration of fibrinolytic substances |
| Pulmonary embolism | Sudden onset of dyspnoea, severe chest pain, and cyanosis; urgent desire to defecate; sudden circulatory collapse and death | Blockage of one of the pulmonary arteries by a blood clot, air or fat | Prevent the development of deep vein thrombosis, administration of prescribed anticoagulants, maintain normal blood volume | Administer oxygen and prescribed medications (anticoagulants), emergency resuscitation if required, emergency embolectomy may be performed |
| Wound infection | Pain, tenderness, redness and swelling around the wound, purulent wound discharge, pyrexia, tachycardia | Invasion of the wound by pathogenic microorganisms | Practise aseptic techniques, using sterile equipment | Administer prescribed medications (e.g. antibiotics, analgesics); prevent cross-infection |
| Wound dehiscence (breakdown or rupture of wound closure) | Leakage of haemoserous fluid from the wound, separation of wound edges, with appearance of loops of intestine at abdominal wound surface | Poor tissue healing, which may be related to malnutrition, obesity, anaemia, wound infection, premature removal of sutures or clips, or stress on the unhealed incision (via excessive coughing or straining) | Prevention, management of malnutrition and anaemia, delay removal of sutures and clips until there is good union of wound edges, avoid stress on incision | Combat shock; cover wound with sterile moist saline dressing; do not attempt to reinsert intestinal loops; provide psychological support; prepare the individual for return to theatre |

*(Rothrock 2015)*

## DECISION-MAKING FRAMEWORK EXERCISE 43.1

You are an Enrolled Nurse who has recently commenced employment in a surgical ward after many years working in a rehabilitation environment. You are asked to collect an individual who is post surgical from the PACU and take him back to the ward under your care.

When you arrive at the PACU you find that the individual has had a percutaneous intravenous central catheter (PICC) inserted in the OR. The postop orders include 2-hourly flushes with normal saline. You have never managed the care of a PICC and have not completed any facility-based competency training in PICC management. The ward operates using the team model for nursing care and you are working with a Registered Nurse sharing a load of eight individuals.

Using the decision-making framework:

1. Do you accept this individual as part of your allocation?
2. What strategies could you use to manage this situation?

## Summary

Surgery is a form of intervention whereby the surgical team operates to remove, repair, reconstruct or replace body tissues or organs. Surgical procedures may be classified as elective, essential, emergency, diagnostic, exploratory, curative, palliative, major or minor. Surgery imposes physiological stress on all the body systems, and psychological stress on the individual and their significant others. Perioperative nursing encompasses the provision of a wide variety of nursing functions related to the individual undergoing surgery and throughout their perioperative experience. Preoperative care is directed towards ensuring that the individual is in the best possible physical and psychological condition to undergo surgery. Preoperative care involves providing information, teaching activities, physical examination of the individual, the performance of laboratory tests and diagnostic studies, checking that informed consent has been obtained and preparing the individual physically and psychologically. The types of anaesthetic used during surgery are classified as general, regional or local. General anaesthetic agents are administered intravenously or by inhalation and promote unconsciousness, analgesia, amnesia and muscle relaxation. Local, or regional, anaesthetic agents are administered through infiltration or by topical application; their action blocks the conduction of nerve impulses to and from specific sites in the body.

Intraoperatively, the nurse, in varied roles, delivers holistic care to the individual while following procedural guidelines set by the agency and other professional bodies. These guidelines and standards are the result of ongoing research and outline best practice in the perioperative environment. Postoperative care includes: the immediate care of the individual emerging from anaesthetic; the preparation of each individual for their return to the ward or DSU; immediate assessment of the individual's condition, and assisting individuals to meet their needs for oxygen and blood circulation; comfort, nutrition and fluids, elimination, movement and exercise, hygiene, psychological support, protection and safety. Care of a surgical wound is directed towards promoting healing and preventing infection. Wound management may involve dressing the wound, care and removal of any drainage tubes and removing sutures or clips. Throughout the postoperative period the individual is prepared for discharge with the ultimate goal of returning to an optimal level of wellness, functioning and independence.

## Review Questions

1. List five (5) different reasons for surgery.
2. What are four (4) significant factors that can affect the degree of risk in an individual facing major surgery?
3. Identify six (6) possible psychological responses you may find in an individual with diabetes who is facing a below-knee amputation of their left leg.
4. Outline what is involved in the preoperative preparation of a surgical individual and identify ten (10) items on the preoperative form that you should check.
5. Identify three (3) types of anaesthesia.
6. What action would you take if an individual's surgical wound dressing was damp with blood?
7. What action would you take if, 6 hours after returning to the ward after surgery, an individual's urinary catheter drainage was 20 mL?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

CHAPTER
44

# Nursing in the emergency care environment

*Jennifer Jennings*

## KEY TERMS

advanced life support (ALS)
basic life support (BLS)
cardiac output
cardiopulmonary resuscitation (CPR)
code blue (medical emergency)
medical emergency team (MET)
modified early warning scores (MEWS)

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define key terms
- State the aims and principles of emergency nursing care
- Recognise and overcome the barriers that can keep nurses from acting in an emergency situation
- Identify and act upon emergency situations according to organisation policy and procedure and within legal and professional requirements
- Apply a problem-solving framework in consultation/collaboration with the Registered Nurse to plan appropriate nursing management strategies
- Identify and respond to the early signs and symptoms of the deteriorating individual
- Assist the Registered Nurse with providing the initial emergency management of the individual until medical support arrives

## CHAPTER FOCUS

This chapter provides a form of knowledge support to equip the Enrolled Nurse with the theoretical concepts and skills required to recognise and respond to emergency situations and utilises the decision-making framework to facilitate the delivery of safe person-centred care. The literature reports that the characteristics of individuals in Australia and internationally are changing. Acute care hospitals now have an increasing percentage of individuals with complex problems who are more likely to be or become seriously ill during their hospital stay (Needleman 2012). The clinical condition of an individual can change at any time; the key is to recognise and respond in a timely manner. In the healthcare facility the nurse is primarily 'on the front line' and usually the one who is the first responder so must be equipped with the skills and knowledge to react appropriately and initiate care until help arrives. The chapter also prepares the Enrolled Nurse to make sound clinical judgments and work as part of a team to provide the best possible care to the individual and family/significant others. There is additional emphasis on the recognition of variations or deterioration in the individual's condition to enable the Enrolled Nurse to respond appropriately and effectively. Concepts introduced include the use of early warning systems (EWS), when to initiate a **medical emergency team** (MET) call and calling a **medical emergency** or **code blue**. Emergency response intervention including **cardiopulmonary resuscitation** (CPR) and basic life support (BLS) are also addressed. Importantly, effective inter/intraprofessional communication is essential and the mnemonics ISBAR—identification, situation, background, assessment and request—and AMPLE—allergies, medications, previous history, last meal, event—which are the handover tools used by paramedics are used to demonstrate effectiveness when communicating and reporting vital information.

## LIVED EXPERIENCE

Being assertive in activating a MET call can make you feel very apprehensive, but the ward nurse just knew the individual was in trouble. I recall one of my colleagues recounting a story of being told by a more senior staff member that, 'The MET team are not going to be happy that you called them.' My personal experience of being a critical care trained nurse and part of a MET team is quite the contrary—when the ward staff call a MET we are there to provide additional support and it is definitely not a bother. A delay due to indecision can result in a MET turning into a code blue. Therefore, when a person deteriorates on a ward that is not a critical care environment, the nurses are first on scene to initiate emergency care. It is our responsibility to ensure that we arm our ward nurses with the skills and knowledge to confidently recognise and respond. Education and simulation activities support the decision-making framework and encourage students to use clinical judgment and critical thinking skills to provide the best possible outcomes for individuals in our care.

**Nicholas Williams, Enrolled Nurse**

# INTRODUCTION

The key elements required to appropriately recognise and treat a deteriorating individual include accurate and timely documentation of vital signs. The ability to interpret vital sign recordings and act quickly on trends of deterioration, as well as reporting, effective communication, management, teamwork and prioritisation of skills assist with better outcomes for the person.

In the clinical ward recognising alterations to the individual's physiological status requires the nurse to have sound knowledge of physical assessment, vital signs in a range acceptable for the individual and awareness of when to respond to alterations in the individual's condition (McDonnell et al 2013). Enrolled Nurses practise under the direction and delegation of a Registered Nurse or nurse practitioner to deliver nursing care and, accordingly, the Enrolled Nurse must work within the policies and procedure guidelines of their organisation. The Enrolled Nurse has a unique opportunity to contribute to the care of the individual with complex medical conditions. Ongoing education based on current evidence allows the Enrolled Nurse to recognise, communicate and assist the multiprofessional healthcare team in providing timely effective care to the individual.

## Aims of emergency care

1. To preserve life
2. To protect the unconscious person
3. To prevent further deterioration
4. To relieve pain
5. To promote recovery.

## Where do emergencies occur?

Emergencies can take place anywhere: the ward area, perioperative unit, radiology and, of course, the emergency department. The outcome of the emergency situation is dictated by numerous factors including recognition and timely response, the experience of attending staff, coordination and communication.

## Early recognition and response to a medical emergency

An emergency is a situation requiring immediate action. Recognising an emergency is the first step in responding. What

happens next may be determined by the following factors that will help you recognise the at-risk or deteriorating ward individual:

- Intuition: 'gut feelings' tell you to observe, look closer and ask questions
- Knowing the individual: ensure that you read the history, the previous shift notes and perform a baseline assessment of the individual
- Pattern recognition: look at the graphical charts and look for subtle changes in trends
- Physiological changes: in most instances these occur gradually.

The key is to ensure that a thorough assessment and a full set of vital signs are performed and documented, and that changes, however slight, are reported to senior staff.

Remember that every time you see an individual you perform some sort of assessment that may include evaluation. Always think DRSABCD (**D**angers, **R**esponsive, **S**end for help, open **A**irway, normal **B**reathing, start **C**PR, attach **D**efibrillator). This process allows you, as the Enrolled Nurse, to continually assess the individual in both the long and the short term. Evaluation brings you back to the beginning of the assessment (see Clinical Interest Box 44.1).

Ask yourself the following questions:

- Has the nursing intervention worked?
- Is there anything else I can do for this individual?
- Does the individual need further intervention?

All nursing assessments and evaluations must be documented and reported to a senior staff member.

## Individual assessment

The assessment process consists of:

- Primary survey—airway, breathing, circulation, disability, exposure and 'don't forget glucose'
- Secondary survey—a thorough systematic assessment, head to toe
- Recording vital signs—temperature, heart rate, respiratory rate, blood pressure and oxygen saturation and pain level.

## Reporting deterioration

- The decision about calling: recognising clinical deterioration and knowing who to call and when to call for help
- Early warning score: knowledge of early warning score systems and hospital protocol

## CLINICAL INTEREST BOX 44.1 Summary of guidelines for responding to an emergency situation

### First person present

1. Assess the area for danger
2. Check the individual for response and conscious state
3. If the individual is unresponsive call for assistance, press the emergency bell to summon help
4. Assess the airway, clear obstructions and perform airway-opening manoeuvre
5. If available/suitable correctly size and insert an oropharyngeal airway
6. Check for normal breathing. If unresponsive and not breathing normally, commence CPR with 30 chest compressions followed by two ventilations
7. Attach a defibrillator as soon as possible and follow its prompts. Ensure that the compressions are not interrupted while attaching the defibrillator
8. Continue CPR until the medical team arrives or signs of life (responsiveness, starts moving and normal breathing) return.

### Second person present

1. Dial switchboard and state:
   - > Type of emergency (e.g. code blue medical)
   - > Location of the emergency: ward, room and bed number
   - > Identity of person who initiated the emergency call
2. Collect the emergency trolley
3. Connect bag-valve mask and attach high-flow oxygen
4. Assist with CPR
5. Commence documentation
6. Prepare an intravenous infusion
7. Draw up the resuscitation drugs
8. Prepare equipment needed for intubation of the individual
9. The nurse unit manager or senior nurse will:
   - > Provide additional personnel if required
   - > Coordinate telephone communications
10. Staff shall provide information and support to friends/relatives of the individual who are present.

*(Australian Resuscitation Council 2016a)*

**Figure 44.1** ISBAR communication tool

*(Adapted from Aldrich et al 2009)*

- Communication and language: use of ISBAR to communicate information rapidly in a logical concise sequence (Hammond et al 2013) (see Figure 44.1).

### CRITICAL THINKING EXERCISE 44.1

**ISBAR tool practice**

Mr Thomas Andrews is 54 years old with a medical history that includes hypercholesterolaemia and hypertension. You find him collapsed on the floor of his room. He had complained of dizziness earlier that morning after getting up to go to the bathroom. There is no evidence in his progress notes that his concerns have been addressed or investigated and there are no recent vital signs charted. His admission notes state that he was admitted the previous day for stabilisation of his blood pressure.

1. Using the ISBAR tool, practise writing a handover with the information provided.
2. What other information do you need to complete the ISBAR tool?

## Managing deterioration

Initiate treatment by performing the initial stabilisation and calling for help. Making treatment decisions will depend on the Enrolled Nurse's scope of practice as this varies from state to state. It may include initiating **basic life support** (BLS).

## Barriers to instigating action

Barriers to instigating action can include:

- Being unsure of what to do: lack of knowledge of signs and symptoms that could signal deterioration
- Being unfamiliar with hospital policies related to calling MET or calling a medical emergency (code clue)
- Nurses feeling uncertain about whether they are doing the right thing in calling the MET
- Checking with other nurses: while seeking confirmation the individual deteriorates further
- Waiting for observations to deteriorate: this is a knowledge deficit related to early warning scores (EWS), the parameters of vital signs or a lack of familiarity with the individual and their baseline vital signs
- Being unable to communicate: language barriers or unable to articulate concise systematic information, unaware of ISBAR.

Clinical Interest Box 44.2 outlines the criteria for all MET teams.

# RECOGNISING AND RESPONDING TO AN EMERGENCY

## Primary care

Recognising an emergency is the first step in responding to an emergency, and giving prompt emergency care saves lives. To be able to provide emergency care you must think and act and communicate in a systematic and coordinated manner, continually assessing and adjusting to changes in the individual's status (Kerr et al 2014). The first person on the scene recognises and responds to the emergency and delivers first aid (Bogossian et al 2014; Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012).

## Secondary care

The next stage involves continual assessment, care management and interventions which may require clinical skills such as cardiac monitoring, ECG interpretation, airway

## CLINICAL INTEREST BOX 44.2 Calling criteria for medical emergency teams used in Australia

Important note: Criteria for calling a medical emergency team (MET) for adult individuals has been developed to assist clinicians to identify individuals at risk. The criteria indicated are the minimum calling criteria. Sites may choose to apply more stringent calling criteria; always refer to the hospital's policies and procedures guidelines (Department of Health 2014).

### MET call criteria—adults

**Airway**

- Difficulty breathing

**Breathing**

- RR <8 or >30 per min
- $SpO_2$ <90% despite $O_2$ 6 L via Hudson mask

**Circulation**

- HR <50 or >130 beats per minute
- Systolic BP <90 mmHg
- Chest pain—new or unrelenting chest pain

**Disability**

- Acute change in consciousness level
- Seizure

**Other**

- Staff member is worried about an individual condition

management, fluid resuscitation and haemodynamic monitoring (ACSQHC 2012).

## CHANGES IN VITAL SIGNS

Vital sign measurement is at the centre of the care we deliver to individuals placed in our care. Changes in vital signs are key indicators of individuals who are at risk of deterioration (Cardona-Morrell et al 2015). Physiological signs that indicate deterioration include the respiratory rate, heart rate and blood pressure, level of consciousness and oxygen saturation (Cardona-Morrell et al 2015). Failure to interpret or inaccurate measurement of vital signs also place individuals at risk of deterioration. Lack of education, training and experience have also contributed to adverse events (Odell 2015). In order to detect changes the Enrolled Nurse must have a sound knowledge of the normal ranges of these physiological measurements (see Chapter 20).

### Modified early warning scores

The idea behind **modified early warning scores** (MEWS) is to improve individual outcomes by detecting and acting upon early signs of deterioration in individuals (So et al 2015) (see Tables 44.1 and 44.2 and Figure 44.2). This will be achieved, in part, through the implementation of the MEWS system that:

- Identifies trends and changes in the individual observations
- Ensures that timely review of the individual occurs and appropriate treatment is provided
- Improves the accuracy of documentation of the individual observations (ACT Health 2007).

A MEWS is calculated each time a set of observations is performed (see Clinical Interest Box 44.3). If a trigger score

**TABLE 44.1 | How the MEWS chart works: MEWS calculation**

| MEWS score | 3 | 2 | 1 | 0 | 1 | 2 | 3 |
|---|---|---|---|---|---|---|---|
| Respiratory rate (breaths per minute) | ≤8 | | | 9–20 | 21–30 | 31–35 | ≥36 |
| $SpO_2$ (%) | ≤84 | 85–89 | 90–92 | ≥93 | | | |
| Temperature (°C) | ≤34 | 34.1–35 | 35.1–36 | 36.1–37.9 | 38–38.5 | ≥38.6 | |
| Heart rate (beats per minute) | ≤40 | | 41–50 | 51–99 | 100–110 | 111–130 | >130 |
| Blood pressure | See Table 44.2 for criteria | | | | | | |
| Sedation score | | | | 0–1 | 2 | 3 | 4 |
| Urinary output (mL/hr) for 4 hours or for 24 hours | <80 <480 | 80–119 480–714 | | 120–800 720–4800 | >800 >4800 | | |

*(Adapted from ACT Health 2007)*

## TABLE 44.2 | Explanation of blood pressure for MEWS criteria

### Additional considerations

| Usual blood pressure | | 190 | 180 | 170 | 160 | 150 | 140 | 130 | 120 | 110 | 100 | 90 | 80 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Current blood pressure | 200s | 0 | 0 | 1 | 1 | 2 | 2 | 2 | 3 | 3 | 4 | 5 | 5 |
| | 190s | 0 | 0 | 0 | 1 | 1 | 1 | 2 | 2 | 3 | 3 | 4 | 4 |

MET, medical emergency team; MEWS, modified early warning scores

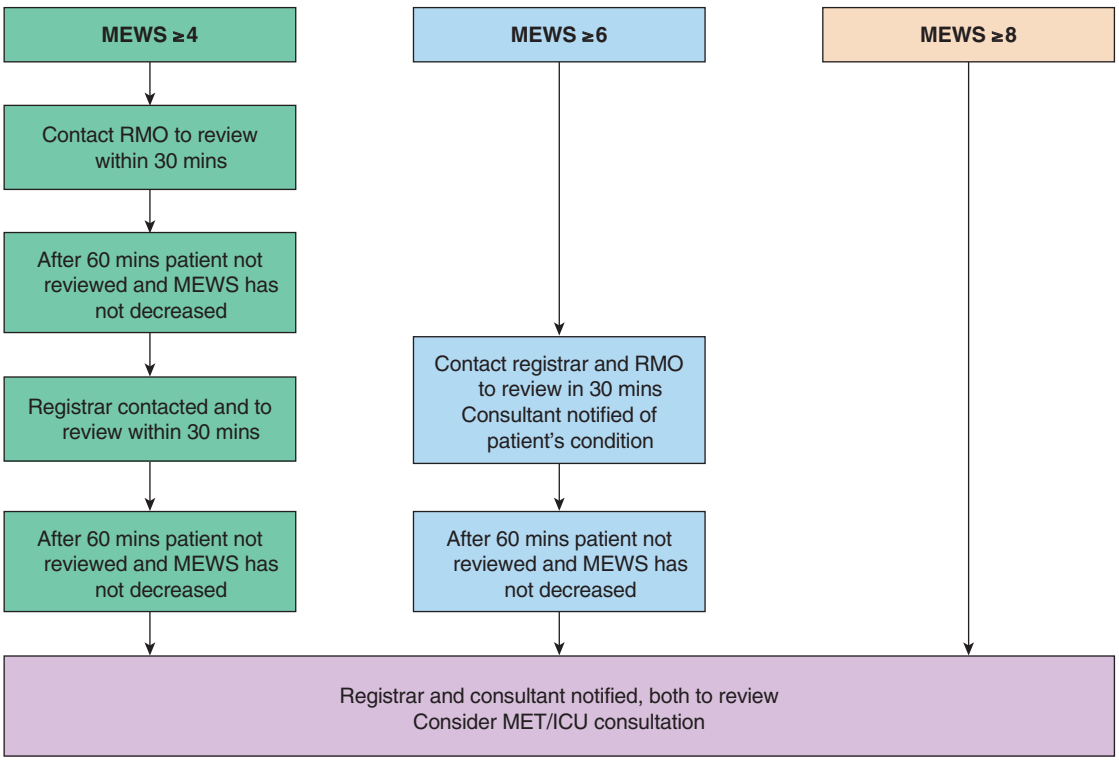

**Figure 44.2** MEWS flow chart using notification guidelines, ACT Health

*(© ACT Health 2007)*

## CLINICAL INTEREST BOX 44.3 Modified early warning scores (MEWS)

- MEWS does not replace calling the medical emergency team (MET)
- If the individual meets the MET criteria a code blue/MET should be called as per hospital MET protocol
- MEWS, EWS systems may vary from one healthcare facility to another
- Ensure you are familiar with the provider's policies and procedures

*(© ACT Health 2007)*

of 4 or greater is reached the activation protocol is initiated. Observations to be recorded include temperature, pulse, blood pressure, oxygen saturations ($SpO_2$), respiratory rate, sedation score and urine output.

Other recommendations of the protocol include that the nurse caring for the individual should report clinical changes when clinical deterioration, other than that assessed by the MEWS criteria, occurs or when sound clinical judgment would suggest that notification is in the best interests of the individual. If the Enrolled Nurse is at all uncertain, consultation with a senior staff member should occur.

## Systematic approach to assessment

One of the crucial steps in providing emergency care is proper assessment. Without timely and accurate assessment the chances of survival decrease. It is very important that individual assessment is conducted in a systematic manner. This is to insure that life-threatening injuries are given immediate intervention to increase the chances of survival. The best way to do that is to start with the following:

### A = Airway

The airway must be assessed for signs of obstruction; for example dentures, vomitus or a foreign body. To effectively assess the airway a jaw thrust or chin lift must be performed to allow for good visualisation and to open the airway. The mouth is opened and turned downwards to allow any foreign bodies or fluid to drain using gravity. Visible material can be removed using the fingers. The finger sweep is the accepted method for removing foreign bodies from the airway (Australian Resuscitation Council (ARC) 2016b).

### B = Breathing

Assessment of effective breathing includes: monitoring the rate, depth and sound of the respirations; looking for the rise and fall of the chest; listening for sounds of the individual breathing and feeling for the individual's breath on the side of the nurse's face; observing for any chest deformity. Use of percussion and auscultation may be appropriate.

### C = Circulation

In almost all emergencies, consider hypovolaemia to be the main cause. Check capillary refill time, which should be less than 3 seconds; look at colour of hands and fingers; assess limb temperature; count and palpate central pulses (rate, quality, regularity and equality); check blood pressure measurement. An appropriately accredited Registered Nurse or medical officer will insert an intravenous cannula, take bloods and administer intravenous fluids.

### D = Disability

Rule out common causes of unconsciousness such as hypoxia or recent administration of sedative or analgesic drugs; review and treat ABCs, check pupils and check level of consciousness (see Clinical Skill 44.1).

### E = Exposure

Examine individual thoroughly; expose the body fully, respecting dignity and minimising any heat loss. Always ensure personal safety. Carry out an initial assessment then reassess. Treat life-threatening problems at each stage before moving on to the next stage. Assess and evaluate effects of any treatment.

### F = Fluids

Include a review of the individual's vital signs chart; be sure to confirm that all your assessment findings have been recorded and making sure that all information is charted accurately; for example respiratory rate and fluid balance including any IV fluids administered and urine output.

### G = Glucose

Ensure the individual's glucose level has been measured and recorded; look for signs of hypoglycaemia and the associated symptoms that may include confusion, decreased consciousness level and skin that is sweaty or clammy.

Report immediately to Registered Nurse if the blood glucose level is below 3 mmol/L or 3–5 mmol/L with decreased conscious state as glucose should be administered.

### H = Holistic

Involving other specialties used within your hospital and health service will improve the individual's standard of care and hospital experience, and create a holistic approach to healthcare in the emergency environment. Speciality teams have proven themselves very effective in reducing mortality and morbidity rates.

# BASIC LIFE SUPPORT

Basic life support (BLS) is a temporary measure providing myocardial and cerebral oxygenation until **advanced life support** (ALS) personnel and equipment are available (ARC 2013). Early detection of an individual's physiological deterioration and prevention of cardiac arrest are now key strategies recognised for individual survival rates in hospitals.

BLS includes airway management skills, rescue breathing techniques, external cardiac compressions and use of the

## CLINICAL SKILL 44.1 Cardiopulmonary resuscitation/basic life support

**Review and carry out the standard steps for all clinical skills/interventions**

| **NMBA Decision-making Framework considerations:** | **Equipment:** |
|---|---|
| 1. Am I educated?<br>2. Am I authorised?<br>3. Am I competent?<br>If you answer 'no' to any of these, do not perform that activity. Seek guidance and support from your teacher/a nurse team leader/clinical facilitator/educator. | Airway equipment (bag valve mask, pocket mask)<br>Personal protective equipment (goggles, gloves, gown)<br>Resuscitation trolley (if available)<br>Automated external defibrillator |

| **Skill activity** | **Rationale** |
|---|---|
| **Danger**<br>Recognise an emergency situation<br>Identify potential/real dangers<br>Ensure area is safe<br>Follow infection control procedures relevant to workplace (personal protective equipment (PPE))<br>Identify correct manual handling procedures | Ensures the environment is safe to attend basic life support for self and others involved, including the individual<br>Appropriate PPE minimises safety issues |
| **Response**<br>Assess individual's conscious status by appropriate tactile and verbal stimulus (using a simple command, i.e. grabbing and squeezing the individual's shoulders firmly)<br>Identify whether the individual is rousable or unconscious | Assesses whether the individual is conscious or unconscious, and CPR is commenced appropriately<br>Using simple commands and not shaking the individual will help maintain spinal precautions and help prevent any further injuries |
| **Send**<br>Identify how to trigger the alarm within the workplace<br>Describe the local clinical emergency response system protocols<br>Note the time<br>Identify the explicit relevant numbers used within the workplace for emergencies<br>If in a community setting, call emergency services | Allows support to be activated and provides assistance and help with the individual.<br>Allows for expert support to arrive quickly |
| **Airway**<br>Assess airway for obstruction<br>Clear airway (describing different methods, i.e. suction/head turn, or roll individual on to their side. Maintain C-spine precautions)<br>Perform chin lift, jaw thrust or head tilt manoeuvre to open airway | Assessing airway and removing debris allows for a patent airway and ensures oxygen/rescue breaths can effectively be administered to individual |
| **Breathing**<br>Maintain open airway<br>Assess breathing for maximum 10 seconds<br>Look, listen and feel technique performed<br>Look for chest rise and fall<br>Listen for outflow of air from mouth and/or nose<br>Feel outflow of air and chest movement | Minimises the amount of time to assess individual's breathing, decreases the amount of down time and oxygen-poor system. Reduces risk of hypoxia<br>Look, listen and feel technique is easy to perform and assesses breathing simultaneously |
| **CPR**<br>For effective chest compressions the individual should be placed in a flat position, with hard surface underneath<br>Commence compression using both hands on the centre of the chest<br>Correct hand position, one hand in centre of chest (heel of the hand) and the other hand on top<br>Maintain correct posture/alignment. (Arms straight and shoulder over chest, using hips as pivot point)<br>Perform cardiac compression to one-third of the chest depth with a rate of 100/min | To provide effective cardiac compressions, hand placement is essential<br>One hand over the other, arms straight and shoulders over chest will decrease the risk of fatigue and create a greater chance of completing CPR for 2-minute cycle. One hand wrapped around the dominant wrist is preferable<br>Compressions to one-third of the chest allow for effective pressure on the heart to pump blood around the body and deliver oxygen to vital organs |

*Continued*

## CLINICAL SKILL 44.1 Cardiopulmonary resuscitation/basic life support—cont'd

| | |
|---|---|
| At 30 compressions, give 2 rescue breaths (1 second per breath) using appropriate workplace equipment. If unwilling/unable for perform rescue breaths, continue chest compressions only<br>Demonstrate appropriate mask positioning, showing good seal (2-person technique if required)<br>Maintain cardiac compressions/rescue breaths at a ratio of 30:2<br>Demonstrate or state when the person performing compressions should be rotated (every 2-minute cycle, when 2 or more rescuers or signs of fatigue) | A ratio of 30 compressions to 2 breaths maintains sufficient oxygen in the blood stream to be pumped around the body<br>Proper mask positioning will ensure full delivery of oxygen or rescue breaths<br>Be aware of fatigue, as need to complete deep chest compressions or 100 compressions per minute |
| **Defibrillation**<br>(Note: if an automated external defibrillator (AED) is available in your workplace and this skill is relevant to your role, proceed to this step. If defibrillation is not included in your role skip this step and proceed to communication)<br>Attach defibrillator as soon as able, turn on and follow voice prompts (as per defibrillation instruction manual)<br>Communicate safety considerations—pad placement (not over pacemaker), individual unconscious, not in contact with fluid, chest clear and dry (shave and dry chest before applying pads firmly if good contact required between pads and individual), pads rolled onto chest, remove metal/medication patches<br>Demonstrate correct pad placement, sternum right parasternal 2nd intercostal space, apex: mid-axillary 6th intercostal space. Or anterior–posterior positioning<br>If shock advised: scan the environment and individual for danger, ensure all persons are clear of individual and environment, verbalise before about to shock individual. State safety considerations (oxygen removed, nil contact with metal, and individual is unresponsive at time of shock delivery)<br>Safely administer shock (as per instruction manual)<br>When safe immediately recommence CPR post-delivery of shock<br>Continue to follow voice prompts until help arrives | Immediately attach the defibrillator when able (while CPR is in progress) to determine if individual needs to be shocked. This allows for greater outcome the sooner the shocks can be administered. Attaching the defibrillator allows the responder/machine to quickly identify a shockable rhythm. Rapid defibrillation is associated with long-term survival<br>Understanding the safety consideration for persons involved and the individual will unsure minimal risk of potential injuries/dangers<br>Correct pad placement ensures the shock(s) are delivered more effectively<br>Consider safety precautions—environment is clear, persons involved are clear, oxygen is removed—to minimise the risk of potential risks/dangers. Oxygen removal also reduces risk of fire/explosion during defibrillation<br>Recommence CPR when safe post shock delivery to minimise the amount of time between effective CPR applications |
| **Communication**<br>Communicate to rapid response/advance life support/ambulance team (communication tools)<br>State when it is appropriate to cease basic life support/CPR (response of life, medical officer pronounces time of death, physically impossible to continue, danger stopping any further rescue attempts)<br>Communicate progress with relatives/significant others where appropriate | Effective communication to further support services will help continue effective treatment of the individual<br>Understanding when it is appropriate to cease CPR/basic life support will avoid unnecessary length of CPR, decreased chance of injury to persons involved |
| Record and document in healthcare record onset of arrest, medication and other treatments given, procedure performed and individual's response | Informs all healthcare professionals of what occurred and allows for appropriate care to be planned and implemented. Accurate documentation is informative and supports the implementation of ongoing planning and care |

*(ARC and NZRC Guideline 2010; Grantham & Narendranathan 2012; Hazinski et al 2010; Mokhtari Nori et al 2012; Rebeiro et al 2014; Salins & Jansen 2011; Soar et al 2010)*

automatic external defibrillator (which was designed for those with minimal training) (ARC 2013). The Australian Resuscitation Council (ARC) recommends that all first responding emergency personnel, whether medical officers, nurses or non-medical personnel, should be authorised, trained, equipped and directed to operate a defibrillator if their professional responsibilities require them to respond to persons in cardiac arrest.

