COMMUNICATION IN PEDIATRIC PALLIATIVE CARE

Mallory Fossa, Julia McBee, and Rachel Rusch

KEY POINTS

- Expert communication skills are essential for the pediatric palliative advanced practice registered nurse (PP APRN) to navigate the myriad of pediatric healthcare experiences.
- As a part of the interdisciplinary palliative care team, the PP APRN is integral to eliciting goals and values with families from consult, through end-of-life, and into bereavement.
- Building on the foundation of nursing, the PP APRN is in an ideal position to bridge the medical and psychosocial aspects of pediatric care.

bilateral middle cerebral artery strokes and evolving herniation with a poor prognosis and profound neurological impairment even if she survived. Jill was devastated and requested meeting with the PPC team to discuss next steps and options for care. The PP APRN and PPC team supported Jill and the NICU team through their difficult decision to discontinue life-sustaining therapy and allow for a natural death. The PP APRN worked alongside the NICU team to optimize Allison's symptom management at end of life. The PP APRN and social worker followed Jill and her extended family into bereavement and coordinated the transport of Allison's ashes back to their hometown.

Only through communication can human life hold meaning.
Paulo Freire

CASE STUDY 1: INVESTMENT VISIT OVER TIME

Allison was a 5-month-old infant girl born prematurely at 30 weeks gestational age with tetrasomy 22q11 and progressive maxillomandibular syngnathia and tracheobronchomalacia. After an emergent tracheostomy placement at her local, rural out-of-state hospital, she was transferred to the Children's Hospital neonatal intensive care unit (NICU) for craniofacial surgical reconstruction. The surgery was considered "elective" with the hope that reconstruction could eventually improve her quality of life. The pediatric palliative advanced practice registered nurse (PP APRN) and pediatric palliative care (PPC) team were introduced to Allison and her mother, Jill, early in her admission for support, given the anticipated lengthy and complicated hospital stay.

Allison's NICU course was initially stable and the PPC team visited 2–3 times a week, building strong rapport and addressing quality-of-life issues which were small but impactful. Since Allison and Jill were out of state, they were alone in the city, with limited psychosocial supports. One intervention was to obtain Jill some "comfort food" and guide her to a local prayer group.

In one of the early visits, Jill shared her worries surrounding Allison's requirement for postoperative opioids after revealing her partner's death from a heroin overdose 3 years prior. The PP APRN validated and normalized these fears and provided anticipatory guidance about the safety and benefits of adequate analgesia and pain management with opioids.

After a month in the NICU, Allison underwent a craniofacial surgical reconstruction. Unfortunately, Allison developed two

INTRODUCTION

Empathetic and effective communication is essential to providing high-quality palliative care to children with life-threatening and serious illnesses in both inpatient and outpatient settings. Recommendations and standards of practice provided within the *Palliative Nursing: Scope and Standards of Practice* and by the American Academy of Pediatrics, the National Consensus Project, Center to Advance Palliative Care, and the National Hospice and Palliative Care Organization underscore the necessity of developmentally appropriate communication for the child, and family.^{1–5} One of the main tasks of the pediatric palliative advanced practice registered nurse (PP APRN) within the interdisciplinary team (IDT) is to align with the child and family, build trust, and create an individualized and goal-concordant plan of care. Along with dedicated psychosocial providers, PP APRNs often serve as the continuity members of the team, providing longitudinal support as other clinicians rotate on and off service. PP APRNs are educated to practice expert and efficient communication throughout a child's illness trajectory.⁶ As continuity providers, PP APRNs act as communication liaisons in a variety of situations, including but not limited to the following:

- Eliciting goals of care and assessing a family's and child's understanding of illness and prognostic awareness.
- Respecting the family's and child's communication preferences for receiving and sharing information.
- Assessing and honoring the family's cultural and spiritual preferences surrounding experience with illness.
- Providing pharmacological and nonpharmacological interventions focused on the child's physical, emotional,

psychosocial, and spiritual well-being consistent with goals of care.

- Ensuring collaborative communication among care teams.
- Leading open and honest communication across care settings between the family and the team members: primary care providers, pediatric subspecialists, psychosocial clinicians, community palliative providers, community hospice providers, therapists, and school professionals.
- Communicating changes in illness trajectory and prognosis, especially as the child approaches end of life.
- Supporting the child's and family's voice in medical decision-making and advance care planning.^{1,3}

This chapter aims to elucidate the role of the PP APRN in providing high-quality pediatric palliative care (PPC) and provide strategies to develop and improve communication throughout the child's experience with illness, their death, and the family's bereavement.

COMMUNICATING WITH CHILDREN, ADOLESCENTS, AND YOUNG ADULTS AND THEIR FAMILIES

UNIQUE COMMUNICATION NEEDS OF THE PEDIATRIC PATIENT

The World Health Organization defines palliative care as "the prevention and relief of suffering of adult and pediatric patients and their families facing the problems associated with

life-threatening illness. These problems include the physical, psychological, social and spiritual suffering of patients, and psychological, social and spiritual suffering of family members."⁷ In order to achieve the goals of PPC for the mind body and spirit, communication is essential. PP APRNs draws on their experiences at the bedside to provide holistic and humanistic care synonymous with the ethos of palliative nursing practice.^{6,8} A major aspect of palliative nursing is communication. To achieve this, the PP APRN utilizes both verbal and nonverbal communication techniques: establishing eye contact with the patient and family, listening carefully, pausing for moments of silence, and staying present and engaged when working with children and their families.^{6,9,10}

Children vary from adults in that their ability to understand concepts depends on their age and development. Providers, including APRNs, should familiarize themselves with developmental concepts when working with children, adolescents, and their families.³ While some parents and clinicians may be uncomfortable with it, children are able to provide insight into how they experience their own health and care.¹¹ Table 32.2 demonstrates general principles of childhood development and the understanding of death and illness for the typically developing child. When communicating with children and their families, it is important to give clear, honest, and consistent information.^{12–14}

Because there are developmental differences between children and adults, decision-making and communication varies from that with adult because with children, discussions occur with the parents. Parents have shared the importance of feeling partnered with the child's medical team.¹⁵ This is defined as shared decision-making, where together the parents and the medical team make decisions for the child with their best interest in mind and which are consistent with the family's

Table 31.1 FIVE DOMAINS OF CHILD AND FAMILY ASSESSMENT

DOMAIN	FOCUS	QUESTIONS TO ASK
1. Who is the child?	Learning who the child is as a person	Tell me about (child's name). How would your friends describe you? What does a good day look like for (child's name)? How do they show you when they are happy? What does a difficult day look like for (child's name)? How do they show you they are upset or in pain?
2. Assessing decision-maker understanding of the illness	Eliciting the decision-maker's insight of the illness	What is your understanding of your child's illness? Tell me about your medical journey . . . What have your doctors told you about your child's name condition?
3. Eliciting hopes	Eliciting hopes and dreams for the future	What are you hoping for? Given what the doctors have told you, what are you most hopeful for?
4. Eliciting worries and fears	Assessing how they are coping	What are you most worried about? Are there other things you are worried about? What keeps you up at night?
5. Strengths and Support	Evaluating how they finding strength and support	Where do you draw your strength? Who is supporting you? Do you belong to a faith community? Do faith or spiritually provide support to you?

From Waldman, Levine¹⁶; Feudtner et al.¹⁷; and Waldman, Wolfe.¹⁸

values and beliefs.^{3,15,19} Parents are often granted the ability to make decisions on the behalf of their child, including adolescents. Decision-making can fall on a spectrum. Children and adolescents who demonstrate understanding of information relevant to their choice and express reason and rationally may be capable of making certain decisions.^{3,19}

INITIAL CONSULT OF THE PEDIATRIC PATIENT

INTRODUCING THE TEAM

When meeting a patient and their family for the first time, it is important for the PP APRN be aware of how or what the family may have been told about PPC. This can be simply be done by asking the family or young adult what they were told when first meeting them. The Center to Advance Palliative Care (CAPC) has developed key phrases and messaging identified through interviews and focus groups with patients and caregivers, including the following descriptions of palliative care:

- Palliative care provides an extra layer of support for families and children with serious illness.
- Palliative care can help provide the best quality of life for children and families.
- Palliative care is a partnership between the child, family, and all medical specialists.
- Palliative care can help children and families manage pain, symptoms, and the stress of serious illness.
- Palliative care is appropriate at any age and stage of serious illness and can be provided concurrently with curative treatment.⁴

Families report valuing sincere communication and genuine relationships with providers.²⁰ The PP APRN is frequently the first team member to clarify the role of the palliative care team, often utilizing language to destigmatize any associations the child or family may have with the term “palliative care.” Patient-centered language should be employed and modeled by the PP APRN when describing the role of palliative care. The PP APRN can use an array of these examples when introducing the team and the services provided before setting up the conversation for the initial consult.¹³ The APRN should also assess the nonverbal cues of the patient and family and/or ask if it is a convenient time to meet with the family. If it is not, the APRN can arrange a time to return to complete the consult.¹⁰

THE PEDIATRIC PALLIATIVE CARE CONSULT

When establishing a relationship with the child or family, the PP APRN can promote an understanding of what is important and how the patient and family perceive the care they are receiving. Fostering this communication begins with an assessment of the child’s current status and the patient or

family’s daily experience. In a PPC consult, there are generally five domains to explore with the child and/or family: (1) learning who the child is as a person, (2) assessing the decision-maker’s understanding of illness, (3) eliciting hopes and worries in the context of their life, (4) assessing how they are coping, and (5) determining how are they finding strength and support¹⁶ (Table 31.1). The five domains are helpful across the spectrum of the relationship and trajectory of illness, from initial consultation to end of life, and are dynamic and evolving. While conducting this initial conversation, the single biggest intervention that the PP APRN will do is to listen.^{10,12} It is important to remember that listening is being fully present; physically, emotionally, and mentally.¹⁰

Establishing a trusting and safe environment is critical to communication and this conversation.^{10,16} By taking the time to learn about the child’s or young adult’s identity or personhood, the APRN can foster a deeply meaningful moment within the chaos of the medical situation.¹⁶ It models to the child, adolescent, or young adult and their family that knowing who they are outside of their medical condition is important to care delivery.³ This information, given either by the child or the family, can provide the PP APRN with insight to how the parents view the child and/or what makes the individual the person they are.¹⁶ Table 31.1 illustrates examples of questions or statements that can be made to help elicit this information.

Once the PP APRN has identified key components of the child’s personhood, the conversation can lead to assessing the

Table 31.2 CHILDHOOD DEVELOPMENT AND DEATH UNDERSTANDING

AGE	CONCEPT
Infants and Toddlers (0-2 years old)	Infants experience loss through their environment as they learn object permanence Death is experienced as separation or abandonment No cognitive understanding of death
Early Childhood (2–6 years old)	Magical thinking occurs in that unconnected actions or behaviors may have caused the death of sibling or family member Death is thought to be reversible or temporary Death may be seen as a punishment
School Age (6–11 years old)	Gradual awareness that death is final cessation of life May believe only happens to elderly, animals, or pets Concrete reasoning allowing understanding of cause and effect May ask direct questions about death
Adolescents/ Young Adults (>11 years old)	Understand death is finite and universal All people and self will die, though latter is far off Comprehend physical and biological process of death Abstract and philosophical reasoning

From Crozier, Handcock¹³; Jonas et al.¹⁴

patient's and family's understanding of the medical condition. The information gleaned from questions around a parent's or child's understanding allows the clinical team to help tailor information in the future or identify areas where further information is necessary for future decision-making.^{12,16} This can also aid the PP APRN in advocating for the child and family based on what is shared in the conversation.³

Parents encounter frequent decision points as they navigate the care for their child with a serious illness. Often, they are attempting to find a path which will result in full recovery or a return to previous baseline. Sometimes it can be difficult for parents or decision-makers to determine whether treatment decisions are leading them toward their desired goal or not.¹⁷ Research has revealed that "parents have deeply held, diverse beliefs about their principal duties for their children."²¹ By eliciting these beliefs, the PP APRN can better understand the framework within which parents are making decisions and how they are thinking about what is important for their child. A few questions include, "What do you think is most important for you to focus on?" or "What do you feel you most need to do to be, in your own judgment, a good parent?"²² As the illness journey proceeds, how parents consider the five domains changes along with their definition of "a good parent." It is therefore important to regularly explore these values with parents, especially as their child's illness progresses.^{16,17,21,22} While it may sound counterintuitive to ask about what a parent or a young person hopes for, doing so offers a useful baseline assessment. When the disease progresses, the recognition that the prior hope for a cure is now likely unattainable facilitates the exploration of other hopes that may be important to the young person and family.¹⁶

It is important to be aware that parents may be holding worries in their mind and heart yet choose not to say them out loud. They report that it is difficult to share these feelings with family, friends, and the healthcare team. Some parents of children with serious illness prefer to convey a positive outward expression, holding their true feelings close.¹⁷ Parents, especially mothers, often experience judgment by others, including family, friends, and community, for their decisions and behaviors.^{17,23} The result may be emotional miscues and consequent miscommunication with the healthcare team.

The PP APRN must be mindful to evaluate communication effectiveness during each family encounter, assessing and shifting strategies as necessary. It may take multiple encounters before a parent can verbalize a deep concern. When members of the child's healthcare team comment that "the parents don't get it," the PP APRN advocates for the parents in conveying they "do get it," they just choose carefully when and to whom to acknowledge their understanding, fears, and worries.¹⁹ Connecting with the consulting team or provider before the visit can provide an opportunity for the PP APRN to potentially focus on eliciting certain concerns, thus better evaluating a family's understanding.³

An essential component of a consultation is the assessment of the psychosocial support system in place for this child and family.¹⁶ This is a cultural assessment that includes the community resources in place and sources of strength and support. Additionally, a brief spirituality screening should be completed.^{3,16} While the goal is not to directly engage in

a theological discussion, the PP APRN should identify spiritual distress as well as spiritual care needs and, when necessary, refer or offer spiritual care services.^{3,16}

In closing the visit, the PP APRN should acknowledge and thank the child or adolescent and family for the information shared. Discussion then shifts to next steps in the relationship and how the palliative care team will support them.¹⁶

When discussing the consult with the consulting team, either in the hospital or in the outpatient setting, it is most respectful to use a person-centered approach. This presentation includes the child's name, history, and diagnosis versus labeling the child by their disease process. For example: "Jane is a 5-year-old girl with a history of AML, admitted for initiation of chemotherapy in the setting of progressive disease" versus "a 5-year-old leukemic admitted for chemo after failing multiple therapies." PP APRNs can model care directed at the whole patient, not just the disease process, by focusing on the physical, social, emotional, and spiritual needs of child and family.²⁴ Table 31.3 provides examples of how to rephrase language when communicating with patients and families.

ESTABLISHING RAPPORT AND INVESTMENT VISITS OVER TIME

Building trust, taking a big picture view of the patient and family, and understanding their unique narrative in times of both health and illness is imperative to providing high-quality palliative care. Unlike the adult population, children receiving palliative care may live for more than a year after the initial inpatient palliative care consultation. This may allow for more time to establish rapport and invest in longitudinal relationships.²⁵ The nature of PPC consultations vary by setting. In the inpatient setting, consult requests are most often for assistance with symptom management, followed by facilitating communication, assistance in decision-making, discharge planning, and, less often, discussions regarding resuscitation status.²⁶ Outpatient consults are generally for establishing goals of care in the medically complex patient and symptom management.

After the initial consultation, even when a substantial role for PPC is not immediately apparent, the PP APRN and PPC team can engage in "investment visits" with the child and family. Investment visits are otherwise known as "holding the space" or "showing up." Although these visits can appear like idle "chit chat," in reality they can aid in rapport building with patients and families and encourage self-care and coping for caretakers and patients. Moreover, these visits allow for development of connections with the family and the entire care team, which fosters improved collaboration and family support at times of unexpected crisis. Frequent visits in times of stability help families associate the PPC team with moments of positivity and hope.²⁷ Use of an IDT is critical because it provides continuity of care among all team members.

The story of Allison and Jill highlights the importance of communication among care teams and the investment in future relationships with primary and consulting providers. It highlights the importance of investment visits as a key element to providing high-quality palliative care to an infant

Table 31.3 PEDIATRIC PALLIATIVE CARE COMMUNICATION FAUX-PAS AND TIPS

TOPIC	COMMON RESPONSE	UNINTENDED MESSAGE	ALTERNATIVE WORDING
Discussion about pain management	"We can best treat your pain by using narcotics."	"And you may become a drug addict."	"We can best treat your pain by using opioid or pain medications. . . ."
Discussion about defining goals of care	"What would you like us to do if . . .?"	Implies that the patient/family can choose from a menu of options.	Use open-ended questions to define treatment goals: "What's most important to you/for your child right now?"
Discussion of disease-directed therapy	"We can use this experimental agent or we can do nothing."	"If we don't opt for medical management, we are 'giving up.'"	"Whether or not we continue with disease-directed therapy, we will care for you and do our best to manage symptoms and optimize your quality of life."
Discussion about medically administered nutrition and hydration	"We could stop the TPN/G-tube feeds."	Discontinuing supplemental nutrition means starving the patient to death.	"Our recommendation is that your child's body is at a point where medically administered nutrition is not going to be of benefit. In fact, it may cause harm and/or suffering."
Discussion about resuscitation	"Do you want us to do everything?"	What would a "good parent" do?	"You have made the best decisions possible and done everything to help your child survive. There are no more medical therapies we know of that will change the disease course. Based on our conversations we would recommend limiting attempts at resuscitation."