According to the ARC (2013), healthcare facilities have a duty of care to ensure staff maintain a level of competence that is appropriate to their role and scope of practice. Consequently all staff with direct individual contact should have access to regular resuscitation education appropriate to their expected skills and scope of practice and this should be offered on a yearly basis (ARC 2013).

Clinical Interest Box 44.4 outlines the contents of a resuscitation trolley.

## Indications

### Respiratory arrest

Respiratory arrest can result from a number of causes, including stroke, drug overdose, suffocation, foreign body airway obstruction, injuries and myocardial infarction. When primary respiratory arrest occurs, the heart and lungs can continue to oxygenate the blood for several minutes, and oxygen will continue to circulate to the brain and other vital organs. Individuals suffering respiratory arrest initially demonstrate signs of circulation. When the arrest occurs or spontaneous respirations are inadequate, establishment of a patent airway and rescue breathing can be lifesaving because they can maintain oxygenation and may prevent cardiac arrest (ARC 2016c).

### Cardiac arrest

Cardiac arrest in adults occurs both in and out of the hospital environment. The causes are numerous, but the expectations of the community are always the same: that professional nurses are able to provide appropriate methods of resuscitation in these situations (NMBA 2010).

In cardiac arrest, circulation is absent and vital organs are deprived of oxygen.

Cardiac arrest can be accompanied by the following cardiac rhythms:

- Ventricular fibrillation (VF)
- Pulseless ventricular tachycardia (VT)
- Asystole
- Rhythms associated with pulseless electrical activity (PEA).

These potentially lethal rhythms will be discussed further later in the chapter.

### Cardiopulmonary resuscitation

CPR is the technique of inflation of the lungs and compression of the heart, used in an attempt to revive an individual who has suffered a cardiac arrest. CPR can restart normal heart action after cardiac arrest or maintain artificial circulation to preserve brain function until further treatment is available (e.g. defibrillation) (ARC 2016d). (See Clinical Skill 44.1.)

Remember: the earlier CPR commences the better the chance of perfusion to vital organs.

### Defibrillation

Defibrillation is the therapeutic delivery of an unsynchronised electrical current to the myocardium. A defibrillation shock, when applied through the chest, produces simultaneous depolarisation (i.e. a short period of electrical asystole) of a mass of myocardial cells. This may enable resumption of organised cardiac electrical activity (Soar et al 2010).

Defibrillation is indicated for:

- Ventricular fibrillation (VF)
- Ventricular tachycardia (VT)
- Asystole.

*Ventricular fibrillation* (Figure 44.3) presents with chaotic electrical activity, the result of multiple ectopic foci (an area in the heart that initiates abnormal beats) that may occur in both healthy and diseased hearts and is usually associated with irritation of a small area of myocardial tissue. The causes may include medication, electrolyte imbalances, ischaemia originating from the ventricles and emotional stress. There are no organised QRS complexes (ventricular contractions). An individual with this rhythm has no **cardiac output**, which means that the individual has no circulating blood volume, therefore no blood circulating to the vital organs (Soar et al 2010). A person who has a VF episode will suddenly collapse or become unconscious, because the brain and muscles have stopped receiving blood from the heart.

*Ventricular tachycardia* (Figure 44.4), a rhythm of ventricular origin, may also be a consequence of a slower conduction in ischaemic ventricular muscle that leads to circular activation (re-entry). The result is activation of the ventricular muscle at a high rate (over 120/min), causing rapid, bizarre and wide QRS-complexes; this arrhythmia is called VT (Soar et al 2010). Ventricular tachycardia is often a consequence of ischaemia and myocardial infarction. In this arrhythmia the contraction of the ventricular muscle is also irregular and is ineffective at pumping blood. The lack of blood circulation leads to almost immediate loss of consciousness and death within minutes. The VF may be stopped with an external defibrillator and appropriate medication. Remember: VT may deteriorate to VF and non-shockable rhythms are not responsive to defibrillation.

*Asystole* is characterised by the absence of any electrical activity on the ECG monitor; sometimes referred to as 'flat line'. Ensure that asystole is not another rhythm that looks like a flat line. Consult with a Registered Nurse or medical officer to rule out any other lethal arrhythmia. Fine VF can appear to be asystole, and a flat line on a monitor can be due to operator error or equipment failure.

The following are common causes of an isoelectric line (baseline on an ECG) that is not asystole:

- Loose or disconnected leads
- Loss of power to the ECG monitor
- Low signal gain on the ECG monitor.

Pulseless electrical activity (PEA) is also known as electromechanical dissociation (EMD). PEA rhythm occurs when any heart rhythm that is observed on the electrocardiogram

## CLINICAL INTEREST BOX 44.4 Emergency trolley contents—adult

NB: Content and drawer location may differ slightly according to trolley used in hospital.

All rubber components (gloves, masks, bagging circuits) contained on the arrest trolley should be latex free.

### Top of Trolley

- Defibrillator/monitor
- Defibrillator pads (mininimum 3, check expiry)
- Packet ECG electrodes (in a plastic bag)
- ECG Leads
- Lateral ventilating bag with size 5 mask attached and connected to $O_2$ (latex free)
- Sharps container (< ¾ full)
- 2 × protective eye goggles
- Medium non-latex gloves
- Full face shield
  Note: Defibrillator to be checked daily
- Check OK symbol
- ECG leads to be attached to defibrillator pocket
  Top:
- 2 × defibrillation pads
- ECG electrodes (in a plastic bag)

### Side of Trolley

- Emergency trolley contents list
- Emergency trolley check book
- C size oxygen cylinder with Twin-O-Vac
- Suction tubing with Yankauer sucker attached
- Cardiac arrest record sheet
- Nurse initiated ALS chart
  Note: Size C $O_2$ cylinder to be at least ¾ full
  Test pressure of at least 350 mmHg

### Back of Trolley

- IV pole
- 2 × tourniquets (latex free)
- Cardiac arrest backboard

### First Drawer

- Minijet drugs
- 5 × 10 mL adrenaline 1:10 000
- 3 × 10 mL atropine 1 mg
- 1 × 10 mL calcium chloride 1 gram
- 2 × 5 mL lignocaine 100 mg
- 2 × 100 mL sodium bicarbonate 8.4%
- 1 × 50 mL glucose 50%
- 3 × 150 mg/3 mL amiodarone HCl
- 2 × 10 mmol/5 mL magnesium sulfate
- 2 × 10 mmol/100 mL potassium chloride
- 3 × 400 microg naloxone hydrochloride
- 2 × heparinised blood gas syringes
- 8 × 21 g needles
- 5 × 10 mL syringes
- 5 × 10 mL 0.9% sodium chloride ampoules
- 5 × interlink vial access cannula
- 1 × UEC/electrolyte Vacutainer
- 1 × FBC Vacutainer
- 1 × blood cross-match Vacutainer
- 1 × Vacutainer holder
- 1 × Vacutainer needle adaptor
- 6 × alcohol wipes
  Note: Check expiry date of all drugs and Vacutainers

### Second Drawer

- 2 × IV cannulas: 14g, 16g, 18g, 20g
- 2 × 12 g dwell caths
- 2 × long IV airways
- 1 × roll Transpore tape
- 1 × roll Lifepac paper
- Packet 6 mm Steristrips
- Packet gauze squares
- 2 × small transparent dressings
- 2 × needleless access Luer lock
- 6 × alcohol wipes
- 1 × 20 drops/mL solution infusion set
- 1 × blood/solution administration pump

### Third Drawer

- Yankauer sucker
- Y-suction catheters size 12F × 2 and 14F × 2
- Endotracheal tubes: sizes 7, 8, 9 introducing stylet
- Laryngoscope with size 4 blade attached
- Laryngoscope with size 3 blade attached
- Magill intubating forceps
- Tracheal dilating forceps
- Cotton tape
- Guarded artery forceps
- 10 mL syringe
- Guedel airways sizes 2, 3, 4
- 4 × water-based lubricant sachets
- Scissors
- 1 × laryngoscope bulb/LED (spare)
- 2 × batteries size C
- Cuff pressure manometer
- Lignocaine spray 10%
- Adult $CO_2$ detector
  Note: Check that both laryngoscope blade globes are functioning.

### Fourth Drawer

- 1 × Hartmann's 1000 mL
- 1 × Gelofusine 500 mL
- 1 × dextrose 5% 1000 mL
- 1 × 0.9% sodium chloride 1000 mL

### Fifth Drawer

- Laryngeal masks: sizes 3 & 4
- Bougie × 1
- Australian resuscitation guidelines
- Lantern-style torch with battery

### Emergency Drugs

**First-line drugs**

- Adrenaline 1 mg (1:10 000) × 4
- Atropine 1 mg × 1
- Amiodarone 150 mg ampoules × 2 and 5% glucose
- Lignocaine 100 mg

## CLINICAL INTEREST BOX 44.4 Emergency trolley contents—adult—Cont'd

**Other medications/equipment**
- Salbutamol 5 mg nebules × 2
- Ipratropium 500 mcg nebules × 2
- Nebuliser device and mask
- Sublingual GTN
- Aspirin 300 mg
- Frusemide

**Intravenous medications**
- Adenosine 6 mg × 10
- Adrenaline 1 mg (1:10 000) × 4
- Adrenaline 1 mg (1:1000) × 2
- Amiodarone 150 mg ampoules × 2
- Calcium chloride 10% 1 g/10 mL (6.8 mmol/10 mL) × 1
- Diazepam 10 mg/2 mL
- Glucose 50% × 1
- Magnesium Sulphate 2.5 g/5 mL
- Midazolam 10 mg
- Naloxone 400 mcg × 1
- Potassium chloride
- Propofol 200 mg/20 mL
- Sodium bicarbonate 8.4% 100 mL × 1
- Vasopressin 20 units/mL

*(Adapted from ARC 2014)*

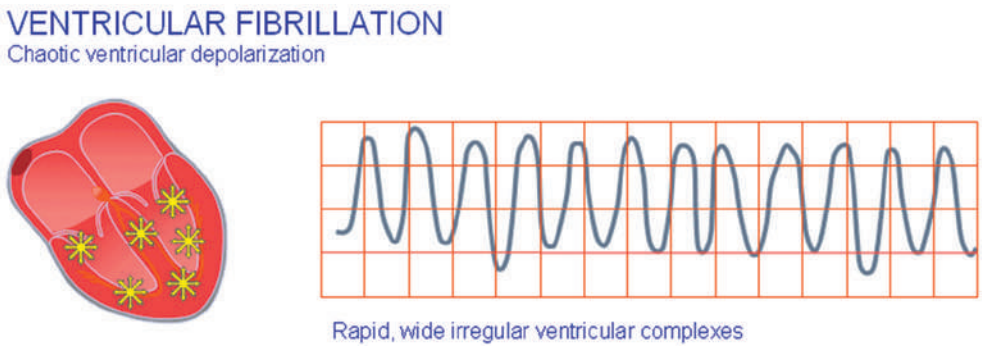

**Figure 44.3** Ventricular fibrillation

*(Malmivuo & Plonsey 1995: Fig 19.3C)*

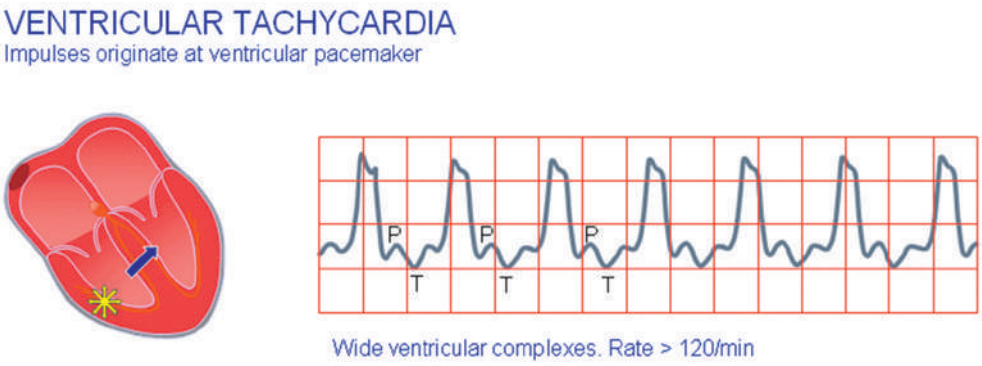

**Figure 44.4** Ventricular tachycardia

*(Malmivuo & Plonsey 1995: Fig 19.3B)*

(ECG) does not produce a pulse. PEA can come in many different forms. Sinus rhythm, tachycardia and bradycardia can all be seen with PEA. Performing a pulse check after a rhythm/monitor check will ensure that you identify PEA in every situation. Pulseless electrical activity usually has an underlying treatable cause. The most common cause in emergency situations is hypovolaemia.

### Danger

Prior to commencing BLS personnel should consider safety and the risks involved.

### Environment

- Move all unnecessary equipment out of the way (i.e. bedside table, head of bed)

- Check for hazards (e.g. equipment, falling debris)
- Observe for fluid spillage or electricity hazards.

### Infection

Infection transmitted from an individual should be considered and appropriate health and safety measures implemented:

- Staff should wear gloves and safety glasses throughout the resuscitation
- Careful handling and disposal of equipment and needles is required during all resuscitation.

### Manual handling

Principles of safe manual handling should be followed for safety of the individual and staff.

## Response

Check for response of an individual who has collapsed by giving a loud, simple command. Stand behind the individual's head and ask the individual if they can hear you, or use tactile stimulation of the individual to determine if they are conscious or unconscious.

Conscious—responds to verbal commands, or by moving.

- Keep the person in a comfortable, safe environment
- Continue to observe closely.

Unconscious—does not respond to verbal commands, does not move.

- Call for assistance immediately
- Proceed with basic life support as per the basic life support flowchart.

## Airway

Manoeuvres to reduce the risk of airway obstruction in the unconscious or unresponsive person include:

- Head tilt/chin lift
- Jaw thrust.

It is important to avoid excessive force, especially where neck injury is suspected, when performing this manoeuvre and ensure the head (NOT the neck) is tilted backwards. The mouth should be opened and turned slightly downwards to allow foreign material to drain. Use the finger sweep using a hooking action or give suction if solid material is visible in the oropharynx of an unconscious person. The person may be turned on their side if the airway needs to be cleared.

## Breathing

Look, listen and feel for 10 seconds to assess for breathing:

- Look for chest movement including rise and fall of the chest. Is it equal?
- Listen for breath sounds including wheezing, and gurgling. Can you hear breath sounds in all areas of the lungs?
- Feel for breath on the cheek or face.

If a person is not breathing normally and is unresponsive, CPR should be commenced with 30 chest compressions followed by 2 breaths, and continued with a ratio of 30:2.

- A resuscitation mask can be used with a one-way, non-return valve.
- If using a Laerdal™ pocket mask, attach oxygen with a flow rate of 10 L/min.

## Circulation

If the person is unresponsive and not breathing normally commence CPR.

The person performing chest compressions should:

- Place the heel of their hand in the centre of the chest with the other hand on top
- Avoid compression beyond the lower limit of the sternum. Compression applied too high is ineffective and if applied too low may cause regurgitation and/or damage to internal organs
- Compressions should be performed with a rocking movement, using the body to apply pressure rather than just the arms. For maximum effect keep your arms straight and elbows fully extended. Position your shoulders vertically above the individual's sternum. If the compressive force is not vertical to the individual's sternum the individual will roll and part of the compressive force will be lost (Rajab et al 2011)
- Note placement for resuscitation—ideally the person is placed supine on a firm surface.

### Depth of compression

- The lower half of the sternum should be depressed approximately one-third of the depth of the chest with each compression.
- This equates to more than 5 cm in adults.

This allows complete recoil of the chest after each compression, to allow for the blood to be pushed around the body (ARC 2016e).

### Rate of compressions

- Rescuers should perform chest compressions for all ages at a rate of approximately 100–120/minute. According to the ARC (2014), the number of compressions will be reduced due to interruptions for breaths given by rescue breathing.
- When performing compressions, if feasible, change rescuers at least every 2 minutes to prevent rescuer fatigue and deterioration in chest compression quality, particularly depth.
- Changing rescuers performing chest compressions should be done with a minimum of interruptions to compressions (Perkins et al 2015).

To avoid fatigue interfering with the delivery of adequate chest compressions:

- Ensure frequent rotation of personnel participating in CPR (every 2 minutes)
- Continue this management until circulation returns or the decision to stop resuscitation is made by the resuscitation team leader (ARC 2016d). See Figure 44.5 for the ARC guideline on CPR.

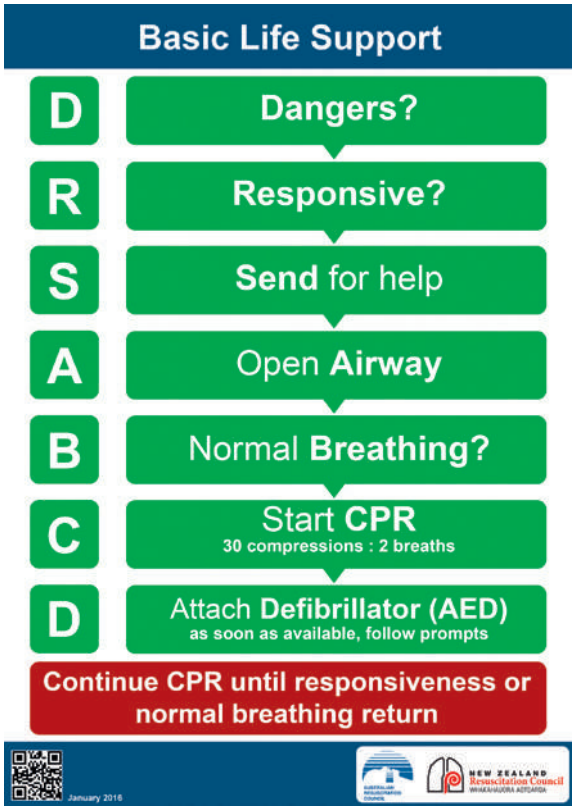

**Figure 44.5** Basic life support

*(Australian Resuscitation Council 2016d)*

## DEFIBRILLATION WITH THE AUTOMATED EXTERNAL DEFIBRILLATOR

The automated external defibrillator (AED):

- Automatically prompts the user regarding intervention
- Automatically analyses the heart rhythm
- Advises and prompts the user to deliver a shock only if needed.

The AED delivers an electrical charge to the person at either 150 J or 200 J, depending on the brand of defibrillator (see Clinical Interest Box 44.5). Some AEDs have a manual override feature allowing responders with greater skill (e.g. critical care trained staff) to have more control over defibrillation. The AED should be connected to the person once they are determined to be unconscious, not breathing normally and show no signs of life (ARC 2016f; 2016g; 2014).

### Preparation of skin prior to pad placement

- Ensure the surface of the individual's skin is dry
- Remove chest hair if required
- Do not delay defibrillation if shaving equipment is not available
- Remove any glyceryl trinitrate (GTN) patches

## CLINICAL INTEREST BOX 44.5 Use of AEDs

The use of AEDs by trained lay and professional responders is recommended to increase survival rates in victims with cardiac arrest. Check local organisation policy regarding AED training, as usually annual training with demonstration of knowledge and skills assessment is a requirement. Please note the ARC guideline 11.4 (2016h) states that 'AED use should not be restricted to trained personnel as the use of AEDs by individuals without prior formal training can be beneficial and may be lifesaving'.

*(Australian Resuscitation Council and New Zealand Resuscitation Council 2010)*

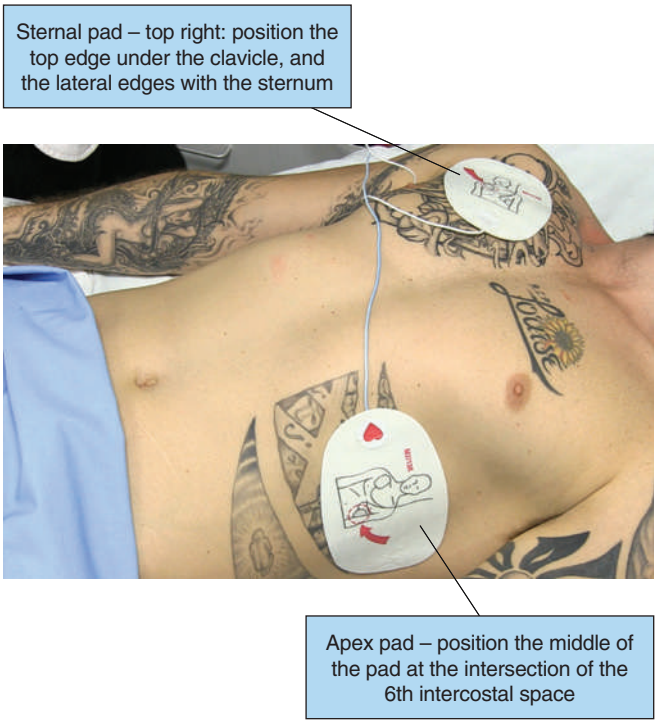

**Figure 44.6** AED pad placement. On large-breasted women the left electrode may be placed lateral to or underneath the left breast

*(© Elsevier Australia)*

- Remove jewellery
- Check for implanted devices (pacemakers).

### Placement of the pads

When applying AED pads (Figure 44.6):

- Remove dressings where pads are placed
- Avoid placing pads over implantable devices (e.g. cardiac pacemaker). If there is an implantable device the defibrillator pad should be placed at least 8 cm from the device
- Do not place AED electrode pads directly on top of a medication patch because the patch may block delivery of energy and cause small burns to the skin. Remove

medication patch and wipe the area before attaching the electrode pad
- In large-breasted women the left electrode or paddle may be placed lateral to or underneath the left breast (ARC 2016f; 2016g; 2014).

### Defibrillator safety

AED instructions:
- Always call 'stand clear' and visually check all personnel are clear prior to discharging the defibrillator
- Do not discharge paddles into the air
- Do not touch the person during defibrillation
- When a shock is delivered the person will usually jump as a consequence of the electrical energy passing through the body and the operator should take care to avoid flailing arms or legs
- Oxygen masks and nasal cannula should be placed a least 1 m away from the person
- Ensure free-flowing oxygen is moved at least 1 m from discharge
- Ensure the person is not near inflammable fluids, fumes or chemicals that could ignite
- Ensure any fluids or water are not present. Dry the individual's chest if necessary as contact with fluid may conduct a shock (ARC 2016f; 2016g; Sunde et al 2010).

If signs of life—including return of a palpable pulse—are evident, successful resuscitation has occurred (at least temporarily) and post-resuscitation care can begin.

## POST-RESUSCITATION CARE

Resuscitation does not stop after the return of a spontaneous circulation. Airway and breathing must be maintained and the blood pressure restored. Hypoxic brain injury, myocardial injury or subsequent organ failure are the predominant causes of morbidity and mortality after cardiac arrests (ACR 2016i; Deakin et al 2010).

Immediate post-resuscitation care should include an ABCDE assessment with the recording of vital signs, and a 12-lead ECG. The medical officer will order a chest x-ray and a full blood screen and any other specific investigations necessitated by the individual's condition (Deakin et al 2010).

Post-resuscitation nursing care needs to achieve certain goals. An example of a nursing care plan has been provided in Nursing Care Plan 44.1.

### Initial objectives of post-resuscitation care

Initial objectives of post-resuscitation care are to:
- Optimise cardiopulmonary function and systemic perfusion, especially perfusion to the brain
- Continue care in an appropriately equipped critical care unit
- Try to identify the precipitating causes of the arrest
- Institute measures to prevent recurrence
- Institute measures that may improve long-term, neurologically intact survival.

The individual post resuscitation is likely to develop electrolyte abnormalities that may be detrimental to recovery. The following investigations may be requested by medical staff. After successful resuscitation you may be required to assist in the following processes, as guided by the Registered Nurse:
- Serum electrolytes: hypo/hyperkalaemia and other metabolic disorders including acidosis and disturbances of magnesium, phosphate and calcium (to treat and prevent further cardiac arrhythmias)
- Arterial blood gases: hypocapnia can lead to cerebral ischaemia after cardiac arrest
- Electrocardiogram (ECG): to monitor rhythm and myocardium damage
- Blood glucose levels: strong association between high blood glucose after resuscitation from cardiac arrest and poor neurological outcome (Deakin et al 2010)
- Transfer of the individual to the special care unit if appropriate
- Consultation for friends and relatives with medical personnel to discuss the event
- Offer pastoral care or services of social worker
- The person should be examined for resuscitation-related injuries (e.g. rib fractures).

#### Emotional care for individual and friends

Nursing skills are important in helping family/significant others to understand and come to terms with a resuscitation

### NURSING CARE PLAN 44.1

**Assessment:** Mr Andrew Thomas has been transferred to high-dependency unit (HDU) post cardiac arrest 36 hours ago; you will be providing ongoing nursing care for this individual.
Mr Thomas's past medical history includes hypertension, elevated total serum cholesterol and osteoarthritis of the knees. At previous baseline, he could walk up to four blocks but felt short of breath with this degree of effort or when climbing two flights of stairs. This pattern has been stable for the past 6 months. He has never experienced chest pain. He attributed his shortness of breath to 'deconditioning' but had not yet discussed this symptom with his GP.
**Issue/s to be addressed:** Decreased cardiac output post cardiac arrest
**Goal/s:** Maintain the individual's blood pressure within an acceptable range to promote warm dry skin, a regular heart rhythm, clear lung sounds and strong bilateral equal peripheral pulses

## NURSING CARE PLAN 44.1—CONT'D

| Care/Actions: | Rationale: |
|---|---|
| Assess neurological status 4 hourly | Restlessness and anxiety are early signs of change in health status and a result of hypoxia and reduced cerebral perfusion |
| Assess heart rate and blood pressure 4 hourly | Increase in heart rate and reduction in blood pressure are indication of deterioration in condition |
| Assess skin colour and temperature 4 hourly | Cold clammy skin is secondary to a compensatory response to stimulation of the sympathetic nervous system, resulting in low cardiac output and oxygen desaturation |
| Assess peripheral pulses 4 hourly | Pulses that are weak and thready could indicate a reduced cardiac output |
| Assess fluid balance and weight gain | Increase in body weight is an indicator of fluid or sodium retention caused by the compromised regulatory mechanisms |
| Assess heart sounds 4 hourly | Different heart sounds can indicate issues with left ventricular ejection (S3 and S4) and a reduction in the compliance of the left ventricle |
| Assess lung sounds 4 hourly | Listen to all lung fields (crackles can indicate accumulation of fluid); look for signs of orthopnoea (difficulty breathing) |
| Continuous ECG monitoring | Monitor for signs of tachycardia, bradycardia, ectopic beats due to electrolyte imbalances—all can compromise cardiac output |
| Assess response to increased activity | Physical activity increases workload on the heart; assess for signs of fatigue and exertional dyspnoea |
| Assess urine output and frequency of urination | The renal system compensates for a low blood pressure by retaining water<br>Oliguria can be an indication of decreased renal perfusion |
| Assess for chest pain | A reduced cardiac output can affect perfusion of the myocardial muscle causing chest pain<br>Indication of imbalance between oxygen supply and demand |

### Evaluation

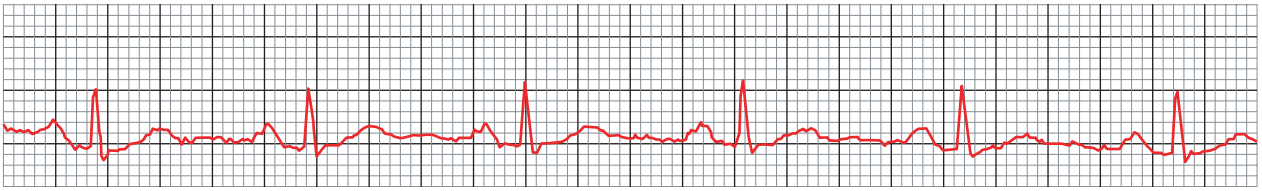
CNS: Alert and orientated, individual educated on the signs and symptoms of chest pain. Individual self-reports no further episodes of chest pain.
CVS: Haemodynamically stable, vital signs maintained within parameters set by medical officer, warm and well perfused. Fluid balance maintained. TED stockings in situ.
RESP: Bilateral equal air entry all lung fields on auscultation. $SpO_2$ on room air 96%, exercise tolerance increasing gradually.
GIT: Bowel sounds all quadrants, bowels opened assisted by stool softeners, tolerating light sodium-reduced diet.
URO: Voiding good clear amounts of urine (see fluid balance chart); individual educated to use urinal so nurse can measure amounts.
INTEG: Skin turgor good, no breaks in skin, reddened areas from defibrillator pads improving.
Person reports that his tolerance to exercise is improving, cardiac rehab continues, SOB minimal and recognises the signs of 'overdoing it'.

**Nursing interventions**

Administer medications as per medication chart, observing for response and indication of side effects. Ask medical officer for parameters for withholding any medications.
Maintain an optimal fluid balance: for individuals with decreased preload, administer fluids as prescribed and monitor closely for effects of the fluid challenge. This will increase extracellular fluid volume and in turn increase cardiac output.
Maintain haemodynamic parameters at prescribed levels as per medical officer's orders through titration of medications and fluids.
Individuals with increased preload should be prescribed fluid and sodium to reduce extracellular fluid volume.
Maintain adequate ventilation and circulation through positioning individual in semi-high Fowler's as tolerated to reduce preload and filling of the ventricles, therefore reducing work on the heart.
Place the individual in a supine position to increase venous return and promote diuresis.
Administer humidified oxygen as prescribed and monitor closely to accommodate increased oxygen demands.
Ensure promotion of physical and emotional rest by restricting activity to reduce oxygen demand, maintain a quiet relaxed environment to reduce emotional stress that can increase the heart rate and increase cardiac demands. Cluster medical and nursing care to allow for rest periods. Monitor the individual's response to activity to ensure the cardiac demands are within an acceptable limit for the individual.
Administer stool softeners to prevent person straining and placing further demands on the cardiac output.
Monitor the individual's sleep patterns and administer prescribed sedatives as rest is important for conserving energy and promoting recovery.
Provide education for the individual and significant other/s including the signs and symptoms of chest pain.
Explain medications including why they have been prescribed, the dose and any side effects.
Explain the importance of a gradual activity regimen and the signs and symptoms of over-exertion.
Explain the importance of diet restrictions, including fluid and sodium intake, the signs of fluid overload including shortness of breath, weight gain and swelling in ankles.

### CRITICAL THINKING EXERCISE 44.2

If you saw the rhythm below after defibrillation, how would you determine if it is pulseless electrical activity?



event. Individuals who survive resuscitation can experience anxiety, depression, post-traumatic stress disorder (PTSD) and difficulty with cognitive functions (Soar et al 2010). Similarly, the conscious, recovering individual may need help in understanding what has happened to them, the immediate consequences and their future. Nurses are often the providers of skilful, appropriate care and support to individuals (Soar et al 2010).

## IN-HOSPITAL MET DOCUMENTATION

The legal requirement for nurses to document individual care accurately and concisely is clear in the professional standards produced by governing and regulatory bodies. Treatment sequences including the 'who', 'what', 'where' and 'when' of interventions and subsequent individual responses must be documented accurately (Mardegan et al 2013). See Figure 44.7.

### Documentation

The role of documenter/scribe should be assigned to a staff member who is experienced with the data needed and how to obtain it. For example, the documenter may need to request that, as any medication is administered by IV push to the individual, the provider announces when it is 'in' so that the time documented is accurate. The documenter should have no other role during the resuscitation so that full attention can be given to collecting the data and following the multiple interventions that often occur simultaneously (Clements & Curtis 2012).

#### Rationale for documentation

- Provides information that can guide continuing care for the individual
- Helps to answer questions the family may have about the event
- Assists the institution to know if resuscitation care has been provided according to current standards
- Identifies quality issues so they can be investigated in a timely manner
- Provides aggregate data that can be used to identify variances of concern and as the base for continuous quality improvement efforts
- Provides information to guide resource allocation related to personnel, equipment and supplies used during resuscitations
- Helps to identify learning needs of staff
- Provides the data to answer research questions
- Can reduce the risk of medical litigation (ARC 2014).

#### Overcoming barriers to accuracy of in-hospital cardiac arrest documentation

Nurses play an important part in ensuring accurate documentation of the course and nature of resuscitation events. Document the incident management, medications and outcomes (as per hospital procedures and policies). When situations arise that compromise individual care nurses must be prepared to initiate and submit critical incident reports. The nurse team leader or delegate of the ward initiating the code blue event is responsible for ensuring all forms are completed accurately (these will depend on the healthcare facility's procedures and policies).

#### Suggestions for documentation

Most hospitals will have a template with guidelines for documentation. The record should include the following:

1. The individual's demographics
2. Times of arrest, initiation of CPR, defibrillation and initiation of ALS
3. Doses and routes of administration of drugs
4. Sequential cardiac monitoring with correlation to the individual's status, therapy and responses
5. Counter shocks delivered
6. Special procedures such as airway support, chest drains or external cardiac pacing
7. Vital signs and the individual's response to any interventions
8. The individual's status and disposition at the end of resuscitation.

Suggested data elements for collection can be divided into three categories of variables:

1. Individual variables (e.g. age, gender, witnessed/unwitnessed, location of event, date/time of event, comorbidities, any allergies)
2. Event variables (e.g. initial rhythm, essential interventions, event times)
3. Outcome variables (e.g. return of spontaneous circulation (for at least 20 minutes), discharge alive from the hospital, neurological status at discharge, length of stay).

Respond MET Record

Respond MET Record

M 16.13

**Figure 44.7** In-hospital MET documentation

Suggested critical time elements should be documented:

- Time from collapse to the beginning of CPR
- Time from collapse to first defibrillation when the initial rhythm is VF or pulseless VT
- Time from collapse to first dose of adrenaline.

## STAFF DEBRIEFING

Debriefing is a process to help people use their abilities to overcome the effects of critical incidents and should be performed within 24 hours post trauma, ideally at the end of the shift. Debriefing allows all personnel involved in the critical event to voice their concerns and reflect on the incident.

The debriefing should include the following:

- Forming a clear idea of the events
- Taking stock of the thoughts and reactions staff have experienced
- Providing information about normal stress responses to abnormal experiences
- Helping to mobilise problem-solving strategies
- Supporting personal needs.

## MANAGING SPECIFIC EMERGENCY SITUATIONS

Anaphylaxis is the most severe form of allergic reaction requiring urgent medical treatment. The Australian Society of Clinical Immunology and Allergy (ASCIA 2015) defines anaphylaxis as:

*any acute onset illness with typical skin features (urticarial rash or erythema/flushing, and/or angio-oedema), plus involvement of respiratory and/or cardiovascular and/or persistent severe gastrointestinal symptoms OR any acute onset of hypotension, bronchospasm or upper airway obstruction where anaphylaxis is considered possible, even if typical skin features are not present.*

**(ASCIA 2015)**

See Table 44.3 for signs and symptoms of allergic reactions.

Emergency management of anaphylaxis includes:

- Placing the individual in the supine position to improve blood return to the heart, as fatality can occur within seconds if an individual stands or sits upright suddenly
- If the individual is having difficulty breathing, allow them to sit, but do not allow them to stand or walk
- Individuals who are vomiting or pregnant should be placed in the left lateral position
- Adrenaline is administered as it is the first-line treatment of anaphylaxis and acts to reduce airway mucosal oedema, induce bronchodilation, induce vasoconstriction and increase strength of cardiac contraction
- Intravenous fluid resuscitation with saline
- The individual's airway is supported with ventilation and/or supplementary oxygen (Simons et al 2011; 2014).

**TABLE 44.3 | Signs and symptoms of allergic reactions**

| Mild or moderate reactions | Anaphylaxis |
|---|---|
| Swelling of lips, face, eyes<br>Hives or welts<br>Tingling mouth<br>Abdominal pain, vomiting (these are signs of anaphylaxis for insect allergy) | Difficult/noisy breathing<br>Swelling of tongue<br>Swelling/tightness in throat<br>Difficulty talking and/or hoarse voice<br>Wheeze or persistent cough<br>Persistent dizziness or collapse<br>Pale and floppy (young children) |

### Shock

Shock occurs when the circulatory system is no longer able to complete one of its essential functions such as providing oxygen and nutrients to the cells of the body or removing subsequent waste. Shock is a potentially life-threatening condition resulting from an imbalance of oxygen supply and demand causing hypoxia. Hypoxia affects cell function resulting in organ failure and potentially death (Richards & Wilcox 2014). There are many causes of shock including sepsis, cardiac pump failure, hypovolaemia and anaphylaxis. Individuals in shock can present with a variety of signs and symptoms and there are multiple factors to be considered, including age and comorbidities. The three stages of shock are considered as compensated, progressive and decompensated (Jones & Rushton 2012).

#### Early signs of shock: compensatory stage

This stage is described as a reduction in cardiac output activated by the baroreceptors located in the aortic arch and carotid body. As the receptors recognise the reduction in blood pressure they reduce the transmission of nerve impulses to the cardiovascular centre in the medulla oblongata. As the individual starts to experience a threat to circulation, this threat starts a chain of responses that are intended to maintain a good circulation. These changes are referred to as the compensatory mechanisms as they are designed to compensate for a problem with circulation that has developed. A person who has an effective compensatory response to an insult of circulation can appear quite well; however, the person may be suffering a serious circulatory problem. It is the signs of compensation that alert the nurse to the fact that the person may be in shock (see Clinical Interest Box 44.6 and Table 44.4). All health professionals caring for individuals potentially at risk of shock should aim to identify and correct shock during this compensatory phase (Moranville et al 2011).

**TABLE 44.4 | Stages of shock**

| | |
|---|---|
| **Early stage (compensated shock): compensatory mechanisms are able to maintain perfusion of vital organs** | |
| Heart rate | Mild tachycardia; bounding pulse |
| Level of consciousness | Lethargy, confusion, combativeness |
| Skin | Delayed capillary refill; cool and clammy |
| Blood pressure | Normal or slightly elevated |
| Respirations | Rapid and shallow |
| **Middle stage (uncompensated shock): compensatory mechanisms are unable to maintain perfusion** | |
| Heart rate | Moderate tachycardia; weak and thready pulse |
| Level of consciousness | Confusion or unconsciousness |
| Skin | Delayed capillary refill; cold, clammy and cyanotic |
| Blood pressure | Decreased |
| Respirations | Rapid and shallow |
| **Late shock** | |
| Heart rate | Bradycardia; severe arrhythmias |
| Level of consciousness | Coma |
| Skin | Pale, cold, marked diaphoresis |
| Blood pressure | Marked hypotension |
| Respirations | Decreased rate and tidal volume |

*(Adapted from Kalla & Herring 2013; Rivers et al 2011)*

## CLINICAL INTEREST BOX 44.6 Compensatory stage

- Reduced urine output
- Increased heart rate
- Increased respiratory rate
- Change in pulse pressure (the distance between the systolic and diastolic blood pressure)
- Delayed capillary refill (2 seconds or greater)
- Thirst

*(Garretson & Malberti 2007)*

## CLINICAL INTEREST BOX 44.7 Decompensatory stage

- Signs of early shock
- Lowered blood pressure
- Altered level of consciousness/unconsciousness
- Bradycardia (slow heart rate)
- Looks very unwell
- Oliguria (less than 30 mL of urine per hour or 0.5 mL per kg of weight)

*(Garretson & Malberti 2007)*

### Late signs of shock: decompensatory stage

The period of compensation provides the body with the opportunity to correct itself. In addition to this, this period of compensation provides health professionals with an opportunity to intervene. If this opportunity is not recognised, or the condition causing the shock is severe, the disease can outstrip the body's ability to compensate and signs of circulatory failure will occur. When this happens, the person is said to have decompensated (see Clinical Interest Box 44.7). Late decompensation is normally easily recognised, as the person deteriorates rapidly (Vadakel & Rizzolo 2013).

### Recognising the individual in shock

Traditionally, the presence of a low blood pressure was a sign that the person was in shock; however, low blood pressure is a very late sign of shock and, as previously mentioned, it is a sign that the person is starting to deteriorate. Many changes can be seen before an individual's blood pressure becomes low and it is these signs you must watch for if you are to accurately recognise the person in the early stages of shock.

### Managing the individual in shock

Although the different types of shock require different approaches, the general management of the person in shock should follow the ABC (airway, breathing and circulation) of resuscitation. After securing the airway, probably one of the most important interventions that ward staff can initiate in a spontaneously breathing person is to administer high-concentration oxygen through a non-rebreathe mask (O'Driscoll 2012).

Management in all types of shock includes the following:

- Basic life support—ABC
- Fluid replacement
- Vasoactive medications (a class of medications used to increase the blood pressure)
- Maintaining a patent airway and adequate ventilation
- Promoting restoration of blood volume; administering fluids and blood replacements as ordered
- Administering medications as ordered
- Minimising factors that contribute to shock
- Maintaining continuous assessment of the person

- Providing psychological support: reassuring the person to relieve apprehension and keep family members/significant others informed. The nurse's ability to recognise and consider the emotional and psychological distress suffered by these individuals could significantly improve the individual's long-term wellbeing (Mirabel et al 2011)
- Providing nutritional support.

It is important to remember to ensure safe administration of ordered fluids and medications, documentation of their administration and evaluation of the effects. Monitor the person for signs of complications and response to treatment. Oxygen is administered to increase the amount of oxygen carried by the available haemoglobin in the blood.

# CARDIAC EMERGENCIES

Any number of factors can disrupt the normal cardiac excitation process, resulting in arrhythmic contractions. Such factors include disease, metabolic and electrolyte imbalances, abnormal autonomic influence on the heart, toxicity to other drugs (e.g. digitalis) and myocardial ischaemia and infarction (Jafri 2012).

## Angina

Angina occurs when the coronary arteries become seriously narrowed by disease and the supply of oxygenated blood to the heart becomes insufficient for the increased oxygen needed (Patton & Thibodeau 2012).

### Manifestations of angina

Individuals often describe the pain as constricting, squeezing or suffocating, usually occurring after exercise. Angina can also be brought on by exposure to cold or emotional stress and is often of a short duration.

### Management of angina

Emergency management of angina includes:

- Reducing the workload on the heart to prevent further damage
- Encouraging the person to rest to prevent further exertion on the heart
- Keeping the person quiet and still
- Moving the person to a warm environment to prevent shivering
- Removing constrictive clothing
- Observing ABC.

### Initial management

- Call for assistance and reassure the person
- The routine use of supplemental oxygen is not recommended. Supplemental oxygen should be initiated if the individual is short of breath or there are signs of hypoxaemia, heart failure or shock (ARC 2016j; Chew et al 2011). There is relatively limited evidence from clinical studies to support the routine use of oxygen therapy in acute coronary syndrome (ACS) (Cabello 2010)
- Pulse oximetry should be used as a guide to administering oxygen therapy (ARC 2016k). The bottom line is that in individuals with suspected or proven ACSs, the routine use of supplemental oxygen is not recommended. However, oxygen therapy is indicated for individuals with hypoxia and those with evidence of shock to correct tissue hypoxia. It is recommended that oxygen administration be targeted to achieve oxygen saturation ($SpO_2$) of 94–98% (Caldeira 2014; Singletary et al 2015)
- Request or assist the Registered Nurse or doctor with gaining IV access if not already established
- Administer prescribed morphine intravenously to relieve pain
- Document effectiveness of pain relief
- Administer dispersible aspirin (instruct the individual to chew tablet)
- Acquire ECG.

## Myocardial infarction: cardiac arrest

Acute myocardial infarction (AMI) is a sudden loss of blood supply to an area of the heart, causing permanent heart damage or death. There are different types of AMI, classified by the location in the heart where the infarct occurs. Blood flow to the myocardium may be obstructed by atherosclerosis or thrombus formation (coronary occlusion). Damage occurs to the heart muscle when blood supply in the coronary arteries is blocked (Patton & Thibodeau 2012).

### Manifestations of myocardial infarction

Individuals can often confuse the pain with indigestion, as it ranges from discomfort to unbearable. The pain is often described as crushing, squeezing, tightness, aching, constricting or heavy, and is frequently around the central chest area, but may radiate to the back, shoulder, neck, jaw and arm. The person may have cool, pale and clammy skin, an early sign of shock. One of the significant differences between angina and a myocardial infarction is that medication or rest does not relieve myocardial infarction pain (Zafari et al 2011).

### Management of myocardial infarction

Emergency management of myocardial infarction includes:

- Keeping the person still and providing reassurance
- Calling emergency help
- Obtaining information about the individual's condition
- Assisting with gaining patent IV access
- Assisting with prescribed medication
- Monitoring vital signs
- Retrieving emergency equipment—emergency trolley including AED
- Being prepared to perform CPR if there are no signs of life following the algorithm for BLS.

When stabilised the individual will be transferred to one of the following: catheter lab for angiogram or ICU/CCU for further management.

## Hypertensive crisis

The definition of hypertensive crisis relies on absolute blood pressure; such numerical digits cannot verify the hypertensive crisis being urgent or emergent (Al Bannay et al 2013). A hypertensive crisis is a severe, sudden elevation in blood pressure that is accompanied by progressive or impending organ damage including irreversible injury to the brain, heart or kidneys. The brain is particularly vulnerable to the effects of severe hypertension. Isolated systolic hypertension, diabetes mellitus and poor adherence to treatments are known predictors of hypertensive crises. Presenting clinical signs and symptoms can differentiate hypertensive emergency versus urgency. Shortness of breath and neurological deficits indicate hypertensive emergency, whereas giddiness and headache are typical of hypertensive urgency (National Heart Foundation of Australia 2010). A hypertensive crisis is not an isolated BP reading but a clinical state and it is not necessary for the person to have a systolic BP >180 mmHg.

Individuals at risk of experiencing a hypertensive crisis include:

- Individuals with primary hypertension—a condition in which the cause of high blood pressure is unknown
- Individuals with secondary hypertension—high blood pressure that accompanies conditions such as renal disease, cardiovascular disease and sleep apnoea.

### Signs and symptoms

Signs and symptoms include headache, dizziness, syncope, numbness, weakness, blurred vision, angina pain, palpitations, peripheral oedema, fatigue and nose bleed.

### Nursing interventions

- Take a set of vital signs including blood pressure measurement on both arms
- Document and report your findings immediately to a senior staff member
- Assist with gaining patent IV access if not already established as the person will require a fast-acting IV antihypertensive medication.

Cardiac monitoring should be in place to monitor the person closely. For this reason the person is in most cases transferred to the intensive care environment for invasive blood pressure monitoring using an arterial line. You may be required to assist the Registered Nurse to prepare the individual for transfer to intensive care unit (ICU).

## Asthma

Individuals with asthma will have airways that narrow in response to triggers making it harder for them to breathe.

Three main factors cause the airways to narrow:

1. The inside lining of the airways becomes red and swollen (inflammation)
2. Extra mucus (sticky fluid) may be produced, which can block airways
3. Muscle around the airways tightens. This is called bronchoconstriction.

In the hospital environment, a person may be exposed to a number of different chemicals and be unaware that this may trigger an asthma attack.

### Signs and symptoms

A person experiencing an asthma attack may exhibit wheezing, chronic coughing, shortness of breath, chest tightness

### DECISION-MAKING FRAMEWORK EXERCISE 44.1

Molly is a student Enrolled Nurse currently on placement in an acute medical/surgical ward of the local hospital. She is working with her buddy nurse Lina and they have been allocated four individuals to care for. One of the individuals, Mr Beckett, complained of a headache and dizziness earlier this morning when he got up to go to the bathroom. Mr Beckett was admitted yesterday for review of his medications as he has hypertension that is not well controlled. Molly also notes that a previous admission was due to a hypertensive crisis. She takes a set of vital signs and notes that his blood pressure is quite high and that he appears quite red in the face. She goes to look for her buddy nurse to report Mr Beckett's vital signs, but is told that Lina has been called away. Molly looks at Mr Beckett's medication chart and notes that Mr Beckett has a new medication ordered that is due to be given.

Molly has not achieved 100% in her medication calculation hurdle so is not permitted to administer medications unless under direct supervision of her buddy nurse or clinical educator. She is concerned about Mr Beckett considering his past admission that involved a hypertensive crisis.

Using the decision-making framework:

1. What should Molly consider when deciding whether she should administer the medication?

### PROGRESS NOTE EXAMPLE 44.1

| | |
|---|---|
| 15/06/2015 2030 hrs | Nursing: Mr Beckett was admitted to the ward this afternoon for review of his medications for uncontrolled hypertension. On his last admission 12 months ago Mr Beckett had a hypertensive crisis. At 1800 hrs Mr Beckett's BP was 190/110 and he reported feeling unwell. The medical officer was notified and medication ordered as per medication chart. At 2000 hrs BP was 150/95 and Mr Beckett reported feeling better.<br>***M. Argote* (Argote) EN student** |

and anxiety. If the attack is life threatening, the person may demonstrate trouble focusing or talking, nasal flaring and cyanosis.

### Nursing interventions

- Think DRABC—person may need supplemental oxygen
- You may be asked to perform ongoing observation—remain calm and reassure the individual
- Measure and document vital signs with continuous pulse oximetry monitoring
- Alert the RN to *any* unusual findings of respiratory assessment
- You may be instructed to administer nebulised medications such as Ventolin (salbutamol) and/or Atrovent (ipratropium). Both are used to treat bronchospasm

Asthma emergency treatment is 4 puffs of Ventolin every 4 minutes until review

- Evaluate the individual's response to the bronchodilator.

## Seizures

Seizure is a sudden surge of electrical activity in the brain that usually affects how a person feels or acts for a short time. It is an event characterised by a sudden, excessive and disorderly (abnormal) discharge of electrons in the brain that may be accompanied by an abrupt alteration in motor and sensory function and level of consciousness.

Seizures are not a disease in themselves. Instead, they are a symptom of many different disorders that can affect the brain. Some seizures can barely be noticed, while others are totally disabling (Berg & Scheffe 2011). Individuals who present to emergency may have seizures that are secondary to causes such as electrolyte disturbances, withdrawal, toxins, infections, central nervous system (CNS) mass lesions or other aetiologies; these are classified as acute symptomatic or provoked seizures (Huff et al 2014).

Causes of seizures include:

- Brain tumours
- Cerebral hypoxia (breath holding, carbon monoxide poisoning, anaesthesia)
- Cerebrovascular accident (infarct or haemorrhage)
- Convulsive or toxic agents (lead, alcohol)
- Alcohol and drug use withdrawal
- Head injury (highest incidence is found in young adults)
- Heat stroke
- Infection (acute or chronic)
- Metabolic disturbances (diabetes mellitus, electrolyte imbalances)
- Kidney failure (uraemia)
- Degenerative disorders (senile dementia) (Berg et al 2010).

### Signs and symptoms

There are six types of generalised seizures:

1. Grand mal/tonic–clonic (loss of consciousness with generalised body stiffening followed by violent jerking)
2. Absence (a short loss of consciousness with few or no symptoms)
3. Myoclonic (sporadic jerks, usually on both sides of the body)
4. Clonic (repetitive rhythmic jerks involving both sides of the body)
5. Tonic (sudden stiffening of the body)
6. Atonic (sudden general loss of muscle tone which often results in a fall).

### Nursing interventions

If you suspect the person is having a seizure, stay with the person, and call for help. **Remember DRSABCD.**

### Initial nursing management

- Position the person to avoid aspiration or inadequate oxygenation
- If possible, a soft oral airway can be placed (do not force teeth apart)
- Suction and $O_2$ must be available
- Monitor respiratory function with ongoing pulse oximetry
- Note the time the seizure started, and what body part it is affecting, with the type of movement involved
- Loosen any restricting clothing; protect the person from harming themself with pillows, bed rails. Remove any furniture from the area but do not restrict the movement of their limbs as this may cause musculoskeletal damage
- Place the person in the recovery position if possible as this will assist the tongue to return to its front-forward position and will also allow accumulated saliva to drain from the mouth. Apply supplemental oxygen and have suction ready.

### Post-seizure care of the individual

- Provide adequate ventilation by maintaining a patent airway
- Suction secretions if necessary to prevent aspiration
- Allow the individual to sleep post seizure
- On awakening, orient the individual to what has occurred
- Provide reassurance as this can be a very distressing event
- Assist the Registered Nurse or medical officer to gain IV access
- Frequent monitoring of neurological status using the Glasgow Coma Scale, including vital signs, must be documented and any changes reported immediately
- Monitor glucose (hyperglycaemia followed by hypoglycaemia is common)
- Treat hyperthermia (occurs often with status epilepticus) aggressively.

## Epilepsy

Epilepsy is a disorder characterised by recurring seizures (also known as 'seizure disorder') parallelled to a seizure described

as a brief, temporary disturbance in the electrical activity of the brain. The human brain is the source of human epilepsy. Although the symptoms of a seizure may affect any part of the body, the electrical events that produce the symptoms occur in the brain. The location of that event, how it spreads and how much of the brain is affected and how long it lasts all have profound effects. These factors determine the character of a seizure and its impact on the individual.

### Terminology

*Status epilepticus*: a prolonged seizure (usually defined as lasting longer than 30 minutes) or a series of repeated seizures—a continuous state of seizure activity. Status can occur in almost any seizure type. It is a medical emergency and can be life threatening.

*Post-ictal phase*: the abnormal condition occurring between the end of an epileptic seizure and return to baseline condition (Fisher & Engel 2010).

### Nursing management in the post-ictal phase

Post-ictal behaviours and symptoms often require special assessment and treatment. Potential complications experienced during the post-ictal period include headache, functional deficits and behavioural manifestations. In the post-ictal phase individuals can experience delirium and psychosis and may exhibit agitation and confusion (Fisher & Engel 2010). Medical and emergency staff require careful training to manage behaviours associated with post-ictal delirium and psychosis in order to protect individuals while their confusion resolves (Krauss & Theodore 2010). See Chapter 35 for more information.

## Summary

The Enrolled Nurse requires the skills and knowledge to respond quickly and effectively in a variety of emergency situations, to be an effective member of a team and to work efficiently in a stressful environment. The Enrolled Nurse, as an integral member of the healthcare team, has a duty of care to deliver care that is holistic, including to the family and significant others. Nurses care for an increasing percentage of individuals with complex problems who are likely to be or become seriously ill during their hospital stay. The basic requirement is always thorough assessment, accurate measurement and recording of vital signs and timely reporting of any changes in the individual's condition, no matter how subtle the changes may appear to be. The effectiveness of handover tools such as ISBAR/ISOBAR ensures that all relevant information is communicated to all parties involved efficiently and effectively.

The inclusion of the Nursing and Midwifery Board's national framework for decision making offers a process to encourage the Enrolled Nurse to apply clinical judgment with decision making to promote safe individual care (Jacob et al 2013).

## Review Questions

1. Explain the aims of emergency care.
2. Provide a brief summary of your understanding of the modified early warning scores chart (MEWS).
3. You are working in the medical/surgical ward and are about to finish your morning shift. You decide to do a final check to ensure you have completed all your individuals' charts when you discover one of your individuals, Mr Lynch, collapsed on the floor in his room. When you enter the room you notice the following:
   - The individual is not moving
   - A vase of flowers is overturned on the floor.
   a. As the first responder what are your immediate priorities?
   b. Explain the assessment process when responding to an individual who is unresponsive.
4. Mr Lynch's medical history includes hypercholesterolaemia and hypertension; he had complained earlier in the day that he 'felt dizzy' when he got up to go to the toilet. There is no evidence in his progress notes that his concerns have been addressed or investigated. His admission notes state that he was admitted the previous day for stabilisation of his blood pressure. Mr Lynch has not had his vital signs measured since 0600 hrs that morning.
5. Reflect on this situation. How could you have managed this situation?

CHAPTER 45

# Nursing care: maternal and newborn

*Kate Stainton*

## KEY TERMS

amenorrhoea
Apgar score
birth
breast milk
caesarean
colostrum
fetal heart rate
fetus
labour
lanugo
lochia
meconium
morning sickness
quickening
trimester
uterine enlargement
vernix caseosa

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Describe the physiology of pregnancy
- Describe the physiological changes that occur during pregnancy
- Discuss the care of the pregnant woman during the pre/antenatal period
- Explain the postnatal care of the woman
- Identify common medications used in the final stage of labour
- Identify activities that should be included in a daily care plan for a normal newborn

## CHAPTER FOCUS

Maternity nursing involves the care of a woman during her pregnancy and labour, and the care of both the woman and her baby during and after birth. Although midwifery is a specialised profession, requiring the learner midwife to undertake a separate educational program, the Enrolled Nurse may be required to assist in the provision of maternity care. It is therefore important that the Enrolled Nurse has a basic knowledge of human growth and development, the processes of normal pregnancy and labour and an understanding of the immediate and subsequent care of the mother and the newborn infant. The actual work and scope of practice of the individual Enrolled Nurse is influenced by the employment setting, their level of competency and employer policy requirements.

The birth of a baby follows a woman's pregnancy and the process of labour. The first part of this chapter focuses on the physiology of pregnancy and the indicators and methods of confirming pregnancy and pregnancy care, which includes preparing for the birth. Later, the four stages of labour, and nursing measures for mother and baby during the postnatal period, are explained.

## LIVED EXPERIENCE

My mother-in-law keeps telling me that if I put my baby on his back to back to sleep he will get a flat head, but the midwives say that sleeping on his stomach will increase his risk of SIDS. I know that sleeping him on his back or side and breastfeeding are two things that I can do to help prevent SIDS. There is so much to learn and take in at the moment; sometimes it is hard to remember it all.

**Kim, talking to Jane, an Enrolled Nurse**

# PREGNANCY

Pregnancy (the gestational process) comprises the growth and development, within a woman, of a new individual from conception to birth. The average duration of pregnancy is 266 days after fertilisation of the ovum, or 40 weeks from the first day of the last normal menstrual period.

## Physiological changes

Pregnancy, which is a normal physiological function, produces changes in almost all the mother's body systems. Most of these changes are temporary and most are the result of hormone actions. These changes prepare the mother's body to protect the developing embryo and fetus, provide for the demands of the **fetus** and prepare to feed the baby when it is born. Profound endocrine changes occur that are essential for maintaining pregnancy, normal fetal growth and postpartum recovery. The hormonal factors involved in pregnancy are listed in Table 45.1.

Pregnancy can be divided into three periods called **trimesters**, each lasting about 3 months (Blackburn 2013; Davidson et al 2014). The first trimester comprises the embryonic phase. The uterus continues to be a pelvic organ. Towards the end of the first trimester it is possible to record fetal heart tones by fetascope or ultrasound. The second trimester comprises the fetal phase of development. During this phase the uterus becomes an abdominal organ. A protective coating called **vernix caseosa** covers the fetus. **Lanugo**, fine downy hair, covers the body. At the end of the second trimester, the fetus resembles a small baby. During the last 3 months of pregnancy the fetus grows to approximately 50 cm and 3.2 to 3.4 kg (Crisp et al 2013). The skin thickens, subcutaneous fat makes the fetus appear rounder and the lanugo begins to disappear. The normal fetus at this stage is ready to make the transition from intrauterine to extrauterine life.

Adaptation to pregnancy involves all of a woman's body systems. The mother's physical response is assessed in relation to normal expected alterations. Women can experience varying signs that can signify pregnancy. The maternal physiological changes during pregnancy are listed in Table 45.2.

### Psychological changes

During pregnancy a woman's psychological status may alter; for example, she may experience anxiety and emotional lability. The pregnant woman's psychological status depends on many factors, including her basic personality, whether the pregnancy was planned and is desired, the strength of her social and family support systems and her self-concept. A number of emotional problems can arise during pregnancy or after the birth. Anxiety or depression can occur antenatally or postnatally (see also Chapter 39).

## Confirmation of pregnancy

The signs of pregnancy are divided into three general groups: possible, probable and positive.

### Possible indicators of pregnancy

Signs of possible pregnancy are those from which a definite diagnosis of pregnancy cannot be confirmed. Signs and symptoms during this stage can often be caused by other conditions. The indications of possible pregnancy are:

- Amenorrhoea
- Nausea and vomiting
- Breast enlargement and tenderness
- Frequency of micturition
- Quickening (Perry et al 2014).

**TABLE 45.1 | Hormonal factors in pregnancy**

| Source | Hormone | Actions |
|---|---|---|
| Ovary | Oestrogens and progesterone during the first few weeks of pregnancy | Oestrogens influence:<br>• Uterine growth<br>• Breast growth<br>• Water and sodium retention<br>• Pituitary hormone release<br>Progesterone influences:<br>• Relaxation of smooth muscle<br>• Relaxation of connective tissue<br>• Secretory changes within the breasts<br>• Development of the lactiferous ducts |
| Placenta | Oestrogens and progesterone when the placenta is fully developed | |
| | Placental lactogenic hormone | Promotes growth, stimulates development of the breasts and plays a role in maternal fat metabolism |
| | Relaxin | Has a relaxant effect, especially on connective tissue |
| Pituitary | Thyroid-stimulating hormone (TSH) | Stimulates release of thyroxine to maintain increased metabolism |
| | Oxytocin | Contraction of the uterus (at the end of pregnancy). Secretion of milk (after birth) |
| | Prolactin | Initiates and sustains lactation (after baby is born) |
| Parathyroids | Parathormone | Maintains normal calcium ion concentration |
| Adrenals | Adrenal hormones (e.g. glucocorticoids and aldosterone) | Increased secretion maintains increased metabolism |

*(Blackburn 2013)*

**Amenorrhoea** (the cessation of menses) in a sexually active healthy woman is often the first indication of pregnancy. However, other factors may cause amenorrhoea, such as eating disorders (anorexia nervosa, bulimia), excessive exercise or changes in metabolism and endocrine function.

The symptoms of nausea and vomiting, which can occur at any time of the day, are often referred to as **morning sickness**. Nausea often occurs between 6 and 14 weeks gestation and is believed to be a result of large quantities of placental hormones (progesterone, oestrogen, human chorionic gonadotrophin [hCG] and human placental lactogen).

Breast enlargement and tenderness are a result of the placental hormones stimulating the breast ductal system in preparation for breastfeeding. Some women experience similar symptoms premenstrually and pregnancy is often overlooked for this reason.

Increased pigmentation of the skin occurs over the face (chloasma), breasts (darkening of the areolae) and abdomen (linea nigra—a dark line extending from the umbilicus to the symphysis pubis).

Frequency of micturition occurs at the start of pregnancy and then again in the third trimester. In the first trimester the enlarging uterus competes for space in the pelvic cavity and exerts pressure on the urinary bladder. In the later stage of pregnancy the descending fetal part of the uterus moves into the pelvic cavity in preparation for birth.

**Quickening** is the result of fetal movement and is first perceived at 16–20 weeks gestation. The sensation is felt by the mother and described as gentle fluttering in the lower abdomen (Pairman et al 2015; Perry et al 2014).

## Probable indicators of pregnancy

Abdominal **uterine enlargement**, the presence of Braxton Hicks contractions and a positive pregnancy test are indicators that a woman is probably pregnant. However, on very rare occasions there may be other conditions or factors (uterine tumours, medications or premature menopause) that cause these events.

Abdominal and uterine enlargement occurs around the 12th week of pregnancy. At this stage the fundus of the uterus can be located just above the symphysis pubis, and extends to the umbilicus between weeks 20 and 22.

Braxton Hicks contractions are irregular, painless uterine contractions that first occur in the second trimester. They are more pronounced in multiparas (women who have had more than one child) and can be mistaken for labour contractions.