From Levettown.⁷¹

and mother in the NICU. This case not only elucidates the necessity for holistic, patient- and family-focused care but also underscores the multifaceted role of the palliative care APRN across the child's illness trajectory.

CULTURAL SENSITIVITY, HUMILITY, AND ATTUNEMENT IN PPC COMMUNICATION

Culture frames one's understanding and responses to illness or death.^{3,29} Personal, familial, and community culture offers structure for daily living, influencing how emotions are experienced and communicated. Learning about a child's and family's experience of living with serious illness from a cultural perspective can provide profound insight into their values, expectations, and hopes that may guide future care-planning discussions. The following questions may be helpful in clarifying the family's understanding of the child's condition as influenced by their cultural or spiritual beliefs and values.^{16,30}

QUESTIONS IN SUPPORT OF EXPLORING PERSONAL AND FAMILY CULTURE

- What is happening (has happened) to your child from your perspective?
- What do you think is causing (caused) this to happen?
- How is your family being affected (have you and your family been affected) by what has happened?
- Has your family experienced anything similar to this before?
- What meaning does this experience have for you and your family?

Health professionals must approach each patient and family system with an intention toward cultural humility and sensitivity.³¹ Cultural humility and cultural sensitivity call on the PP APRN to be humble and aware of their own deficiencies in knowledge of other cultures; it requires continued education and the investigation of implicit and explicit bias.³² PP APRNs may be an important voice in aligning and speaking thoughtfully to a family's individual value system, especially when it may differ from that of the personal perspectives of a primary medical team.³ Continued education, in partnership with psychosocial colleagues when possible, will aid in providing culturally respectful and supportive communication, particularly for marginalized populations. Please refer to Chapter 20, "Health Disparities in Palliative Care and Social Determinants of Health," for additional information and guidance.

The PP APRN, in partnership with IDT members when possible, may also assess for culturally influenced communication cues by watching how family members interact with each other and the medical team, noticing personal space or boundaries, eye contact, or the extent of physical touch. These observations can then be communicated to the team as the partnership between the patient, family, and PPC team continues.

Noticing a parent's nonverbal behavior can provide opportunity to glean important insights about how best to provide culturally respectful communication. For example, the PP APRN observed a father's distraught behavior after participating in his daughter's family-centered PICU rounds. The PP APRN remarked, "I'm noticing that something is troubling you." To which the father responded in a heightened tone, "All of these medical details are keeping me from my

real duty, praying for my daughter's healing." The father then shared his beliefs about healing as a practicing Christian Scientist. While the father desired PICU medical interventions for his daughter—something that he mentioned was not supported by his church elders—the daily rounding information conflicted with his deeply felt responsibility to pray for healing. The PP APRN helped the parents and PICU team to determine a rounding schedule that created a supported environment for the father to remain in prayer when needed.

Medical interpreters should be used whenever English is not the family's primary language. In one study exploring the experiences of Mexican American and Chinese American families, parents described more anger, distress, and sadness during their child's illness when interpreters were absent because trust eroded when parents felt they were provided insufficient information.³³ In preparation, clinicians should inform the medical interpreter about the nature of the planned discussion and then debrief accordingly, especially if interpretation involves delivering difficult or sad news.

Even though PP APRNs must do their best to understand a family's cultural lenses, they can never fully understand another's perception. As an example, one PP APRN entered a baby's room with the goal of learning her family's progress in decision-making for a potential surgery. The grandmother was weeping as she rocked her granddaughter. The anguish on her face was evident, prompting the APRN to say, "Your tears reflect much emotion." The grandmother replied, "I weep because I have not received a call today from my family in Syria. They usually call each day, so that I can know they are safe from the violence happening in our country. Children are being murdered there by the minute! Here, I safely hold my granddaughter in my arms, knowing your team will do everything to save her life. Yet back home, life is being wasted, thrown away. How . . . how do I make sense of all of this?" The APRN sat quietly with the grandmother as she rocked and wept, recognizing through this exchange that this family was holding more on their minds than the PPC team could ever comprehend. The PP APRN demonstrated cultural sensitivity as well as created space and acknowledgment of the situation by listening and remaining silent, showing that she understood the significance of what was said.^{10,12}

SPIRITUALITY AND COMMUNICATION

Patients and family members may share their spiritual and/or religious beliefs when reflecting on their ongoing coping and their hopes for the future. When possible, partnership with spiritual care providers and chaplains ensures comprehensive support around one's individual and familial spiritual needs. In this way, the PP APRN respects the expertise found within collaboration with chaplain colleagues and maintains appropriate therapeutic boundaries when engaging in communication around one's religious and spiritual beliefs.³⁴

At times, a family may share their hope for a miracle or for divine intervention to cure their child of their illness. This

may be seen by some clinicians as a distressing expression of denial, ending further supportive and productive communication. The PP APRN, in partnership with the interdisciplinary PPC team, may see this as an opportunity for further assessment and learning about a family's expressions of hope.³⁵ After thoughtful and supportive assessment to assure that the family has an appropriate understanding of their child's condition, the PP APRN may discover that the hope for a miracle may be a space of helpful coping for a family because it may be too difficult to live in the space of worry around a child's death in every moment. Utilizing this language to communicate that hope and worry can exist side by side for parents, the PP APRN can provide a safe and supportive place to reflect on both. Some helpful language can be provided through VitalTalk's proposed NURSE statements^{10,36} listed here.

Naming: Name the child's and family's expressed emotion.

Understanding: Empathize with and acknowledge the child's and family's emotional response.

Respecting: Praise the child and family for their expert role in their child's care.

Supporting: Demonstrate support of the family's needs and/or decisions.

Exploring: Ask the child and family to elaborate their feelings, concerns, or hopes.

Some examples of potential language to use when engaging families around themes of hope include the following:

What I hear you saying is that you are worried for your child's future and also want to hold your hope for their survival.

What would a miracle look like to you and your family?

Hope and worry can exist side by side. I deeply admire and appreciate your openness in sharing this with us.

What else do you hope for?

We hope so, too. And we are worried.

CHILDREN'S VOICES, FAMILIES, AND DECISION-MAKING

CASE STUDY 2: ADVANCE CARE PLANNING WITH THE ADOLESCENT OR YOUNG ADULT

Jamilla, a 17-year-old girl, first learned of her diagnosis of rhabdomyosarcoma in the pediatric ICU. She had been admitted for respiratory failure due to pleural effusions from her metastatic lung disease. Jamilla shared with her nurses that she was scared of treatment, "If I'm going to die anyway, what is the point?" Due to her presentation, palliative care was consulted shortly after

diagnosis. Jamilla revealed feeling scared about the side effects of treatment, specifically the pain. She wanted to maintain her identity and independence. While she felt uncertain about pursuing treatment, she acknowledged that she would move forward with disease-directed therapy, mostly for her family. It was important for Jamilla to have assurance that her team would manage her symptoms and have open and honest communication with her and her family. Although her parents understood that Jamilla's cancer was very aggressive and that there was a high likelihood she would relapse from her disease, they remained very hopeful for a cure. Together, they all agreed to pursue disease-directed therapy.

It became clear that Jamilla was thinking about her mortality and wanted a place to share what was important to her. The PP APRN introduced Jamilla and her family to *Five Wishes*. Among the things she documented was her desire to die at home, her desire to have her hair washed by her mother, and her wish for people to pray for her "because my parents would want it." Jamilla even added a list of songs she wanted played at her memorial service in the margins of the Five Wishes document. When her cancer recurred, Jamilla agreed to second-line treatment although she was uncertain if she would pursue further chemotherapy. Her mother was tearful and supportive, recognizing Jamilla's individual experience of her disease and her mortality. Jamilla shared how she worried about letting her oncologist down by stopping treatment. The PP APRN acknowledged Jamilla's bravery and thoughtfulness, advocating for her with her oncologist. The PP APRN coordinated Jamilla's admission to hospice to honor her wishes of being at home with her family and for her symptoms to be managed as her cancer progressed.

Listening carefully to the child or young adult's experience of living with serious illness represents the heart of PPC. The child's voice is best heard through the combined skills and expertise of the IDT. The PP APRN collaborates with a variety of expressive therapies, including art, music, play, pet, and bibliotherapy, to connect with children, helping them to communicate their experiences at their own pace. As play is the language of children, play therapists, child life specialists, or psychologists trust the child's inner direction to lead play and conversation, allowing them to express their fears, hopes, and perceptions of the situation.^{10,36} When children or young adults are diagnosed with a life-limiting illness, they may worry about the loved ones they may be leaving behind or of being forgotten.¹² Engaging in legacy activities have helped these young people communicate and strengthen bonds even after death.^{12,37,38} By partnering with other members of the IDT, different age-appropriate activities can be offered to the patient, including but not limited to storytelling, song-writing, creating a digital storyboard, or simply drawing pictures.^{12,39}

As the PP APRN builds a trusting and open relationship with the child or adolescent and family, it is important to explore the child's own understanding of their illness or prognosis. These conversations are often delicate, and the PP APRN should be aware of the patient's nonverbal cues.^{10,40} Using or modifying the five domain questions can help the team

understand what the young person is thinking of or worried about.^{16,41} Identifying the patient's personal goals, beliefs, and values as they relate to quality of life is the initial and essential element to advance care planning conversations.^{12,41} When the palliative care team worked with Jamilla, they first worked to establish her understanding of her disease as well as the treatment plan. They were able to learn that it was important for Jamilla to maintain her own sense of "personhood," which helped to establish the framework by which they worked with Jamilla and her family. While families may discuss future issues without the help of a skilled facilitator, having a clinician for more challenging conversations, such as those around advance care planning, may allow for improved communication between all parties.⁴² Box 31.1 identifies tools across the age spectrum that can be used to evoke the child patient's voice.

Although a child may possess a mature understanding of their serious illness, they may choose to refrain from sharing this knowledge with others. In addition, families may engage in a phenomenon of mutual care. The child and parent(s) experience similar concerns yet attempt to protect one another from their sorrow and negative emotions or the possibility of negative outcomes by avoiding open discussion with each other.^{19,43,44} Just as parents take seriously their role to protect and nurture, children want to please and live up to the expectations of parents, possibly resulting in crucial

conversations left unspoken. Other times, parents recognize, understand, and wish to honor their child's cues to not speak out loud of dying but rather to focus on living.⁴⁵ When parents share their worries with the PP APRN around disclosing prognostic information with their child or adolescent, the APRN may provide examples of how often the child is already thinking about the changes in their body and that disclosure allows adequate time for them to process their illness, thus decreasing fear and anxiety of the unknown.^{38,45}

COMMUNICATING WITH ADOLESCENTS AND YOUNG ADULTS

Establishing communication preferences with adolescents and young adults (AYAs) is paramount to the development of rapport as well as partnership in advance care planning. This population has described the need for honest and respectful communication as key components of relationship building, and this communication has been shown to affect the young person's perception of healthcare.^{46,47} When meeting initially with the AYA patient, the PP APRN can ask questions around communication preferences including, "How do you like to hear medical information? With your family/support person? By yourself?" Acknowledging that there may be information they do not wish to hear and taking their lead shows respect for their sense of personhood. Some may wish for this information at a later date, so remaining flexible is key to communication with the AYA population.^{40,48} Additionally, it is important to explore with this population from whom they would like to hear the information. Most AYAs prefer information to come from their clinicians, while others may want to hear it from their parents.^{40,47} When Jamilla shared with the PP APRN that she preferred to hear information from her doctors, with her parents, and ultimately made her own decisions about her care, this was communicated with the other members of the care team.

DISCLOSURE OF DIAGNOSIS AND PROGNOSIS: CHALLENGES IN THE PEDIATRIC POPULATION

Parents often worry about delivering bad news to children in an effort to protect them.^{48,50} This basic parental instinct should not be overlooked or misunderstood as poor prognostic awareness. Families experience profound grief when hearing their child has a life-threatening illness, which is compounded by the idea of disclosing the diagnosis. A mother of a teen with a newly diagnosed diffuse intrinsic pontine glioma (DIPG) once tearfully stated, "I can barely comprehend what lies ahead; it makes me sick to imagine telling my son he has a year to live." Families agonize over what information should be shared and by whom. Barriers to parents disclosing a poor prognosis to their child (as described through self-report) include emotional distress and information overload, inadequate knowledge on how to disclose, and worry over burdening their children with bad news.^{45,50} A father of a 10-year-old girl with metastatic osteosarcoma explained, "she should be

playing soccer with her friends, not thinking about what a prosthetic leg will feel like."

There is an extensive history of clinicians also feeling uncomfortable engaging in difficult discussions regarding diagnosis and prognosis for fear of taking away hope and causing distress.^{43,51} For physicians, this fear frequently comes from a lack of training in medical schools and residency programs on how to communicate difficult news.⁴³ For pediatric APRNs, there is a similar fear from lack of training or mentorship in delivering difficult news. The hesitancy of APRNs to discuss a poor prognosis can lead to patients misjudging their chance of cure or life prolongation, which may impact their decision-making.^{43,52} In an effort to avoid openly discussing a poor prognosis, APRNs often use optimistic language and frequently wait for patients and families to ask specific questions directed at prognosis.⁵³

A recent study of AYAs with cystic fibrosis (CF) revealed that patients with CF want their parents to be involved in discussions regarding prognosis and believe that their provider should be the one to initiate such disclosures.⁴⁷ Approximately one-third of the study participants reported learning of their prognosis and clinical trajectory from their CF healthcare providers, one-third deduced the progressive nature of CF from their own health decline, and the rest gleaned this knowledge from their parents or from online sources.⁴⁷ The patient participants often felt that prognosis was "sugar coated" by whomever disclosed the information, be it providers or parents. Interestingly, when patients learned of their prognosis, 62% reported no impact on future CF treatments and 38% reported a positive impact on their attitude. None of the study participants reported that disclosure had a negative impact on their emotional state or adherence to treatment regimens. The majority (77%) of patients reported that learning of their prognosis had no effect on their overall goals of care and life plans, and, if it did, it was positive.⁴⁷

Although the evidence supports developmentally appropriate, open, and honest disclosure of diagnosis and prognosis, the matter is complex and case dependent.⁴³ In the field of PPC (and pediatrics in general), it is imperative to view the child as part of a larger family infrastructure influenced by history, values, culture, and religion. In particular, culture and religion may weigh heavily on a parent's willingness to disclose diagnosis and prognosis.^{3,43,45} In some cases, parents may instruct medical personnel to omit facts regarding a diagnosis and, in rare cases, to even lie. In these cases, clinicians can offer a "compromise" that strikes a balance between upholding their code of ethics as clinicians and respecting a family's wishes and maintaining trust and alliance.^{19,45} Helpful phrasing may include "We will honor your communication preferences with your adolescent; however, if they ask us direct questions regarding their disease and prognosis, we cannot lie."³ Unfortunately, these instances are often fraught with distress for the interdisciplinary healthcare team, especially in cases involving adolescents.

Every family system functions differently and has its own unique communication preferences.^{43,45} To build trust and rapport, clinicians must respect the framework and

preferences of the family first and foremost. After receiving permission from the family to disclose a diagnosis, medical information, and prognosis, finding the right time, environment, IDT members, and developmentally appropriate language is imperative for effective communication.^{10,54} Once the stage is set, it is crucial to address the child's goals, hopes, worries, understanding of illness, and coping mechanisms.

Sometimes, there may be a conflict between the culture of healthcare and the culture of the child and family. In these instances, it is helpful to further explore the family's culture, values, and belief systems.⁴³ It may be culturally inappropriate for some discussions to occur, or there may be the need for spiritual providers or community leaders to be part of the conversations. Discussions with parents and children regarding prognosis may evolve and shift over time as an illness progresses.⁴³ Repetitive attempts at forced conversations with family systems who decline communication and prognostication can cause undue distress to the child and family and border on harassment. In these cases, the risk of negatively impacting a family's experience with illness and grief and disrespecting their culture outweighs the benefit of total disclosure. Maintaining the treatment alliance and trust, openness to compromise when required, and honesty when questions are posed directly are all of paramount importance.^{19,50,53}

ADVANCE CARE PLANNING

Ultimately, when eliciting the child's voice or hearing parents values, the PP APRN is initiating pediatric advance care planning conversations.⁴¹ As a child's or AYA's disease advances, it may be helpful to have more discrete conversations around the topic of end of life. It is important to recognize that parents or patients may be reticent to engage in these difficult conversations.⁵² However, those who do acknowledge that it gives them a sense of control, empowers parents to make good decisions aligned with their definition of being a good parent, and facilitates coping.^{41,42,44,55} To facilitate advance care planning discussions, the PP APRN may wish to access the *Decision-Making Tool* (DMT) developed by the Pediatric Advance Care team at Seattle Children's Hospital. Similar to other tools, the DMT provides a flexible structure that addresses the medical, psychosocial, and spiritual concerns of the decision-maker.⁵⁶ Or the PP APRN may use one of the advance planning tools available from Aging with Dignity.⁵⁷ *My Wishes* is a child-focused tool which allows for younger, school-aged children to draw or write their responses. *Voicing My Choices* and *Five Wishes* are for AYAs. While some healthcare providers may choose to allow the AYA to work independently, working together can provide a chance to further strengthen the patient-clinician relationship.⁴¹ When completed and signed before witnesses or notarized, *Five Wishes* is recognized in many states as a legal advance directive for persons over the age of 18.⁵⁷ When participating in these discussions with parents and young persons, the PP APRN should remain mindful of the desire to maintain hope while promoting the important conversations across the illness trajectory, even when death approaches.⁴¹ Once the tools are completed

by the child and family, the PP APRN plays a key role in disseminating the desired plan to the entire team.