A pregnancy test may be performed after the first missed menstrual cycle. Pregnancy tests use maternal blood or urine to determine the presence of the placental hormone human chorionic gonadotrophin (hCG). A positive result from a pregnancy test is considered an indicator of probable

## TABLE 45.2 | Physiological changes in pregnancy

| Area of change | Description |
|---|---|
| Uterus | Increase in size to about 30 × 22 × 20 cm (at term)<br>Increase in mass to about 1 kg (at term)<br>Cervix becomes softer (in preparation for labour)<br>A plug of mucus (the operculum) is formed by, and remains in, the cervix from the eighth week until labour begins<br>The uterus forms into two segments; the lower segment is thinner and becomes soft and dilated towards the end of pregnancy<br>Painless, irregular contractions (Braxton Hicks contractions) occur throughout pregnancy |
| Vagina | In early pregnancy, the vagina (and cervix) change in colour from pink to dark red/blue<br>The amount of acidic vaginal secretions increases<br>Thickness increases, due to venous dilation |
| Breasts | Increase in size and mass<br>Nipples enlarge and become more prominent and darker in colour<br>Areolae become darker<br>Prominent sebaceous glands (Montgomery's tubercles) appear on the areolae at about 12 weeks<br>Increased sensation and tingling<br>Colostrum (the fluid secreted during pregnancy) can be expressed at 16 weeks |
| Skin | Darker pigmentation in the nipples and areolae, on the face (chloasma) and on the abdominal midline (linea nigra)<br>Stretch marks may appear on the abdomen, breasts and buttocks<br>Spider naevi (bright red lesions with minute radiating branches) may appear on the face and upper chest |
| Musculoskeletal system | Spinal curvature changes to compensate for the abdominal enlargement, resulting in arching of the back<br>The symphysis pubis and sacroiliac joints become mobile and the pelvis becomes wider, due to softening of the connective tissue in preparation for labour |
| Urinary tract | Relaxation of smooth muscle causes the ureters to become dilated, elongated and kinked<br>These changes may lead to stasis of urine and infection<br>Frequency of micturition may occur in the early months, as the uterus occupies more of the pelvis<br>Reduced muscle tone in the pelvic floor, and increased pressure from the growing fetus, may result in stress incontinence towards the end of pregnancy |
| Gastrointestinal tract | Hormonal and mechanical changes (e.g. increased hormonal levels and reduced intestinal motility) may result in morning sickness, gastric acid reflux and constipation |
| Cardiovascular system | Blood volume increases by 40–50%<br>Cardiac output is increased because of increased blood volume<br>Haemodilution (due to increased plasma volume) results in lowered haemoglobin level<br>Coagulability of blood is slightly increased<br>Reduced tone in blood vessels may result in varicose veins |
| Respiratory tract | Ventilation rate is increased to obtain the higher amounts of oxygen required |
| Basal metabolic rate (BMR) | In the second half of pregnancy, BMR increases by 15–25% to cope with the increased demands |
| Body mass | Increases by about 25% of the pre-pregnant weight. Weight gain is due to the growth of the uterus and breasts, the uterine contents, increase in maternal blood volume and interstitial fluid and maternal storage of fats and protein |

*(Blackburn 2013; Pairman et al 2015)*

pregnancy. Provided that they are carried out precisely according to the given instructions, home pregnancy tests based on the amount of hCG in the urine are capable of greater than 97% accuracy.

Professional pregnancy tests based on urine or blood serum are even more reliably accurate. The most highly reliable test is the radioimmunoassay (RIA), a technique in radiology that can accurately identify pregnancy as early as 1 week after ovulation. While attributed with high levels of accuracy, pregnancy tests cannot be classed as absolutely certain indicators because there are factors that may interfere with the reliability of test results. These factors include premature menopause, the effects of taking some particular medications (anticonvulsants or anti-anxiety drugs) and the presence of a malignant tumour or haematuria (Murray & McKinney 2014).

### Positive indicators of pregnancy

The most positive sign of pregnancy is a growing and developing baby (Perry et al 2014). The fetal heartbeat can be detected as early as 10 weeks gestation using equipment such as a tocograph pelvic ultrasound or Doppler device. This scan enables (allows) the examiner to detect and record the fetal heart rate and therefore confirm pregnancy. The Doppler can be used to listen to the baby's heart rate from 18–20 weeks gestation onwards.

Fetal body parts can be felt by an educated examiner (medical officer, obstetrician or midwife) from the second trimester onwards. This gives the examiner an indication of the position of the fetus, which is vital during the third trimester when discussing birthing options.

## Estimated date of delivery

The date when the baby is due (confinement date) may be calculated by dates or using ultrasound. Calculation by dates to determine the estimated due date is made by ascertaining the first day of the last known menstrual period and adding 9 months and 7 days. Calculation by ultrasound is made by using height frequency, short wavelength and soundwave reflections to visualise the size of the fetus.

Estimated date of delivery (EDD) may be calculated by using the date of the LNMP, an early dating ultrasound or a scan at 18–20 weeks. The EDD according to the LNMP (last normal menstrual period) is used if:

- The LNMP is reliable (the woman is certain of the first day of LNMP and she has a regular 28- or 35[1]-day cycle)
- The early dating scan calculates the EDD to be within 5 days of a reliable LNMP due date.

The EDD according to the early dating ultrasound is used if:

- The LNMP is unreliable and/or
- The early dating scan calculates the EDD outside 5 days of a reliable LNMP due date

[1]Add 7 days to the EDD when a woman has a regular 35-day cycle

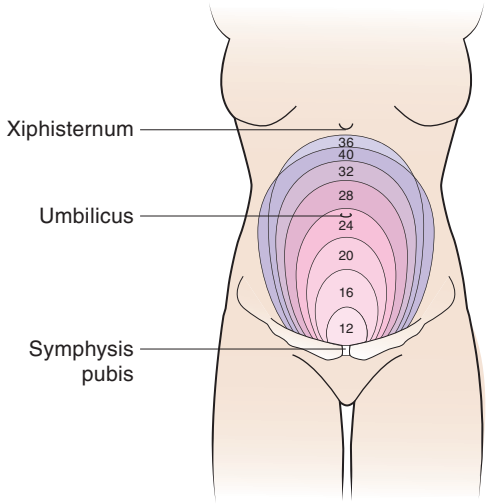

**Figure 45.1** Fundal height of the uterus

- Ultrasound performed prior to 14 weeks is more accurate for estimating gestation.

The 18–20-week scan should be used if:

- There was no dating scan performed and
- The LNMP is unreliable and/or
- The 18–20-week scan calculates the EDD outside 10 days of a reliable LNMP due date.

Fundal height is used to indirectly measure fetal growth in relation to gestational age. Fundal height, measured in centimetres, should equal the number of weeks of gestation plus or minus 2–3 cm (Murray & McKinney 2014). Calculation by assessing the fundal height (Figure 45.1) is made by measuring the height of the uterine fundus from the symphysis pubis.

## Minor discomforts associated with pregnancy

The pregnant woman may experience one or a variety of minor disorders or discomforts, many of which are the result of increased secretion of hormones or pressure from the uterus and its contents on other body structures. Table 45.3 lists the potential discomforts and outlines guidelines that can be used to increase women's levels of comfort.

# PRENATAL CARE AND PREPARATION

Prenatal (or antenatal) means before birth. The aims of prenatal care are to:

- Promote a healthy pregnancy and normal labour
- Promote the birth of a healthy, living baby
- Prepare the woman and her partner for labour and birth
- Detect and manage any complications.

## The initial consultation

The woman's initial consultation concerning her pregnancy may be with her general practitioner, obstetrician or a midwife. The first consultation involves obtaining a

**TABLE 45.3 | Health education: management of minor discomforts during pregnancy**

| Discomfort | Management guidelines |
|---|---|
| Morning sickness | Small, frequent dry meals<br>Fluids in between meals<br>Something to eat (e.g. a dry biscuit) before getting out of bed in the morning<br>Avoid fried and heavily spiced foods |
| Indigestion | Small frequent meals<br>Avoid spicy foods if not used to them<br>Elevate the head of the bed |
| Constipation | High-fibre foods<br>Adequate fluids<br>Exercise |
| Fainting | Avoid sudden postural changes<br>Avoid constrictive clothing<br>Avoid lying on the back during late pregnancy<br>Avoid fatigue |
| Backache | Maintain correct posture<br>Daily rest periods<br>Wear low-heeled shoes<br>Sleep on a firm surface (e.g. place a board under the mattress) |
| Varicose veins | Avoid long periods of standing<br>Avoid constrictive clothing<br>Elevate the legs whenever possible<br>Wear supportive stockings<br>Avoid sitting or standing with the legs crossed |
| Urinary tract infection | Adequate fluids<br>Perineal hygiene measures (e.g. wiping from front to back after elimination) |
| Leg muscle cramps | Avoid standing for long periods<br>Elevate the legs whenever possible<br>Relieve symptoms by pulling upwards on toes |
| Haemorrhoids | Avoid constipation<br>Relieve discomfort by applying cold compresses or icepacks |

*(Perry et al 2014; Lowdermilk et al 2014)*

comprehensive health and social history, thorough physical examination, and discussion on selecting where the woman wishes to give birth (Perry et al 2014).

The physical examination includes checking the blood pressure, heart, lungs, palpating the abdomen and assessing weight, height, body build and skin colour. Samples of urine and blood are obtained and tested. Urine is tested to diagnose pregnancy and to detect the presence of abnormalities; for example, glucose or protein. Blood is tested to determine blood group and Rhesus (Rh) factor status, haemoglobin level and the presence of rubella antibodies. It may also be tested to exclude certain disorders such as blood-borne viruses (e.g. human immunodeficiency virus (HIV) and hepatitis) and sexually transmitted infections (e.g. syphilis).

Problems may occur when a mother has an Rh (D) negative blood group and her baby is Rh (D) positive. If during pregnancy or labour the baby's blood cells cross the placenta into the woman's bloodstream and the woman produces antibodies to the baby's red blood cells problems such as severe anaemia, brain damage or even death may occur. This condition is known as haemolytic disease of the newborn. RH (D) immunoglobulin (also known as anti-D) is an antibody injection that can help prevent the woman developing antibodies to her baby's blood. This will help prevent potential harm to the baby during the pregnancy but also help protect babies in future pregnancies. It is given during pregnancy or soon after birth for all Rh (D) negative women who have an Rh (D) positive baby (Australian Red Cross Blood Service 2014).

A cervical smear and/or cervical swabs may be obtained if the woman has not had regular Papanicolaou (Pap) smears or if infection is suspected. This may be delayed until the woman has her 6-week post-birth check-up.

If pregnancy is confirmed, the obstetrician will discuss with the woman possible options regarding the birth. The woman may choose to give birth in a hospital, or in a birthing centre; she may also choose not to continue with the pregnancy (Pairman et al 2015).

Prenatal education may be provided by the obstetrician, midwives or childbirth educators. The educational aspects of prenatal care are listed in Table 45.4.

### Subsequent consultations

The frequency with which subsequent visits occur depends on the obstetrician and the needs of the woman, but the usual practice is to schedule visits every 4 weeks until 28 weeks, then every 2 weeks until 36 weeks, then weekly until birth.

Prenatal care involves:

- Gestation and estimated due date (EDD)
- Blood pressure
- Fundal height measurement
- Fetal movements
- Auscultation of the fetal heart
- Abdominal palpation.

The standard antenatal check provides the basis for routine biophysical screening, assessment, referral and education (Pairman et al 2015). Blood tests or other investigations, for example ultrasonic examination, may be performed as part of routine care or when other tests or physical symptoms indicate there is a need.

## LABOUR

**Labour** is the process in which the woman has uterine contractions to assist with her baby's **birth**. The process also

## TABLE 45.4 | Prenatal education

| Aspect | Description |
|---|---|
| Diet | A balanced diet designed to meet the nutritional requirements of pregnancy:<br>• An extra 600–800 kilojoules per day in the last 6 months of pregnancy<br>• An extra 500 mg of calcium per day in the last 4 months of pregnancy<br>• An extra 3 mg of iron per day throughout pregnancy<br>• Increased amount of vitamins, supplied by suitable foods rather than artificial supplements<br>• Total daily intake of about 10 500 kilojoules |
| Exercise | • Moderate exercise encouraged (e.g. a daily walk or swim). Some activities (e.g. vigorous athletics) may need to be avoided if the woman has a history of abortion or premature labour<br>• Prenatal classes educate the woman in specific exercises designed to prepare her for labour and birth |
| Rest | • Fatigue should be avoided by obtaining sufficient sleep and by having numerous short rest periods during the day |
| Hygiene | • Normal hygiene practices should be continued. Vaginal douching is to be avoided |
| Clothing | • The woman is advised to wear comfortable non-constrictive garments, and shoes with low heels<br>• Maternity girdles are available, which provide support for just above the symphysis pubis and the lower back |
| Preparation for labour and birth | • Education on childbirth and relaxation techniques is conducted on an individual or group basis by midwives or physiotherapists. The woman's partner is also encouraged to attend the childbirth education program, which prepares the couple for labour and birth. The classes include instruction in relaxation techniques<br>• The couple is also informed of the physiology of labour and encouraged to discuss all aspects of pregnancy, birth and care of the baby |
| Manifestations of complications | The woman is advised to contact her obstetrician or the hospital immediately if there is:<br>• Vaginal bleeding<br>• Abdominal or 'menstrual-type' pain<br>• Severe headaches<br>• Drainage of fluid from the vagina<br>• Excessive vomiting<br>• Blurred vision<br>• Difficulty in passing urine<br>• Swelling of the hands, feet or face |
| Manifestations of labour | The couple are informed of the manifestations of the onset of labour:<br>• Regular contractions<br>• Vaginal 'show' (blood-stained mucus)<br>• Drainage of amniotic fluid from the vagina (ruptured membranes) |
| Breasts | • Maternity brassieres are designed to support the breasts as they increase in size and mass<br>• If the nipples are flat or inverted, nipple shields may be worn under the brassiere. The shields depress the areolae and allow the nipples to extend |
| Sexual activity | • Sexual activity may be continued throughout the pregnancy, unless there is a risk of haemorrhage (e.g. from a malpositioned placenta (placenta praevia))<br>• If the woman has a history of spontaneous abortion, she may be advised to avoid sexual intercourse during the first 3 months of pregnancy |
| Environmental hazards | Factors potentially harmful to the pregnancy should be avoided:<br>• Smoking is linked to abortion, intrauterine growth retardation and perinatal death<br>• Alcohol is linked to physical and mental fetal abnormalities and fetal growth retardation<br>• Many drugs, prescribed and unprescribed, are linked to physical and mental fetal damage<br>• Exposure to microorganisms (e.g. the rubella virus) in the first 3 months can result in fetal abnormalities<br>• Immunisations generally should not be performed during pregnancy because of possible damage to the fetus<br>• Exposure to radiation during the early weeks of pregnancy may inhibit normal cell division<br>• Exposure to pesticides and other chemicals may result in fetal abnormalities |

*(Murray & McKinney 2014; Lowdermilk et al 2012)*

includes the vaginal birth of the placenta and membranes. Normal labour occurs spontaneously at about 40 weeks of pregnancy and lasts for up to 24 hours after onset. Factors that cause the spontaneous onset of normal labour include changes in hormonal levels, uterine distension, fetal pressure and a sudden reduction of intrauterine pressure when the membranes rupture (Davidson et al 2014; Murray & McKinney 2014). Labour is divided into four stages; Table 45.5 lists the characteristics of each stage. During labour the uterus contracts rhythmically to dilate and efface (take up) the cervix and push the fetus through the birth canal. After the baby is born the uterus continues contracting to aid in birth of the placenta and membranes.

Labour and childbirth are normal events, accompanied by a variety of emotions, such as excitement, fear, anxiety and anticipation. As the management of, and attitudes towards, labour and birth differ widely among different cultures, expectant women, obstetricians and midwives, practices are adjusted according to individual needs, knowledge and experience. The following section addresses the general aspects of care and support throughout labour and birth.

## The first stage

### Latent stage

Latent stage refers to a period of time, not necessarily continuous, when the woman has painful contractions with some cervical change, including cervical effacement and dilation up to 4 cm.

### Active or established first stage

In this stage there are regular, painful contractions associated with progressive cervical dilation from 4 cm.

Care during the first stage involves monitoring the progress of labour, monitoring the condition of the woman and unborn baby (fetus) and promoting physical and psychological comfort. Progress of labour is monitored by assessing the strength, frequency and duration of contractions, by palpating the abdomen to assess the position and descent of the fetus and by performing vaginal examinations only when deemed necessary to assess the degree of cervical dilation and the position of the presenting part of the fetus. The condition of the woman and her response to labour are monitored by checking her vital signs, by observing urinary output and testing the urine for the presence of protein and ketones, and by observing her for the manifestations of fatigue, discomfort or pain.

The health of the unborn baby is monitored by assessing the fetal heart. As the **fetal heart rate** and rhythm is the main indicator of the baby's health, the heartbeat is regularly assessed during labour. The heart rate should remain between 120 and 160 beats per minute and the beat should remain strong and regular. Assessment may be performed by listening to the heart through a fetal Doppler placed on the woman's abdomen or by using a fetal monitoring device, such as electronic fetal monitoring, known as a cardiotocograph. Fetal monitoring devices provide an audible and/or visual record of the fetal heartbeat (Pairman et al 2015; Perry et al 2014).

**TABLE 45.5 | Stages of labour**

| Stage | Characteristics |
|---|---|
| First | Contractions occur at fairly regular intervals, from about every 10 minutes at the onset of labour to about every 2 minutes at the end of the first stage<br>The cervix is effaced (raised up)<br>The fetal head begins to descend in the pelvis<br>The cervix is gradually dilated<br>The membranes may rupture, and release amniotic fluid |
| Second | Strong contractions occur, lasting about 60 seconds and becoming expulsive, and the woman experiences a desire to bear down<br>The woman uses abdominal muscles and the diaphragm to assist in pushing the fetus down the birth canal<br>The muscles of the pelvic floor are displaced by the advancing fetal head<br>The vagina is dilated, and the perineum is thinned and flattened by the advancing head<br>The vulva and vaginal orifice bulge and the anus dilates as the head advances<br>The baby is born |
| Third | After a brief period the placenta separates from the uterine wall<br>Uterine contractions restart to expel the placenta and membranes<br>Signs of separation and descent of the placenta are:<br>• A small rush of blood from the vagina<br>• The cord lengthens at the vulva<br>• The uterus is firmly contracted and the height of the fundus drops to umbilical level |
| Fourth | In the 1–2 hours after birth of the baby and expulsion of the placenta and membranes, the uterus begins the process of involution. Involution is the return of the uterus to its normal size. The fourth stage of labour completes when the mother's body has returned to physiological stability |

*(Davidson et al 2014)*

Another way that the condition of the fetus is assessed is by observing the passage of 'liquor' draining from the woman's vagina. Normally the liquor remains clear and straw coloured, while green-tinged liquor indicates the presence of meconium. The passage of **meconium** (the dark green tarry substance formed in the fetal bowel) by the fetus while still in the uterus indicates that the fetus is physically distressed because of a period of fetal oxygen deprivation.

### Promoting comfort

Unless there are factors that may compromise the condition of the woman or her baby, the woman is encouraged to do

whatever will contribute to her comfort. She may choose to walk around or may prefer to sit or lie down. The woman may like to engage in some form of activity, such as reading, watching television or listening to music. Some women find that frequent warm showers enhance their comfort, while others may prefer to have their partner or the midwife massage their abdomen and back.

During the first stage the woman may need to be encouraged and supported to use the relaxation techniques learnt in prenatal classes. She is encouraged to empty her bladder at least every 2 hours, as a full bladder can inhibit uterine action. The woman is also encouraged to consume frequent small amounts of clear fluids (e.g. 75 mL/h). Because the absorption of food is slowed down during labour and because there is the possibility that a general anaesthetic may be necessary, solid food is generally restricted during labour. The input and output of fluids are monitored to assess for the manifestations of the woman becoming dehydrated. Because the process of labour requires the expenditure of large amounts of energy, the woman may become fatigued. Fatigue is minimised by encouraging rest and relaxation and by relieving discomfort of pain.

Strong contractions may cause considerable discomfort, and the measures used to minimise and relieve discomfort will vary according to the needs and choices of each woman. Measures to relieve discomfort aim to reduce pain and tension without causing any harmful effects to the woman or baby. Measures include practising relaxation techniques, assuming the most comfortable position, back and abdominal massage, using music as a distraction and medications. Medications such as analgesics may be prescribed. Any medication administered must not cause harmful effects to the baby or retard the progress of labour. Analgesic medications may be administered by inhalation (e.g. nitrous oxide and oxygen), intramuscular injection (e.g. pethidine) or intrathecal injection of local anaesthetic solution into the epidural space surrounding the spinal cord, from which the nerves supplying the uterus or cervix arise (epidural analgesia).

Throughout the first stage the midwife should provide emotional support and encouragement, and do all that she can to ensure that the labour is not a distressing experience (Murray & McKinney 2014; Perry et al 2014).

## The second stage

Traditionally, and currently, the definition of second stage labour commencement is described as when the cervix is fully dilated. The duration of second stage is therefore based on when the woman is diagnosed as being fully dilated by the midwifery or medical staff.

Although it may be accompanied by some anxiety, the second stage of labour signals the imminent birth of the baby. It concludes with the actual birth of the baby (Murray & McKinney 2014). Progress of labour and the condition of the unborn baby are monitored as in the first stage, but at more frequent intervals. During contractions the midwife and/or partner should offer encouragement. As the fetal head reaches the pelvic floor, most women experience the urge to push (Murray & McKinney 2014). Automatically the woman will begin to exert pressure downwards by contracting her abdominal muscles while relaxing her pelvic floor. This bearing-down reflex is an involuntary reflex response to the pressure of the presenting part on stretch receptors of pelvic muscles. The midwife then encourages the woman to push when the urge to push is felt, rather than giving a long prolonged push on command.

Between contractions the woman may wish to have her lower back massaged, and should be encouraged to rest. Small sips of fluid or ice chips should be offered to moisten her mouth, and the woman may wish to have her face wiped at frequent intervals. Labour is often hard and tiring work. The woman is encouraged to adopt the position in which she feels the most comfortable for the birth. Physical support may be needed to maintain the woman in a suitable position. She may wish to have her back supported by pillows, depending upon the position she adopts (see Case Study 45.1).

### CASE STUDY 45.1

**Mandy and Tom**

Mandy had been in labour for 12 hours and delivered a 3.9 kg male infant vaginally after a normal pregnancy, labour and delivery. She and her husband Tom have another son at home aged 18 months. Mandy had just transferred into the ward an hour before and the report you received was that all her assessments were normal. She uses her call bell and when you go to answer, she shows you her perineal pad which is saturated.

What nursing actions should you take?

## The birth

The birth of the baby may take place with the mother lying down, standing, squatting or kneeling. Some maternity units and birth centres are equipped to accommodate the woman and her partner in a home-like environment, with some women choosing to have a water birth. During birth of the baby the obstetrician or midwife assists by gently controlling the emergence of the head to prevent perineal damage. In some instances an episiotomy (incision into the perineum to enlarge the vaginal opening) may be necessary. Sometimes the application of obstetric forceps to the fetal head may be necessary to assist in its passage through the birth canal.

During an uncomplicated birth, after the baby's head has cleared the vagina, the shoulders and the rest of the baby's body are gently pushed out. Immediately after birth, provided that everything is normal and as expected, the baby is generally placed on the mother's abdomen. The umbilical cord is clamped in two places and cut between the clamps (Davidson et al 2014). Although about 95% of babies present head first, a small number are born buttocks first (breech presentation).

The second stage is completed when the baby is born, which is an emotional time for everyone involved in the birth process. The baby is placed on the mother's abdomen, and

both she and her partner can look at and caress their infant. The obstetrician or midwife remains nearby so that the condition of both mother and baby can be monitored. It may be necessary to aspirate mucus from the baby's mouth to prevent inhalation. The midwife encourages the mother to initiate skin-to-skin contact with her baby: the baby is placed at her breast and encouraged to suckle. This is thought to help establish the attachment process between mother and baby, and suckling promotes uterine contractions, necessary for expulsion of the placenta.

### Caesarean birth

A **caesarean** birth is the birth of the baby through a surgical abdominal incision. The incision is usually made just above the pubic bone in the lower part of the abdomen. When the uterus is cut through the lower part this approach is referred to as a lower uterine segment caesarean section (LUSCS). Some caesarean births are planned in advance (elective caesarean) because of existing problems with the pregnancy. These may include presentation and size of the fetus, hypertension, maternal diseases, prolapsed umbilical cord or placenta praevia. In other cases, the decision to perform a caesarean is made during the course of labour. This is called an emergency caesarean. An emergency caesarean section may be indicated for a variety of reasons, including maternal complications, such as severe bleeding or pre-eclampsia, fetal distress or failure to progress in labour. Most women who have had a LUSCS are eligible for a vaginal birth after caesarean (VBAC) (Murray & McKinney 2014; Perry et al 2014).

## The third stage

During this stage the placenta and membranes are expelled. In most settings, oxytocic medications such as ergometrine or syntometrine are given to promote uterine contraction and reduce the risk of postpartum haemorrhage. After expulsion of the placenta the woman's vulva and vagina are swabbed clean so that the areas can be inspected for any lacerations or tears. Any laceration or episiotomy is repaired. A sterile vulval pad is applied to collect the vaginal discharge. The woman is assessed for signs of haemorrhage and for any adverse effects of the birth. To assist with involution (decrease in size of the uterus), the midwife will massage the uterine fundus through the abdominal wall to promote contraction and retraction. The placenta and membranes are assessed to see if they are normal and complete. If they are incomplete, there may be fragments retained in the uterus, preventing uterine contraction and providing a focus for infection (Davidson et al 2014).

## The fourth stage

The fourth stage of labour is the first 1–4 hours after birth of the placenta, or until the mother has regained physiological stability (Lowdermilk et al 2014). During this time the midwife's role includes monitoring the mother for her emotional health and wellbeing, levels of pain, bladder function, blood loss and recovery from anaesthesia. The midwife also provides the initial care for the new baby. The role also includes providing emotional support that may be necessary for the mother, family or significant others. It should be acknowledged that not all mothers will have partners, not all will have the family support they may desire and this may be a time when particular sensitivity is required.

## Cultural influences on birthing practices

The needs and wishes of the woman during pregnancy, labour and the postnatal period may be influenced by her cultural background. This may be very different from that of the midwife, but must be understood and respected. Australia is a multicultural society, and providing for the many different cultural preferences of women requires flexibility on the part of midwives and nurses. There are differing cultural beliefs of significant importance to women concerning:

- Who should be present during the labour and birth
- Showering or bathing after birth
- What is considered an appropriate diet for a new mother
- How long and how much a woman should rest after the birth
- What should happen to the baby (e.g. when breastfeeding should begin, what clothing and adornments should be used)
- Specific rituals and practices that promote healing of the body
- What should happen to the placenta.

Cultural attitudes vary enormously. For example, in over 50 known cultures, including Filipino, Vietnamese, Korean and Mexican, it is not the cultural norm for women to give infants colostrum, and breastfeeding is delayed until the milk has come in (Ladewig et al 2014). In most South-east Asian cultures it is seen as essential that the woman is not exposed to anything cold after the birth, as this is believed to risk the onset of arthritis and bladder problems. Many people of Vietnamese culture believe that showering and washing the hair too soon after giving birth leads to recurring headaches and hair dropping out quickly in old age. Many people in Hmong culture believe that when a person dies they must collect the person's placenta (termed 'black jacket') and put it on the deceased so they can be allowed entry into heaven. For this reason a Hmong woman may be very anxious about what is happening to her placenta and may request that it be given to the family for burial at the woman's home. Clinical Interest Box 45.1 provides examples of cultural preferences in women who are of Chinese and Samoan descent.

When nurses understand the beliefs behind particular cultural practices, the risk of confusion and conflict concerning what the woman chooses to do during and after the birth of her baby is reduced (Pairman et al 2015). However, care should be taken not to generalise about what happens in particular cultures because attitudes, values, beliefs and practices can vary significantly even within each cultural group (see Chapters 10 and 11). In addition, the process of assimilation into a new culture may alter traditional beliefs and practices. Clinical Interest Box 45.2 provides examples of traditional birthing practices in the Indigenous population of Australia.

## CLINICAL INTEREST BOX 45.1 Cultural preferences in women of Chinese and Samoan descent

### Women who are of Chinese descent

Many Chinese people, when they are ill or pregnant, assume a 'sick role' in which they depend heavily on others for assistance. This means that some healthcare providers may be seen as uncaring because they encourage independence rather than catering directly to the wishes of the individual.

Pregnancy and especially childbirth are believed to disturb the balance of hot and cold required for good health. Because of this, various dietary and behavioural practices are customary to keep the mother and baby physically healthy including:

- Eating special soups and chicken/chicken broth
- Not eating lamb because of the belief that it may cause the baby to develop epilepsy
- Not eating pineapple because it is believed to cause miscarriage.

*Birth*

Many Chinese people believe that a woman should not cry out or scream during labour.

Women may experience distress if not given a choice between cultural traditions and Western practices. Women may prefer sitting or squatting to give birth. Ideally, the labouring woman's mother or mother-in-law attends childbirth, rather than the father of the child. This practice varies among communities.

#### After birth

Some women may observe a period of confinement after birth, during which they rest, dress warmly, limit showers and eat only foods classed as hot. Staff may need to discuss the option of exercises to avoid deep vein thrombosis while in bed (e.g. bending knees, moving legs).

According to some customs in Guandong and Hong Kong, postpartum women may not eat with other family members for up to 1 month due to the notion of pollution linked to lochial discharge. For the same reason, postpartum women may abstain from sexual relations.

#### Infant care

Women are often expected to follow certain traditional practices advocated by older female relatives. However, practical constraints mean that many Chinese women opt for an approach to child rearing which combines practices from both Australian and Chinese culture.

Infants may be over-wrapped and slept in prone position. Many Chinese people believe that infants should not be dressed in used clothing as the baby may take on the characteristics of those that wore the clothes previously. Therefore, the family may bring new clothing for the baby instead of dressing the baby in hospital clothing. Disposable shirts may be acceptable. Infants may be separated from their mother for at least the first 24 hours. This tradition is practised to allow the postpartum woman to rest. The Australian practice of leaving infants with their mother should be discussed with women of Chinese background. Some women believe that if a newborn child is praised, bad spirits will take the infant away or the child will fall ill. Grandmothers, particularly the father's mother, are often very involved with the new infant and the new mother's recovery. They should be acknowledged when caring for the mother and during teaching sessions.

#### Infant feeding

Colostrum may be considered stale or dirty and discarded. Staff may need to explain the benefits of colostrum feeding and encourage women to feed their infant. Babies may be fed with boiled rice water or formula instead of colostrum during the first 2 days.

### Women who are of Samoan descent

Samoans often view pregnancy as a sickness. Pregnant women are cautioned against being alone in the house or going outside, especially after dark. Samoans believe that a lone pregnant woman can be hexed by evil spirits, causing abnormalities to the unborn child. A pregnant woman should always be accompanied by an elderly woman, even to the toilet. Samoans believe that pregnant women should avoid heavy work which may lead to the displacement of internal organs.

For their first delivery, Samoan women usually return to their mother's home and after a confinement period, the new family returns home. This should be kept in mind since in Australia, Samoan women may have no parental support. Episiotomy is not considered a part of usual delivery-related procedures. Birth attendants usually perform a cut on the umbilical cord after it has stopped beating. After birth, the baby is massaged with blood from the placental part of the umbilical cord. Health professionals should be aware of this practice.