As advance care planning conversations occur, they should be documented in the chart as either an advance directive, delineation of code status, or an out-of-hospital order for life-sustaining treatment. When the health of the child appears to be declining, clinicians and parents may choose to engage in conversations around limiting interventions and the placement of do-not-resuscitate (DNR)/do-not-intubate (DNI) orders as well as other limitations to medical interventions or technology.^{17,55} It should be noted that holding hope for a cure does not prohibit parents or young adults from reaching agreement on DNR/DNI orders. In fact, establishment of patient and family preferences at end of life has shown to empower decision-making and provide peace of mind.⁵⁵ Although difficult, these conversations have been documented to reduce stress, depression, and anxiety in the bereaved.^{42,45} It is also important to reframe these decisions as loving decisions that minimize suffering or undue distress⁵⁸ (see Chapter 32, "Advance Care Planning").

WHEN EXPECTATIONS OF CARE BETWEEN FAMILIES AND PRACTITIONERS DIFFER

Conflict may occur when the healthcare team perceives that the child is suffering while parents are saying, "We want everything done." Often, the hope is that the PP APRN or PPC team will step in and resolve the conflict. PP APRNs play a key role in holding conversations about care choices should the child's condition deteriorate. Strong external reactions by parents or team members are often rooted in equally strong internal beliefs of wanting the best for the child. Using phrases like "I'm curious," or "Help me understand" and consciously using "and" instead of "but" are useful in drawing out the differing perspectives of the parties.^{10,59}

The PP APRN can help parents consider limiting treatments or shifting the treatment focus from high-tech, invasive medical interventions to less invasive yet still intensive caring or comfort-focused measures.²² Parents' expression of "wanting everything" done for their child is often a reflection of their fear and anticipatory grief. It is this grief that translates the parents' plea into the following sentiments, "Care for us," "Care about us," "Don't abandon us," and "We are terrified to think that our child will die."⁶⁰ In this situation, the burden of decision-making should *not* be placed on the shoulders of families with phrases that reflect an abdication of responsibility such as "You (the child/family) need to decide what you want us to do if . . ." Rather, the APRN should partner with families, making honest recommendations for next steps in the child's care based on the team's combined medical expertise while honoring the child's and family's expertise about their values as they intertwine with the child's declining physical reality. The PP APRN can take the lead in understanding what "doing everything" means to the parents, providing affirmation of both the parents' love for the child and the team's ongoing commitment.^{60,61} Table 31.3 offers language for conversations that may lead to unintended miscommunication.

CONTINUITY OF CARE: COMMUNICATION ACROSS SETTINGS

The PP APRN is in a unique position to provide continuity of care as patients and families make transitions between the community and the hospital.⁶² Parents of seriously ill children have shared that it can be burdensome to reshare experiences to additional providers. While this may not be completely avoided, the PP APRN may make attempts to coordinate and collaborate with the child's caregivers when changes occur, whether in the hospital or in an outpatient setting.^{62,63} By fostering communication between community providers and hospital providers, a more seamless experience may allow for improved patient and family care.

Palliative care teams may have their own home-based programs or collaborate with those in the community. Pediatrics is unique in that children under 21 qualify for concurrent care while under hospice care.⁶² Even when patients qualify for home hospice, concurrent care allows pediatric patients to receive the hospice benefit while continuing with disease-directed therapies and interventions.^{62,64,65} This may mean that a patient moves between acute care and the home hospice setting.⁶² PP APRNs are often the bridge for communication with hospice staff to learn about ongoing conversations occurring at home regarding goals of care as well as any changes in symptom management needs. The same communication can prove beneficial as a model for home-based palliative care when available or provided by a hospice agency.⁶²

When children are not on hospice and for whom ongoing communication in the outpatient setting is required, the PP APRN may provide assistance in psychosocial support as well as symptom management. Creating open lines of communication between the child and family and the PP APRN allows for this ongoing communication no matter the location of the child (home or hospital).³ Phone calls and email can be productive and helpful ways to ensure continued comprehensive care is provided. When available, clinic visits can also be a useful space in which to reflect on a family's values and speak to future times when more acute goals-of-care discussions may arise. Access to palliative care through telehealth is changing the way palliative care teams can support families. In areas where access to palliative care may be limited, telehealth may provide the bridge for continuity of care.^{66,67} Whether it is through telehealth, regular outpatient appointments, or home-based palliative care, conversations that may be emotionally heavy that occur in the less acute setting can provide a rich opportunity for exploration and support.^{62,66}

COMMUNICATION AS DEATH APPROACHES

As the child nears the end of their life, communication with the patient and family becomes incredibly crucial. As with advance care planning, preparing families for the death experience is paramount.^{3,58} Unless it is asked, the PP APRN and team will not know whether it is helpful for the child or family to engage in explicit conversations about end of life. Bereaved

parents have shared how important it is to work with providers who provide honest and compassionate information.^{3,63} Additionally, the NCP *Clinical Practice Guidelines* recommend a bereavement assessment be conducted.³ When possible, the PP APRN should explore with families where they would prefer to be at the time of their child's death. For some this may be at home, while others have shared that it feels better to be admitted to the hospital, receiving care from the nurses and doctors who have been caring for them throughout the illness.⁵⁶ It can be helpful to provide information about the dying process, allowing caregivers to prepare and consider how to spend the time they have with their child.^{3,19,58}

It may feel unimaginable for a parent to consider having conversations with their child about death and their wishes should they die. Often, this communication is initiated by the child.⁴⁹ A child may also ask the question: "Am I going to die?" or "Where do I go after I die?" which may catch the clinician or parent off guard. Just as it is recommended that other care providers provide honest communication, it is important to provide this counseling to parents.^{58,63} A parent's instinct may be to provide reassurance or redirection by answering, "No, we are going to keep fighting." The PP APRN can often model this language by asking the child or the parent, "Why are you asking me this right now?" or asking for further clarification with the statement, "Tell me more."⁵⁸ Children should not be told that they or their sibling will "go to sleep" or other language around sleep when discussing death. A teenage patient with a brain tumor shared they were told this by their neuro-oncologist, and they then set hourly alarms to wake up in hopes that this would prevent them from dying. Children may express their worries about the changes they feel in their bodies and fear of the unknown. Parents and providers can respond with these phrases.

Your body is starting to shut down and you may die soon.

You will never be alone.

We will help you feel as comfortable as possible.

You are very sick right now.

The team is worried you won't get better and you may die. But you aren't dying right now.

Is that something you want to know in the future, when time may be limited?

The PP APRN should offer frequent guidance and support to parents and other providers surrounding these difficult conversations.

STAFF COMMUNICATION AND SUPPORT

While the primary focus when caring for children with serious illness or those nearing the end of their life is the patient and family, the PP APRN should consider the team caring for the patient and family. The staff who care for these children may experience their own sense of grief, which can impact them both personally and professionally.⁶⁸ The palliative care

team should be aware of and recognize potential staff distress and be prepared to support them. Encouraging debriefings, regular group discussions, and self-care practices following challenging situations may be helpful to all care providers.^{68,69} Providing a safe space for staff to process their own experience may prevent provider burnout and allow for continuation of high-quality care.⁶⁹

BEREAVEMENT SUPPORT

It is a responsibility of the PPC team to provide bereavement support and assist the family in accessing community supports when needed. Initially, a member of the PPC IDT may aid in guiding the family in regard to funeral arrangements, identifying support for siblings, and providing opportunity to express initial experiences of grief. The PP APRN collaborates and coordinates with the PPC social worker or other team members in calling on a family, which can provide the opportunity for continued connection and processing. Mailing bereavement cards signed by team members and filled with handwritten words may provide the opportunity to reiterate the ongoing connection and availability of continued support to a grieving family. Inserting specific language related to the deceased child and their family creates a card that is personal and thoughtful in its communication. Listed here are some examples of helpful language to include when writing such cards or sending mailings that include additional resources.

I am thinking of (child's name) and your family so much.

I will never forget how (child's name) loved Legos and playing with their sister.

(Child's name) smile always lit up the room.

You are such remarkable parents. Your love for (child's name) is profound.

It was an honor and a privilege to be a part of caring for (child's name).

Our team is here for you and your family; we continue to think of you and offer our ongoing support.

Parents often say they would like to connect and learn from parents who have gone through similar losses. Offering a bereavement group for the families of children treated at the same institution, although with a variety of diagnoses, has been successful.⁷⁰ The PP APRN can partner with PPC social workers and spiritual care providers to form such support groups, offering parents a way to form new communities and healing bonds. The PP APRN can also make referrals for individual or family counseling, transitioning the family to community providers who will continue to offer comprehensive, supportive bereavement care.

After a child's death, the parents may ask the PP APRN or social worker to arrange bereavement visits with primary providers so they can reconnect, ask lingering questions, or review autopsy results. Such parent-clinician conferences

allow the parents to review events around the child's death, provide feedback to staff on the family's experience, and receive emotional support.⁷¹

SUMMARY

High-quality, expert communication with children and families is central to the delivery of excellent palliative care across the illness trajectory. As valued continuity members of the team, PP APRNs are poised to make a difference with their voice, their touch, and their perseverance in showing up and staying present in moments of both unimaginable suffering and joy. They honor these children, their parents, and their extended families throughout the process and recognize the power of love in birth, life, and death.

SECTION VI

COMMUNICATION IN PALLIATIVE CARE

ADVANCE CARE PLANNING

ADVANCE DIRECTIVES, MEDICAL ORDER SETS, AND SURROGATE DECISION-MAKING

Hannah N. Farfour

KEY POINTS

- Advance care planning (ACP) is a process through which individuals can use their values, goals, and preferences to outline medical care consistent with their wishes.
- Advanced practice registered nurses (APRNs) should understand opportunities and barriers in ACP and advocate for and engage in effective ACP in diverse populations.
- APRNs should support patients, surrogates, and family members as they participate in ACP and make decisions regarding treatment preferences.
- Preferences for medical care should be documented in legal documents as well as within the medical record.
- Billing codes have been created to support ACP conversations and documentation.

is documented as “full.” There were sparse medical records from visits with other health team providers from prior years.

Important things to consider:

1. When is the appropriate time to engage in advance care planning (ACP)?
2. Is there a structure that the APRN can follow for initiating ACP?
3. Are there cultural or spiritual considerations that the APRN should explore prior to engaging in conversation?
4. If information is gained through ACP, where should it be documented?
5. Are there any potential biases or assumptions that either the patient or healthcare team may have?

CASE STUDY: ADVANCE CARE PLANNING

Ms. W was a 62-year-old retired schoolteacher who identified as African American. She was unmarried, had a long-time partner, Joan, with whom she lived. She was recently diagnosed with Stage IV triple-negative breast cancer after presenting to an emergency department with shortness of breath, where she found to have a malignant pleural effusion and sepsis secondary to a urinary tract infection. The inpatient palliative care team was consulted to assist in goals-of-care delineation and symptom management; however, over the past 2 days, the patient declined the team’s attempts to visit. The primary oncology registered nurse (RN) for Ms. Watts called the palliative advanced practice registered nurses (APRN) and shared that she had spent the past several days trying to encourage Ms. W to see the team for help with cancer-associated pain and shortness of breath as she felt like these symptoms were poorly controlled. She shared that Ms. W does not complain but was unable to move/reposition without significant discomfort, and the primary service was focused on cancer diagnosis and management. The APRN reviewed the chart and noted that there was no advance directive or living will within Ms. W’s electronic medical record. Her code status

INTRODUCTION

An understanding of patients’ care goals is an essential element of high-quality and patient-centered care. Advance care planning (ACP) is the process that includes communication and documentation that supports this understanding. ACP supports adults at any age or stage in health in understanding and sharing their personal values, life goals, and preferences regarding future medical care, with the goal of helping the individual receive medical treatment consistent with their wishes. High-quality ACP is an individualized and patient-centered process that includes assistance in the appropriate documentation of personal preferences and discussion about preferences with key family members, close friends, and surrogate decision-maker, as well as healthcare providers. Ideally, ACP is an ongoing process among patients, families, and healthcare providers that begins while individuals are healthy and able to communicate their wishes, and these are readdressed at transitions in care.¹ These discussions can serve to prepare the patient and surrogate decision-makers to participate with clinicians in making the best possible “in the moment” decisions as they navigate medical care during serious illness. This process is influenced by legislation and institutional policies, as well

as by cultural factors in addition to healthcare provider and patient conversations.²

ROLE OF THE PALLIATIVE APRN IN ADVANCE CARE PLANNING

The palliative advanced practice registered nurses (APRN) plays an important role in providing high-quality ACP through expert communication with the patient, family, and/or surrogate decision-maker. Numerous studies have shown that the overall quality of communication between healthcare providers and patients with advance illness is poor. Good communication has been associated with higher patient satisfaction, better patient outcomes, less patient anxiety, better adherence to treatments, and better care at the end of life.³ However, there are often barriers in initiating this communication such as time, provider/patient discomfort, inability to transfer documentation across continuum of medical care, and a lack of understanding of prognosis or illness trajectory by the patient or healthcare provider.^{4,5,6} Studies show that often patients wait for their healthcare providers to initiate these conversations, and, historically, they only happen in a small number of interactions.³ There have also been many barriers in providing effective ACP in racially and ethnically diverse populations as these individuals may not be aware of community interventions to facilitate ACP or feel uncomfortable in engaging in these conversations. The role, perspective, and training of a palliative APRN allows for crucial and effective conversations to occur that not only elicit preferences in care but ensure that the medical care provided is in alignment with these preferences.

A structured but adaptable approach that is focused on person-centered care is important for effective ACP discussions (see Box 32.1).^{7,8} These discussions are appropriate along the continuum of care and may be a short and focused discussion or evolve into a detailed conversation regarding specific medical interventions involving multiple healthcare providers and/or family members. For example, if an individual is healthy, then the initial conversation could serve to discuss documentation of a surrogate decision-maker and to normalize the discussions surrounding preferences in care. ACP conversations can be readdressed at any point along the continuum, but specifically when there is a diagnosis of a life-threatening illness and with each transition in care. Unfortunately, these discussions often occur late in an individual's disease trajectory, resulting in care that does not correlate with care preferences.³ Furthermore, discussions surrounding ACP information must align with and potentially enhance an individual's readiness stage. These stages range from precontemplation, to preparation, to action, and then to maintenance.⁹ Frequently, it is the palliative APRN who initiates the conversation to begin the process. In the precontemplative stage, these conversations may not lead to actionable items but will introduce the concept and value of ACP, and the conversations may evolve over time. As a palliative care specialist, the APRN will also be engaged in more complicated discussions due to medical complexity as well

Box 32.1 STRUCTURE OF ADVANCE CARE PLANNING (ACP) CONVERSATIONS

Step 1: Prepare for the conversation

Action:

- Attempt to ensure that diagnosis, prognosis, as well as treatment options are agreed upon by clinicians caring for the patient.
- Identify relevant cultural and spiritual norms.
- Identify who needs to be present, such as family or surrogate decision-maker, for the conversation.
- Determine meeting location, preferably in a quiet place.
- Determine which clinicians should be present to facilitate the conversation.
- Determine if an interpreter needs to be included for either the patient or family.
- Choose a time that will allow for optimal patient engagement.

Step 2: Ask for permission and preferences in how they want medical information

Action:

- Introduce topic.
- Assess readiness to discuss and address any barriers if needed.
- Choose and involve a decision-maker.

Helpful phrases:

"I would like to have an understanding about your preferences in medical care. This process is called advance care planning. Are you familiar with this term?"

"Is it OK if we discuss your current health and preferences for medical care?"

"Have you ever thought about who you would want to make medical decisions for you if ever you were unable?"

Step 3: Assess knowledge

Action:

- Determine what the patient, family, and/or surrogate decision-maker understands about their current clinical condition.

Helpful phrase:

"So that I know where to begin, tell me what you understand is going on medically?"

Step 4: Provide information

Action:

- Share information in a simple and unambiguous format that may address any gaps in understanding.
- Correct any misunderstanding.
- Discuss prognosis with individual's permission.

Helpful phrases:

- “I worry that the treatment you are undergoing may not give you what you are hopeful for.”
- “Is it OK if we talk about time?”

Step 5: Honor emotion

Action:

- Acknowledge that the conversation may have brought up emotion.
- Allow for time to process the information prior to continuation.

Helpful phrases:

- “I wish things were different.”
- “This is hard.”

Step 6: Determine values for care and treatment priorities

Action:

- Explore what it means to live well.
- Recognize that there are many influencers of values/beliefs such as race and culture.
- Discuss acceptable disease states and specific scenarios when appropriate.
- Consider a scenario at end of life.

Helpful phrases:

- “Given what we have discussed today, what is most important for you to focus on with the remaining time?”
- “What are you hopeful for?”
- “Some people have thought about how they prefer to be cared for if they should stop breathing due to their serious illness. Some individuals choose attempts of resuscitation and others choose to be made comfortable. Have you ever thought about this situation?”

Step 7: Agree on a plan

Action:

- Offer value-centered recommendations.
- Make specific plans.
- Review that together you will readdress decisions over time to ensure that care continues to be in alignment with preferences.

Helpful phrases:

- “Based on what you have shared with me today, I recommend that you elect a do-not-resuscitate status.”
- “We will continue to address your preferences to ensure that your medical care remains in alignment.”

SPIKES: A six-step protocol for delivering bad news- application to the patient with cancer. *Oncologist*.2000;5(4):302–311; and Back, A, Arnold, R., Tulsky, J. *Mastering Conversations with Seriously Ill Patients: Balancing Honesty with Empathy and Hope*. New York: Cambridge University Press; 2009.

as intricate patient and family needs. Therefore, the palliative APRN should be an expert communicator and should role-model a structured approach to engaging in goals of care conversations.

The goal of ACP is to help ensure that individuals receive medical care that is consistent with their preferences and values. Legislation, institutional policies, and cultural factors influence ACP development and growth. There are documented benefits for ACP such as improved communication between patients, surrogates, and clinicians.⁹ Patients also have reported a greater source of control and increased quality of life.¹⁰ Surrogate decision-makers have also benefited from reduced stress, anxiety, and depression as surviving family members.¹¹ Healthcare benefits include a decrease in unwanted intensive medical interventions, hospitalizations, and hospital deaths, as well as earlier palliative care consultations and hospice utilization.¹² Due to the diversity of approaches to ACP and diverse individual needs, it remains difficult to determine through research if ACP actually yields medical care concurrent with preferences.¹ Thus, the role of the palliative APRN is extremely important in facilitating and documenting these discussions along an individual's health trajectory. The impact of this engagement may be felt across the medical system.

BILLING

In an effort to improve healthcare professionals' discussion of ACP with patients, family members, or surrogates, the Centers for Medicare and Medicaid Services (CMS) introduced *Current Procedural Terminology* (CPT) reimbursement codes for ACP visits in January 2016.¹³ These codes (99497, first 30 minutes with a minimum of 16 minutes; and 99498, add on for additional 30 minutes) can be used if a healthcare professional provided an explanation and discussion of the advance directive, discussed goals of care, or engaged patients, family member, and/or surrogate decision-makers in discussion as the clinical situation allows.^{13,14} Thus far, the use of ACP codes is increasing slightly annually, with older female and White beneficiaries' most frequently receiving an ACP claim.¹³ Palliative care professionals are the subset of medical providers using the code the most frequently.¹⁵

HEALTHCARE DECISION-MAKING

Autonomous individuals are free to hold certain views, make certain choices, and take certain actions based on personal values and beliefs.¹⁶ An individual's ability for self-determination is based on the principle of autonomy and on respect for the individual. Thus, autonomous individuals are free to make personal and variable healthcare decisions. These decisions can range from simple to complex and may change over the course of an illness or injury trajectory. For example, the voluntary choice of an informed person with decision-making capacity determines whether any treatment,

including life-sustaining therapies, is initiated, continued, or withdrawn.¹⁷ These decisions are best made when the individual is informed and afforded the time needed to make a decision. Palliative APRNs can be an important part of this process. They can assess whether patients have decision-making capacity, provide the information that patients need to make decisions, and determine whether patients understand the information provided.

The palliative APRN will need to perform an assessment if there are questions regarding decisional capacity. There is not a uniform approach for determining capacity, but a structured interview is recommended.¹⁸ The APRN may find it helpful to assess decision-making capacity by determining if (1) the patient can make and communicate a decision; (2) the patient is able to articulate an understanding of the medical situation and prognosis, the nature of the recommended care, alternative courses of care, and the risks, benefits, and consequences of each alternative; (3) decisions are consistent with the patient's known values and goals; and (4) the patient uses reasoning to make the choice¹⁹ (see Box 32.2). In complex cases, it would be helpful to use a tool such as the MacArthur Competency Tool for Treatment, which allows for a structured interview with good interrater reliability. There is special training available to develop skills in implementing the tool.²⁰

A patient's decision-making capacity can change over even a short period of time based on a variety of issues, including, for example, the time of day (the patient may have clear cognition in the morning after a restful night of sleep) and when certain medications are given (especially medications that impair cognition). Palliative APRNs must assess each patient's decision-making capacity and have ongoing discussions with patients about their preferences for care, including end-of-life care.

**Box 32.2 HELPFUL QUESTIONS FOR ASSESSING
DECISION-MAKING**

1. What is your understanding of your health or condition now?
2. What is the therapy/treatment likely to do for you? What are the likely positive and negative outcomes of the therapy/treatment from your perspective?
3. What are you hoping the treatment will do for you?
4. What do you think will happen if you do not have the therapy/treatment?
5. What do you think will happen if you do have the therapy/treatment?
6. How did you decide to accept or refuse the therapy/treatment?
7. What makes the therapy/treatment seem better or worse than the alternatives?^{219–30}

ADVANCE DIRECTIVES

The process of ACP gained support, as well as garnered skepticism, with the creation of the *Patient Self-Determination Act* in 1990. This statute required healthcare agencies that received funding from Medicare or Medicaid to provide information about the patient's decision-making rights regarding participation in healthcare decisions, ability to accept/refuse medical treatment, and the right to create an advance healthcare directive to ensure these wishes are communicated to healthcare providers.²⁰ This legislation did not mandate healthcare providers to have conversations with patients regarding their disease trajectory or prognosis. After this statute, the implementation of the creation of advance care directives had a heterogenous approach with limited success in widespread adoption. Approximately 1 in 3 individuals completes an advance directive, with the majority being older, female, and White.²¹ Over the past years, there have been targeted interventions across national, state, and community levels to increase the creation of advance directives. These interventions include national and state databases for the storage of the documentation of advance directives and living wills. There are also websites or smart device applications that provide education in varying platforms, guidance, and forms for the documentation of ACP, with attention given for health literacy, language, and cultural nuances (see Table 32.1). Individuals do not need to have communication with a healthcare professional to create an advance directive. The most common types of advance directives are living wills and durable power of attorney for healthcare documents.

LIVING WILL

A living will is a type of advance directive that outlines patient preferences for treatments like cardiopulmonary resuscitation (CPR), medically administered nutrition and hydration, life-sustaining treatments, and comfort care. A living will takes effect when a patient can no longer speak on his or her own behalf and when the condition discussed in the advance directive is met. For example, a patient's living will may state, "I do not want life-sustaining treatments if I am in a permanent state of unconsciousness or a persistent vegetative state, or my condition is terminal." Each state has different rules about whether a living will or advance directive is recognized.

DURABLE POWER OF ATTORNEY

A durable power of attorney for healthcare might also be referred to as a *healthcare proxy* or a *surrogate decision maker*. In these legal documents, a person designates the person who will make medical decisions on his or her behalf if something happens in the future and the individual no longer has decision-making capacity. Each state has its own legal form to designate the surrogate decision maker. Some forms are recognized within contiguous states.

ROLE OF THE PALLIATIVE APRN

Legal requirements and laws related to advance directives vary from state to state. Palliative APRNs need to know the legal requirements in the state where they practice and whether specific living will and healthcare proxy documents are available in their state. It is also important to know if witnesses are needed and if the documents need to be notarized. Palliative APRNs should know if advance directive documents developed in other states can be honored in the state in which they practice.

It is important for palliative APRNs to ask patients if they have written advance directives. If the patient has a living will and/or a durable power of attorney for healthcare, the palliative APRN should review the document(s) with the patient and ask the patient to confirm that his or her wishes are still the same as that written in the document(s). If a patient would like to change the documents, the APRN supports the patient in doing so and offers assistance or direction as needed. The palliative APRN should document all advance directive discussions. If patients do not have advance directives, they should be provided with information regarding why they are important, encouraged to develop them, and helped to do so.

Advance directives should be completed early so that there is a clear understanding of what each patient's preferences are for palliative and end-of-life care. The palliative APRN should review each patient's advance directives periodically because preferences can change. Patients should be encouraged to communicate any changes in treatment preferences or in their healthcare proxy with their healthcare providers. The palliative APRN plays a vital role in ensuring that these changes are documented.

Patients should discuss their treatment preferences not only with clinicians but also with their proxy decision-maker and close family members and friends. Patients should know that if they would like the palliative APRN's support while discussing or sharing advance directives with family members, the APRN will help them to do this.

If the patient has a living will and/or a durable power of attorney for healthcare, copies of the documents should be

distributed to key people. A copy can be given to healthcare providers so the documents can be added to the patient's medical record and placed in an area that can be easily accessed. If an electronic medical record system is used, the advance directive documents can be scanned and included in the electronic record.

Patients should also be advised to keep copies of advance directive documents in several places. One copy should be scanned into the healthcare record. The original copy may be kept in a personal safe or safety deposit box. Other copies should be given to the patient's surrogate decision-maker and to other close family members. It is also a good idea to have a card in one's wallet stating that the patient has an advance directive and describing where it is located. An individual may also be able to scan the advance directive and store it in an email, or on a phone, computer, or other smart device so that it can be easily accessed.

MEDICAL ORDER SETS

Out-of-hospital do-not-resuscitate (DNR) orders were historically developed in an effort to honor individuals' wishes to avoid cardiopulmonary resuscitation (CPR) and limit aggressive interventions. They were honored by emergency personnel, but they were often not honored if a patient was admitted to an acute care setting.

Many states have now passed legislation regarding medical order sets. There are state variations, but the order sets are commonly referred to as the medical orders for life-sustaining treatment (MOLST) or the provider/physician orders for life-sustaining treatment (POLST). The MOLST and POLST documents are portable order sets that were developed for patients with serious health problems. The objective was to respect the patient's wishes regardless of the setting. MOLST and POLST documents are honored in the home, acute care, long-term care, palliative care, and hospice settings. Thus, multiple documents are not needed in different settings; the same document follows the patient as he or she moves from setting to setting.

These medical orders are written to ensure that care is provided according to the patient's wishes. The document includes information regarding patient preferences for CPR, medically administered nutrition and hydration, antibiotic use, other life-sustaining therapies, and comfort care. The documents address the entire spectrum of care, from aggressive treatment to comfort care interventions.

A MOLST/POLST differs from an advance directive in that it is a portable medical order. Individuals may have both an advance directive and a MOLST/POLST. The documents should complement each other. Some individuals will have just the MOLST/POLST. MOLST/POLST forms create a legal obligation that medical professionals will honor the individual's treatment preferences.

As with other aspects of ACP, palliative APRNs need to be aware of state legislation related to these medical order sets. The MOLST and POLST forms are signed by the patient's physician or, as allowed in some states, the form can be signed by an APRN or a physician assistant. Depending on the state, the patient and his or her surrogate may sign the document. Orders on the MOLST/POLST form do not expire and can be revised by voiding the form and completing a new one.

As with the living will and durable power of attorney for healthcare documents, it is important that these order sets are completed and reviewed to ensure that care is consistent with the patient's preferences because a recent study shows that MOLST/POLST forms can be inaccurate, undisclosed, or not consistent with patient preferences.²²

SURROGATE DECISION-MAKING

As individuals become seriously ill or move closer to end of life, they may lose the capacity to make decisions. It then becomes the responsibility of the surrogate decision-maker, either by proxy or by previous selection and documentation as a durable medical power of attorney, to engage in legal decision-making on behalf of the patient. Each state has differing laws about who should serve as a surrogate decision-maker but often members of the family are designated in this role.

As with other ACP documents, the document designating a healthcare proxy should be shared with the individual's healthcare providers. The palliative APRN should ask each patient if the person designated as surrogate decision-maker knows that he or she is aware of this designation. The APRN should also ask the patient if they have reviewed the living will and, if applicable, MOLST/POLST documents with the surrogate decision-maker or healthcare proxy. Engaging in these conversations is an essential part of helping the surrogate decision-maker to fully understand the patient's wishes.

The healthcare proxy or surrogate decision-maker needs to know that they will be involved in the decision-making process if the patient no longer has decision-making capacity. The role of the surrogate decision-maker is to make decisions on the patient's behalf. The surrogate decision-maker will make decisions based on information that the patient wrote in a living will, advance care planning documents, and discussions

between the surrogate decision-maker and the patient had about the patient's wishes.

Periodically, when advance directive documents are reviewed, it is important for the palliative APRN to review the healthcare proxy document and confirm that the person designated as healthcare proxy has not been changed. If patients want to make changes, they should be encouraged to develop a new document. A healthcare proxy needs to change if the surrogate dies or if the relationship changes between the patient and the surrogate.

If the patient has not designated a healthcare proxy or surrogate decision-maker, the palliative APRN should discuss this process and provide the patient with information regarding how to do this (see Table 32.2). Selecting the right person is key to successful proxy selection. When selecting a surrogate decision-maker, individuals should consider someone who can be trusted to make sound decisions, is emotionally stable, who would be comfortable asking healthcare providers questions, and is available.

If the time comes that a patient cannot communicate or no longer has decision-making capacity, then the palliative APRN and other members of the healthcare team will turn to the surrogate decision maker if important decisions need to be made. The surrogate decision maker is responsible for making decisions based on what the patient would want done. This supports the patient's previously stated wishes and honors and respects them. If the surrogate decision maker does not know what the patient would want, then they must make decisions based on what they thinks would be in the best interest of the patient. The palliative APRN should acknowledge that serving as a surrogate can be stressful. It is important to educate the healthcare proxy that a blended approach to decision-making that balances the individual's preferences with the surrogate's judgment about what would be best for the patient may lead to better surrogate satisfaction.²³

If a patient did not designate a healthcare proxy and cannot communicate his or her wishes and is unmarried, the team turns to the family for advice. Decades ago, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research recommended that the family is the patient's best advocate if the patient does not have decision-making capacity.²⁴ The palliative APRN should

Table 32.2 SURROGATE DECISION-MAKER

CHARACTERISTICS	POTENTIAL ACTIONS
18 years of age or older	Choose medical caregivers
Can talk to you about your wishes	Chooses tests, treatments, or medications
Can be there for you when you need them	What happens to body after death
You trust to follow your wishes	Agree to, refuse, or withdraw any life support or treatment
www.prepareforyourcare.org	

ask the family if the patient ever stated what he or she would want at the end of life.

Most states have surrogacy laws that specify who can make decisions for a patient. These state laws should be followed when determining which family member has legal authority to make decisions for a patient without decision-making capacity. Legally determined standards are typically set and need to be followed by the palliative APRN. A patient's spouse is typically legally authorized as the primary decision-maker. If the patient's spouse has died or the patient is divorced, the next legal decision-maker might be the eldest adult child. In other states, all adult children need to come together to make a decision. It is important that palliative APRNs know and understand surrogacy laws. In cases of conflict, or where no previously designated surrogate is available, it may be necessary to petition a court to appoint a surrogate.²⁴ The appointed guardian then serves in the role of surrogate.

If the patient does not have decision-making capacity, then the designated healthcare proxy, surrogate decision-maker, or the family member legally designated to make decisions for the patient does so based on the patient's preferences identified in the living will. If there is no living will, then decisions may be guided by conversations that the surrogate previously had with the patient. If a patient had no living will and did not state what he or she would have wanted at the end of life, *substituted decisions* are made. This is when decisions are made based on what decisions the surrogate decision-maker thinks that the patient would make. If the surrogate decision-maker has no idea what decision the patient would make, a *best interest decision* is made. This decision is based on what might be best for an average person.

Although one person is designated as surrogate decision-maker, multiple family members are often present and involved when a patient nears death. Even though one decision-maker has legal authority for decision-making, it is common for the surrogate decision-maker to include multiple family members in discussions regarding goals of care, especially in the context of end-of-life care.²⁵ Surrogate decision-makers commonly seek advice and help from other family members when making end-of-life decisions.²⁶ Families have found advance directives helpful when making end-of-life decisions related to life-sustaining therapies.^{27–32}

Making end-of-life decisions on behalf of someone else places a tremendous burden on surrogate decision-makers.^{33,34} Some family members may support and some family members may not support the surrogate decision-maker as he or she comes to terms with the decision that needs to be made. It is important for the palliative APRN to help and support the surrogate decision-maker and the patient's family through this process. Once decisions are made, the APRN should ensure that the decisions are respected and honored.