#### After birth

In Samoa, the placenta is usually expelled by pulling, while the abdomen is massaged. Sometimes the father is asked to apply force to facilitate expulsion. Care should be taken to ensure that the placenta is offered to the new parents. In Samoa the placenta is disposed of in various ways. It may be wrapped in a cloth and buried in the ground by close family members, burned in a hole dug in the ground or thrown into the sea. It may be believed that the newborn is at risk if anything happens to the placenta. In Samoa, after labour, the woman's abdomen may be firmly bound with cloth to prevent the uterus from 'falling down'. This remains in place for up to 1 month. After delivery, women traditionally

## CLINICAL INTEREST BOX 45.1 CULTURAL PREFERENCES IN WOMEN OF CHINESE AND SAMOAN DESCENT—cont'd

receive abdominal and pelvic floor massage to correct any displacement that may have occurred during labour. They will then bathe. Sometimes, a bowl of steaming water is placed between a woman's legs, so that the rising steam can cleanse the birth canal. In Australia, Samoan women could be asked if they would like a hot water bottle to replace this procedure.

Once postnatal procedures are complete, a woman may be given a bowl of sago cooked in coconut cream and flavoured with lemon leaves. According to Samoan practice, a woman should rest for a month after her first delivery. After subsequent deliveries, she should rest until the infant's umbilical cord falls off. The benefits of early physical activity after birth should be discussed with Samoan women in Australia.

**Infant care**

Samoan infants are usually bathed immediately after birth. A newborn is usually placed in cold water to make them breathe.

**Infant feeding**

Samoan midwives may recommend that a woman breastfeed immediately after birth; others give boiled water only for up to 5 days. Samoan infants are fed on demand. Breastfeeding is considered to be a contraceptive.

*(Queensland Health 2009)*

## CLINICAL INTEREST BOX 45.2 Cultural beliefs and childbirth of Indigenous people in Australia

Birth is seen very much as 'women's business' in Aboriginal society. Education has been traditionally undertaken through observation and involvement in the life of the extended family, with elders imparting specific knowledge as required. Traditionally men have not been involved during the pregnancy or the birth and appeared to play a minor role in baby care and child raising.

Much of this is changing as Aboriginal people move in from the bush to town living, and family support systems shrink. Western ideas are being embraced as young Aboriginal people seek inclusion in the wider Australian way of life. Many Aboriginal women now give birth in hospitals, often far from family and friends. The traditional women's business of childbearing seems to be breaking down in some places, as men accompany their partners during labour and birth in hospitals.

*(Pairman et al 2015; Queensland Health 2009)*

## CRITICAL THINKING EXERCISE 45.1

You are caring for Hong, a young woman who came to Australia from China a year ago. She gave birth to her first baby earlier today. The midwife has instructed her to get up and go and have a shower. Hong is crying and distressed and tells you that 'the midwife doesn't understand'.

1. What do you think might be the reason for Hong's distress?
2. How could this misunderstanding have been avoided?
3. What will you do now to relieve Hong's distress?
4. What other cultural issues need to be explored to ensure that care is culturally appropriate?

# POSTNATAL CARE

The postpartum period is called the puerperium. Sometimes called the fourth trimester of pregnancy, the puerperium begins after childbirth and continues for the following 6 weeks (Davidson et al 2014). This is the time during which the changes to the woman's body brought about by the pregnancy gradually resolve. It is also a time of adjustment to changed responsibilities. Mothers generally return home within days of the birth, so it is important to provide as much help and education as possible before discharge. While this section focuses mostly on care in the birthing centre or hospital, the ongoing needs of the mother, baby and family should be considered so that support can be planned as necessary for the remainder of the puerperium.

After the third stage of labour is completed, the mother's immediate comfort is promoted by ensuring that any wet or soiled clothing is replaced, and by offering her a drink and snack. She and her partner should be allowed to spend time together with the baby. If the mother is exhausted she may appreciate being left to rest or sleep.

## Care of the mother

The degree of care required will depend on a variety of factors, such as where the birth occurred, how long the mother remains in the maternity unit or birth centre, whether the birth was full or preterm, if it was uncomplicated, whether there were multiple births and whether there are any postnatal discomforts or complications. In addition, care must be adapted to meet any specific cultural needs. The woman who has had a caesarean birth must also be assessed like any other postoperative person. Postnatal care is directed at promoting the health of both mother and baby. Aspects of care include promoting:

- Adequate rest
- Reduced risk of infection
- Freedom from discomfort or pain

- The establishment of lactation and breastfeeding
- Maternal bonding and attachment
- The mother's confidence in caring for her baby (Perry et al 2014; Murray & McKinney 2014).

Assessment is made of the **lochia**, the vaginal discharge that occurs after birth. Lochia consists of blood and broken-down endometrium and is discharged for up to 3–4 weeks after birth. At first it is bright red in colour, then becomes pink and ultimately presents as a colourless or white discharge. Lochia should not have an offensive odour or contain any blood clots; the presence of either indicates the possibility that products of conception have been retained in the uterus. Observe for character, colour, odour and presence of clots. Clinical Interest Box 45.3 outlines the assessment of lochia. Nursing Care Plan 45.1 outlines the care of a postnatal woman and Progress Note Example 45.1 shows an example of an entry into progress notes.

Perineal care involves daily showering to cleanse the area, and frequent changing of vulval pads. If a perineal tear occurred or if an episiotomy was performed, care may be needed to reduce discomfort and prevent infection around the area. Local care may involve the application of cold packs to the area, or sitz baths to which salt has been added. A soft cushion to sit on or lying on the side to feed may help to relieve perineal soreness, and analgesic medications such as

## CLINICAL INTEREST BOX 45.3 Changes in lochia that cause concern

**Change**

- Presence of clots
- Persistent lochia rubra

**Possible problem**

- Inadequate uterine contractions that allow bleeding from vessels at the placental site.
- Inadequate uterine contractions; retained placental fragments; infection

**Nursing action**

- Assess location and firmness of fundus
- Assess voiding pattern
- Assess activity pattern
- Assess for signs of infection
- Record and report findings

*(Ladewig et al 2014)*

## NURSING CARE PLAN 45.1

**Assessment:** Kylie Jones, delivered a 3.5 kg male infant earlier this morning. She had an epidural anaesthetic during a 12-hour labour. She had a greater than normal blood loss at delivery. The midwife has asked you to get her up and walk her to the toilet. She says she has full return of sensation to her legs but feels a little light headed. As she stands up, Kylie says she feels weak and dizzy. Her gait is unsteady so you lower her back to bed to prevent her from fainting.
**Issue/s to be addressed:** Risk of injury related to postural hypotension
**Goal/s:** To remain free of complications related to mobilisation post delivery

| Care/Actions | Rationale |
|---|---|
| Allow Kylie to rest before attempting mobilisation | Rest will allow dizziness to pass and circulation to stabilise |
| Assist with ambulation | Orthostatic hypotension may occur, and having someone present helps prevent injury |
| Check Kylie's blood pressure before getting her out of bed again | A decrease of 15 to 20 mmHg in systolic pressure on rising indicates postural hypotension |
| Instruct Kylie to bend her knees and move her feet when she first stands | Will increase venous return from the lower extremities |
| Initiate measures to prevent injury if Kylie were to faint | |

**Evaluation**

Kylie requested assistance when ambulating initially and sustained no injury during her postnatal stay.

*(Murray & McKinney 2014)*

## PROGRESS NOTE EXAMPLE 45.1

| | |
|---|---|
| 12/04/2015<br>1030 hrs | Nursing: Kylie supervised with mobilisation to toilet as feeling light headed getting out of bed for first time after delivery. BP checked and no postural drop noted. Instructed to call for assistance when next wanting to mobilise. Call bell left within reach. Kylie stated she will do this.<br>***L. Adams* (Adams) EN** |

paracetamol may be prescribed. Observe for haematoma and oedema.

Fundal height is assessed by the midwife and documented each day to monitor involution of the uterus. It may be necessary to massage the fundus to promote uterine contraction. The height of the fundus decreases by about 1 cm each day until, by the 11th or 12th day, it can no longer be palpated abdominally. The firmness, height and location are evaluated.

The breasts and nipples are assessed each day for any red areas, oedema, cracking or bleeding. Palpation of each breast detects any areas of hardness, which may indicate blocked milk ducts.

Vital signs are assessed with abnormalities reported. The extremities are evaluated for signs of thrombophlebitis. The bladder is observed for fullness, output, burning and pain. The bowels are assessed to determine passage of flatus and bowel sounds and for defecation.

Postnatal exercises are started on the first day. They are designed to strengthen the pelvic floor and abdominal muscles. An instruction sheet illustrating the exercises to be performed is generally given to the mother and explained by the midwife.

Evaluation of the woman's emotional status involves observing family interaction and support and any signs of a depressive state. The woman should also be observed for interest in the newborn, eye contact, touch contact and the ability to respond to the infant's cries (Davidson et al 2014). Signs of the 'baby blues' include being teary, irritable, overly sensitive in interactions with others and moody. The 'baby blues' usually clear up after a few days with no other treatment except support and understanding. If the woman's mood does not lighten it may be a sign of something more serious, like depression or anxiety (see Chapter 39).

Postpartum teaching covers topics such as nutrition, rest, breast care, exercise, activity, urinary and bowel function, blood loss, perineal care, contraception, sexual activity, postpartum signs and symptoms that should be reported, infant care and feeding, postpartum depression, available resources and follow-up care (Murray & McKinney 2014).

A balanced diet, which provides adequate nutrients and fibre, is advised. In the hospital setting a dietitian may be responsible for accommodating special cultural needs in relation to diet but often family members will want to bring meals from home for the new mother. If the woman is breastfeeding, she should consume an extra 2500–4000 kJ/day above the requirements of pregnancy. This provides the extra energy required to produce milk. In addition to nutritional requirements, the lactating mother requires 3 L of fluid a day.

The lactating mother is advised to avoid consuming foods that may affect her lactation and can upset the baby. This is very individual and may include highly spiced foods. The woman who wishes to breastfeed should also be advised of the substances known to be excreted in the **breast milk**. Substances that should be avoided or taken sparingly include:

- Nicotine
- Alcohol
- Caffeine
- Laxatives
- Anti-infective agents
- Sedatives.

## Minor postnatal discomforts

Some discomforts are associated with the postnatal period (Murray & McKinney 2014). These include after-pains, constipation, difficulty with passing urine and engorged breasts. After-pains are cramps that may occur for a few days after birth, as the uterine muscles contract during the process of involution. Mild pain relief medication may be prescribed.

Constipation may result from inadequate fibre or fluid intake. The woman may also be afraid to go to the toilet post birth as it may increase her levels of pain and discomfort. Increasing fibre in the diet and maintaining a high fluid intake is important and, if necessary, a stool-softening medication may be prescribed. Analgesia may also be given prior to the woman going to the toilet.

Difficulty in voiding may be experienced initially because of loss of bladder tone, bruising of the urethra or perineal soreness. Some women may find that voiding in a bowl or bath of warm water eases the soreness. If the woman finds that this helps, she should be advised, as a precaution against infection, to wash the perineal area gently after voiding.

Engorged breasts may occur a few days after the birth because of increased blood supply to the breasts in beginning lactation. The breasts may become full, distended, hard and uncomfortable. The midwife should advise mothers that this is not unusual and that wearing a supportive nursing bra, even during the night, will help, provided that it is not too tight. Breastfeeding the baby at frequent intervals (2–3 hours if necessary) helps and promotes engorgement to diminish naturally. A qualified midwife or lactation consultant should be contacted to assist women who are concerned about breast engorgement.

## Breastfeeding

Breastfeeding is the optimal method of feeding the baby. While most women will choose to breastfeed, there are others who, for a variety of reasons, will prefer not to. While it is important that a woman be advised of the benefits of breastfeeding, it is also important that she is not made to feel guilty if she chooses to bottle-feed.

### Lactation

During pregnancy, placental hormones, oestrogen, progesterone, hCG and placental lactogenic hormone stimulate the development of glandular tissue and ducts in the breasts. **Colostrum** is the fluid secreted by the breasts during pregnancy and during the first few days after birth. It is a thin, yellow serous fluid consisting of water, protein, fat, carbohydrates and immunologically active substances. When the placenta is expelled after birth of the baby, the anterior pituitary gland releases prolactin, which activates the mammary cells to produce and release milk (Davidson et al 2014).

Lactation depends on the maintenance of milk production and on the 'let-down' reflex, whereby milk is ejected from the breasts. The let-down reflex is stimulated by a neurogenic reflex, with oxytocin released from the pituitary gland in response to suckling, forcing milk out of the alveoli in the breasts. The let-down reflex, which generally occurs a short time after the baby begins to suck on the nipple, can also be stimulated when the mother sees, hears or thinks about her baby. Conversely, the reflex can be inhibited by anxiety, fear or tension.

Breastfeeding has advantages for both the mother and the baby. Breast milk is free from microorganisms, is easily digested, contains all the essential nutrients necessary for the baby's development and contains immunoglobulins and other substances that protect the infant from some infections while the immune system is underdeveloped. Breastfeeding aids involution of the uterus and is generally emotionally satisfying for the mother. Breastfeeding is also convenient and economical.

## Management

The four basic principles to correct attachment are that the:

1. Baby must be close to mother and facing her
2. Baby's mouth and mother's nipple are in alignment
3. Mother holds her breast in such a way that the baby can grasp a large mouthful of breast tissue
4. Baby's mouth is gaping wide with tongue forwards and down in order to be able to take a large amount of breast tissue into the mouth (Murray & McKinney 2014).

## Preparing to feed

The mother:

- Should be comfortable
- Can be either sitting straight and well supported or lying down
- Can have pain relief as required.

The baby is:

- Unwrapped
- Well supported and held close
- Facing the mother (The Royal Women's Hospital 2013).

## Attaching the baby

The mother:

- Supports her breast with her free hand with her fingers well back from the nipple/areola
- Holds baby close enough to maintain chin contact with the breast.

The baby:

- Exhibits rooting reflex—opens mouth wide.

After the mother has latched her baby to her breast, the baby is stimulated to start suckling when it feels the nipple touching the junction of the hard and soft palate.

## Indications of good attachment

FEEL—a 'drawing' sensation may be felt by the mother. There may be some 'nipple stretch' soreness in the first few days (peaking days 3 to 6) of feeding. This usually occurs with the first sucks of the feed and eases after milk transfer is evident. The 'let-down' itself may or may not be felt by the mother

LOOK—the baby's mouth is wide open and the chin is in contact with the breast. The tip of the nose may be touching or free of the breast. Baby's head is tilted back slightly so that the chin is pushing into the breast.

LISTEN—the baby's swallows may be audible. There should be a change from short 'suck/suck' pattern to deeper 'suck/swallow' cycle.

To detach the baby from the nipple, the mother should place a finger into the side of the baby's mouth to let air in to break the suction. Gentle detachment helps to prevent the development of sore nipples.

After the feed the baby is checked to ensure that it is clean and comfortable, and should then be placed in its cot without too much handling. The mother should ensure that her nipples are clean and dried. Expressed breast milk is rubbed into the nipple after the feed then allowed to dry to protect them against soreness or cracking.

The baby is fed when hungry (demand feeding). Each baby is an individual and some may require breastfeeding as frequently as every 2 hours, while others will be content if they are fed every 3–4 hours. The length of time the baby feeds also varies. The baby and mother establish their own feeding routine, and the mother's milk supply adjusts according to demand.

Breast milk may be expressed, either manually or with a breast pump, if necessary. Expression may be necessary to relieve discomfort if the breasts are overfull, to help stimulate milk production or to put breast milk into a feeding bottle; for example, if the baby requires feeding when the mother is temporarily unavailable. Expressed breast milk can also be provided by the mother if the baby is premature or ill and is unable to feed at the breast.

Breastfeeding difficulties sometimes arise, for a variety of reasons:

- Maternal anxiety or frustration about breastfeeding
- Cracked nipples, which cause pain when the baby sucks
- Inverted nipples, which are difficult for the baby to grasp
- Breast engorgement, which prevents the milk from flowing readily
- Over-abundance of milk, which flows too quickly causing the baby to splutter and perhaps vomit
- Failure of the let-down reflex
- Inability of the baby to suck well enough at the breast.

Management of breastfeeding difficulties depends on the cause, but with time, patience and encouragement, most can be overcome. Organisations such as the Australian Breastfeeding Association provide support and advice on how to prevent and deal with breastfeeding difficulties.

Artificial bottle feeding is the method of infant feeding women choose if not breastfeeding their babies. Artificial feeds are generally based on cow's milk, although other preparations are available, such as soy-based formulas. The formula selected will depend on the needs of the mother and the baby.

## CLINICAL INTEREST BOX 45.4 Baby Friendly Health Initiative (BFHI)

BFHI is a global initiative introduced by the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF) to implement practices that protect, promote and support breastfeeding.

1. Have a written breastfeeding policy that is routinely communicated to all healthcare staff
2. Train all healthcare staff in the skills necessary to implement this policy
3. Inform all pregnant women about the benefits and management of breastfeeding
4. Place babies in skin-to-skin contact with their mothers immediately following birth for at least an hour and encourage mothers to recognise when their babies are ready to breastfeed, offering help if needed
5. Show mothers how to breastfeed and how to maintain lactation even if they should be separated from their infants
6. Give newborn infants no food or drink other than breast milk, unless medically indicated
7. Practise rooming-in: allow mothers and infants to remain together 24 hours a day
8. Encourage breastfeeding on demand
9. Give no artificial teats or dummies to breastfeeding infants
10. Foster the establishment of breastfeeding support and refer mothers on discharge from the facility

*(BFHI 2009. © Baby Friendly Health Initiative (BFHI), Australian College of Midwives 2016. All rights reserved)*

Some formulas are expensive, others may not be readily available or the baby may require a special formula, such as soy-based or lactose-free. Whichever formula is selected, the mother must know how to make it up, how to store it and how to care for the bottles and teats. This information is given by the midwife during the mother's stay in hospital.

As a response to the falling breastfeeding initiation and retention rates worldwide, UNICEF/WHO published the 10 Steps to Successful Breastfeeding in the early 1990s (see also Clinical Interest Box 45.4 and Case Study 45.2).

## CRITICAL THINKING EXERCISE 45.2

You are caring for Maddy, a 25-year-old woman who 3 days ago gave birth to her first baby. She tells you her breasts feel really heavy, tight and uncomfortable and the baby is not feeding properly.

1. What is the likely reason for this discomfort?
2. What might help to relieve the discomfort?
3. What advice would be appropriate in relation to promoting satisfactory breastfeeding?
4. What are your responsibilities as an Enrolled Nurse in this situation?

## CASE STUDY 45.2

**Angela, Brett and Alex**

I had Alex 2 days ago. I had to have a caesarean delivery, as he was breech. I was worried that I wouldn't get to bond with him, but as soon as he was delivered they quickly dried him and gave him to me for a cuddle for a few minutes before my husband Brett left with him and the midwife for the ward. I really hoped to be able to breastfeed, so once they told me I had to have a caesarean delivery, I was worried I would not be able to breastfeed so easily. When I told my midwife this, she reassured me that it would be okay and they even brought Alex back down to the recovery area once I was there so that I could try to breastfeed. With the midwives' help, he went on first go. I couldn't believe it! We are doing really well, and with help from the midwives, I have been able to get the hang of breastfeeding him. Now that I am up and about we are managing ourselves most of the time, but the midwives are available to help if I need them.

**Angela, first time mum, talking about breastfeeding her infant**

How can the midwife help Angela establish breastfeeding during the initial breastfeeding session?

## Immediate care of the baby

Immediately after the birth the midwife or obstetrician checks that the baby's airway is clear and that it is breathing normally. Ventilation is initiated in response to high blood carbon dioxide level, stimulating the respiratory centre in the medulla. In the first few breaths, air is drawn in to expand the alveoli in the lungs, thus oxygenating the blood. Because the newborn baby has a limited ability to regulate its body temperature in relation to the environment, care is taken to ensure that it does not become cold.

One minute after birth, and again at 5 minutes, the **Apgar score** estimation is performed. The Apgar scoring system gives an estimation of the baby's condition and is an indicator of whether special resuscitation measures are required (Murray & McKinney 2014). Table 45.6 illustrates the Apgar score chart. A total score of 10 indicates that the infant is in optimal condition; if the score is 6 or less the baby requires immediate attention. A score of 8–10 is normal, a score of 4–7 indicates that the infant's condition is moderately depressed, while a score of 0–3 indicates a severely depressed condition.

In a healthcare setting such as a hospital or birth centre, an identification band is placed on the baby's wrist or ankle for identification. This identification procedure must be performed before the baby is removed from the mother's bed; this is essential to prevent any later confusion about which baby belongs to which mother. The baby is weighed and measured and the information documented (Perry et al 2014). It is recommended that every baby be given an

**TABLE 45.6 | Apgar scoring**

| Factor | Score | | |
|---|---|---|---|
| | 2 | 1 | 0 |
| Heart rate | >100 | Slow (<100) | Absent |
| Respiration | Good cry | Slow weak cry | Absent |
| Colour | Pink all over | Centrally pink, but with blue extremities | Blue, pale |
| Muscle tone | Well flexed | Fair (some flexion of extremities) | Flaccid |
| Irritability | Cry | Grimace | None |

*Murray & McKinney 2014; Lowdermilk et al 2014*

## CLINICAL INTEREST BOX 45.5 The role of vitamin K

Vitamin K is needed by humans to cause blood to clot. Without vitamin K small cuts can go on bleeding for a long time, small injuries can cause a lot of bruising and bleeding can occur in many parts of the body, including in the brain, causing a stroke.

Vitamin K is mostly made by bacteria in our gut because humans are unable to make vitamin K themselves.

### Vitamin K at birth

All newborn babies have low levels of vitamin K. Only a little vitamin K goes through the placenta to the baby, and at birth a baby's gut is sterile (there are no bacteria in the gut).

After birth there is little vitamin K in breast milk and breastfed babies can be low in vitamin K for several weeks until the gut bacteria start to make it.

Infant formula has added vitamin K, but formula fed babies have very low levels of vitamin K for several days.

### Why is it given?

It is recommended that all babies are given vitamin K at birth to prevent a bleeding problem called vitamin K deficiency bleeding (VKDB). This bleeding is rare even when babies are not given extra vitamin K, but if it happens it can cause severe harm to a baby, including death or severe brain damage.

*(NHMRC 2010; Pairman et al 2015)*

intramuscular injection of vitamin K as a preventative measure against bleeding tendencies (see Clinical Interest Box 45.5).

An initial examination of the baby is performed soon after the birth so that any abnormal findings can be acted on as soon as possible. Table 45.7 outlines the findings expected in a normal newborn. The examination assesses the baby's ventilation, colour, muscle tone, reflexes, movement and the presence of any obvious abnormalities. Later a more thorough examination is performed. See also Figure 45.2.

**TABLE 45.7 | The normal newborn**

| Anatomy | Characteristics |
|---|---|
| Head | Average circumference 35 cm<br>Anterior fontanelle—no tension or depression<br>Posterior fontanelle—palpable<br>May be elongated from moulding as the skull bones glide over each other during passage through the birth canal |
| Face | Nose and cheeks may have tiny white spots (milia) |
| Skin | Normal colour for race<br>May be covered with lanugo (fine downy hair)<br>May be vernix (white, greasy protective substance) in the skin folds |
| Eyes | Dark blue; white sclera<br>Blink reflex present |
| Thorax | Average circumference 34 cm<br>Expands symmetrically with ventilations<br>Breast tissue palpable in males and females |
| Abdomen | Prominent but not distended<br>Moves up and down with ventilations<br>Umbilical cord blue/white |
| Limbs | Symmetrical, warm, rounded<br>Move freely<br>Hands and feet may be slightly cyanosed |
| Back | Spine straight, intact, easily flexed |
| Genitalia | Male: large in relation to body, scrotum contains both testes, foreskin adheres to glans, urethral meatus central on tip of penis<br>Female: prominent labia and clitoris, vaginal opening visible |
| Anus | Patent |

*(Davidson et al 2014; Hockenberry & Wilson 2014)*

## Subsequent care of the baby

Care of the baby in the period immediately after birth is directed towards keeping the baby adequately nourished, clean, warm and free from infection. Careful observation is necessary to detect any problems should they occur. In most healthcare agencies it is common practice for the baby to remain in the same room as the mother. This is termed rooming-in and enables the mother to care for the baby from

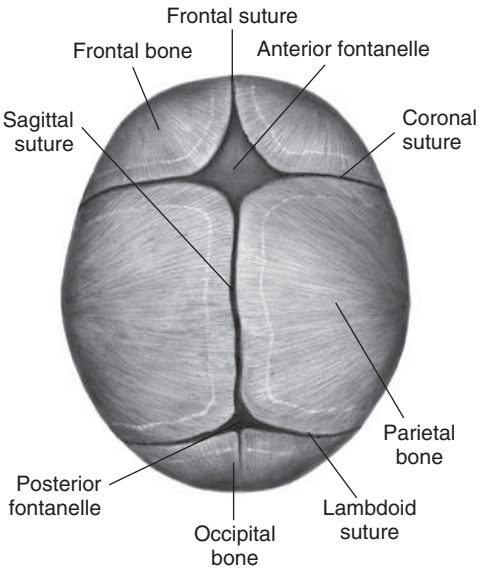

**Figure 45.2** Fontanelles and suture lines

*(Crisp et al 2013)*

**Figure 45.3** Parent–child nurturing

*(© privilege/Shutterstock)*

**TABLE 45.8 | Newborn vital signs**

| Vital sign | Normal range |
|---|---|
| Pulse | 120–160 bpm<br>During sleep as low as 100 bpm; if crying, up to 180 bpm<br>Apical pulse counted for 1 full minute |
| Respirations | 30–60 respirations/minute<br>Predominantly diaphragmatic but synchronous with abdominal movements<br>Respirations are counted for 1 full minute |
| Temperature | Normal range: 36.5–37.5°C<br>Axillary: 36.4–37.2°C<br>Skin: 36–36.5°C<br>Rectal: 36.6–37.2°C |

*(Ladewig et al 2014; Murray & McKinney 2014)*

the beginning (Figure 45.3). The mother gets to know, and gains confidence in caring for, her baby. The midwife is available to offer guidance and encouragement in all aspects of infant care.

## Supporting thermoregulation

Maintenance of body temperature is vital. The core temperature of the term newborn is 36.5–37.5°C (Blackburn 2013). Hypothermia can cause problems such as hypoglycaemia, as the newborn uses glucose to generate heat and respiratory distress, because the metabolic rate is higher and consumes more oxygen. The first bath is not undertaken until the temperature is between 36.5°C and 37°C.

## Obtaining vital signs

Respiratory rate: It is best to obtain this before disturbing the baby. Count the respirations for a minute. The rate can be auscultated with a stethoscope, or a hand can be placed lightly over the abdomen—watch for the rise and fall.

Heart rate: Assess using a stethoscope at the apex of the heart. Count for 1 minute.

Temperature: Axillary temperatures are most commonly used for the well newborn infant. A thermometer is placed in the axilla, parallel to the chest wall.

Table 45.8 gives the vital sign parameters for a healthy newborn.

## Hygiene and skin care

Healthcare settings establish their own protocols for washing or bathing newborn babies (neonates). The baby is usually washed or bathed daily; a mild pure soap may be used. It is important that the infant's skin is kept clean and dry, with special attention being paid to the scalp, skin folds and genitals. The buttocks and groin area are washed with plain water or cleansed with a mild lotion each time a wet or soiled nappy is removed. A protective cream or lotion may be applied.

Disposable or cloth nappies may be used. The mother may need some advice on how to fold and apply napkins.

If the baby's fingernails are long, the infant may scratch their face and the scratches may become infected. Mittens may be worn to prevent the infant from scratching.

The bath is a good time to observe the newborn for general wellbeing, activity and behaviour.

## Umbilical cord care

Care is aimed at preventing infection. The remnant of the cord is observed every time a napkin is changed, until it has separated and the umbilicus has healed. It is kept clean and dry and observed for any bleeding or signs of infection. It becomes dry and brownish black as it dries. The cord remnant separates from the umbilicus by a process of dry necrosis on days 6–8. The parents are taught to report redness of the area or a moist or a foul-smelling cord. See Figure 45.4.

## Elimination

Most newborns void within 12 to 24 hours of birth. Infants void at least one or two times during the first 2 days and at least 6 times a day by the fourth day. Any unusual colouration or odour must be reported to the medical officer. The baby's first bowel action consists of meconium, the dark green tarry substance formed in the intestinal tract during intrauterine life. Seventy per cent of newborns pass meconium in the first 12 hours (Davidson et al 2014). When the baby begins to take milk, there is a gradual transition to the normal yellow stools of the neonate. The stools gradually change during the first week. They become loose and are greenish yellow with mucus; these are called transitional stools. Breastfed babies pass stools that are yellow to pale brown, soft and unformed. There may be three to six stools a day. The stools of an artificially fed baby are yellow to pale green, firmer and have a distinctive odour. They are generally fewer in number.

### CRITICAL THINKING EXERCISE 45.3

You are helping care for an infant who was born 20 hours ago, and the mother tells you that the infant has not passed meconium yet. What should you do?

## Identification

Identification bands with pre-printed numbers are placed on the infant and the mother. If the infant is separated from the mother, the bands should be checked to ensure they match. Infants are usually labelled with two bands as the bands easily fall off. Identification procedures should follow the Australian Commission on Safety and Quality in Healthcare National Standards for patient identification bands in Australia (ACSQHC 2012).

## Nutrition

The baby is fed when hungry. Frequent feedings, for example every 2 hours, may be indicated if the baby shows signs of hypoglycaemia. Signs of hypoglycaemia in the newborn include: jitteriness, poor muscle tone, sweating, respiratory difficulty, low temperature, poor suck, high pitched cry, lethargy and seizures. A heel stick is performed when obtaining capillary blood for glucose screening.

## Weighing and measuring

In healthcare settings the neonate is generally weighed every second day to assess weight gain or loss. More frequent weighing is indicated if the birth weight was low or if the baby is losing excessive weight. A loss of up to 10% of the birth weight is normal in the first 3–4 days; after this, the baby should begin to gain weight. It is expected that the baby will be back to its birth weight within 10–14 days (Pairman et al 2015).

The length and head circumference are routinely measured. Measurements are noted for gestational age assessment.

## Infection control

Infections that are harmless to adults may be fatal to the newborn because of immaturity of their immune system. The baby is protected from infection by normal hygiene practices, the most important aspect of which is washing the hands thoroughly before attending to the baby. Anyone with an infection is advised to limit close contact with the baby.

## Temperature control

As the neonate's temperature-regulating centre is not fully functional, the baby must be protected from extremes of environmental temperature. Conduction, convection and radiation can be used to add heat to the body. This can be achieved by maintaining the room at an even, comfortable temperature, dressing the baby in suitable clothes and wrapping the infant in warm lightweight rugs.

Overheating is also avoided as a measure to prevent sudden infant death syndrome (SIDS). Parents are taught how to wrap and position their infant as part of health education prior to discharge (SIDS and Kids 2014) (see Clinical Interest Box 45.6).

## Screening tests

Newborn screening (NBS) is a publicly funded system for testing newborn babies' blood for about 30 rare conditions. All newborn babies are offered screening in Australia. The blood test is taken by heel prick, usually between 48 to 72 hours after birth. Collection of several blood spots is made onto an absorbent card and sent for analysis. After the dried blood has been tested, it will be stored in the laboratory for varying periods in different states of Australia. The conditions tested for include phenylketonuria (PKU), congenital hypothyroidism, cystic fibrosis (CF), galactosaemia and a number of other extremely rare conditions. Some of these conditions can result in physical and/or intellectual problems if not treated promptly, and are often referred to as inborn errors of metabolism (Dempsey et al 2014; Pairman et al 2015).

Newborn hearing testing is a free universal hearing screening that has been in use in Australia since 2000.