DIVERSE POPULATIONS

There is a significant need to develop interventions to enhance ACP in diverse populations. Rates of ACP among racial and ethnic minority and those with limited health literacy

are much lower than in White individuals.³⁵ For example, African American individuals are less likely to receive end-of-life care aligned with their preferences and are less likely to receive hospice services.^{36,37} The completion of ACP in this population remains less than 25%.³² ACP disparities persist for LGBTQ+, incarcerated, and homeless populations as well.^{38–40} Some of the reasons for these disparities include the lack of ACP knowledge, lack of trust, experiences of racism or discrimination, low health literacy, or a preference for others to make medical decisions on their behalf. As this gap has been identified, there is evolving research on systemic interventions to better support ACP in those facing complex barriers. This research varies widely. Some of this research includes using decision aides such as videos and the creation of easy to read documents in a variety of languages.⁴¹ An example of this intervention is *PREPARE for Your Care*, (<https://prepareforourcare.org/welcome>) which is a resource that offers videos, simple advance directives, and education in simple terms in a multitude of languages. It remains challenging to create and research scalable interventions to meet the needs of diverse populations.

The palliative APRN is in an important position to advocate for and employ strategies to engage in effective ACP in special populations. To effectively provide palliative care to all individuals, an APRN should be committed to continually expanding awareness of their own biases and perceptions specific to race, ethnicity, gender identity, gender expression, sexual orientation, immigration status, refugee status, social class, religion, spirituality, physical appearance, and abilities.¹⁹ This is an active process, one that requires personal reflection and awareness. For example, there could be assumptions made, such as a good death is one at home with loving individuals present. Unfortunately, many individuals do not have a safe home and/or caregivers to care for them at end of life. Thus, this assumption could contribute to negative experiences at end of life, although this is not the intention of the healthcare provider. By understanding the complex barriers to ACP in special populations and recognizing that ACP is a highly personalized process, the palliative APRN can help to address the gap between the medical preferences of diverse populations and the medical care received.

WHAT COVID-19 TAUGHT US ABOUT ADVANCE CARE PLANNING

The emergence of the novel coronavirus brought challenges to healthcare systems globally and put the spotlight on ACP in a time of medical uncertainty and in some cases limited resources. COVID-19 highlighted the lack of ACP, the lack of availability of surrogate decision-makers, and put tremendous stress on healthcare providers. Palliative care specialists and organizations supported the frontline by adapting and disseminating communication tools for the intricacies of prognosis sharing and care planning in medical uncertainty. Their challenge was to also support surrogate decision-makers who often were not prepared for the role

and whose decision-making was complicated by not being able to see their loved ones due to visitation restrictions. Outpatient palliative care providers were calling patients to readdress preferences and facilitate documentation in a time of much uncertainty. These visits shifted to telehealth as shutdowns and attempts to protect patients and health-care workers hurtled technology forward. The challenges of this work, whether directly performed or supported, took a toll on everyone. Yet it did move forward discussion and implementation of ACP across the continuum as the effects of poor planning created a significant burden on the medical care teams as well as patients.

On a community level, individuals used tools to create their own advance directives. For example, COVID-19 led West Virginians to call their state center for end-of-life care for forms, urgent desire to initiate ACP, temporary rescindment of treatment-limiting forms, and questions on how to honor patients' wishes in advance directives and medical orders in light of their COVID-19 status.⁴² Another study reviewed the monthly rates of completion, completion of number of goal-setting modules, and distributions of preferences for care for care on the free advance care planning website, *OurCareWishes.org*. It showed a 4.9 times increase in advance directive completion as well as more comprehensive completion since the onset of COVID-19.⁴³ This increase shows that community-facing tools that have been refined through years of implementation can accommodate to large shifts in the completion of ACP documentation necessitated by the COVID-19 pandemic.

SUMMARY

Palliative APRNs play an essential role in the ACP process. They can educate and help patients to develop living wills, designate healthcare proxies, and develop MOLST/POLST documents. Conversations that palliative APRNs have with the patient, surrogate, and family not only help to identify the patient's wishes but also help to ensure that these wishes are honored and respected.

FAMILY MEETINGS

Jennifer Gentry, Kerrith McDowell, and Paula McKinzie

KEY POINTS

- Excellent communication is the foundation for effective family meetings.
- Leading family meetings is a key role for the advanced practice registered nurse (APRN).
- The APRN must prepare for a family meeting.
- When there is conflict, the palliative APRN must address the emotion from the patient and/or the family.

CASE STUDY: CONFLICTING GOALS

Mrs. R was a 55-year-old woman with a history of substance misuse disorder, hypertension, and an anoxic brain injury following an out-of-hospital cardiac arrest 3 months ago. She was admitted to the hospital with worsening myoclonus and an unstageable sacral ulcer. Mrs. R had a tracheostomy and a percutaneous gastrostomy tube (PEG); she was noncommunicative and dependent for all activities of daily living (ADLs). She was cared for at home by her family with assistance from the community palliative care team. The palliative advanced practice registered nurse (APRN) was consulted to assist with clarifying goals of care with Mrs. R's family. A family meeting was arranged after reviewing the medical record, examining the patient, and obtaining information from the care nurse and primary team. The family meeting participants included the palliative APRN, the palliative care social worker, the patient's spouse, Lester, and Mrs. R's son from a previous relationship, Randy. After introductions, the APRN reviewed the issues leading to the hospital stay, purpose of the meeting, and family perception of the illness.

APRN: Would it be OK to talk about Mrs. R's illness and what has been happening with her health so that we can provide the best possible care?

LESTER: Sure . . . I've been so worried about her and I didn't know what else to do.

APRN: Tell me more about what has been worrying you.

LESTER: I was doing everything they [the home palliative care team] told me to do but she kept having twitching and the wound was worse. . . . I didn't want her to suffer so I called 9-1-1. [Lester sighs and appears fatigued.]

APRN: I can only imagine how difficult that this was.

LESTER: It has been really tough, and I feel like I am running out of steam and don't have enough help.

APRN: I hear that this is really difficult and exhausting.

RANDY: She is my mother and you [speaking to Lester] never include me in what is going on. I know she can get better and you are just giving up and calling hospice. [Randy abruptly storms out and slams the conference room door. The palliative social worker leaves the meeting to check on Randy while the APRN continues to speak with Lester.]

LESTER: "I know he [Randy] is having a hard time with all this . . . he had a hard time seeing her this way. The doctor's told us that she is dying and he just can't accept that."

Over subsequent follow-up family meetings and discussions, the decision was made to focus all efforts on aggressive symptom management and comfort. Tube feedings were discontinued, and Mrs. R was transitioned to an inpatient hospice setting to receive continued symptom management and family support.

INTRODUCTION

When a serious illness occurs, patients and their families may find themselves at the mercy of a complex and often unyielding healthcare system with limited insight into their situation and how to proceed. Nonexistent or poorly delivered communication during the course of an illness may result in conflict, confusion, frustration, and mistrust. Thoughtful communication and facilitated family meetings can go far to bridge the communication gap. These can take place in the acute care setting, clinic, home, or long-term care setting. Leading a family meeting is an essential skill for the palliative advanced practice registered nurse (APRN).^{1,2} By its nature, palliative care is interdisciplinary and collaborative. As leaders on the interdisciplinary team, palliative APRNs frequently lead formal and informal family meetings, discuss prognosis, clarify goals of care, assist with advance care planning, deliver bad news, and provide care when death is imminent.^{2,3}

Communication expertise is a core competency for palliative APRNs and is woven throughout the scope and standards of palliative nursing practice.¹ Principles of good communication include use of open-ended questions, sitting down, maintaining eye contact, being present, listening, use of empathic responses, and attending to emotion.³⁻⁵ Whether practicing in an inpatient acute care setting, an outpatient clinic, or hospice, APRNs lead and participate in complex communication episodes with patients and families.^{1,2} Despite having an important role in family meetings, APRNs may feel

unprepared to lead them.⁶⁻⁹ This chapter reviews the literature around family meetings and the process for effective family meetings.

DEFINITION OF FAMILY MEETINGS

While no single definition of a family meeting exists, these meetings may be described as a facilitated, dynamic means of exchanging information about illness, prognosis, and treatment options with the patient, family, and healthcare team. “Family” is described by the patient or, if they are not able to participate, by designated surrogate decision-makers or next of kin. Family meetings, also referred to as *family conferences*, provide a vehicle for two-way communication about the goals, values, concerns, and decisions needed to formulate a plan of care.

Seaman and colleagues have proposed five goals for clinician–family communication which are of key importance in family meetings: establish trusting relationships; providing emotional support; facilitate understanding of diagnosis, prognosis, and treatment options; helping clinicians understand the patient as a person; and creating conditions for deliberation about decisions.¹⁰ Family meetings have been reported to result in improved family perception of empathy and goal-concordant care, and can serve as a way provide interdisciplinary family support.^{4,11} Although recommendations exist for routine family meetings, further research is needed to support the most effective manner, timing, and use of family meetings as a communication tool.¹²⁻¹⁴

The family meeting has been called the major “procedure” of the palliative care clinician or the major tool on which to base palliative care interventions.^{15,16} For this “procedure” to be effective, the palliative APRN must use excellent communication skills, including active listening, empathy, a nonjudgmental approach, and observation.^{7,17,18} Essential elements of communication required during a family meeting include listening, information gathering, imparting information, therapeutic presence, and sensitivity.^{7,18} Information must be provided in a manner that is educationally, culturally, and developmentally appropriate without overwhelming the recipients’ coping styles.^{17,18} To best facilitate these meetings, the APRN must have a working knowledge of common conditions and disease processes and their trajectory and prognoses, as well as potential technology and treatment options, to guide patients and families in making informed decisions about their healthcare.^{1,17} APRNs frequently provide palliative care and associated communication in many different settings. Care provided by APRNs is rated highly in terms of satisfaction and the achievement of comfort.^{2,19} In a systematic review of outcomes, the care provided by APRNs has been shown to be similar to that provided by physicians.^{20,21} Patients rate APRN care delivery as high-quality and highly satisfying.²¹ To be the most effective, palliative APRNs should be allowed to function fully within the scope of their education and training. It is within the APRN’s scope of practice to lead family meetings and discuss prognosis, disease process, and therapeutic options.^{1,2}

Box 33.1 TRIGGERS FOR FAMILY MEETINGS

Long length of stay
Significant clinical change
Prognosis discussion or high risk of mortality (e.g., multiple organ system dysfunction for 3 or more days, global cerebral ischemia after resuscitation, Stage IV malignancy)
Disagreement among family, team, and patient about prognosis or goals of care
Transitions in care (e.g., from hospital to hospice, change in goals of care)
Within 72 hours of ICU admission
Need for treatment decisions such as tracheostomy or percutaneous endoscopic gastrostomy (PEG) tube

From Weissman¹⁵, Widera¹⁶

Family meetings should not be used only when there is a crisis.^{2,9,14,15} Proactive use of family meetings, ensuring adequate preparation, are essential components for success.¹⁵ The APRN addresses potential barriers to family meetings by identifying and setting aside specific times for family meetings, supporting communication skills training for clinicians, and using assistance from members of the interdisciplinary team to help with the logistics of scheduling, coordinating, and finding a location for the meeting.^{14,15} It has been suggested that identifying specific indications for family meetings and palliative care consultation may promote the involvement of palliative care and family (Box 33.1). The need for a family meeting could be triggered by clinician assessment of clinical changes, the need for transitions in care, discussion of prognosis, the need to make treatment decisions, or disagreement among family members and clinicians.^{15,16} Patients and families may also request family meetings as palliative care moves upstream.

RESEARCH ON FAMILY MEETINGS

Miller and colleagues examined palliative care consultations, mainly provided by APRNs, for patients in skilled nursing facilities.²² The authors concluded that these palliative care consultations had good patient outcomes because they resulted in lower use of acute care services and lessened the burden of care transitions. Palliative APRNs embedded in an oncology clinic demonstrated improvement in areas requiring complex communication including advance care planning and end-of-life hospice discussions.²³ Nurse-led family meetings have been shown to increase family satisfaction and improve communication in support of shared decision-making.²⁴ Over the process of developing and employing communication skills in family meetings, nurses have reported increased confidence in communication, improved listening skills, deeper understanding of families, and higher levels of professional satisfaction.^{7,25} Appropriate education and mentoring were essential components of the success of nurse-led family meetings.^{7,8,24,25}

Despite the importance of communication skills, a lack of emphasis has been placed on communication education and training in nursing programs.^{7,8,26,27} Palliative care team members without specific counseling backgrounds, including nurses and physicians, often have not received training in meeting facilitation or conflict resolution. Additionally, advanced practice providers and APRNs may lack an understanding of their role in family meetings or feel unempowered to be active participants.^{28,29} Fortunately, like other clinical skills, communication and facilitation skills can be effectively taught using simulated patients, mentoring, expert observation, and feedback.^{6,7,18,30}

Regular communication and family meetings may have immediate and long-term benefits for patients and families. A common reason for palliative care consultation is to facilitate communication.^{23,31,32} Temel and colleagues noted that for patients with advanced gastrointestinal and lung cancers, early palliative care involvement was associated with improved quality of life and mood, and patients found discussions of prognosis to helpful.³¹ Trends in hospital-based palliative care between 2013 and 2017 indicate that a majority of palliative care consultations were obtained to facilitate communication.³² A mean of 1.3 family meetings per palliative care consultation was identified, and a large number of palliative care consultations were associated with multiple family meetings during one admission.³² Conclusions from several systematic reviews suggest low-quality evidence for family meetings and identified areas for additional research, such as perspectives of the individual participants, the most effective clinician participants, and timing and frequency of family meetings in inpatient settings.^{27,33} In a structured palliative care communication intervention in the intensive care unit (ICU) setting, family-caregiver anxiety and depression did not improve following family meetings facilitated by palliative care providers.³⁴ The investigators theorized that outcomes may have been impacted by lack of interdisciplinary and ICU team participation in the family meetings, which underscores the importance of collaboration in family meetings.³⁴ Though nurses are in an ideal position to lead and participate in family meetings, in one study nurses were rarely asked by the family or other healthcare team members to contribute to the discussion.²⁸ As leaders of family meetings, palliative APRNs have an obligation to include the valuable input of bedside nurses and other interdisciplinary team members in family meetings.¹

Communication in the context of palliative care consultation has been shown to improve respect for treatment preferences, emotional and spiritual support, and symptom management.^{22,23,35,36} Without the information that may be gained in a family meeting, clinicians may struggle to predict patient preferences.^{37,38} Evidence has demonstrated that physicians do not accurately assess a patient's quality of life, functioning, or preferences for cardiopulmonary resuscitation (CPR) even if there is a relationship with the patient over time.³⁹ Palliative care consultation teams have been shown to improve symptom management, quality of life, and processes of care, such as transitions across care settings and documentation of patient goals.³²

OUTCOMES OF POOR COMMUNICATION

Poor communication has been identified as the greatest source of anxiety and frustration for family members.^{9,14,38} Several counterproductive behaviors that clinicians may unintentionally use may result in conflict and suffering in a family meeting (Box 33.2): (1) forcing the discussion, (2) linking relief of suffering with limited life expectancy, (3) pressuring through repeated attempts to persuade, (4) misdiagnosing denial, (5) presenting information out of context, and (6) making treatment recommendations without incorporating the context of the surrogate's perception of the patient's wishes.^{40,41}

Poor-quality communication during family meetings may lead to misunderstandings, missed opportunities, and distress for all involved.¹⁶ Medical jargon may not be well understood, and the importance of every single word must be measured. It is not surprising that family members view emotional support provided through empathic communication as critical, and it is associated with better psychological outcomes.⁴² When the family is not fluent in the language to be used during a family meeting, the use of an interpreter is best practice.^{16,43} Family members should not be used as interpreters during family meetings because it puts them in an awkward situation of both responding to information and having to convey difficult news.^{16,43} English terms that may be used in the context of family meetings such as "palliative," "hospice," and "DNAR" (do not attempt resuscitation) may not have a corresponding word in other languages or may be translated into a more negative context.⁴³ Interpreters may not have had specific training in palliative care related communication such as delivering bad news and can benefit from a pre-meeting to review the medical history, information to be discussed, key participants, and current understanding if known.⁴³ The

Box 33.2 COMMON CLINICIAN COMMUNICATION ERRORS

Proceeding without assessing readiness: Forcing the goals-of-care discussion when the patient or family is not ready.

Linking relief of suffering with demands to accept limited life expectancy: "I'm sorry, but there is nothing else we can do for you. Should we just keep you comfortable now?"

Misdiagnosing denial: Patients and families may have the initial, "This is not happening" response as part of normal grief, self-protection, and coping.

Destructive debates: Repeated attempts to convince the patient and family of a certain viewpoint (e.g., repeated attempts to "get the DNR").

Presenting hypothetical decisions in an impersonal manner without a context: "If your heart and lungs stop, what do you want us to do?"

Making treatment recommendations without incorporating the context of the surrogate's perception of the patient's wishes: "Based on what you know (about the patient) what would be important to them in this situation?"