**Figure 45.4** Umbilical cord care

## CLINICAL INTEREST BOX 45.6 Safe sleeping

- Sleep baby on the back from birth, not on the tummy or side
- Sleep baby with head and face uncovered
- Keep baby smoke free before birth and after
- Provide a safe sleeping environment night and day
- Sleep baby in their own safe sleeping place in the same room as an adult caregiver for the first 6 to 12 months
- Breastfeed baby

*(SIDS and Kids 2014)*

## CLINICAL INTEREST BOX 45.7 Assessing for jaundice

- Observe skin in a well-lit room
- Press skin with thumb until the skin lightens
- Observe level of jaundice using Kramer's rule
- Visual estimation should not be relied on to estimate the bilirubin level in an infant with jaundice

| Zone | Baby's body area | Approximate bilirubin level |
|---|---|---|
| 1 | Head and neck | 100 µmol/L |
| 2 | Upper body (chest) | 150 µmol/L |
| 3 | Lower body, below the belly button and upper thighs and arms | 200 µmol/L |
| 4 | Lower legs and forearms | 250 µmol/L |
| 5 | Hands and feet | Above 250 µmol/L |

*(Kramer 1969; NICE 2010)*

Screening can be done any time after the newborn is 12 hours old.

## Neonatal disorders

Only brief mentions of some of the disorders that can affect neonates are included here. For detailed information, the nurse should refer to a current paediatric text. Disorders may be minor and temporary, major and permanent or life threatening. They include:

- Prematurity
- Low birth weight
- Jaundice
- Hypoxia
- Atelectasis
- Hyaline membrane disease
- Hypoglycaemia
- Persistent vomiting
- Birth injuries
- Congenital abnormalities.

Jaundice is a yellow discolouration of the skin caused by an excess of bilirubin in the blood. There are two main types of neonatal jaundice: physiological and pathological. Physiological jaundice is due to the inability to break down bilirubin due to immaturity of the liver. It appears 2 to 4 days after birth and lasts for 1 to 2 weeks. It is commonly treated with phototherapy. Pathological jaundice can occur if there is an incompatibility of the mother's and neonate's blood group (Dempsey et al 2014; Pairman et al 2015).

Clinical Interest Box 45.7 outlines the procedure for assessing the newborn for jaundice. It describes Kramer's rule (Kramer 1969). This rule is based on the way the jaundice will tend to 'migrate' down the baby's body, as the bilirubin levels rise. In essence, the baby's body is categorised into five zones with an estimated bilirubin level for each zone. If the jaundice is believed to be between 200 and 250 µmol/L or more then transcutaneous bilirubinometry and a blood test will be used to estimate the exact bilirubin level. Visual estimation should not be relied on to estimate the bilirubin level in an infant with jaundice (National Institute for Clinical Evidence (NICE) 2010).

## Summary

A nurse may be required to assist qualified midwives in the care of mothers and their newborn babies. This chapter has briefly outlined the basic knowledge that is essential for the nurse who undertakes this role: the processes of normal pregnancy, labour and birth and the postnatal care of the mother and her baby. It is recommended that nurses gain an understanding of cultural differences in birthing beliefs and practices of the women they care for during and after the birth of their babies. It is also recommended that nurses access current paediatric textbooks to gain or enhance knowledge of neonatal care and disorders that may be encountered in the areas of maternal and child health nursing.

## Review Questions

1. Describe the physiological changes of pregnancy.
2. How and why is fundal height measured during antenatal visits?
3. What is the expected uterine growth at 16 and 20 weeks of gestation?
4. Immediately after the birth of a baby an assessment is performed on the neonate. What is this called and what does it entail?
5. What are the findings expected in the normal newborn infant?
6. What assessments of the mother are made in the postpartum period?
7. When is the newborn screening test attended?

## DECISION-MAKING FRAMEWORK EXERCISE 45.1

Alexa, a newly graduated EN, is working in the postnatal unit with Kate, a midwife. They are sharing the care of a group of postnatal women and their infants. Kate asks Alexa to insert an indwelling catheter into Sue Brown in room 6, as she could not void post delivery of her infant earlier that day. Alexa had learnt about insertion of IDCs during her course but had never inserted one before.

Using the decision-making framework, what is Alexa's scope of practice in relation to this scenario?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing in the community

*Kym Louise Strachan*

CHAPTER 46

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define the key terms
- Explain the role of public health in community-based care
- Discuss primary healthcare
- Describe the role of the community health nurse
- Identify the models of care used in community health practice
- Explain the issues that affect nurses who are involved in home care
- Describe the common competencies and skills of the community health nurse
- Define person-centred care

## KEY TERMS

community-based healthcare
community nursing
models of care
person-centred care
primary healthcare
public health

## CHAPTER FOCUS

There has been a gradual change in Australian healthcare policies with an increased focus on primary healthcare in the community. These changes have occurred as a result of public health policies aimed at maintaining health and preventing illness, a consumer push for more healthcare options, earlier discharge from acute hospitals and containment of costs.

This chapter discusses the diverse role of the nurse who works in the community in Australia. It also explains the principles of primary healthcare and how they are practised in the context of the public health paradigm. Community health and healing are also explored. The factors that impact the health of individuals, families and communities are discussed. The role, skills and competencies of the community health nurse are broadly examined. Reference is made to the literature and research on the topic, in deference to evidence-based principles.

## LIVED EXPERIENCE

My husband is 76 years old and is getting more and more forgetful. He retired from the public service 15 years ago and has had well-controlled epilepsy for the past 40 years, but I think his medication makes him very slow. I am 72 years old and we have been married for 51 years. I am happy to look after him but it is getting harder and harder. He used to pay all the bills, do all the driving and help around the yard but he is now finding this too hard. I don't drive, I have recently had two knee replacements and I have a bad back. We live in our own home but are struggling to get by. I can't do yard work and the housework is getting harder for me too. I am worried that my husband might have dementia and that we will not be able to live together any more. I never thought I would be in this situation, not being able to be together and care for us both.

**Edna**

# COMMUNITY HEALTHCARE

Community healthcare has been changing. More attention is directed to the provision of disease-recovery nursing care for transitioning individuals as they move out of the hospital environment and into the community context. Early intervention measures for people living with chronic conditions are focused on preventing re-admission into the acute healthcare system (Paterson et al 2012). Community nurses increasingly assist individuals and their carers/families to self-manage their health situation within their home environment and thus require a **person-centred** approach to care (Paterson et al 2012; Kitson et al 2012).

A social view of health considers other determinants of health such as economic and social factors (National Rural Health Alliance 2014; Australian Government 2013). The social determinants of health have been recognised and asserted by the World Health Organization (WHO 1978). 'Health for all', a philosophy developed by the WHO, has been promoted in many countries (WHO 1978). An example of this within Australian society can be seen in Indigenous populations where statistics indicate a causal link between economic and social factors and chronic disease such as asthma and diabetes (Paterson et al 2012). A social view on health impacts on the provision of care for people in the community.

Illness is influenced by how an individual experiences medically diagnosed pathophysiology which may have characteristic signs and symptoms (McMurray & Clendon 2011). The interactions between factors affecting health are illustrated in Figure 46.1.

According to Moore (2009), the 'extension of health services beyond the medical treatment model to a social model, and beyond the institutional to the community context, has seen "patients" now described also by terms used in social settings as "clients"'. Service users include the individual and their primary carers who access a service with the individual's consent. With the introduction of the National Safety and Quality Health Service Standards (Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012) and in particular Standard 2 'Partnering with Consumers', this has evolved to also include the term 'consumer'. Such a change illustrates an increased focus on active partnerships between health service organisations and consumers, and focuses on responding to consumer needs (ACSQHC

## CRITICAL THINKING EXERCISE 46.1

Mr Jobe, 32, is homeless and spends most nights sleeping in the park. He has asthma and chronic bronchitis. Sometimes he drops in at the local charity food kitchen. He likes to pay his way and usually offers to help with the clean up. Recently he has been short of breath. What interventions would you consider to improve Mr Jobe's health and quality of life?

**Figure 46.1** Interactions between factors affecting health *(McMurray & Clendon 2011)*

2012). In Australia, community-based services are moving from being population-based to focusing on specific at-risk sub-groups (Lewin et al 2011).

## The health of a community

Baisch (2009) suggests that 'community health is grounded in philosophical beliefs of social justice and empowerment … and … is achieved through participatory, community development processes based on ecological models that address broad determinants of health'. Community nurses are critical in helping individuals, families and communities become whole by acting as a conduit or facilitator for positive change and improved health outcomes. This concept is illustrated in the model for community healing in Figure 46.2.

According to the ARC Centre of Excellence in Population Ageing Research (2014) factors that impact on the context of community care include:

- The changing and diverse complexity of illness and disease comorbidities that people experience as they live longer
- The increasing number of people who want to be cared for in their homes
- Healthcare delivery that is becoming more complex with multiple services that require multidisciplinary team approaches to care provision and complex policy and strategic guidance to ensure quality and safe outcomes.

People with chronic illness face many challenges. Helping a person to be more empowered is the role of any nurse. Empowerment is beneficial as it enhances a person's capacity to develop personal resources to manage their particular situation.

## Public health

**Public health** philosophy strives to re-orientate health systems towards health and wellness rather than disease and illness. Philosophically, the values for public health are based on notions of health for all, social justice and equity (Gruszin et al 2012).

The Public Health Association of Australia's (PHHA) vision for a healthy population is 'healthy people living in a healthy society and a sustaining environment, improving and promoting health for all' (PHAA 2011). Public health action has had a significant impact on improvements in the health of the Australian population. Key issues such as control of infectious diseases, environmental health, improved maternal and child health, better food and nutrition, injury prevention and chronic disease prevention are all contributing factors to improved population health (Gruszin et al 2012).

Fleming and Parker (2009) suggest that 'public health is about preventing disease, illness and injury, together with

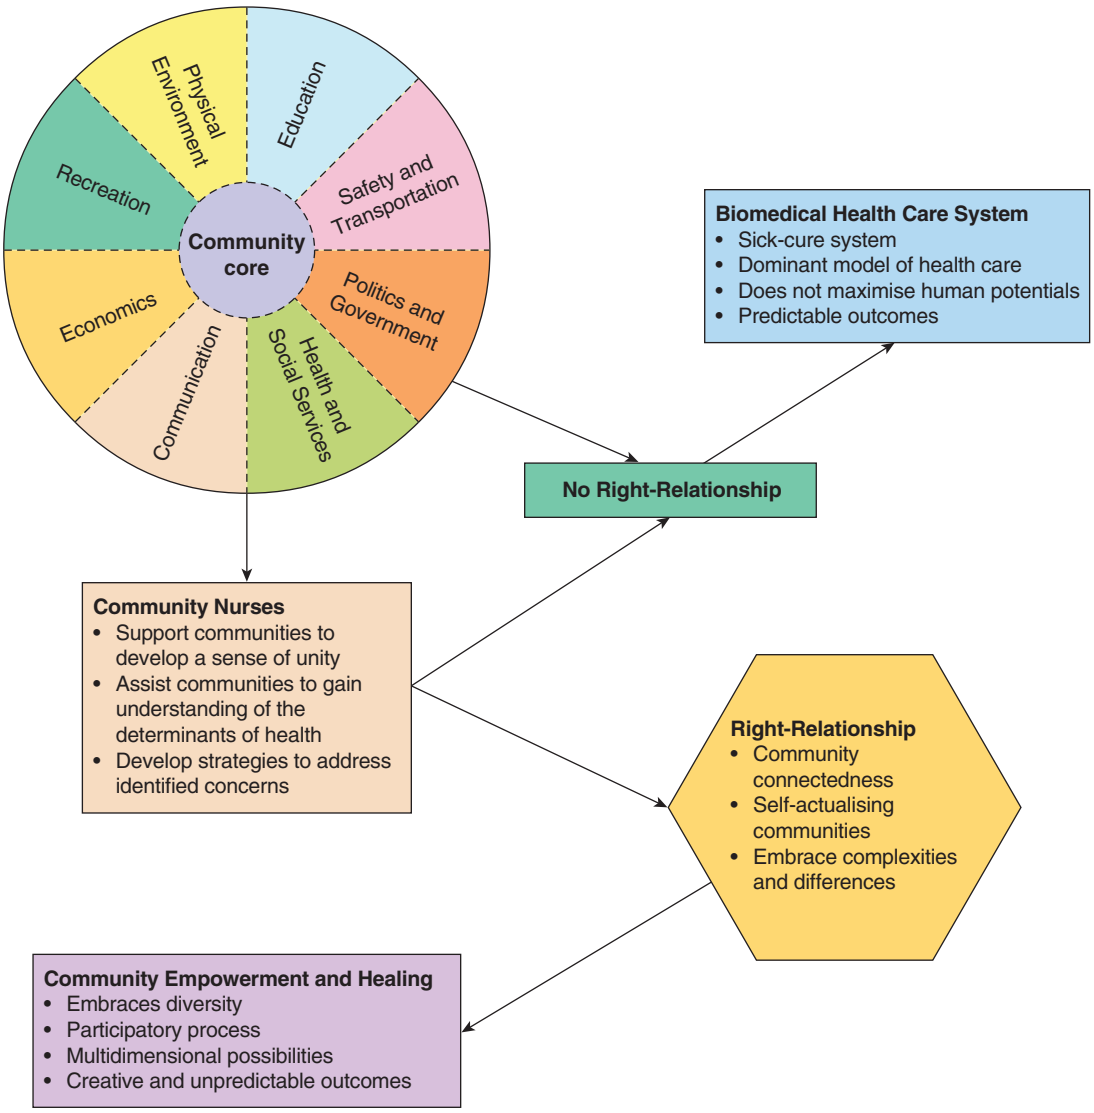

**Figure 46.2** Model for community healing

*(Francis et al 2013)*

promoting the quality of life of human populations. This is a very complex process and requires the committed skills and expertise of many different professional disciplines'. These authors have summarised the roles and functions of the public health workforce as:

- Understanding the context for public health activity and its role and functions
- Providing clarity around political impacts on public health
- Applying a range of methodological approaches to understand data
- Having a theoretical understanding of the disciplines that underpin public health and their contribution to strategy selection
- Understanding a range of skills around surveillance, prevention, promotion and restoration of the population's health
- Developing and analysing policy
- Planning, implementation and evaluation
- Using evidence-based practice
- Using advocacy, communication and negotiation skills
- Working intersectorally and with multidisciplinary groups
- Demonstrating ethical practice (Fleming & Parker 2009).

## Community health nursing and primary healthcare

Community-based nursing services comprise continuing nursing care, which may be preventative, curative, rehabilitative, supportive or palliative. Community health nursing focuses on promoting and preserving the health of population groups (Hales 2010a). Community nurses have a role in

promoting community health through primary healthcare. **Primary healthcare** is a model of community-based health service delivery that is part of the publicly funded health system in Australia. It focuses on decreasing the burden of chronic disease, decreasing the burden on hospitals and health services, and increasing equity in access to healthcare (Henderson et al 2013). **Community nursing** in Australia draws much of its revenue from a complex mix of health, community, veterans', fee-for-service and aged care programs which are funded by different levels and arms of government (Taylor 2008).

Primary healthcare reflects care that transitions health system boundaries and focuses attention on community needs (Henderson et al 2013). Primary healthcare takes a person-centred approach which minimises the potential for harm, because the individual's values and preferred approaches to health are respected (Eckermann et al 2010). The outcomes of primary healthcare, apart from better health, should be empowerment and self-reliance. Primary healthcare every day, according to Eckermann et al (2010), should be holistic in its approach. This involves:

- High levels of trust and community participation
- Shifting the power and control to those whose health is at stake.

**Community-based healthcare** is a primary healthcare system that provides holistic health-related services within the context of people's daily lives, and is directed towards a specific group within the geographical neighbourhood. To be effective it needs to:

- Provide easy access to care
- Be flexible in responding to the care needs that individuals and families identify
- Promote care between and among healthcare agencies through improved communication mechanisms
- Provide appropriate support for family caregivers
- Be affordable (Hales 2010a).

A range of services delivered in community-based settings in Australia are designed to provide early intervention to maximise health and wellbeing outcomes and prevent or slow the progression of ill health. These services are funded by the state and federal governments, private services and volunteer-led and community-based organisations and they play an important role in meeting the needs of people with, or at risk of, poorer health (Department of Health (Victoria) 2012). Australia also has many not-for-profit home nursing organisations, the Royal District Nursing Service (RDNS) being one of many that delivers general and specialised nursing and healthcare in individuals' homes, and which is 'committed to improving and maintaining our clients' quality of life and independence by providing tailored care to meet their individual needs' (RDNS nd).

According to the National Primary Health Care Strategy in Australia, general practice is the centre of the primary healthcare system. A primary healthcare nurse works autonomously and collaboratively to promote, improve and restore health. Primary healthcare nursing encompasses population health, health promotion, disease prevention, wellness care, first point of contact care and disease management across the lifespan. The setting and the ethnic and cultural grouping of the people determine models of practice. Partnerships with people—individuals, families, communities and populations—to achieve the shared goal of health for all is central to primary healthcare nursing. According to Henderson and colleagues (2013) primary healthcare nursing includes Registered and Enrolled Nurses working in a wide variety of areas including maternal and child health, general practice, community health, schools sexual health and mental health (Hoare et al 2011). However, with significant policy changes in the primary healthcare arena, the focus remains firmly on general practice and increasing the scope of the practice nurse in community-based healthcare (Henderson et al 2013).

According to Woods (2010), recent health reform in Australia which seeks to curtail the burden of chronic disease by adopting a primary healthcare approach challenges community health nurses to demonstrate their understanding and capacity to practise according to primary healthcare principles. Woods suggests that there is a need to formulate an Australian model for community nurses and national competencies through a national professional body. Community health nursing competencies are discussed later in this chapter.

## COMMUNITY HEALTH NURSE ROLE

Competencies integral for community health nurse care are discussed later in this chapter; however, the community health nurse competency statement from Queensland Health (2009) in Clinical Interest Box 46.1 encapsulates the role of the community health nurse in Australia.

According to the Australian Nursing and Midwifery Federation (2014) community health nurses practise primary healthcare in a diverse range of settings. They provide continuous monitoring of the health status of communities and respond to episodic health needs. Community health nurses need to be creative, adaptable and responsive to a variety of norms, cultures and value systems whether they are working with individuals, families or community groups. According to the Australian Nursing and Midwifery Federation (ANMF) (2011), community health nursing is 'a combination of nursing practice, public health practice, health promotion and primary healthcare'. Central to the role is working with

### CLINICAL INTEREST BOX 46.1 The role of the community health nurse

The community health nurse is a professional who delivers evidence-based nursing care to individuals, families, significant others and defined communities, underpinned by the principles of primary healthcare and health promotion, supporting self-reliance in recovery from illness, enhancement of health or management of chronic and terminal conditions, in a setting which is optimal for the person or community.

*(Queensland Health 2009)*

local communities to prevent illness and promote health for all ages by identifying barriers to health and wellness. Key concepts such as self-determination and empowerment of people to change unhealthy lifestyles and also care for individuals on discharge from acute care in their homes are central to the role of community nurse (Australian Nursing and Midwifery Federation 2011).

**CRITICAL THINKING EXERCISE 46.2**

Consider the community health nurse competencies described in this chapter. Which of the competencies would be within the scope of practice of the Enrolled Nurse?

### Teamwork in community care

Community nurses base their practice on the concepts of partnership, collaboration and empowerment (Hoare et al 2011). Partnerships between community members and healthcare professionals are critical for collaborative decisions that promote awareness and understanding of a community's health needs (Chapman et al 2008; Paterson et al 2012).

A study by O'Neill and Cowman (2008) investigated community nurses' understanding of an interdisciplinary team-based approach to primary care using a qualitative research design. Their conclusions were that nurses can contribute significantly to the re-orientation and development of primary care services. Collective team efforts enhance individuals' care and effective teamwork requires a greater understanding of group processes and team development.

As well as community nurses there are many other healthcare workers who provide community-based healthcare, both in centres and in people's homes. Some of these include occupational therapists, physiotherapists, social workers, dietitians, general practitioners, home care workers, volunteers, personal carers and home maintenance workers. Collaborative working relationships between healthcare workers, institutions and agencies are essential for providing coordinated care for individuals in the community. Competencies identified as being vital for collaboration include effective communication skills, mutual respect and trust and a team decision-making process with shared responsibility for the outcome (Hales 2010a).

### Home care

The terms used to describe the provision of nursing care in people's homes varies but can include domiciliary nursing, ambulatory care, community health nursing, district nursing, hospital in the home and home care. Regardless of the title, home care requires specialised skill sets of advanced nursing care as nurses may work in an environment which necessitates that they work independently, and includes coordination of services, provision of direct care, assessment, consulting, education, administration and research activities (Hales 2010b).

The Registered Nurse working in home care may also be responsible for the direction and supervision of unregulated care workers as well as the Enrolled Nurse. The role of the home health nurse includes being: advocate, carer, educator, case manager or coordinator. The home care nurse also needs to consider other perspectives related to working in a person's home environment: the person's safety, legal and ethical issues, infection prevention and control and nurse safety (Hales 2010b).

## MODELS OF CARE IN COMMUNITY HEALTH

Various approaches are emerging to address community health, such as integrated health, community initiatives, coalitions, managed care, case management and outreach programs (Hales 2010a). See Clinical Interest Box 46.2 for the effectiveness of a community nursing model of care and Clinical Interest Box 46.3 for a summary of these **models of care**.

## ISSUES FOR COMMUNITY HEALTH NURSES IN HOME CARE

Isolation is an issue for some community nurses. Rural and remote community nurses work in diverse settings, often in isolated practice in resource-poor environments with their practice influenced by the geography of the community, issues of transportation, communication and personal safety (Francis & Chapman 2008; Baldwin et al 2013; Ellis & Chater 2012).

In addition to incident management and reporting, the community nurse has mandatory reporting requirements as part of their duty of care to the person. These requirements include reporting all:

- Suspected incidences of child abuse and neglect
- Suspected incidences of elder abuse
- Cases of inappropriate use and storage of firearms
- Unexpected deaths (Maddock & Trowbridge 2008).

### CLINICAL INTEREST BOX 46.2 Effectiveness of a community nursing model of care—research

Edwards et al (2009) undertook a study to determine the effectiveness of a new community nursing model of care on quality of life, morale, depression, self-esteem, social support, healing, pain and functional ability of individuals with chronic venous leg ulcers. A randomised controlled trial was used with participants randomised to either a Leg Club model of care, which emphasised socialisation and peer support, or the traditional community nursing model of home visits by a Registered Nurse. Participants in the Leg Club model demonstrated significantly improved outcomes in quality of life, self-esteem, healing, pain and functional ability.

## CLINICAL INTEREST BOX 46.3 Models of care

- Integrated healthcare system—makes all levels of care—primary, secondary and tertiary—available in an integrated form
- Community initiatives—members of the community establishing health priorities, goals and actions to achieve goals
- Community coalitions—individuals and groups having a shared purpose of improving community health
- Managed care—multidisciplinary teams working together to provide cost-effective and quality healthcare across the care continuum with the managed care organisation liaising between individuals, provider and payer
- Case management—tracks individuals' needs and helps them access services through a variety of care settings to ensure continuity. Case management is defined as a collaborative process of assessment, planning, facilitation and advocacy for options and services to meet an individual's health needs through communication and available resources to promote quality cost-effective outcomes. It is a dominant model used in community mental healthcare
- Outreach programs—link people who have difficulty accessing services with the formal healthcare system
- Solution-focused nursing—considers the sociocultural as well as the individual world of a person with nurses being proactive in promoting health and wellbeing rather than reacting to palliate symptoms.

*(Aged and Community Care Services Australia & Case Management Society of Australia 2006; Henderson & Walter 2009; Hales 2010a; McAllister 2010)*

Giving culturally safe care is also an integral requirement in community healthcare. Cultural safety is an outcome experienced by the person receiving care and is described as 'the effective nursing of a person/family from another culture by a nurse who has undertaken a process of reflection on own cultural identity and recognises the impact of the nurse's culture on own nursing practice' (Te Kaunihera Tapuhi o Aotearoa Nursing Council of New Zealand 2015). Culturally safe nurses accommodate and respect a diverse range of views on health and healing (Stein-Parbury 2009). Refer to Chapter 10 for further reading on cultural diversity in healthcare.

Aboriginal health workers are vital in Aboriginal health services as they are better equipped to provide services to Indigenous populations, and bridge the gap with non-Aboriginal health professionals in their community (Eckermann et al 2010). As stated by Eckermann and colleagues (2010), 'some Aboriginal people maintain that the cornerstones of their culture are lore, law, language and land, which forms the basis of their identity'. See Chapter 11 for further reading on Indigenous health.

Personal safety is an important consideration for the nurse who makes home visits. Strategies to eliminate or manage risks must be implemented. Risks include: working as a sole practitioner; being 'on call' in remote communities; the gender bias (most community health nurses are female); dealing with hazards in the home such as obstructions and debris; aggressive dogs; having to use mobile telephones, especially in rural Australia; dealing with angry and aggressive individuals and domestic violence; driving; needlestick incidents; and working alone (Henderson 2009; Newman & Berens 2010).

### CRITICAL THINKING EXERCISE 46.3

The community health nurse role involves case management and can be challenging. As an Enrolled Nurse working in this environment what are the key components of your role?

## Skills and competencies of the community nurse

The competencies of community health nursing that make it a unique specialty are actually attributes that are desirable in nursing practice, regardless of the setting (DeBrew & Lutz 2010). Community nurses must be compliant with the legal and regulatory requirements of the jurisdictions in which they practise. Enrolled Nurses who work in community health must work within their scope of practice under the supervision of the Registered Nurse. The Community Nurses Special Interest Group (2013) and the Australian Nursing and Midwifery Federation (2014) developed competency standards for the community health nurse (see Clinical Interest Box 46.4). They make the distinction between the competencies of the beginning practitioner and the practitioner with advanced skills.

Queensland Health (2009), with the Institute of Primary Health and Ambulatory Care and the Institute of Women's and Children's Health, Townsville Health Service District, developed community health nursing competency and skills checklists designed to support the transition of nurses into community health nursing. These competency and skills checklists were derived by reviewing a number of services; categorising and summarising competency, competency units and skills; and consulting with stakeholders. A refined list of competencies emerged to reflect community nursing in the Townsville Health Service District. Standards and competencies that exist from national, state and organisational levels take precedence—with the competency and skills framework intended to fill a gap and add refinement to a specific area of

## CLINICAL INTEREST BOX 46.4 Competencies of the community health nurse

**Domain one: professional practice**

Standard 1: Demonstrates a comprehensive knowledge of community health nursing incorporating population health, primary healthcare and health promotion
Standard 2: Advocates for individuals/groups/communities and their rights for community health nursing service, primary healthcare, health equity and healthy environments, policies and legislation
Standard 3: Practises within an ethical and professional nursing framework
Standard 4: Practises in accordance with legislation affecting community health nursing practice and primary healthcare
Standard 5: Demonstrates leadership in the development, coordination and management of systems and processes to anticipate and facilitate safe quality health and wellbeing services

**Domain two: critical thinking and analysis**

Standard 6: Participates in continuing professional development (CPD) of self and others
Standard 7: Practises within an evidence-based framework

**Domain three: provision and coordination of care**

Standard 8: The community health nurse (CHN) conducts comprehensive and systematic assessment, planning, implementation and evaluation in an ongoing way in collaboration with the individual, family, group, team and community
Standard 9: Coordinates, organises and provides integrated health promotion (IHP) considering a whole of community approach
Standard 10: Facilitates a physical, emotional, social and cultural environment that promotes individual/group/community safety, security, respect and health and wellbeing

**Domain four: communication and collaboration**

Standard 11: Establishes, maintains and concludes therapeutic relationships with individuals, groups and communities
Standard 12: Collaborates with the multidisciplinary team to provide community health nursing

*(Community Health Nursing Special Interest Group 2013; Australian Nursing and Midwifery Federation 2014)*

## CLINICAL INTEREST BOX 46.5 Community health nurse competencies and skills

**Competency Unit 1 Community health appraisal and screening**

Skill 1 Surveillance
Skill 2 Disease and other health event investigation
Skill 3 Outreach
Skill 4 Screening
Skill 5 Case finding

**Competency Unit 2 Healthcare delivery**

Skill 6 Referral and follow-up
Skill 7 Case management
Skill 8 Delegated functions (assessment, nursing diagnosis, planning, implementation, evaluation)

**Competency Unit 3 Education and support**

Skill 9 Health teaching
Skill 10 Counselling
Skill 11 Consultation

**Competency Unit 4 Community development**

Skill 12 Collaboration
Skill 13 Coalition building
Skill 14 Community organising

**Competency Unit 5 Political action**

Skill 15 Advocacy
Skill 16 Social marketing
Skill 17 Policy development and policy enforcement

*(Copyright Townsville Health Service District, Queensland Health 2009)*

nursing practice. Five competency units and 17 skills are described in Clinical Interest Box 46.5.

## THE NURSING PROCESS AND COMMUNITY NURSING

The nursing process is used in community health and community-based nursing, as in many other areas of nursing care (see Chapter 17). As a logical framework for nursing care, the steps of assessment, nursing identification of issues, planning, implementation and evaluation are particularly useful for individuals receiving care in the community. The nursing process is instructive in providing a formalised and documented problem-solving strategy (Luxford & Avery 2010). Using tools designed to help in decision making, such as the nursing practice flowchart developed by the Australian Nursing and Midwifery Council in 2007 and now available from the Nursing and Midwifery Board of Australia (NMBA), is recommended (NMBA 2010). Nurses in community care also use critical-thinking skills to resolve issues, manage risks and make appropriate referrals (Luxford & Avery 2010). Community nurses need to reflect at the analytical and personal levels about the individuals in their care and the larger community, and also about themselves and their own role and function in the community they serve. See Chapter 16 for further reading on critical thinking, problem-based learning and reflective practice.

Nurses working in the home setting have the opportunity to observe individuals in their own environment, enabling a more holistic assessment (see Clinical Interest Box 46.6). The focus on a person's choice and autonomy means that

individuals and families are encouraged to participate actively in the nursing process. As a result, the individual and their family may be more proactive in the implementation phase, significantly contributing to the success of the care plan as they work towards their own goals. An example of a care plan has been provided in Nursing Care Plan 46.1.

## CLINICAL INTEREST BOX 46.6 Program snapshot: Refugee Health Nurse Program, Victoria

The Refugee Health Nurse Program provides a coordinated approach using community nurses who have expertise in working with culturally and linguistically diverse and marginalised communities. These nurses work in community health services with high refugee populations. The program has three aims: increase refugee access to primary health services; improve the response of health services to refugees' needs; and enable individuals, families and refugee communities to improve their health and wellbeing.

*(http://refugeehealthnetwork.org.au/)*

### NURSING CARE PLAN 46.1

**Assessment:** Community medication review
**Issue/s to be addressed:** Medication compliance in elderly person recently discharged from hospital after an acute myocardial infarction
**Goal/s:** Ensure individual understands all medications, what they are for, when and how they should be taken

| Care/Actions: | Rationale: |
|---|---|
| Explain discharge medications<br>Discuss blister packs for ease of medication management<br>Discuss possible MedsCheck with local pharmacist<br>Help write a daily/weekly medication plan for the individual | To increase individual's understanding and compliance with medications to help prevent re-admission to hospital or a negative health outcome related to medication mismanagement |

**Evaluation:**

Medications taken as directed.
MedsCheck undertaken.
Blister packs in situ.
Nil further readmission related to medication management.
Referrals to pharmacist and general practitioner regarding medication review.

## CASE STUDY 46.1

Rebecca is an Enrolled Nurse who works in a community-based nursing service. In a typical day Rebecca sees 10–15 individuals in their homes. The activities she is involved in include hygiene assistance, wound care, monitoring blood glucose levels and assisting individuals with the application of compression stockings.

Rebecca is responsible for organising her own day, which starts at the office base with a handover and ends there with time allowed to debrief with the coordinator and other staff. Rebecca's days are not often the same and she finds herself regularly involved in providing health education and emotional support to individuals and carers, as well as information on other services that are available in the community.

1. What are some of the community services in existence that could benefit the individuals Rebecca cares for?
2. What are some relevant health promotion/education programs that could benefit the individuals Rebecca cares for?
3. One of the individuals Rebecca cares for in the community has a BGL of 27.9 mmol. What action would she take?
4. When assisting an individual in the shower, Rebecca notices significant bruising on her arms. When questioned, she tells her her son did this but that he didn't mean to hurt her. What is Rebecca's responsibility in this scenario?
5. What are some of the key personal safety strategies Rebecca would implement when working in community nursing?

## Summary

There has been an increased focus on preventative care and wellbeing promotion in recent years. Community care is increasingly helping individuals transition from acute services to care and enabling services in the community. The philosophy of public healthcare and the practice of primary healthcare underpin the delivery of community health services in Australia. Integral to this service is empowering communities to become healthy while addressing the non-traditional determinants of health such as social and economic factors. Community nurses have particular competencies and skills which are now being formally recognised. Nurses providing care in the community, and in particular home care, have specific issues which impact on their practice. The nursing process informs care delivery along with applying critical thinking strategies and decision-making tools to assist to manage risks and resolve problems. Several case studies illustrate particular aspects of community-based healthcare.

### DECISION-MAKING FRAMEWORK EXERCISE 46.1

You have just been employed at a large, busy general practice surgery. You have been asked to do a day shift under the supervision of a senior Enrolled Nurse who has worked at the practice for the past 4 years. The general practitioner on shift has said they are happy to provide support if needed. You have been asked to do all wound care appointments, triage of walk-ins and follow-up phone calls of the clinic's diabetics.

Using the decision-making process address the following:

1. Do you accept this allocation of duties?
2. Considering the staff on this shift, is the model of nursing care appropriate?
3. What (if any) are the issues that could potentially result in you working outside of your scope of practice?
4. Identify the potential and/or actual flaws within this scenario.

## Review Questions

1. What is meant by a social view of health?
2. What are the philosophical values of public health?
3. What influence does public health aim to have on the Australian healthcare system?
4. What are some of the key benefits of primary healthcare?
5. List some models of care used in community health.
6. Define community health nurse as an occupation.
7. What are some of the issues community nurses face in home care?
8. Describe 'cultural safety'.
9. What are the steps in the nursing process?

Answer guide for the Review Questions, Critical Thinking Exercises, Decision-Making Framework Exercises and Critical Thinking Questions in Case Studies are hosted on Evolve: http://evolve.elsevier.com/AU/Koutoukidis/Tabbner/

# Nursing care in rural and remote areas

*Melissa Taylor*

CHAPTER 47

## LEARNING OUTCOMES

At the completion of this chapter and with further reading, students should be able to:

- Define key terms
- Compare and contrast health status and needs between urban, rural and remote communities
- Identify how regions are classified as rural or remote in Australia
- Identify the key infrastructures for effective healthcare service delivery in remote settings
- Identify and discuss potential sources of stress related to working in a remote health context
- Describe the characteristics of rural and remote area nursing
- Describe the challenges a nurse may face when providing nursing care to people living in rural and remote areas

## KEY TERMS

classification
geographical isolation
remote area health services
remote area nurses
rural health services
rural nurses
telehealth

## CHAPTER FOCUS

Rural and remote nursing is any type of nursing practice that involves the provision of nursing care in a centre that is geographically removed from a major city (Berman et al 2012). This chapter provides an overview of rural and remote healthcare environments, focusing on related workforce development and health service delivery in Australia. This chapter also discusses the role of the rural and remote nurse, including the challenges such nurses face while providing nursing care in these communities. Key factors such as geographical isolation and sociological and cultural challenges are explored.

## LIVED EXPERIENCE

My first trauma came into the clinic only 1 week after I had started as a remote area nurse in Far North Queensland. A man with a severe head injury was brought in by the local ambulance; he was unconscious and showing signs of shock. All I could do was get orders via the telephone from a doctor thousands of miles away and wait for the emergency air ambulance to arrive. It was one of the most challenging experiences of my nursing career and I have been a nurse for 30 years.

**Yvonne, Remote Area Nurse, Qld**

# INTRODUCTION

In Australia, 66% of the country's people live in metropolitan regions, with 31% residing in regional and rural areas, and only 3% living in remote areas (Brown & Edwards 2012). The concept of remoteness is an interesting and complex one, and is central to a chapter on rural and remote health practice.

A common distinction between **rural health services** and **remote area health services** usually involves the presence (rural) or absence (remote) of a medical officer. In addition, rural communities usually have a 24-hour healthcare facility with medical service capabilities at all times, whereas most remote areas rely on health centres that are open during office hours and an on-call service after hours (Brown & Edwards 2012).

Significant factors for the role of the rural nurse are the context of the environment; its location and distance from a tertiary referral centre; the size of the facility; the healthcare team in which nurses work; the working conditions; and the profile of the rural community in which the nurses care, work and reside (Mills et al 2011). For example, for a resident of Yuendumu in the Western Desert, Northern Territory, access to health services and education services and the degree of perceived 'remoteness' will differ from that of someone in a regional centre such as Alice Springs or a rural town like Goondiwindi. There will also be variations over time—for example, when the Yuendumu road is washed out or when drought occurs. For health professionals at Yuendumu, perceived remoteness would also differ. An Aboriginal health worker is likely to be in their home community and therefore close to family, albeit far from most formal educational opportunities. However, the remote area nurses (RANs) are likely to be remote from family and professional support, as well as being physically remote from the closest regional centre. For many nurses the opportunity to provide nursing care within or near their home town locality is appealing and provides a rewarding and challenging career pathway. Within Indigenous communities in Australia, the opportunity for Aboriginal healthcare workers to engage within their community and work with and for the community is available. This is achieved through the role of the Aboriginal healthcare worker, trained specifically in the needs of Indigenous populations to work within the healthcare team for Aboriginal and Torres Strait Islander people.

Several **classifications** are used in Australia to define 'rural' and 'remote' and these are often used to allocate both services and resources. The most commonly used systems are:

- Accessibility/Remoteness Index for Australia (ARIA or ARIA+) classification
- Australian Standard Geographical Classification (ASGC) Remoteness Areas classification. This is based on the road distance to the service centres.

These classification systems do not take into account the socioeconomic status, population size or cultural factors (Brown & Edwards 2012).

The proportion of the rural and remote population in Australia that is Indigenous is high (Anderson et al 2006). Therefore, there are often cultural and cross-cultural issues distinguishing service provision in rural and remote areas. As a nurse working in a rural setting there are often significant issues that arise that may result in staff leaving the area, taking away their valuable knowledge and expertise (Muecke et al 2011; Diaz et al 2015).

In any culture there exists a set of values, beliefs, rituals and practices and understanding and adapting to these is often a complex and difficult pathway. Working as a non-Indigenous nurse within an Indigenous community can highlight many differences in ideals, expectations and understanding of the healthcare setting (Muecke et al 2011). These can vary according to the location and remoteness of the setting; however, they are reliant on the nurse being able

to understand and adapt. Often the support structures are limited and require the nurse to become familiar with tradition and culture and adapt work practices to achieve this. Sometimes this results in an inability to work within the area and a high mobility or transient characteristic in the workforce of the area. Positive work relations can be developed and grown with local elders within the community and in the inclusion and support that can be provided by an Aboriginal healthcare worker. Getting to know and understand the community that you work within is important to gaining a better understanding and socialisation within a rural or remote area.

Resourcing within remote centres differs greatly from that provided within a tertiary referral setting. The availability of public (and often private) transport decreases with increasing remoteness. Coupled with poorer socioeconomic status, unsealed and sometimes unmaintained roads, and seasonal variations in road access, access to health and other services is often poorer in remote communities and towns (Cleland et al 2010).

Health services in remote areas have distinctive features. One of these is that they tend to be supply driven. That is, access is constrained by the availability of suitably experienced staff and appropriately resourced clinics. In urban and many rural areas, services are more demand driven. The population exists for a variety of services and access to these is within driving or public transport distances. In other words, with a better supply (and diversity) of health staff and facilities, persons can access doctors, health clinics and allied health professionals as often as they need and can afford. Additionally, remote health services are predominantly state/territory government funded, whereas in urban and most rural areas there is a greater private component, and a greater use of Medicare funding.

## REMOTE AND RURAL AUSTRALIA

The remote areas of Australia generally pose particular challenges for the consumers and providers of health services. The Australian outback is characterised by large distances, extremes of climate, formidable geography, poor health status, diverse cultures, sparse population and tenuous infrastructure. There is nothing better than raising a family within a rural setting, being able to run through paddocks and gain an appreciation for animals, food supply chains and the great outdoors. This concept of living in a rural locality creates a sense of life on a farm, fresh food, water and the great outdoors; however, according to the Australian health-related statistics, individuals in rural areas are at greater risk of health-related problems than those in urban areas (Jukkala et al 2010; Cleland et al 2010).

### Significant issues

#### Government

In Australia, the majority of remote health services are provided or funded by state and territory governments. In cross-border regions, there are differences and difficulties over policies, laws and historic traditions. Superimposed are the Commonwealth, state and local government divisions of responsibility, which also vary from area to area. The Commonwealth has responsibility for some aspects of health, such as general practice (GP) services, immunisation and some Indigenous health services; however, the state government has authority over most areas of health service. The Commonwealth and the states and territories may also have jurisdiction over land, particularly crown land, mining and conservation (Cleland et al 2010). It is these government boundaries that require additional communication and planning for people from within health services to achieve an outcome for an individual.

In many ways the bush is the battleground on which the issues of state and federal politics are fought. It is also the place where the lack of defined responsibilities for the different tiers of government in areas such as health is more apparent. Medicare services versus state-government-funded health services, native title, mining, fishing rights, forestry, environmental control and conservation are a few of the major issues in remote and rural Australia.

#### Health resources

The health status of people living in remote areas is significantly worse than those living in urban areas. People living in remote areas have less access to health resources, and have traditionally had services delivered mainly by remote area nurses—hence, they have had little or no access to MBS and PBS funding. Findings of the Australian Institute of Health and Welfare (AIHW 2008; 2011) include:

- The supply of GPs and retail pharmacists falls sharply in remote zones
- Nurses provide a higher proportion of healthcare in rural and remote Australia than in metropolitan Australia
- The number of medical specialists per capita is substantially lower
- Nursing home availability decreases with increasing remoteness
- Medicare data indicates that people living in rural and remote zones are using fewer services than those living in metropolitan zones
- Overall hospitalisation rates are highest for those living in the remote zone.

### Comparison of health needs of urban, rural and remote communities

Internationally there is a disparity in health status in favour of urban populations and Australia reflects this trend, with current morbidity and mortality data showing a significant rural/remote–urban differential. Examples of this include:

- Australia's farming population has a distinctive illness/injury profile, characterised by high rates of unintentional injury and fatality
- Geographically the healthcare workforce is unevenly distributed and problems of access extend beyond 'mere distances to services' (AIHW 2011)

- Cardiovascular death and hospitalisation rates increase within increasing remoteness (AIHW 2010:vii)
- Rural and remote health services are more dependent on primary healthcare services with medical support provided by general practitioners (GPs)
- People living in rural and remote areas generally receive a smaller share of overall health spending; there are fewer GPs, specialist nurses and health professionals; and more limited access to specialist services (National Strategic Framework for Rural and Remote Health 2011)
- People living in rural and remote areas are often required to travel large distances to attend medical appointments with even greater distances to seek specialised treatments.

## HEALTH AND ILLNESS PATTERNS IN RURAL AND REMOTE AUSTRALIA

Australian statistics indicate that rural and remote Australians are disadvantaged compared with urban-dwelling Australians on a number of critical indicators (AIHW 2008). These include income and poverty levels, unemployment rates, education achievement and living costs. The rural/remote population also experiences poorer health than their urban counterparts, with health status and life expectancy decreasing the further the individual resides from an urban centre. Needless to say, they also have less access to health services. Rural and remote Australians also display higher rates of disability, premature mortality, morbidity, hypertension and mental illnesses. Health risk factors such as smoking, alcohol consumption and environmental dangers are greater in rural areas; as are rates of injury (including particularly high rates of child accidents) and chronic conditions (especially asthma and diabetes).

These higher morbidity and mortality rates are exacerbated by poor infrastructure supports (inferior roads, long distances to services and lack of transport options) and are often a deterrent to help-seeking behaviours, thus further impacting on health outcomes.

Needless to say, Indigenous Australians experience not only significantly lower life expectancy rates than their non-Indigenous counterparts but also higher rates of most ill health and trauma, particularly higher rates of chronic conditions and accidents.

### Rural/remote Australia, population health and provision of services

Healthcare provision and access is one of the most significant issues for rural and remote Australia. Despite the evident health needs (as briefly outlined above), health services in rural and remote Australia remain stretched and underfunded and there is a widespread lack of specialist services. Inaccessible areas, particularly small, remote communities, are likely to have a poorer health status and poorer standard of care. This corresponds with less availability of services or ability to access services. There are many reasons for this with the biggest being the size of the area that needs to be serviced and the distance between the services that are currently offered.

Rural/remote populations have greater difficulty accessing basic services, including general practitioners. There is considerable evidence of service paucity and overstretched resources, with patterns indicating declining service provision at the same time that demand is increasing. Health disadvantage and poorer standards of service delivery are well-established factors of rural/remote life in small communities throughout Australia yet government policy responses generally do not seem to be able to ameliorate this issue, thereby limiting appropriate and effective responses (Alston & Dietsch 2008; Nankervis et al 2008). It is a complex issue and one that is not easily resolved. Given the enormity of distance that health services are required to cover it is an ongoing debate and dilemma for any government in power.

Positively, living in a rural or remote setting provides health workers and the local community with a sense of community. There is a noted reliance on each other, the community and the service providers that do have services in town. In the event of trauma, natural disaster or illness it is not uncommon for community to 'pitch in' and help out in many and varied ways (Corbett & Williams 2014; Kitchen et al 2012; Kutek et al 2011; Shamah 2011).

This sense of community provides psychological support and reassurance for community members and also for healthcare workers who can sometimes be caught between the professional requirements of the registration standards of an Enrolled or Registered Nurse and that of community member. As a nurse there is a privacy privilege that allows for the disclosure of personal medical and personal information relevant to the provision of care; however, there remain distinct confidentiality requirements of professionals (Kutek et al 2011). In 'tight-knit' communities this requires health professionals to be discreet and have the ability to maintain confidentiality and trust in all conversations.

There is an increasingly well-documented, uneven geographical distribution of the healthcare workforce. But while there are fewer doctors per capita in rural and remote areas compared to urban areas, the contribution and importance of other health professionals must not be underestimated (Hughes 2009). The Australian government has introduced many initiatives: for examples refer to the Department of Health and Ageing, Office of Rural and Regional Health. However, it remains to be seen whether these initiatives to maintain and increase the numbers of health professionals in remote and rural areas will be effective in the longer term.

Nursing schools now focus attention on clinical placements within rural and remote settings in an aim to showcase the positives of working within these. For many students this is their first time experiencing a rural locality and for some it offers the chance of future work opportunities. For many it is the opportunity to become part of the community, learning from Enrolled and Registered Nurses within the area.

The early focus of such initiatives was on the medical workforce, with programs for nursing and allied health professionals coming later. Recruitment is only part of the story; retention is impacted by a number of factors including 'living in a fishbowl', often being the sole provider, blurred professional and personal boundaries, the requirement for a broad range of skills and limited opportunities for professional development, to name but a few.

Those who provide healthcare services certainly understand that their roles differ compared with those of their urban counterparts, and they know that they need extended and additional skills to work in rural and remote contexts. Healthcare delivery in rural geographical locations is challenging and rural nurses need to be more 'multiskilled generalists' (Bish et al 2012; 2014; Nankervis et al 2008).

The diversity of situations rural nurses attend requires them to make decisions independent of other health professionals. This requires that nurses are prepared, skilled and educated in contemporary practice to manage and coordinate situations from outpatient clinics to multi-trauma life-threatening situations (Bennett et al 2012; Keast 2014; Nankervis et al 2008). Coupled with this demand is the geographical barrier to access of education; however, the improvement in telehealth and internet accessibility has slightly diminished this barrier.

Rural and remote health is a complex problem that does not have one neat fix, nor does it belong to one government department. There is a need for a whole-of-government response: a national, coordinated approach that takes into consideration the needs and diversity of the population.

According to a 2009 statement released by the National Rural Health Alliance (NRHA), Australia faces the 'perfect storm' in its healthcare system, with increasing demand, inadequate infrastructure, a rapidly ageing workforce and escalating costs. Many rural regions are growing rapidly, primarily through the boom in mineral exports and the subsequent location of a high proportion of health activity. Rural and regional Australia is central to Australia's economic success and deserves to be a high priority in health service considerations.

## Geography, space, place and health

Health status comparisons are typically assessed through rates of life expectancy, morbidity and mortality. As referred to previously, life expectancy rates have been found to be significantly higher in urban areas compared to rural and remote areas. The rates ranged from 78 years in major cities to 72 years in very remote areas. Therefore, it is not surprising that all-cause mortality rates of Australian people increased with the level of remoteness. Most rural men are hard workers in the agricultural sector—and the appropriate services may not be available to them nor affordable to access in another locality. Likewise, property landholders may struggle with workload requirements resulting in the inability to take time 'off the land' to attend health ailments. Within rural industry time off leaves properties unattended or with less than the required staff to enable functioning of the property, with resultant loss of income. This, coupled with the ongoing struggle that nature presents with drought, flood and fire, and the political landscape with mining and changes in export market requirements, add greater pressure to those working and managing rural properties.

The common leading causes of death in rural areas include cardiovascular and respiratory diseases, as well as injury (e.g. poisonings, motor vehicle accidents and suicides). A recurring theme in rural and remote demography is that population density is low and dispersed. These characteristics impact on healthcare services, particularly the ability to sustain healthcare services at accessible locations.

While an increase in local hospital closures in rural and remote locations has resulted in a reduction of primary care and an increase in travel, this has not been the sole rural healthcare issue. Additional healthcare concerns include quality of care, specialisation of services, ambulatory care and emergency treatment, all factors that can negatively impact the health of rural people.

In large part, distance, isolation and dispersed populations have been the leading causes of these problems. These common characteristics have led to difficulties in recruiting—as well as retaining—qualified and skilled professionals. The

### DECISION-MAKING FRAMEWORK EXERCISE 47.1

It is an evening shift at the local hospital and you are working with a Registered Nurse (RN) who is busy in the office area with an upcoming audit. There are a total of 11 inpatients allocated to you and the RN. One of these inpatients was admitted 24 hours ago with a diagnosis of urinary tract infection. At 1800 hrs the RN asks you to complete a set of observations and prepare the next round of antibiotics for this patient (this will be the fifth dose) and she will be with you in a minute. You have just completed the observations for the inpatient and notice that this person has a temperature of 38.6°C. You notice that the antibiotics due at 1400 have not been given. You have only just finished your medication endorsement and are not really familiar with the antibiotic prescribed.

1. What handover do you provide the RN to alert them of the clinical situation evolving?
2. What is your responsibility in relation to the clinical error that has been identified with the omission of a medication at 1400?
3. Within the scope of the EN what are the supervision requirements relating to the administration of IV antibiotics?
4. Practise the conversation with the RN to ensure that you are able to effectively communicate and work together within the scope of practice of both RN and EN.

urban and more prosperous areas are disproportionately home to the skilled healthcare workforce in most, if not all, countries around the world.

Many promising health service initiatives in rural and remote areas have not been sustained, with the result that many communities still lack adequate health services and residents often forgo care at times of need. It is appropriate to consider the critical factors driving the need for changes in healthcare models and what impediments exist to achieving equitable access to healthcare regardless of geographical or socioeconomic circumstances (Humphreys & Wakerman 2008).

An extensive history and many issues and factors have dramatically shaped rural and remote Australia. Many of these are not unique to Australia; across the globe countries are experiencing significant and often rapid changes in geographical redistribution of their populations. These changes are mainly caused by political, economic and climate factors.

Alston (2009) discussed some of the global factors that have led to large-scale movements of people from rural to urban areas; these are mostly to do with security of employment, loss of services and jobs and climatic conditions (e.g. the natural disasters in early 2011, the drought of 2014–15).

For many reasons there is a growing diversity of rural and remote populations and a high level of unemployment and welfare dependency. The factors that have shaped and continue to shape the culture of rural and remote areas include people movements, changes in agricultural prosperity, workforce changes, globalisation (growth of the international marketplace) and 'detraditionalisation' and diversity of rural and remote areas. More than a decade ago, Welch (2000) wrote about the determinants of rural health and much of what she discussed is still the case today. Her argument is that while Australia is one of the most highly urbanised countries in the world, the economy is still dependent, to some degree, on the rural sector. The general perception of rural Australia as a homogenous mass of people, experiencing health and healthcare in a similar way, is not the case in reality.

### CRITICAL THINKING EXERCISE 47.1

There are many challenges facing nurses working in the area of rural and remote health (geographical isolation, environmental, sociological or cultural factors). These challenges often create barriers to care provision.

1. Discuss why the following factors are a challenge to individuals living in a rural or remote area:
   - Geographical isolation
   - Environment (population size)
   - Sociological issues (e.g. employment)
   - Cultural diversity.
2. What individual nurse practice changes do you need to consider in care delivery and decision making to be an effective nurse providing quality care in the rural or remote setting?

## REMOTE AREA AND RURAL NURSING

In any healthcare service in Australia, nurses make up the greatest number of health professionals in the workforce, and this is even more so in rural and remote areas. Nurses working in these areas must possess high-level clinical skills across a range of specialty areas (Berman et al 2012).

The healthcare team within a rural community is made up of different members including medical officers, nurses, allied health professionals (e.g. physiotherapists, dietitians and speech pathologists), a general practitioner or Royal Flying Doctor Service clinic doctor/nurse, community health and, within some communities, Aboriginal healthcare workers and the possibility of a nurse practitioner. Interestingly, not all members of the team will be located within the local area. Some members of the team will be accessed via the phone link within the telehealth systems and sometimes via a visiting practitioner who periodically comes to town. This approach provides the benefits of holistic and culturally sensitive health services without the need for individuals to travel large distances.

The inclusion of Aboriginal healthcare workers aims to achieve better health outcomes and better access to health services for Indigenous people. These quite distinctive healthcare providers communicate and plan care often by telehealth or phone consultation to achieve the optimal outcome for residents residing in rural and remote localities. The role of the Registered and Enrolled Nurse often comes with advanced practice opportunities to ensure that the people being cared for have access to services that are usually offered by other members of the healthcare team. For example, nurses within rural and remote areas may have prescribing rights for some medications, are able to perform Pap smears and, in some areas, x-rays. Advanced practice standing differs between the Registered and Enrolled Nurse; however, opportunities are offered that are not available within regional or metropolitan areas.

### Remote area nursing

Nurses in remote areas are required to manage medical emergencies and trauma, usually with assistance via telephone or, in some instances, telehealth from medical colleagues hundreds, even thousands, of kilometres away. **Remote area nurses** provide the following care:

- Age-appropriate wellness check-ups and healthcare
- Detection and monitoring of chronic disease
- End-of-life care
- Examination and diagnosis, and prescribing (in Australia only) and dispensing medications as part of routine practice
- Follow-up nursing and medical care after transfer back to the local area from a regional or tertiary health facility
- Community development and health promotion activities
- Public health programs (e.g. screening and surveillance).

This care often occurs in a cross-cultural environment that operates with languages, knowledge and cultural systems different from those of the healthcare providers (Brown & Edwards 2012).

## Rural nursing

The lack of other healthcare professionals will determine the scope of practice of the rural nurse. In Australia, and internationally, **rural nurses** have a more generalist role as the population declines and nurses have to work with remotely located allied healthcare and medical practitioners. Rural nurses also require a broad range of skills and knowledge (Brown & Edwards 2012). The team comprises Registered Nurses, Enrolled Nurses and Aboriginal and Torres Strait Islander healthcare workers. In some settings a nurse practitioner or Enrolled Nurse may also be an Aboriginal healthcare worker. Each member of the nursing team provides care within their level and scope of practice. For many years nursing within rural and remote areas has been identified with a 'bush' nursing model of care. That is, a generalist yet expert role that has extended beyond nursing care realms of those working in larger centres, with inclusions of prescribing rights and extended assessment and treatment plans, to name a couple of areas.

Extensions now exist to these roles of nurses in rural and remote settings and the role of the nurse practitioner has evolved (Gardner et al 2006; Klein 2007; Corbett & Williams 2014). Often it is these services led by a nurse that now provide a greater ability within a health service to provide frontline care and referral within rural and remote communities. This positive inclusion within the workforce is not in all areas but where evident is key to prompt and efficient care delivery, coordination and referral without delays in service delivery (Corbett & Williams 2014).

## Characteristics of remote and rural nursing

The characteristics of remote area and rural nursing in Australia are usually not experienced in other nursing contexts. Clinical Interest Box 47.1 shows examples of rural and remote nursing characteristics.

The need for remote area and rural nurses to work at an advanced practice level increases as the size of the healthcare service decreases. Clinical Interest Box 47.2 outlines some of the activities that remote area and rural nurses undertake.

The professional support available to remote area and rural nurses is outlined in Clinical Interest Box 47.3.

### CLINICAL INTEREST BOX 47.1 Characteristics of remote area and rural nursing

- Providing care to small, dispersed and highly mobile populations
- Climatic extremes
- Providing care to populations with high morbidity and mortality
- Working in the context of a lack of social and human services infrastructure
- Working in isolation, which is geographical, social, professional and cultural
- Absence of remote health standards, credentialling or remote service accreditation
- A strongly multidisciplinary approach with flexible professional boundaries, often with a horizontal style of management
- Advanced and collaborative practice
- Lack of boundaries between home and work
- Frequently on call
- Dependence on remote technologies
- High level of traumatic events
- Autonomy and flexibility
- Cross-cultural environment
- Frequently lacking formal preparation for the advanced and extended practice role
- Primary healthcare approach

*(Brown & Edwards 2012:213)*

### CLINICAL INTEREST BOX 47.2 Nursing activities for remote area and rural nurses

- Assessment, diagnosis and treatment of acute conditions
- Early detection and co-management of chronic disease
- Child health, and growth and development monitoring of 0–5-year-olds
- Health promotion activities (immunisation programs, outbreak control and sexually transmitted infection control), environmental health and nutrition programs
- Dispensing medications
- Management of acute trauma and medical emergencies
- Evacuating an individual via road, sea or air

*(Brown & Edwards 2012:216)*

# EFFECTIVE HEALTHCARE SERVICE DELIVERY IN REMOTE SETTINGS

Effective healthcare service delivery in remote settings can involve working in teams and in partnership. Health professionals need to share problems and be prepared to resolve differences. The key to achieving successful partnerships is a willingness to consider and respect the perspectives and needs of others (Brown & Edwards 2012).

## Recruitment and retention of workforce

The difficulties associated with recruitment and retention in small rural and remote health services are widely recognised. A wide range of measures have been implemented by

## CLINICAL INTEREST BOX 47.3 Professional support for remote area and rural nurses

In Australia the following organisations support nurses:

- CRANAplus is the professional organisation representing health professionals of all disciplines who work in rural and remote areas
- Rural Nursing and Midwifery Faculty of Royal College of Nursing Australia provides professional support for rural nurses
- The National Rural Health Alliance (2010) is the peak multidisciplinary body for rural and remote health
- The Rural General Practice Network supports rural health professionals

*(Brown & Edwards 2012:217)*

governments and health authorities in an attempt to redress these issues.

The 2008 paper by Humphreys and Wakerman represents the first time health workforce retention benchmarks and recruitment costs have been identified for rural and remote primary healthcare services located in different geographical contexts. Its outcomes enable health services to know what is a reasonable length of service that might be expected from health workers employed in different rural and remote contexts, what are the real costs associated with replacing staff who leave and how the service might fashion its workforce retention strategy and incentives most appropriately to better serve the needs of its health workers. Additionally, this research identified sentinel indicators which will enable health services and health authorities to better use their human resource data to monitor workforce performance and plan future retention measures designed to maximise length of service.

Accessible in situ healthcare services are not only preferred by people within communities, but arguably result in better health outcomes, whether it be in terms of more responsive treatment to acute care needs or increased likelihood of adopting health promotion and early intervention behaviours. Maximising the retention of existing health workers is the key to ensuring the maintenance of locally available, appropriate, sustainable rural and remote health services across this vast land.

The Services for Australian Rural and Remote Allied Health (SARRAH) position paper *Principles of recruitment and retention of allied health professionals serving remote Australian communities* (February 2010) provides information and recommendations regarding principles and strategies to be developed, funded and implemented to support the recruitment and retention of an allied health practitioner (AHP) workforce for remote communities in Australia. A consistent, national approach to recruitment and retention of AHPs adopted at national, state and local levels is required to ensure that remote communities have access to the range of allied health services necessary to meet their current and projected health needs.

## Working in health teams and partnerships in rural and remote contexts

Successful teamwork is an essential ingredient for providing an effective health service in rural and remote contexts. Proficient teamwork can also enhance satisfaction, productivity and survival; whereas dysfunctional teams compound the considerable challenges that already exist for rural and remote health professionals and the consumers of the service (see Case Study 47.1).

There are many leadership styles and a number are seen in healthcare. Historically nursing has seen autocratic leadership or a 'top-down' style of leadership, with tasks and skills delegated as deemed relevant. Jeon et al (2010) explored the notion that leadership plays a critical role in setting the climate for practice development and the outcomes of care; according to Cook and Leathard (2004) and MacPhee (2012) this is particularly relevant within the complex and continually changing world of health. It is the effect of leadership that will determine an organisation's ability to change and learn and it is the organisation's willingness that will promote or inhibit change within the organisation. This creates challenges for nurses as they have to balance their leadership role between resolving immediate and conflicting clinical pressures, as well as continuing to make progress in staff development and the identification and implementation of the latest evidence within their nursing practice. Through development and promotion of clinical nursing leaders for the future, rural facilities can aim to achieve the goal of providing quality nursing care within supportive work environments that use evidence to guide their nursing practice.

Successful leadership in healthcare is greater than defining and engaging a specific leadership style and through research conducted by Stanley (2009) a model of congruent leadership was developed. Stanley (2009:63) affirmed that it is 'congruent leadership that responds to challenges and critical problems with actions and activities in accordance with staff values and belief.'. Nursing clinical leadership is about the leadership demonstrated within a nursing clinical setting. A nurse will lead their team in accordance with the clinical demand they meet each day and it is in these areas that the need for nursing leadership is important. The nurse in their clinical setting (ward, unit or residence) will utilise decision-making capacity in line with clinical needs, staff relations, organisational capacity and scope of practice.

As nurses, we are all leaders of the care we provide, the communication we have with our colleagues, individuals in our care and their families and the professional approach that we use. It is about how we treat each other and the people we care for. In a rural setting this is also the social network of the nurse and a balance must be maintained between professional and social identity.

## CASE STUDY 47.1

Working in teams is complex and multifaceted irrespective of the clinical setting. Team work requires all members of the team to listen, participate and respond to each other in amicable ways. In nursing, teamwork also requires a 'hands on' assistance approach to achieving individualised care in timely and efficient ways.

Below a remote area nurse describes how the health centre staff were having some communication problems and needed to look at new ways of building their team in a more positive way. A new assistant director of nursing position was being advertised and it was hoped that this role would assist the team to improve the following team concerns:

This is how the team did not work:

- We had an old-fashioned, vertical structure. The doctor was above the nurse, the nurse was above the Aboriginal health worker (AHW) and we were all above the community and anybody from outside the community. There was division along professional, gender, cultural and experience lines. So each of us needed to 'divide to rule' or to at least have a say. This was a very unhappy team
- The team did not build a sense of community. The health centre was not then a community health place; it was a 'sickness' place—the place of last resort. Things looked efficient; everyone knew their place (like it or not). The trains ran on time; the problem was there was no one on the train, only the drivers, and the community got nowhere
- This situation manifested in late presentations. Families and individuals delayed at home ill, so the children came very late, often when they were too sick to treat locally. The traditional healer would not come near the health centre as they clearly felt uncomfortable and culturally unsafe.