Box 33.3 BARRIERS TO FAMILY MEETINGS

Fear of loss of hope/patient distress
Lack of time/resource intensive
Lack of training/low confidence in communication ability
Cultural differences
Logistics (lack of space, multiple providers, scheduling conflicts)
Provider burnout/low priority

From Piscitello¹⁴, Wright⁴⁴, Weissman⁴⁵, Wu⁴⁶

literature supports the use of medical interpreters as “culture brokers” with a knowledge of language and an awareness of cultural nuances so that they can provide information in the most respectful manner.⁴³

If family meetings are beneficial, why do they happen late in the course of illness or not at all?^{14,44} Recommendations have been made to hold a family meeting in the ICU within 72 hours of admission to promote family satisfaction and communication.³⁶ The authors of a retrospective study of family meetings in the ICU noted that almost half of the patients had not received a family meeting 5 days following admission and that timely family meetings were highly associated with death during the ICU stay.¹⁴ The authors hypothesized that clinicians may be using family meetings to negotiate discontinuation of life-sustaining technology rather than as a vehicle for family support and patient autonomy.¹⁴

Several barriers to timely family meetings have been identified (Box 33.3). Wright and colleagues suggest that conversations about difficult things like poor prognosis and end of life are avoided for fear that the patient will “lose hope” or experience distress.⁴⁴ Despite the ambivalence that patients and providers may have about difficult discussions, patients with terminal cancer who participated in these discussions were less likely to receive aggressive ICU care, mechanical ventilation, or attempts at resuscitation and did not experience higher rates of depression.^{6,16,44} When patients underwent more aggressive medical treatments at the end of life, they experienced a lower quality of life before death, and their caregivers were at a higher risk for depression.¹⁶ Other potential barriers to family meetings include lack of time, resource intensiveness with involvement of multiple providers, lack of provider training in communication and facilitation, cultural differences, lack of space, and provider burnout.^{14,33,44–46}

SETTING THE STAGE FOR FAMILY MEETINGS

Several essential components of family meetings have been identified.^{16,47} The mnemonic VALUE has been developed and used as a communication strategy to facilitate proactive family meetings for patients dying in the ICU (Box 33.4).^{27,47} Proactive family meetings and use of palliative care interventions have been associated with reduction in ICU utilization

**Box 33.4 STEPS IN COMMUNICATION USING
THE VALUE MNEMONIC**

Value and appreciate what family members have to say.
Acknowledge emotion of the patient and family.
Listen to concerns expressed.
Understand/learn about who the patient is through open-ended questions.
Elicit questions from the patient and family.

at the end of life.^{47,48} Additionally, fewer nonbeneficial interventions were done in those who received a proactive family meeting, and there was a lower incidence of depression, anxiety, and posttraumatic stress disorder among survivors in the 3 months following the death of the patient.^{12,47} Several models have been proposed for family meetings; these contain four overarching components: (1) conference organization, including the setting, participants, and structure of the meeting; (2) negotiation or building consensus and reaching decisions; (3) personal stance or the attitude and mode of information delivery; and (4) emotional work or use of empathic responses^{16,49} (Box 33.5).

THE STEPS OF A FAMILY MEETING

PREPARATION

Identifying the Decision-Maker and Who Should Be Present

Patients with capacity have a right to self-determination and should be included in decisions about their healthcare, per

**Box 33.5 ESSENTIAL ELEMENTS OF A FAMILY
MEETING**

1. Prepare for meeting through chart review and clinician discussion to ascertain

From Widera¹⁶, Baile⁴⁹

their preference, but the reality is that many deaths occur in the hospital and ICU, where patients are frequently too ill to participate in decision-making.^{9,12,50,51} Deaths commonly occur after the decision is made in a family meeting to discontinue life-sustaining measures or limit treatment. Attempts to prepare the family for this outcome should be made by the provider during the family meeting in the acute care setting.^{38,52}

Family members often serve as surrogate decision-makers for incapacitated patients.^{12,27,38,52} The definition of “family” is very individual, and family members may include anyone who is important to the patient, rather than just a legal or biological relative. A surrogate decision-maker or next-of-kin status is individually defined by the state via statute. Some patients have such an individual designated through written advance directives or a durable power of attorney for health, in the event they are not able to speak for themselves.⁵³

The ethical principle of substituted judgment is applied when there is no advance directive and the patient lacks decision-making capacity.⁹ Palliative APRNs must be knowledgeable about the laws in their practice location so they can determine the appropriate legal decision-maker. The palliative APRN must also identify other persons important to the patient who should be included in a family meeting. Although the legal surrogate may be authorized to act on behalf of the patient, there may be others who hold great influence in the decision-making process. They may include relatives, close friends, or spiritual care providers who know the patient’s wishes and can contribute to the meeting. Even with a written advance directive, surrogate decision-making can be difficult. Surrogate decision-makers’ ability to predict what the patient would have wanted in a given situation may be inaccurate, and authorizing overtreatment is a common error.^{42,54}

Shared decision-making, a dynamic process in which the responsibility is shared by the treating provider and the patient’s family, has been endorsed by numerous professional societies.⁵² It is best carried out using a stepwise approach.⁵² Family members who are involved in decision-making frequently report feeling overwhelmed and overburdened by the responsibility (Box 33.6).^{38,42,55} Exploring the family’s preferred role in the decision-making process and the uncertainty about the prognosis is essential and should be reassessed frequently. Some families prefer that the provider make

recommendations; others prefer to accept ultimate responsibility for the decisions made.

Participants from the clinical team should be limited to those crucial for information, decision-making, and family support. The patient’s care nurse, spiritual care provider, social work, essential consultants, the primary team, and palliative care provider may attend.¹⁶ Having a large number of participants from the clinical team may be overwhelming for a smaller family group. Depending on where the meeting is held, logistics may dictate who may attend in person, but, even in the clinic and home, other providers may participate virtually. For patients and families lacking proficiency in English, a trained medical interpreter should be available by phone or in person.^{16,43}

Meeting Place

Finding an appropriate setting and space for the meeting may seem like a simple task, but healthcare facilities are designed for utility and may not provide the patient- and family-friendly space needed for family meetings.⁵² However, at home and in residential settings, there are often more private meeting areas. An ideal space would allow for privacy, adequate seating, and use of technology, such as speakerphones and computers to allow for participation of distant family members.⁵² While technology can facilitate communication, it may also be a distraction. Clinicians should silence their cellphones and pagers prior to the meeting and may consider asking family members to do the same. Evidence to support the best physical arrangements for family meetings is lacking, but arranging the room and seating to allow good eye contact and observation of participants’ nonverbal communication may be helpful.^{15,16,52} In some cases, a patient with decision-making capacity may be too ill to move to a separate location, requiring the meeting to be held in the patient’s room. The space may not accommodate seating for everyone, but at a minimum the person leading the meeting should be seated.

History and Medical Facts

Another element of preparation includes being knowledgeable about the medical facts in the case.^{15,27,52} Prior to a family meeting, the palliative APRN should review the medical history, consult with members of the team knowledgeable about the patient’s situation, and become familiar with the patient’s psychosocial, spiritual, and family background.^{1,2} Key stakeholders and subspecialists to be included or consulted prior to the meeting should be identified prior to the meeting and invited as appropriate.²⁷ “Who is the health provider you trust the most (on the medical team)?” can be a helpful question to pose ahead of time to patients and families in an effort to identify important stakeholders. If other team members will be attending the meeting, set aside a few minutes to discuss key facts, such as prognosis, treatment options, and concerns, before the meeting. In the pre-meeting conference, everyone attending should be clear on the purpose of the meeting, which team member is leading the meeting, and what role each team member will play.

Box 33.6 SAMPLE QUESTIONS TO CLARIFY ROLES IN DECISION-MAKING

“How has your family made decisions in the past?”
“Some families make decisions as a group and others appoint a spokesperson. Can you help me understand how your family makes decisions?”
“I can see how difficult this is for you. Would it help if I make a recommendation?”
“Would it be helpful to include your family in these discussions and decisions?”

From Pecanac⁴¹, Kavalieratos⁵⁶

MEETING STRUCTURE

INTRODUCTIONS

Everyone present in the room should be introduced, and their role and relationship to the patient should be made clear. In large groups, the person leading the meeting or a designee may wish to discreetly jot down this information to refer to later. Consider the role of the interdisciplinary team members, such as social work, to help mitigate complicated family dynamics.⁵² Ground rules can often help and include clarifying the legal decision-maker if the patient lacks decision-making capacity and noting that there will be an opportunity for everyone to ask questions and participate during the meeting.

ELICIT UNDERSTANDING AND INFORMATION NEEDS

Beginning the discussion by asking an open-ended question like “What have you heard so far?” or “How do you feel things are going at this point?” provides important information about the patient’s and family’s perception and allows the APRN to use active listening skills and assess the family’s need for information.⁵⁰ Using the phrase “What do you understand?” may get at the information needed but should be used cautiously as patients and families may perceive this as condescending or may conclude that the clinician views them as uninformed. While many patients and families want as much information as possible, this is not always the case.⁵⁵ The need for information is very individual and should be determined prior to the meeting.^{27,52,55} The palliative APRN should avoid making assumptions about the type and amount of information that should be disclosed. Culture and health literacy may dictate what and how information is shared.⁵⁵

PROVIDE INFORMATION

Deliver information using an honest and direct manner while continually assessing the response and nonverbal communication.³ Some families report that statistical data regarding outcomes is helpful in decision-making while others state this is not useful information and can be overwhelming.⁵⁵ Checking in about the group’s understanding should be done frequently and with tact and diplomacy. A question like “Am I making sense to you so far?” “Does this make sense to you?” or “Sometimes I forget that I use medical jargon. Would you mind sharing what you heard me say, so that I know I am being clear?” puts the responsibility for communication difficulties on the provider and not on the recipient’s lack of understanding.

RESPOND TO EMOTION

The palliative APRN should pause after information is delivered and allow the group to process it and express emotion. The natural inclination may be to “fill the space” with words, but the APRN must recognize that silence and presence are vital communication tools.^{3,16} Expressions of emotion and

distress are common during palliative care consultation.¹⁶ Anxiety and fear were the most frequently encountered emotion, followed by sadness, anger, and frustration.¹¹ Expressions of distress and emotion should be handled by clinicians with compassion and empathy.^{3,4,16,52} Allowing time to speak and express emotion has been correlated with higher levels of satisfaction when patients and families speak more than the clinician.¹¹ Addressing emotions, while intuitive for some, is a skill that can be learned like any other.^{4,7} The NURSE mnemonic has been suggested as a way to remember five different skills for handling emotions (Table 33.1).⁵⁰ In some instances, the patient or family members may state how they are feeling, and the palliative APRN can reflect back the emotion; in other instances, it may be helpful for the APRN to name what he or she observes and allow the patient or family to validate or clarify. Although no one can fully appreciate another person’s exact situation, the palliative APRN can still convey empathy for what the patient and family are experiencing. Acknowledging and offering respect for the emotions being expressed can go far toward building a trusting and supportive therapeutic relationship. Respect and affirmation can be conveyed through the APRN’s body language and facial expression as well as with words.

There may be a point in the conversation where the palliative APRN is unsure where things stand based on a patient’s quietness or lack of emotion. Using empathic curiosity is a way of exploring, using an open-ended question such as “Are you able to tell me what you are thinking at this point?” or

Table 33.1 EMOTION-HANDLING SKILLS USING THE NURSE MNEMONIC

EMOTION-HANDLING SKILLS	PHRASES TO USE/QUESTIONS TO ASK
N: Recognizing and naming emotion	“I’m hearing that you are really concerned and upset about this situation.” “I wonder if you are feeling angry about this?”
U: Expressing understanding and “normalizing” the emotion	“I can’t imagine how difficult that it must be, seeing your loved one go through this.” “I wouldn’t be surprised if you were feeling really sad.”
R: Acknowledging and offering respect	“I really appreciate your commitment to your loved one and all the time that you have spent at the hospital.” “I have great respect for the care that you have given your loved one.”
S: Offering support and demonstrating commitment to the patient and family	“We will continue to adjust your pain medications until you are comfortable.”
E: Explore to gain clarity and insight into the story/experience	“Tell me more about . . .” “I heard you say that you felt confused. Can you say more about this?”

From Martin⁵⁰

“We have been discussing some difficult things. How are you doing with this?”⁵⁰

All of the skills to address emotion ultimately offer patients and families support, but none of them specifically addresses the fear of what may happen in the future. In today’s healthcare environment, it is crucial to help families plan for what may be coming next.⁵² Assuring patients that they will continue to receive personal care, skilled assessment, and pain and symptom management while attending to psychosocial, spiritual, and emotional needs no matter what happens or what decisions they make will go far to allay this fear. Offering false promises of support that is not possible should be avoided, however. Support can be conveyed by making good handoffs, advocating for the needs of the patient and family, and using words that affirm commitment such as “we will continue to care for you and your loved one.”

DEVELOPING THE PLAN

In some cases, the emotion of the situation is so overwhelming that it may be best to summarize, plan another meeting, and adjourn. In other situations, further conversation and goal-setting flow naturally from the conversation. Clarifying goals through open-ended questions like “Given what you have heard, what is most important to you now?” and “What things are you hoping for?” can help the palliative APRN make recommendations based on the values and expectations of the patient.⁵²

Realistically, it may take several communication episodes or meetings to fully develop the plan of care. While a “meeting before the meeting” can be helpful for the team, a post-meeting debriefing can be just as useful. Delivering bad news and attending to emotion can be stressful for healthcare providers who may or may not have a long-standing relationship with the patient.⁵⁶ Taking time to talk about what went well and areas that could be improved upon and assessing the patient’s and family’s response can be therapeutic as well as educational.

DOCUMENTATION

Documentation of the family meeting is part of the process of communicating with other members of the team and helps to promote continuity (Box 33.7). Several important pieces of information should be included in the documentation for both communication and billing purposes.^{16,27,35} It may be helpful to provide a copy to the patient and family for their review and reference and, with the movement of “open notes” in the electronic medical record, they will be able to more readily access it.

DELIVERING BAD NEWS

In addition to leading family meetings and facilitating communication for patients and families, the palliative APRN may be in the position of delivering bad news. Bad news has been defined as any information that adversely alters one’s

Box 33.7 KEY ELEMENTS OF DOCUMENTATION FOLLOWING A FAMILY MEETING

1. Date and time and where meeting took place (emergency department, intensive care unit, medical floor, clinic, home) which helps to later understand the context of the meeting
2. Participants including patient, family, and the healthcare team. If the patient was unable to participate, note the reason (e.g., “The patient lacked decision-making capacity and was unable to participate.”)
3. Purpose of meeting or necessity for medical decision-making
4. A brief summary of information discussed, including:
 - Current state of illness
 - Patient and family illness understanding
 - Prognosis
 - Treatment plan
 - Specific discussions of bad news
5. Patient and family response (e.g., “After the current state of illness was discussed Mr. Rose states: ‘It has been really tough and I feel like I am running out of steam and don’t have enough help’”)
6. Specific treatments discussed or decisions made (e.g., advance care planning, resuscitation status, medically administered nutrition and hydration, other life-support measures)
7. Disposition planning, including referral to home health, hospice, skilled nursing facility placement, financial concerns, caregiving concerns
8. Concerns, questions, and areas of disagreement or agreement
9. Plan of care or decisions made
10. Next steps or follow-up plan with the patient and family
11. Time the meeting started and ended

From Widera¹⁶, Singer²⁷

expectations for the future.⁴⁹ When delivering bad news, the APRN must use all the principles of good communication, including active listening, open-ended questions, and attention to emotion, as previously described. Just as with a family meeting, appropriate preparation is essential. Preparation includes familiarity with the medical history, arranging the best physical setting possible, and ensuring that the appropriate team members are present.³⁶ Beginning with a question to elicit understanding is the best starting place.⁴⁹ After hearing from the patient and family, correct misunderstandings or validate accurate information.

Communication experts recommend using a warning phrase, commonly referred to as a “warning shot,” to allow the patient and family to prepare—something like, “I have some serious news to share with you.” After delivering the news, pause and allow the information to be absorbed.⁴⁹ Give the patient and family adequate time to express emotions and use open-ended questions. Continuously assess their nonverbal communication and response to the news. Whether the meeting ends after the bad news is delivered or if a detailed plan of care is developed, the APRN should summarize and clarify plans for follow-up with the patient and family before adjourning.

DISCUSSING PROGNOSIS

Discussions of prognosis are common during family meetings and palliative care consultation.⁵⁷ Predictions of survival may weigh heavily in decisions to pursue aggressive treatments or choose a less aggressive plan of care.⁵⁸ The palliative APRN must be prepared for these discussions and knowledgeable about both prognostic indicators and limitations in the ability to prognosticate. In several studies, surrogate decision-makers have indicated that (1) avoiding these discussions is an unacceptable way to maintain hope and (2) they wanted to receive more than only bad news.⁵⁷ “Hope for the best and prepare for the worst” addresses the challenge of providing an honest prognosis with hope and optimism.

Help families not only hear but see the prognosis. Do not give only prognostic information but also provide education on the disease process using drawings or radiographic images. Showing the evidence of the condition or the effect of treatments helps the APRN put the discussion into the context of the patient’s goals. Instead of asking, “Do you have any questions?” the APRN should ask, “What questions do you have?” Although surrogates sometimes want numeric estimates of prognosis, clinicians may be reluctant to provide them for fear of misinterpretation.⁵⁵ For example, a 95% estimate of death may be reframed positively by a family as a 5% chance of survival. Given the challenges of providing precise estimates of life expectancy, a common approach is to provide ranges (e.g., hours to days, days to weeks, weeks to months). Performance scales, such as the Palliative Performance Score, may be used to support prognostication.⁵⁹

Communication of prognosis may be an iterative process involving information provided at a family meeting being reinforced over time by various members of the team, including the bedside nurse and social worker. Surrogate decision-makers may employ coping strategies to balance the tension between honesty and hope.

1. *Focusing on minutia:* Small positive changes, such as improvement in urine output or respiratory rate or the patient’s level of consciousness, provided both information and hope.⁶⁰
2. *Relying on personal knowledge and beliefs about the patient:* The decision-maker believes he or she can interpret a patient’s response that a stranger would not be able to identify or the patient has unique strengths unknown to the medical team. For example, the family may believe a facial expression is special communication meant only for them and not the medical team or that the patient is a “fighter.”⁶⁰
3. *Seeking information and support from sources outside of the medical team:* The decision-maker may contact friends, family, and others with similar experience or a medical background, as well as online resources.⁹
4. *Avoidance and disbelief:* Some surrogates avoided doctors whom they perceived as pessimistic, or they expressed blatant disbelief.⁶⁰

5. *Optimism grounded in religious beliefs or a worldview different from that of the medical team:* For example: “The doctors do what they need to and God will do the rest.”⁵⁴ Research has illustrated the limitations of the palliative care clinician’s ability to predict life expectancy.⁶¹

The significance of functional prognosis should not be underestimated. For many persons, loss of cognitive or functional abilities resulting in dependence on others would be in conflict with their goals and values and may directly impact decision-making. Studies have demonstrated that the most common prognostic error among providers, including palliative care clinicians, is overestimating life expectancy.⁶¹

Predictions of survival for patients with specific diagnoses have also been studied. For example, in cancer patients, functional status is the single greatest prognostic factor.^{45,51} The Karnofsky Performance Status (KPS) score, Palliative Performance Scale (PPS) score, and Eastern Cooperative Oncology Group (ECOG) score are commonly used to rate a patient’s performance status.^{45,62} For patients with a poor functional status (defined as spending more than 50% of their day in bed or chair), a rough estimate of survival is less than 3 months.^{45,62} For patients with end-stage renal disease on maintenance hemodialysis, several variables have been independently associated with mortality, including older age, dementia, peripheral vascular disease, decreased albumin, and a negative answer to the “surprise question” (“Would I be surprised if my patient died within the next 6 months?”).⁶³ Predicting survival in disease states like congestive heart failure remains difficult given the increasing use of advanced therapies, such as transplantation and ventricular assist devices (VADs), as well as the risk of sudden death.⁶⁴

Prognosis can include much more than just survival estimates. Medical decisions should not be made in isolation, but rather in context with long-term implications. Together, this may help patients and families make more informed choices. Patients and families need explanation that treatments like feeding tube insertion may lead to other consequences, such as skilled nursing facility placement or use of physical and chemical restraints.⁶⁵

DISCUSSING TECHNOLOGY AND WITHHOLDING, DISCONTINUING, WITHDRAWING TREATMENTS IN FAMILY MEETINGS

Use of aggressive therapies and technology is common in seriously ill patients and those at the end of life.⁴³ APRNs must be knowledgeable about commonly used technologies and how the use of technology fits into the context of the patient’s goals of care¹⁰ (see Chapter 54, “Discontinuation of Cardiac Technology”; Chapter 55, “Discontinuation of Respiratory Technology”; and Chapter 56, “Discontinuation of Other Life-Sustaining Therapies”). In family meetings, use of technology should be closely tied to the patient’s values and goals as well as to what is feasible and the long-term implications of particular decisions.¹⁰ Although withholding and

discontinuing therapies are viewed as ethically equivalent, they may be perceived very differently.^{41,66} Families may feel they are playing a more active role or are the cause of a poor outcome by discontinuing a therapy already in use rather than never initiating it in the first place. Clinicians may also make a moral distinction between withholding and discontinuing and may be more comfortable withholding than discontinuing therapies^{66–68} (see Chapter 53, “Navigating Ethical Dilemmas”).

The APRN must recognize and support families who are struggling with these painful decisions and help them prepare for outcomes that will include consequences of treatments.⁶⁸ Reframing the situation may be helpful. For example, if a decision is made to discontinue ventilator use in a patient with end-stage lung disease based on knowledge of the patient’s wishes, the disease is allowed to follow its natural course and is actually the cause of death, not the removal of the ventilator. Words matter greatly in these discussions. Well-intended clinicians may use phrases like “withdrawing care” when they really mean discontinuing a specific treatment.⁶⁹ The palliative APRN must communicate that, although specific treatment is no longer to be used, attention to care and comfort will continue. See Section IX of this book, “Ethical Dilemmas,” which includes chapters on the discontinuation of cardiac, respiratory, and other interventions.

RESUSCITATION

CPR techniques were developed in the 1960s with the purpose of supporting individuals experiencing a significant out-of-hospital healthcare emergencies, such as a heart attack, drowning, or accident. They were not intended to become part of routine treatment at the time of death from a terminal illness.⁷⁰ In our current healthcare system, though, use of CPR is an “opt out” request, and the default assumption is that everyone desires CPR.⁷⁰ Many patients and families do not understand the low likelihood of survival in a person with advanced disease and may believe that the chances of a good outcome are much higher.⁷¹ Discussing do-not-resuscitate (DNR) status during a family meeting is best done in the context of the overall goals of care.⁷² Making recommendations tied to the ability of resuscitation attempts to meet the patient’s goals rather than asking a question is often a more effective approach. Phrases like “If your heart and lungs stop, do you want to us to do everything?” The phrases “Restarting your heart” and “Putting on a breathing machine” convey a false assurance of success and reversibility.⁴⁵ Families may worry that if doing everything possible includes CPR, then the opposite is doing nothing. Patients and families may be under the false assumption that “do not resuscitate” is the same as “do not treat” or being abandoned.⁷³ The APRN should reassure the patient and family that they will continue to be cared for and that treatments that support their goals will continue. The following dialog is a good example of explaining DNR status.

PATIENT: I would never want to be kept alive on machines . . .
APRN: You have told me that you would prefer your death to be peaceful and that you want to be at home. I would

recommend that we make your wishes clear to the medical team and place a do-not-attempt-resuscitation order in your medical record. We will continue to provide all the appropriate treatments to manage your symptoms and support the quality of life that we have discussed.

IMPLANTABLE CARDIAC DEVICES

Despite the benefits of implantable cardiac devices such as pacemakers, VADs, and defibrillators in terms of improving and lengthening life, all of the patients who receive them will eventually reach the end of their lives⁷³ (see Chapter 13, “The Palliative APRN in Specialty Cardiology”). As many as 30% of patients with implantable cardiac defibrillators receive shocks as they approach the end of life, which can lead to significant distress for patients and families alike.⁷³ Ideally, conversations about deactivation should occur when the devices are implanted, and the issue should be readdressed as the underlying heart disease progresses.⁷³ Decisions about device deactivation should occur in the context of goals of care and resuscitation discussions during a family meeting. The APRN should obtain a history from the patient and family about their past experience with a device (e.g., prior defibrillator activations). Some patients may have little memory; others may describe the episode as being painful or frightening (“being kicked in the chest” or “an explosion”). If a decision is made to deactivate the device, the APRN should prepare those involved for what to expect when the device is deactivated. Patients may incorrectly assume that deactivation is a surgical procedure or that death will occur when the device is turned off. The APRN should assess the patient’s and family’s understanding and provide appropriate education about the deactivation process and its implications.

VADs are surgically implanted pumps to support damaged left, right, or both ventricles. Discussion related to discontinuation of VAD therapy should be in the context of goals in a family meeting when there are complications or the device no longer supports the desired quality of life. The APRN should advise patients and families that after VAD discontinuation time of survival may range from a few minutes to a few days⁷⁴ (see Chapter 54, “Discontinuation of Cardiac Therapies”).

MEDICALLY ASSISTED NUTRITION AND HYDRATION

For many patients and families, medically assisted nutrition and hydration are not medical treatments but symbols of love and care. Any suggestion that these elements be withheld or discontinued can be perceived as tantamount to neglect. Current guidelines advise against placement of percutaneous endoscopic gastrostomy tubes (PEG) in patients with advanced dementia, yet many of these tubes are inserted.^{65,75} Clinicians may lack knowledge about risks and benefits of these tubes and may feel pressure from families to place them or fear litigation.⁷⁵ During a family meeting, it is important for the palliative APRN to help families make the connection between medically assisted nutrition and hydration as a treatment and how it supports or does not support the goals

of care. For example, use of medically administered nutrition and hydration in a frail elderly person with advanced dementia will not help the person get stronger, prevent aspiration, reverse the underlying disease, or prolong life.⁶⁵ Without the clinician's direction, families may continue to harbor erroneous beliefs about the benefits of medically administered nutrition and hydration. The astute palliative APRN can show the family how they can demonstrate love and care in other ways, such as inviting family participation in careful hand feeding or providing oral or other physical care⁶⁵ (see Chapter 56, "Discontinuation of Other Life-Sustaining Therapies").

CRITICAL CARE OR EMERGENCY DEPARTMENT FAMILY MEETINGS

Twenty percent of all deaths in the United States occur in an ICU.^{38,55} Decisions to withhold or discontinue specific ICU treatments are often done in the context of a family meeting.¹⁴ Family meetings in the ICU have been associated with higher levels of satisfaction, and guidelines recommend that family meetings occur within 72 hours of an ICU admission.³⁶ Family meetings in the ICU have been associated with higher mortality rates, which may reflect the increased importance of and attention to communication in end-of-life situations.¹⁴ Improved communication and additional family support in the ICU have been associated with a shorter ICU length of stay.^{38,48}

The need for family meetings in the emergency department (ED) may parallel those in the ICU. ED visits may be precipitated by a health crisis in which discussion of prognosis and treatment is of vital importance.⁷⁶ (See Chapter 10, "The Palliative APRN in the Emergency Department.") The chaotic ED environment presents significant communication challenges independent of the crisis situation. Palliative care consultation in the ED is a growing area and has been associated with improved quality of life without change in survival.⁷⁷ More research is needed to understand the use of family meetings in the ED.

When a person is ill enough to require ICU care, it may be too late to discuss values and wishes with the patient, and the information must be obtained from surrogates.^{12,27,38,54} The "U" in the VALUE mnemonic (Box 33.4), understanding the patient as a person, involves engaging surrogate decision-makers by using open-ended questions. The APRN can ask questions such as "Tell me about your loved one," "What things did he/she enjoy doing?," "What was life like for him/her prior to this illness?" to help the family or surrogate decision-maker construct a picture of the patient and what was important to him or her.^{5,7,10,12,47} Discussions should point surrogates toward what the patient would have expressed for him- or herself rather than what the surrogate would want, or to determine what is in the best interest of the patient when his or her wishes are not known.⁹

Of all of the ICU technologies, mechanical ventilation is the most common life-support measure to be discontinued.³⁸ Other ICU technologies that may be discussed during

family meetings include continuous renal replacement therapy (CRRT), vasopressors, and extracorporeal membrane oxygenation (ECMO). The APRN should have a basic understanding of these therapies and the implications for their use or discontinuation if they are to be addressed during a family meeting.

DEALING WITH CONFLICT

Conflict in family meetings is to be expected.^{58,78,79} Conflict may be defined as a disagreement or difference of opinion on the management of a patient involving more than one individual and requiring a decision or action.^{58,78} The conflict may be between family members, within the team, or between the team and the family. Nurses may be the team member most likely to identify conflicts.^{58,78} A common area of disagreement between team and family and between family members is around decisions to withhold or discontinue life-sustaining therapies.^{58,78,79} Decision-making around life-sustaining therapies may be complicated by uncertainty about the clinical outcomes and prognostic challenges. Conflict often arises when families request more aggressive treatment than the team believes to be appropriate.⁵⁸ Other sources of conflict may include the surrogate's inability to make a decision or the lack of available decision-makers.

The burden of decision-making is not insignificant for families who must process complicated information during a time of uncertainty and unprecedented stress. The shift toward autonomy in decision-making has, in some cases, allowed the healthcare team to take a passive approach and avoid the obligation to provide recommendations based on their experience and medical knowledge.⁷⁹ Palliative APRNs should be aware of the risk factors for conflict that have been identified.^{58,78}

1. An ICU setting where life-sustaining treatment is in use or being considered
2. An unmarried patient
3. A decision-maker (patient or family member) who is medically naïve or views the body in more mechanistic terms
4. A decision-maker (patient or family member) who has underlying cognitive or mental health concerns
5. A prior history of poor coping skills (in patient or family member)
6. A history of substance abuse (in patient or family member)
7. A culture in which the patient or family member is traditionally mistrustful of the medical establishment
8. A belief system of patient or family member that allows for miracles as the sole option

When there is conflict about the goals of care and the reality of the medical situation, recognize and respond to

emotion. Grief, anger, mistrust, unfinished personal business, and guilt may lie beneath the more visible conflict.⁵ Using emotion-handling skills such as NURSE (see Table 33.1) or “wish statements” can help diffuse conflict.³⁵ By saying “I wish there was a more effective treatment for your mother’s condition,” the APRN is entering into the patient’s situation empathically but at the same time acknowledging that the situation is not reversible.⁵ Empathic responses, especially when there is conflict, will help to foster trust and build a therapeutic relationship.^{3–5}

Although lack of information may also precipitate conflict, attempts to convince the family of a certain viewpoint may deepen the divide. Seeking understanding and clarity about the family’s position is essential: “I heard you mention that you want everything done for your loved one.” Please help me understand what ‘everything’ means to you.” Even when there is disagreement, it is important to seek common ground. It may be that the medical team and family can only agree that they both want what is best for the patient and decide on a time to meet again.

SUMMARY

Family meetings are an essential tool in palliative care. More research is needed to examine the best timing, participants, and methods for use of family meetings. By the nature of their education and expertise, palliative APRNs often lead these meetings. APRNs must be skilled in principles of good communication, including attending to emotion and negotiating conflict, to provide effective care through family meetings. The APRN should pay careful attention to advance preparation and take a “time out” to make sure that everyone is ready before continuing. Above all, proceed with sensitivity, employ empathy, and listen before speaking.

COMMUNICATION AT THE END OF LIFE

Marlene E. McHugh, Penelope R. Buschman, and Susan M. Delisle

KEY POINTS

- Communication at the time of death requires sensitivity and compassion.
- The palliative advanced practice registered nurse (APRN) must communicate effectively and compassionately with the patient, family, and healthcare team at the end of life.
- Using a family systems theoretical framework enhances the ability of palliative APRNs to assess and intervene with patients and families at the end of life.
- The COVID 19 pandemic has highlighted unique communication challenges for the palliative APRN.

CASE STUDY 1: FAMILY DECISION-MAKING IN A PATIENT WITH DEMENTIA

Mr. H was a 76-year-old man with a history of hypertension and mild dementia who resided in a skilled nursing facility. He was brought by ambulance to the emergency department (ED) with acute dyspnea and fever.

The ED advanced practice registered nurse (APRN) who assessed him in the ED telephoned Mr. H's healthcare agent, his eldest daughter, to disclose that his clinical picture of respiratory distress, confusion, fever, and hypoxia, along with his chest imaging, were consistent with severe pneumonia, and that intubation, mechanical ventilation, and intensive care unit (ICU)-level care would be required. The APRN advised that even with this manner of invasive support, his overall prognosis was poor given his age and severity of illness. His daughter was then asked to provide consent for treatment. Although she had traveled to the hospital, she was not allowed entry to the ED due to COVID-19 no visitor rules. Her father had not done any advance planning, nor had he ever expressed his thoughts about resuscitative measures. Therefore, she requested a conference call between the medical staff and her other siblings in order to have a fuller discussion regarding what her father would have wanted under the current circumstances. However, she was told that these decisions had to be made quickly, as his condition was deteriorating. She gave verbal consent for intubation, ICU transfer, and specified his code status as full code.

Mr. H spent the subsequent 5 weeks in the ICU with COVID-19 and underwent antiviral treatment and antibiotics for a superimposed bacterial infection. His hypoxia improved, but he remained unable to tolerate ventilator weaning. His family had

been unable to communicate with him because he required sedation and paralytics in order to promote ventilator synchrony. In response to the no visitor policy, the ICU team developed an ad hoc position called the "family liaison." The ICU family liaison APRN provided daily medical updates via telephone to the family and utilized a tablet to allow the children to see their father. With the tablet placed by his ear, although he was unresponsive, they could speak to him on a regular basis.

Despite weaning sedation, Mr. H had persistent ventilator dependence, so the team planned a virtual family meeting to discuss options for care, including the indications for tracheostomy placement. The ICU family liaison APRN and ICU social worker coordinated a video conference that included the ICU attending physician, a Spanish translator, and the patient's children. Potential treatment options included compassionate extubation and comfort-focused care or tracheostomy surgery. The team advised that tracheostomy might facilitate ventilator weaning, and the family provided consent for this intervention.