A successful appointment was made to the team and a new nurse took charge of the team and negotiated a change of focus and leadership style. This led to the following experiences:

- The nurses and AHWs together with the visiting doctor worked collaboratively and developed a plan to manage children who didn't appear to be growing well. Mothers with sick children would come to the health centre a lot. The children presented as very weak and undernourished, usually with an associated infection. The nurse and the AHW would examine the child, undertake the relevant investigations for the presentation and if necessary refer to the doctor for further review, examination and tests. This is where the senior clinician would take the lead
- Sometimes the child would be referred back—medical causes excluded, it seemed there were problems with access to food. Questions would be asked as to why? Was it an issue of money, understanding or home situation? This was where the AHWs would take the lead. Together the health staff would visit the home and talk to the family but the AHWs took the lead on this. 'First to speak, first to walk into the home'
- Sometimes the numbers of children would get too big for the team to manage effectively. Too many children were malnourished or were not adequately recuperating after an acute illness. So the health staff took the information to the community. The community leaders started looking at funding programs for child feeding and maternal education. Then they looked at the community and family issues that were directly impacting on the health and wellbeing of the kids and used the state of the children as a springboard for a range of actions. This is where the community took the lead.

1. How would you describe this leadership change in focus for the healthcare team?
2. What benefits does the shift in leadership have for a nurse working in the setting?
3. What benefits do the shift in leadership and resultant outcomes have for the individual using the health service?

## Features of remote health teams

Rural and remote health teams have a number of features, some that they share with teams in urban areas and some that are unique to the rural and remote context. Generally they operate in areas of high morbidity and mortality, and hence have a greater health need; extreme isolation; harsh environments; often in cross-cultural contexts including the city/bush cultural divide, with a highly transitory, cross-discipline membership. These factors provide not only the greatest challenges and but also the greatest potential accomplishments of teams in rural and remote areas. The experience of operating effectively as a team member enhances interpersonal skills, problem-solving capacity, conflict management skills and mutual support. It is common for rural and remote team members to become long-term friends. The intense teamwork experience creates friendship and support that can extend into the future.

Working within a rural and remote health setting can be rewarding and provide opportunities that are not able to be experienced in any other setting. As Mitchell and Hussey (2006) described it, 'working in one's own community can be rewarding but stressful; there is a perception that you are "everything to everyone"'. However, it is the reward that encourages staff to continue to work in these settings, the satisfaction that all that could be done has been done. It is the sense of belonging and the sense of community that holds nurses in high regard in these settings. As one nurse describes it:

*I came to work here 5 years ago; I had never lived in a rural area but trained as a Registered Nurse in a regional university. I did a clinical placement at a rural hospital and loved every minute of it. I then applied for a graduate position here and have not left. I love it, the people, the work, and the opportunity. I have since completed my rural and remote*

*practice qualification and want to seek a role as a nurse practitioner one day.*

**(Carina, RN)**

***Multidisciplinary team*** Rural and remote health teams are multidisciplinary, involving Aboriginal health workers, doctors, nurses, community welfare and allied and other professional groups, as well as administrative and management staff. They require each member to have specific areas of expertise as well as advanced generalist skills and the capacity to support and complement each other. The inclusion of the Aboriginal health worker seeks to provide the key link between culture, the people and their health.

As one healthcare worker outlined, 'these ties to the community and local health networks provide us with a real sense of what is going on and what is needed at a grassroots level' (Mitchell & Hussey 2006).

It is through a combined team approach that care is coordinated and provided to those in need or those who require primary health strategies within the community setting. Nurses provide the dominant service within rural and remote communities from both a preventative and an illness or injury management perspective. This often overlaps with roles and responsibilities of other members of the healthcare team; however, it is unavoidable due to the nature of the work. This is commonly a source of conflict in those teams whose members originate from traditional practice backgrounds of urban hospitals and private practice and are more familiar and comfortable with the models of clear boundaries between professional roles, responsibilities and authority.

From a positive perspective, multidisciplinary teams with overlapping roles reduce professional barriers and barriers between individuals and increase the team's capacity to deal effectively with the greater demands of the service, while utilising individual expertise appropriately.

One of the few constants of rural and remote area teams is the changing membership as a result of staff turnover. Staff change is a major feature of rural and remote health teams. It is influenced by many external forces, such as emergencies, the family setting back east, west, north or south, ageing parents, children's education and so on. The high staff turnover is a strong argument for working in teams in remote health.

Teamwork is highly valued within the rural and remote health context (Lawrence et al 2015). As in so many other areas of rural and remote practice there is a huge learning curve (and unlearning in terms of past hierarchical team processes) to come to grips with. In summary, teamwork is about constant adaptation and change: adaptation to new members and rapidly changing circumstances as well as health systems. In the vortex of external change the team needs to be a haven of support for the individual health professional, a motivator through shared visions of the future, a creator of learning opportunities and a way to reality test expectations.

## STRESS RELATED TO WORKING IN A REMOTE HEALTH CONTEXT

Stress reactions can be described as a process of adaptation, a concept that can apply to stress associated with rural and remote practice. When health professionals begin work in a situation they have not worked in before, a period of adjustment is expected. The adjustment process will give rise to varying levels of stress (i.e. psychological 'strain'). This will persist until they gain a level of mastery (i.e. become comfortable and effective) in their new environment.

High turnover of staff in rural and remote areas prevents the development of an experienced workforce whose members have completed their adaptation process and become effective health professionals. This means that the bulk of the rural and remote workforce is at the beginning of their learning curve. Collective memory of what has gone on before, what works and what does not work tends to be short, resulting in the same mistakes being made over and over again. It is difficult to establish or maintain efficient and effective remote health services when health professionals are constantly being replaced.

### What is stressful about remote practice?

Stress is an issue that impacts on all health professionals, regardless of where they work, whether in towns, cities or the bush.

### DECISION-MAKING FRAMEWORK EXERCISE 47.2

You are working with a Registered Nurse in the emergency area of a rural health facility. The staffing in the area is yourself as EN and the RN; the ward area attached to the emergency area has an RN and EN working in the area alongside a ward assistant. The morning has been extremely busy and you are aware that the RN is with an acutely unwell person in the resuscitation bay. A local resident arrives at the triage desk and informs you they have cut themselves with a machete knife while harvesting broccoli. Their arm is currently wrapped in a towel; however, there are traces of blood evident on the towel. You take the person's details and move them to a cubicle where they can be seen and let the RN know what has occurred. The RN tells you to deal with the situation, assess the wound and let her know what needs to happen.

1. Do you leave and assess the person's arm?
2. What strategies can you use within the EN scope of practice in caring for this person?
3. Considering the staff in the whole facility at the time of this presentation, what other strategies could you utilise?
4. How would you effectively discuss these strategies with the RN and maintain harmony within the team?

Commonly accepted sources of stress in rural and remote work environments can be:

- The job—for example, workload (too much or too little), role ambiguity, lack of control and conflict
- The organisation—for example, working conditions, lack of recognition and support and unsuitable staffing levels
- Organisational change—changes to procedures, new technologies and expectations of transfer or retrenchment
- Violence and other traumatic events in the workplace.

While stressors in the rural and remote work environment, such as heat, dust and humidity, are easy to recognise, many of the causes of stress in the rural and remote workplace may not be so obvious. Health professionals may be stressed by uncertainty about their roles, by the responsibilities they carry, by their workload, by the way their working lives are organised, by the content of their jobs or by the network of interpersonal relationships that characterise their day-to-day existence.

## Lack of anonymity and personal privacy

Life in small remote communities is sometimes described as 'living in a fish bowl'. All areas of the remote health professional's life may come under scrutiny and provoke comment from local residents, not just about their professional abilities.

Many people value the interconnectedness of small communities, particularly if there is a community culture of helping each other out in hard times. Many would suggest that urban dwellers miss out on this sense of community. For example, many urban dwellers might not even know their neighbours.

However, like most things in remote areas, knowing everybody and everyone knowing the nurse is a two-edged sword. In some situations it is a blessing. In others it may be a curse.

Accountable practice can take on a new dimension: residents happy or unhappy with service provision have ample opportunities to express their satisfaction or dissatisfaction directly to the health professional.

Lack of anonymity of health professionals and individuals (and their families) in small communities may raise issues about confidentiality. For example, a common rule of thumb in terms of maintaining confidentiality has been that workers may talk about work-related issues with others (e.g. colleagues or partner), but only if they can do so in a way that does not identify those involved. This is hard to achieve in small communities when most people know most of what goes on and the people involved.

Opportunities for health professionals to talk about their work with others or to safely express any anger or frustration may be restricted as a result. Yet, the need to talk over work-related issues is recognised as an important part of debriefing following a stressful day.

Lack of anonymity of health professionals and individuals may also pose ethical challenges. For example, health professionals are generally discouraged from providing health services to friends and family. Ethical guidelines for professional practice have been developed to suit urban health professionals, who usually deal with individuals who are strangers to them. While practising in small community settings nurses may find themselves in breach of the ethical guidelines set down by their professional body.

Lack of anonymity also impacts on the health professional's ability to maintain privacy and personal space. In some instances on-site health professionals may be seen as a community resource, with the expectation that they will be there to meet the health needs of the community at any time of the day or night. On-site health professionals may be accessed by health service consumers wherever they are in the community, regardless of what they are doing—shopping or socialising, for instance.

This might be a negative or positive experience—depending on whether the health professional finds this level of trust and responsibility to be enriching or whether they see it as an intrusion.

*I feel quite alienated by having to be a doctor 24 hours a day in the supermarket and everywhere else. General practitioner*
**(Tolhurst & Bell 1997)**

*It's almost impossible to get enough personal space for myself … I was speaking to a friend the other day and I said I felt like a sitting duck in a shooting gallery that's going back and forwards waiting for someone to get me. General practitioner*

**(Tolhurst & Bell 1997)**

*I wouldn't work anywhere else. Where else could I care for a person with a snake bite at the beginning of my shift, assist with the plaster cast on a gentleman with a broken arm, attend a community immunisation clinic before lunch and provide a talk to school children on looking out for a mate with epilepsy in the afternoon. No other nursing job would allow me to be in all these places, it would be multiple positions, not as I love it … it is my everyday.*

**(Joan, RN)**

If you have grown up in a small community, this may not seem a big issue to you. If you are not accustomed to these levels of connectedness and visibility, then a period of adjustment will be necessary before a level of comfort is achieved.

## Lack of boundaries between work and home

The division between the nurse as a person and the nurse as the health professional tends to be less clear-cut in small rural and remote communities. This is partly due to the lack of natural circuit breakers between work and home, and between personal and professional.

City workers and health professionals who provide visiting health services can do their job and then leave their professional role behind and return home to personal lives relatively unconnected to their work. They may have a choice of recreational activities to participate in, and access to a range of other people, friends and acquaintances that are not connected to their workplace. This allows some down time to relax following work demands.

In small and remote communities, work and home life are less easily differentiated. Home may be just a stroll away from work or home may be in living quarters in the hospital grounds. If the health professional is on call their movements may be restricted. Rural and remote communities tend not to offer the same range of recreational activities available in town. In addition, friends and acquaintances tend to be drawn from contacts made in the workplace. Areas of common interest may be work-related.

For health professionals who live on-site in the remote community, the lack of boundaries between work and home may become particularly apparent when they are required to be on call. Their home becomes part of the workplace; people knock on their door to request assistance.

In such contexts, it may be difficult for remote health professionals to find time and personal space to just be themselves and to escape from their professional roles. This can impact on their ability to achieve rest time and to express parts of themselves not related to their work.

## Housing issues

The difficulties in establishing personal boundaries sometimes extend to the health professional's living space. Housing issues in rural and remote areas traditionally have been long-standing sources of conflict and stress for many health professionals. While health professionals recruited from outside the community may be provided with accommodation, local people (e.g. health workers) may not have accommodation provided (yet they may share the same issues of inadequate and overcrowded housing as others in Indigenous communities).

In some instances the lack of guest accommodation in remote communities (e.g. motels or guesthouses) means that there may be an expectation that health professionals will provide accommodation for health professionals and others that visit the community.

Some health professionals are required to leave the remote community to access annual or other leave so that the relieving/locum health professional can use their accommodation.

## Unrelenting demands

Health professionals who have grown up in the community may find the demands on them from friends, families and health service individuals to be unrelenting.

*I work in a multidisciplinary health service within an Indigenous community. I am a single parent and live with my four children just out of town and work 4 days a week within the service. Many of the individuals are family to me and this makes it difficult when I see the decisions they make and the complications I tend with respect to their failing renal function and diabetes management. Sometimes it is hard to differentiate between nurse and family member; it tears me apart.*

**(Deb, RN Indigenous health)**

*A position became available and I went to the deputy director of nursing and said, 'I'd love the role' and she said, 'Good, you can have it.' That was it, applications done and dusted, appointment made.*

**(Bish et al 2013:385)**

The unrelenting nature of remote work is a particular issue for on-site health professionals who may be required to be on call frequently. Sole health professionals may be on call 24 hours a day, 7 days a week.

*Sue received a call alerting her to a vehicle rollover out of town. The ambulance was sent and staff began preparing the clinic's rooms awaiting the arrival of the injured. A man arrived and said, 'No, it's nothing, it was just me', and he had a broken hand. I relaxed a bit. About half an hour later noise was heard outside and 17 further people presented—they were all in the vehicle rollover. The event required the whole nursing team, a 24-hour shift, and six people evacuated.*

**(Keast 2014:19)**

Sleep deprivation may become an issue at times. Even losing a single night's sleep can impair performance. Both short-term and long-term memory is affected after a night without sleep, and performance is slower (Silva-Costa et al 2011). Without enough sleep, individuals can have problems paying attention, and they can miss information due to lapses in attention (Silva-Costa et al 2011). People deprived of sleep also tend to be more irritable than usual.

### CASE STUDY 47.2

You have applied and successfully been appointed to a position within a rural hospital located 1100 km west of where you currently live. You have visited the town only once before and do not know anyone except the director of nursing (DON) and one staff member who you met at the interview. Your first shift commences and you start to introduce yourself to the other staff and the people that you will be caring for. A woman arrives at the front counter and asks how her husband is today. You ask her who he is and she responds with, 'Why don't you know and who are you anyway?'

1. What is your response?

Later in the evening you notice the same lady crying as she makes herself a cup of tea. You go to see if she is okay. She responds by telling you that their farm is not doing so well, the drought has meant they have had to sell a large number of cattle and feed is running low for those animals that remain. She tells you she has been hiding the severity of the feed issue from her husband as he is so unwell. By now, you know that her husband is a 60-year-old man with a recent diagnosis of bowel cancer who has been transferred back to the local hospital from a long stay for surgery, radiotherapy and chemotherapy in a tertiary facility. He remains in hospital as he still is receiving treatment for an infection within his bowel.

2. How do you respond to this woman and what support mechanisms do you see could be provided in the rural and remote setting?

## Cultural adaptation

All rural and remote communities have their own culture, whether agricultural, fishing, Indigenous, mining, railway or tourist. Being familiar with the culture and the demand that this places to be able to successfully work and reside in an area requires attention, discretion and understanding. Working within and with cultures and building community trust are inherent features within the *Code of Professional Conduct for Nurses* (NMBA 2008).

Culture shock can be a significant issue confronting healthcare workers in any healthcare setting but more so in the rural and remote space. Particularly of interest is non-Indigenous workers working within Indigenous communities as culture shock is not just about the healthcare worker and adjustments to the culture, but also the adjustment of the people in the area to a new worker from perhaps a differing background, culture or ethnicity (Muecke et al 2011). In transitioning into a setting priority needs to be given to gaining an understanding of the community expectations, the practices and ideologies of the community; introducing yourself and attending appropriate social events to engage in local heritage; listening to the local conversations; working with staff with experience in the area; and sharing your experience and knowledge where it is deemed appropriate.

***Indigenous communities*** The greater the difference between the health professional's cultural background and the community's culture(s), the greater the adaptation required before they master the new environment sufficiently to become effective and competent. This is particularly apparent for non-Indigenous health professionals recruited to work in remote Indigenous communities (Francis et al 2012).

Adjustment (and re-adjustment) is likely to occur when a health professional begins work in a remote area for the first time. For example, when a local from the remote community begins work within the bureaucratic environment of the health department, when a health professional moves from one remote community to another or during periods of organisational change.

*If you work in bigger hospitals you seem to have more support ... here you are limited. You depend on your colleagues ... who you can debrief with, who would experience and understand the way you feel.*

**(Kenny & Allenby 2013)**

*We carry so many portfolios ... I'm the [three specialist nursing roles] ... I have to have all these audits and stats done by the end of every month, effective discharge stats, nursing care stats, I have to have my floor report every month, and care for the people I see on my shifts.*

**(Kenny & Allenby 2013:196)**

Some health professionals feel they must exchange their own cultural values for the cultural values of the remote community they are living or working in. This is not so, nor is it necessarily desirable. Living one's own life according to one's own cultural values helps to maintain a sense of security, meaning and identity. However, this concept applies to individuals accessing health services as well as health professionals.

Nonetheless, the remote health professional will need to develop sufficient understanding of the culture(s) of the remote community and the impact of their own behaviours if they are to be effective and culturally safe when working within the cultural context(s) of a particular community.

Living and/or working in a culture other than your own can be a disorienting experience. Some speak of experiencing 'culture shock' while adjusting to living and working in a culture other than their own.

As health professionals learn new knowledge, skills and attitudes and adapt to the remote community over time, it is almost inevitable that they will be changed in some ways. It can be disconcerting for some health professionals working in rural or remote environments to find that a period of re-adaptation is required upon returning to the city or 'mainstream'. Many report feeling uncomfortable and out of place for a while until they re-adapt to their own culture and the non-remote setting.

## Issues of isolation

Isolation in remote communities can occur at several levels: geographical, professional and cultural. **Geographical isolation** is something that cannot usually be changed and is by definition part of remote health work. For those who grew up in the remote community, it may not necessarily be seen as unusual or a hardship.

A sense of isolation may be relative. A person's sense of geographical isolation may be reduced by, for example, roads being upgraded, frequency of air services, owning their own vehicle, networking with outside organisations or maintaining contact with others, both inside and outside the community.

For community members the need for accurate and timely healthcare is important. The need also for preventative health information is important. How to balance and manage the needs of individuals within communities can be assisted with the inclusion of information sourced and accessed via the internet or telephone. It is these services that can be updated and managed remotely that can assist communities to gather information to prevent health concerns or to assist in their management. It is also a key link to understanding a diagnosis or treatment plan. Healthdirect is one of these services that is available via the internet, or via a phone app. Healthdirect offers the community within Australia with resources in relation to symptoms, conditions, medications and treatments with a 1800 telephone number for health-related questions or advice. The service also offers information and guidance to healthcare professionals working in areas of isolation or rurality. Through the use of the internet or smart phone applications access has become easier; however, there are still barriers within levels of literacy or the lack of suitable phone or internet coverage.

Healthdirect is also a source of information for nurses working in the remote setting and is an ideal way of sharing reliable and evidence-based information with the community. Often working alone, without colleagues to consult or discuss

clinical and other issues with, can increase the stress associated with many situations. Some remote health professionals may feel isolated within their own professions. Remote workers are not only minorities within the population, but also within their own professions. Urban health professionals may have different agendas and issues of concern.

A sense of professional isolation can be reduced by, for example, joining and participating in professional bodies which contain other remote health professionals, networking with other remote health professionals, subscribing to professional journals or undertaking further study. If the health professional has not grown up in the cultural context of a particular community, be it mining, tourism, railway or Indigenous, then a sense of isolation may arise, particularly until they learn enough to feel comfortable or become competent within that particular cultural context. This is commonly cited as a barrier to recruitment and retention of remote health professionals. Certainly, for new graduates or those new to remote area work practice, it may be difficult to access the ongoing supervision and mentoring which is necessary as they adjust to their new role.

A sense of cultural isolation can arise as a consequence of being a member of a minority culture within a larger cultural group. This can be felt not only when recruited from outside the community, but also when working in an organisational setting which does not share your values, cultural or otherwise. A sense of cultural isolation may be reduced, and a sense of security and identity maintained, by maintaining links with the health professional's own culture, particularly during the early stages of cultural adaptation.

### CRITICAL THINKING EXERCISE 47.2

Take a piece of paper. List the positive aspects of working in a remote context on one side of the page, and list the negative aspects of working in a remote context on the other side. How many factors appear on both lists? That is, do the blessings of remote practice also contain the potential to become 'curses'? Do the positives outweigh the negatives?

## Trauma and violence

Traumatic events are those in which the individual experiences some form of threat to their own or others' lives, or are exposed to the threat or actual death of others, particularly under violent, shocking or horrific circumstances, and may also involve exposure to gruesome images. During or after the event the individual may feel an overwhelming sense of horror, terror or helplessness.

Individuals who are exposed to such events may experience a characteristic set of psychological and behavioural reactions that have their roots in the human stress response. Considering the great diversity of human nature and cultures, the uniformity of the experience of traumatic stress reactions is remarkable and suggests a biological basis to the reaction pattern, and also that the reaction pattern is a form of adaptation which has survival value.

As in day-to-day stress, a traumatic event is a combination of the actual event—which contains the potential to traumatise, whether the health professional perceives the event to be personally traumatic—and the health professional's reactions during and after the event. The experience of traumatic stress is an essentially human and normal response to extremely stressful situations.

Violence against health professionals is not uncommon in remote areas (Hills 2008; Taylor 2013). The effects of social tensions and violence in the remote community can also impact on the workplace. The emotional aftermath, although a normal reaction following such events, can be a difficult and challenging experience. While early intervention strategies, such as psychological support and debriefing, aim to prevent long-term psychological harm from occurring, some health professionals may become overwhelmed by their experience and go on to develop posttraumatic stress disorder.

Remote area health professionals may be particularly vulnerable to the impact of traumatic events; for example, road accidents, natural disasters, death of friends and physical assault (Lenthall et al 2009).

While employers have a duty of care to prevent traumatic events where possible, and to support workers in their recovery, it is also important that health professionals accept responsibility for their own role in maximising their recovery following such events.

Living and working within a rural or remote setting can be difficult particularly when traumatic events occur. The role of healthcare worker can involve being a provider, community support and personal involvement. The importance of identifying personal boundaries and the maintenance of an individual's scope of practice and ethical conduct is complex (Kutek et al 2011). The support that a nurse requires during these times is also difficult (e.g. deciding who to talk with when the involvement is widespread in the community). Such is often the case when a major road trauma or suicide occurs within the community resulting in the 'loss of a local'. Support for nurses and the awareness of ethical and legislative boundaries are vital; however, they are often limited in the rural and remote space (NMBA 2008).

The key importance in dealing with traumatic events is the post-event debrief time that should be conducted within the healthcare team at a time and place suitable to participants. Boundaries should be established and the ability to grieve, converse and gain a sense of closure be established for individuals participating. Often this is a complex process given the professional and personal boundary blur. The *Code of Professional Conduct for Nurses* in Australia sets the minimum Standards for Practice of a nurse in Australia (NMBA 2008). Within the Code are 10 Standards with Standard 5 pertaining to the respect of dignity, culture, values and beliefs of individuals and Standard 8 specifically relating to preserving the trust and privilege in the relationship between nurses and those receiving care (NMBA 2008).

**CRITICAL THINKING EXERCISE 47.3**

What are your views on being accessed after hours—for example, while shopping or at a community social event? What are your personal guidelines regarding what you see as acceptable and not acceptable in relation to this issue?

## ACCESS TO HEALTH SERVICES IN RURAL AND REMOTE AREAS

### Telehealth

One of many strategies currently being used to deliver healthcare services to rural and remote communities is telehealth. **Telehealth** is defined by the World Health Organization (WHO) as 'the use of information communication technology applications to provide health and long-term care services over a distance' (Berman et al 2012). There have been many reported examples of ongoing use of telehealth in Australia and clinical reports of positive results for people suffering from ongoing effects of acute illness and chronic illness and for their carers and rural and remote health service providers. It is anticipated that improved communications through teleconference and videoconference facilities will be the basis of strategies to ensure equitable access to healthcare and form the framework for future healthcare provision in rural and remote Australia (Berman et al 2012).

Telehealth is being extended into rural Australia as the use of digital infrastructure improves. There are many advantages for the nurse working in a rural or remote facility; for example, nurses are able to communicate with experts in trauma centres in relation to individual care situations as they present rather than managing a person based on the team's knowledge or limited prior exposure. This provides a sense of security for healthcare teams in rural and remote areas and also provides the best possible approach to timely, lifesaving or immediate advice from a specialist consultant from a tertiary setting.

*Telemedicine* refers to the practice of a medical consultant having communication, consultation and the provision of advice or care planning and medical intervention in a setting outside the area usually within rural or remote facilities (Wesson & Kupperschmidt 2013).

The challenges that present within a rural setting are often complex and require a nurse to manage the situation until medical assistance arrives. As a nurse working in a rural setting it is important that the provision of care for a person and their carer is completed in partnership. Decision-making processes, the model of care used in the setting and the delegation and responsibility of all staff within their scope of practice are vital to positive outcomes (Australian Commission on Safety and Quality in Health Care (ACSQHC) 2012). Individuals using health services should participate in making decisions about their own healthcare.

In the provision of care consideration needs to be given to the individual roles of the healthcare team and the required resources of each health service organisation. The National Safety and Quality Health Service Standards identify key processes to ensure that there is early recognition of the deteriorating person and prompt and effective management of individuals in these circumstances (ACSQHC 2012). Time is a critical factor in managing a deteriorating individual and for nurses in rural and remote health areas the access to more specialised services can sometimes be complex. This is where telehealth can prove very advantageous to the healthcare team.

### Transferring to regional or metropolitan health services

At times people in rural and remote areas are required to travel to a regional or metropolitan specialist centre. This process can often be a source of great anxiety and stress for the person, their family and community. As a nurse working in urban, regional, rural or remote communities it is important to have an understanding of the issues relating to transfer for treatment (Berman et al 2012).

The Royal Flying Doctor Service (RFDS) supports residents in rural and remote communities requiring access to high-level care. In one day in Australia, the RFDS flies more than 65,000 km and performs more than 100 medical evacuations, and over 85,000 consultations are conducted each year. The RFDS provides more than emergency retrieval and transfer services; it plays a key role in the provision of health prevention and screening programs and general practice clinics run in isolated areas on a regular basis (Berman et al 2012).

Angel Flight is a charity service that provides flights for non-urgent travel to and from medical appointments. The staff and pilots are volunteers and the service relies on fundraising to exist. A referral must be completed and submitted to Angel Flight up to 2 weeks before the required travel depending on the location. This can be completed by a nurse, doctor or allied health professional. This service is not for individuals with acute care needs as no medical assistance is provided onboard the plane, but is for people needing to attend medical appointments.

For community members within a rural or remote location within Australia there exists within each state a transport system of support. The level of support is both physically and financially driven for those needing medical care outside their local community. The patient-assisted travel schemes (PATS) provide a subsidy to help with travel, escort and accommodation expenses incurred by those living within a rural or remote area. The scheme is available to individuals who need to travel to medical appointments or hospitals more than 100 km from where they live. As a nurse it is important to communicate with individuals about the scheme and how to apply for assistance during times when medical referral away from home is needed. The link to the scheme is available within the list of online resources.

Clinical Interest Box 47.4 outlines the considerations to take into account when someone in your care is being transferred to another healthcare service and requires retrieval services.

## CLINICAL INTEREST BOX 47.4 Considerations for healthcare transfer

- Does the person have anyone to travel with them, or meet them at the destination?
- What is the name of the facility they are being transferred to?
- How will they get to their destination?
- What is the anticipated length of stay?
- Do they require accommodation for support person and/or themselves?
- What arrangements need to be made for their home, work or family?
- Do they have necessary items such as a small amount of money, toiletries and a change of clothes, contact details or identification documents?
- What are the weight requirements or size restrictions of the transfer vehicle?

*(Berman et al 2012:168)*

## Summary

In this chapter we undertook a broad comparison of the health status and needs of urban, rural and remote communities and outlined some of the features of remote environments. We also looked at the key infrastructures for effective healthcare service delivery in rural and remote settings in general and discussed potential sources of stress related to working in a remote health context.

The roles of the remote area and rural nurse were explained, including recognition that these nurses require a high level of knowledge and clinical skills. We noted that advances in technology may have a substantial impact in the future on the ability of Australians living in remote and rural areas to receive healthcare in their home communities with a reduced need to travel for specialist or follow-up support services.

## Review Questions

1. What indicators would you use to define remoteness? Think about these in order of priority for you as a health professional working in a remote location.
2. List 4–6 key features of rural or remote healthcare environments in Australia.
3. What are the key factors and processes that have led to poorer health service delivery in rural and remote areas than in urban areas?
4. List the common characteristics of rural and remote nursing.
5. What are the key determinants of health affecting the rural or remote geographical area in Australia and how do these impact on the care provided in rural facilities?
6. Identify key ways of engaging with the rural or remote community to minimise culture shock and to become part of the setting.
7. What nursing codes of practice relate to the nurse working in Australia? Discuss the impact of the *Code of Professional Conduct for Nurses* on nurses in rural and remote settings.
8. Telehealth and telemedicine are more widely available in rural and remote settings in Australia with greater digital infrastructure.
   a. What advantages and disadvantages does this have on care in the rural or remote setting?
   b. What advantages does this have on nursing practice in the rural or remote setting?

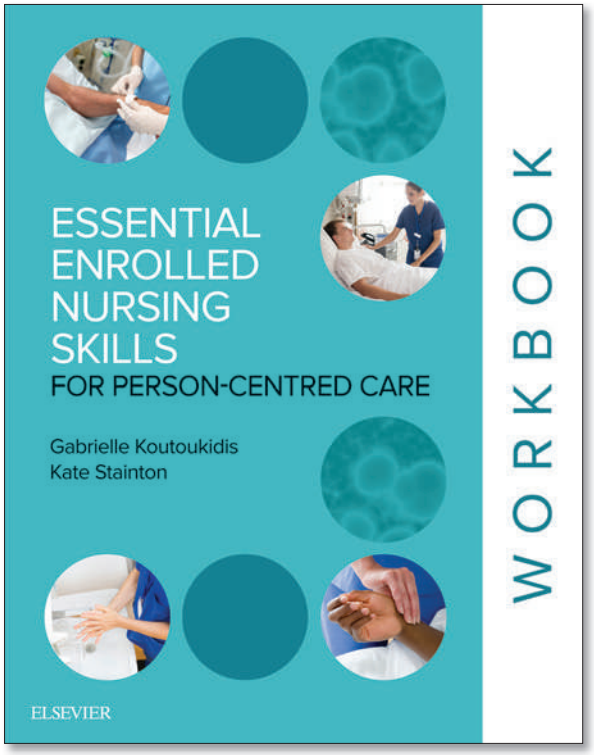
## The Essential Enrolled Nursing Skills for Person-Centred Care

By Gabrielle Koutoukidis and Kate Stainton



**To find out more, or to buy now, visit elsevierhealth.com.au**

*Essential Enrolled Nursing Skills for Person-Centred Care* is an indispensable tool that will assist you in mastering the clinical skills that form part of your assessment as a Diploma of Nursing student.

**Key Features:**

- Directly aligned to *Tabbner's Nursing Care: Theory and Practice*, 7th edition
- 83 clinical skills, each featuring:
  - A step-by-step approach
  - Rationale to help understand how and why a skill is performed
  - Equipment checklist
  - Competency checklist, providing a valuable tool for assessment
  - Reflection opportunity at the end of each competency checklist to encourage learning
  - The decision-making framework for the EN
- Aligned to the new 2016 Enrolled Nurse Standards for Practice