After the tracheostomy and two additional weeks of ventilator support, Mr. H was still unable to tolerate lessening of ventilatory support. In a second virtual family meeting, the hospital team was reassembled to confer with the patient's children because the patient was deemed to continue to lack capacity. The medical team proposed the surgical implantation of a percutaneous gastrostomy tube, which would make him a candidate for discharge to a long-term facility that could accommodate tube feedings and ventilator support. In this discussion, his children collectively felt that tube feedings and indefinite tethering to a ventilator would not be what their father would have wanted.

At the request of the ICU team, a palliative APRN called the patient's daughter and organized a conference call with all the children, allowing the family to express their views on their father's values and what they hoped for him. Interdisciplinary support from palliative care social work and chaplaincy was also provided telephonically. The family elected to transfer Mr. H to the hospice unit for discontinuation of the ventilator and intensive symptom management. In addition, there was the opportunity for in-person goodbyes because the hospice unit was able to accommodate family member visitation at imminent end of life.

INTRODUCTION

Communication across settings at the end of life involves not only the patient and family but also multiple APRNs and

other members of the healthcare team. The case study demonstrates two essential teaching points: effective communication skills used by the APRN while caring for patients with serious or life-threatening illnesses and the need for earlier palliative care consultation. The current pandemic highlights various communication challenges that are unique during this time.¹

The work of palliative nursing is born of the knowledge of family systems theory, communication skill, and bereavement theories, as well as expert assessment and patient/family teaching. It is also made manifest in a delicate dance of unspoken communication between the nurse and the relationships served: the intuitive knowing of nurses as relationships change dramatically, as death approaches, and ultimately in the basic tenet of palliative nursing that our care is family-centered and, if done well, is relationship-centered.²

The American Nurses Association (ANA) requires nurses to provide comfort, and this includes expertise in the relief of suffering whether physical, emotional, spiritual, or existential. Increasingly, this means that the nurse's role includes discussing end-of-life choices before a person's death is imminent, being present at the time of death, and providing care to the family dealing with loss.³ The following sections from the *Code of Ethics for Nurses* serve as support for this position statement.

Provision 1.2

- Nurses establish relationships of trust and provide nursing services according to need, setting aside any bias or prejudice. When planning patient-, family-, and population-centered care, factors such as lifestyle, culture, value system, religious or spiritual beliefs, social support system, and primary language shall be considered. Such considerations must promote health, address problems, and respect patient decisions. The respect for patient decisions does not require the nurse agree with or support all patient choices (p. 1)

Provision 1.4

- Nurses should promote advance care planning conversations and must be knowledgeable about the benefits and limitations of various advance directive documents. (p. 3)

Provision 2.3

- Collaboration intrinsically requires mutual trust, recognition, respect, transparency, shared decision-making, and open communication among all who share concern and responsibility for health outcomes. Nurses assure that all relevant persons, as moral agents, are participatory in patient care decisions. Patients do not always know what questions to ask. Nurses assure informed decision-making by assisting patients to secure the information that they need to make choices consistent with their own values.⁴ (p. 6)

In 2016, the ANA underscored the need for nurses to collaborate with other members of the healthcare team to ensure adequate symptom management, optimal support, and expertise in understanding and navigating the ethical issues involved in care. More specifically, nurses are expected to be able to discuss death comfortably with patients and families, encourage

their participation in decision-making (including goals of care and advance directives), and also collaborate with care team colleagues to ensure that timely and accurate information is being shared.³ This position statement provides direction to nurses as they support and advocate for patients and families in preparation for impending death.

In 2017, the ANA in partnership with the Hospice and Palliative Nurses Association (HPNA) published the *Call for Action – Nurses Leading and Transforming Palliative Care*, challenging nurses to be leaders in palliative care and delineating roles for primary and specialty care.⁵ Identifying nurses as critical partners in the care of persons and families living with serious and life-limiting illness requires them to develop astute listening and communication skills as they guide patients and families in goals-of-care conversations and care planning discussions.

Effective communication skills are requisite in palliative care. These include the ability to share developmentally appropriate information, practice active listening, encourage the expression of goals and preferences, and assist with medical decision-making. In addition, skill is required in advocating for patients by extending communication to include all members of the healthcare team.⁶ The function of communication is to reduce uncertainty and to provide a basis for action. Information conveyed wisely and with sensitivity can improve the patient's and family's ability to act now and in the future and strengthens the patient–nurse relationship. In contrast, ineffective communication can cause harm, “paralyze” action, and destroy the relationship. Nurses must have the skills necessary for these discussions to provide valuable support for patients to achieve their goals at the end of life.^{5,6}

COMMUNICATION FOR THE PALLIATIVE APRN

While there is widespread agreement about the importance of effective communication in palliative care and, to that end, the development of myriad tools in the form of protocols, algorithms, and step-wise guides, the approach has been largely pragmatic. While valuable in terms of providing language to guide the APRN into sensitive conversation, these tools have limitations. Ferrell writes, “that true advances in communication in serious illness will only occur through a deeper reflection. Beyond the right words or steps, what are the real human dynamics. . . ? What is the essence of a compassionate conversation?”⁷ (p. 304)

Communication in palliative care seen as “compassionate conversation” has the potential to create a deep relational connection between caregiver and patient. It is this form of communication woven through the fabric of care that begins at the time of diagnosis and continues throughout the life of the patient and in bereavement for the family. Communication is beyond information sharing about a disease, its treatment, and the prognosis. It is about establishing a context of trust and truthfulness. Sourkes writes that truth is neither principle nor rule but rather a state in which there can be interaction, astute listening, and deep respect.⁸ Trust unpins communication within the partnership among patient, family, and caregiver and is integral to the practice of palliative care.⁸

Nursing theorist Hildegard Peplau's theory of interpersonal relations provides a conceptual framework derived in part from the empirical study of human interactions that is helpful to an understanding of communication. In her seminal work, Peplau describes the nurse–patient relationship as the human connection central in a most fundamental way to the provision of care.⁹ Within this relationship, which is largely unscripted, is the potential to connect and overcome separateness, creating the essence of communication, especially at the end of life.⁹

Communication, as a broad construct, includes any behavior or action, intentional or not, that influences the attitudes, ideals, or responses of another human being. Communication is transactional and occurs between and among persons. Yet Levetown notes that, too often, caregivers place emphasis and focus on conveying information, with little regard for feelings, relationships, and continuity in care.¹⁰

One of the most complex and amazing developments of the first 3 years of life is the transformation of newborns who communicate through body language and vocalizations into children who use multiword utterances to describe their imaginations, emotions, memories, and wishes. While infants can communicate with their caregivers at birth, the reciprocal partnership in which complex symbolic ideas are exchanged, conflicting agendas are negotiated, and feeling states are shared must await a series of developmental advances. These advances depend on both the hardwiring in the child's central nervous system and, over time, the child's experiences within a family. Thus, the factors that support the evolving development of the ability to communicate are found in the family and social environment. Language, one means of communication, is a complex, conventional system of symbols that are combined and used in a rule-governed way. Language is culturally bound and learned initially within the family of origin and later in education systems.¹¹ Communication occurs in multiple ways and forms, in addition to the written and spoken word, through the medium of movement, expression, music, art, and, of course, play.

Communication in palliative care and especially at the end of life is the focus of this chapter. Understanding communication in its broadest sense, appreciating the significant barriers altering its effectiveness, and developing strategies both personal and in practice ultimately will enhance the work of palliative nursing. Conscious nonverbal communication is rarely practiced, yet it can be as powerful as verbal communication at the end of life.¹²

PALLIATIVE APRN COMMUNICATION AT CRITICAL JUNCTURES

The palliative APRN assesses the patient's and family's communication style, with attention to primary language, culture, religious beliefs, and literacy (in both ability to understand language and health literacy). When English is not the primary language of the patient or family, a translator (not a family member) must be enlisted either in-person, virtually, or telephonically. Understanding cultural diversity and cultural preferences and the need for equity and inclusion must characterize the APRNs palliative care practice. Support and respect for

cultural preferences during illness, the illness continuum, and end of life are integral to the delivery of culturally congruent care.¹³

Before the palliative APRN communicates with the patient and family, they must gather essential information. The APRN must understand the patient's past history diagnosis, the underlying pathophysiology of the condition, the current medical treatment and plan for future treatment, any side effects of treatment, whether a treatment is curative or palliative, and where the patient is being treated. It is also important that the palliative APRN understand prognostic scores like Palliative Prognostic Score, the Karnofsky, and Eastern Cooperative Oncology Group scales, which will help determine whether treatment is an option based on the patient's functional status.

Often there is overlap in the roles and functions of palliative interdisciplinary team members. This can be a challenge for palliative APRNs, given their advanced educational preparation and the long-standing relationships that they may have with patients and families. It is important for the palliative APRN to recognize that the characteristic of a well-functioning team is that all members share equal responsibility for care and promote nonhierarchical team structures.

Prior to family meetings, it is best practice that the palliative APRN organize a team pre-meeting. The purpose of the "meeting before the meeting" is to determine which member will lead the meeting and what members of the team will provide information to the patient and family. Various team members should be included in this meeting, with the focus being organized delivery of information (Box 34.1).

Box 34.1 ONGOING COMMUNICATION WITH THE FAMILY

1. Coordinate a meeting with the family, which may be a virtual meeting. Make sure to have an interpreter, if there are language barriers.
2. Offer information about their loved one's care and treatment options.
3. Gain insights as to their understanding about the present situation.
4. Reconfirm for the family the contact information for the treating team, the nursing unit, and the primary nurse.
5. Discuss if care is congruent with the patient's wishes.
6. Acknowledge the psychological and emotional work of trying to make care decisions for a loved one if they are not able to be present.
7. Offer and provide support in family decision-making. This may include an offer of chaplaincy or social work.
8. Always ask if they have any questions regarding the care of their family member.
9. Before ending the meeting, summarize what was discussed and the next steps.

Adapted from End-of-Life Nursing Education Consortium.¹

COMMUNICATION ACROSS THE TRAJECTORY OF ADVANCING ILLNESS AND AT THE TIME OF DEATH

As illustrated in Figure 34.1, communication with patient and family changes over the course of advancing illness, building on early assessment, a growing trust, and a deepening connection. The focus shifts from advance care planning discussions and settings for care, sharing bad news at the time of diagnosis, to maintaining connection through transitions in illness. The preference for site of death may change based on the patient's wishes, the symptom burden, and the family's resources. Participants in the planning process are palliative care team members, primary care providers, and the ever-changing staff of physicians and nurses on hospital units, as well as home care providers. Flexibility is required as new information and options are offered and changing goals of care are reviewed. Moving across this trajectory provides an opportunity for palliative APRNs to be proactive in anticipating care issues and integrating them with the patient's and family's individual needs. In addition, APRNs provide guidance in the context of a nurtured trust.

Palliative APRNs may have patients who express the desire to die. Van Loon posits that wishes to die expressed close to the end of life have many meanings requiring evaluation. They may reflect the person's wish to end a life in which suffering has become unbearable or burdensome.¹⁵ Palliative APRNs may evaluate patients for depression and suicidal ideation using the PHQ-9 depression scale.¹⁶ Breitbart et al. report that desire for

hastened death among terminally ill cancer patients is common and that depression and helplessness are strong predictors of this desire. The authors recommend that interventions including pharmacological and behavioral treatment as well as social support be integrated into palliative care for their patients.¹⁷

COMMUNICATION WITH FAMILIES ABOUT THE STAGES OF DYING

*I've learned that people will forget what you said,
people will forget what you did, but people will never
forget how you made them feel.*

Carl W. Buehner (1971)

The concept of anticipatory guidance is often used by palliative APRNs to prepare a patient and family for a specific developmental milestone or crisis. In working with families whose loved ones are imminently dying, the palliative APRN should expect to discuss the dying trajectory, death itself, and common concerns that they may have and are afraid to ask. Many families will be interested in understanding the process of dying and what they should expect. Communication helps their final planning stages as a unit of care. However, some families will choose not to have information shared with them, and this should be respected. Recognition of the trajectory of imminent death is essential for clinicians in order to provide the most appropriate interventions for the patient and family. Some commonly anticipated questions are listed in Box 34.2.

Actions for Palliative APRNs

Trajectory of Advancing Illness

Figure 34.1 Communication across the trajectory of advancing illness and at time of death.

From McHugh ME, Buschman P. Communication at the time of death. In: Dahlin C, Coyne P, Ferrell P, eds. *Advanced Practice Palliative Nursing*. Oxford: Oxford University Press; 2016: 305–404.¹⁴

Box 34.2 COMMON QUESTIONS FROM FAMILIES

- How long does my loved one have?
- Should I/we stay at the bedside?
- Is my loved one in pain/suffering?
- What do we do after my loved one has passed away?

From McHugh, Buschman.¹⁴

The proximal reality of a patient's death is typically very difficult for families. APRNs are often in a position to provide guidance for families observing clinical changes in their loved one. Table 34.1 lists the stages of the dying process that APRNs can discuss with families as they observe the clinical stages of dying.

Without an invitation, families may be reluctant to initiate discussion, fearful of hastening death by speaking of it. The APRN may use the following questions with patient and family to promote planning for an expected death:

1. Have you thought about what it will be like for your family when your loved one dies?
2. Sometimes families find it helpful to discuss planning for rituals after death such as a funeral, memorial service, or some special remembrance for your loved one before they die. Would this be helpful for you?
3. Have you considered how you will include family members, particularly young children, in your family ritual of mourning?

The emphasis of end-of-life communication with the patient is presence, standing with and bearing witness, providing comfort for the family, discussing any wishes for end-of-life rituals and funerals, and making referrals to hospital- and community-based resources. Holmberg describes poignantly in the following passage communication in action between family caregivers and palliative nurses at the time of death. When knowing that no words could make the loss bearable, there was just empathy and compassion to offer.¹⁹

The nurses made the examinations that are legally required to declare death. Then they and the family all gathered in the kitchen. There was a time to tell

about the last hours, there were opportunities to weep, to share hugs. The nurses said they would help out dressing my son and arrange for the rest of the family to say goodbye. His wife changed his clothes and ironed his shirts. One of the nurses and my son's younger brother arranged my son on his bed and lit a candle in the window. The nurses took charge of the practicalities. They arranged for the last transportation. And they stayed as long as the family members wanted them to. There was an atmosphere of respectful silence in the house.¹⁹ (p. 283)

SUDDEN, UNEXPECTED DEATH: SUICIDE, HOMICIDE, VIOLENCE, ACCIDENTAL INJURY, SUDDEN ONSET, OR WORSENING OF DISEASE

The challenges are significant when a person dies unexpectedly and the family does not have an ongoing connection with a caregiver. Much of the initial communication focuses on events surrounding the death as well as on resources in the community for the family (Figure 34.2). The APRN must remain in the room to answer medical questions and lend a respectful presence. Because of the unexpected nature of the death and lack of preparation, family members may be in shock and require the services of social workers, chaplains, and psychiatric staff. Family members may require assessment for self-harm, harm to others, or damage to the environment.

The palliative APRN meeting the family for the first time will be asked for information and clarification. Accompanying the family to the emergency room or morgue to view the patient's body requires a calm presence and the ability to prepare the family for what they will see, such as changes in skin color or visible injuries. If the family wishes to touch their loved one, they should be prepared for changes in body temperature. Immediately after death, family members may be encouraged to touch the body's core area, rather than the extremities.

In unexpected death, the palliative APRN, in concert with team members, may refer families to community resources for bereavement counseling. Family members who threaten suicide or who may be at risk for suicide may need to be accompanied to a hospital ED by family members or by the APRN for a full psychiatric evaluation.

Table 34.1 STAGES OF THE DYING PROCESS

EARLY	MIDDLE	LATE
• Bedbound • Loss of interest and/or ability to drink/eat • Cognitive changes: increased time spent sleeping and/or delirium	• Further decline in mental status to obtundation (slow to arouse with stimulation; only brief periods of wakefulness) • Terminal secretions—pooled oral secretions in the larynx as a result of loss of the swallowing reflex	• Coma • Fever • Altered respiratory pattern—periods of apnea, hyperpnea, or irregular breathing • Mottled extremities

From Weissman.¹⁸

Figure 34.2 Communication at the time of death and beyond with family. From McHugh ME, Buschman P. Communication at the time of death. In: Dahlin C, Coyne P, Ferrell P, eds. *Advanced Practice Palliative Nursing*. Oxford: Oxford University Press; 2016: 305–404.¹⁴

BARRIERS TO COMMUNICATION AT THE END OF LIFE

Perhaps the most obvious and far-reaching barrier to the provision of therapeutic communication at the end of life lies in our failure to teach and model the process. Levetown notes that far more time is spent focusing on facts and descriptions of procedures than on the process of communication. Moreover, efforts to elevate healthcare communication, empathy, and patient- and family-centered care as competencies within education have thus far failed.¹⁰ Clearly, communication across the trajectory of illness and so importantly at the end of life deserves space and time in our curricula and clinical supervision. In specific vulnerable populations of patients, circumstances and conditions impede the communication process and challenge the palliative nurse to find innovative approaches.

GERIATRIC PATIENTS WITH COGNITIVE AND SENSORY DEFICITS

Geriatric patients may lose physiological function and capacity, which serve as more powerful determinants of prognosis than chronological age.²⁰ Delirium and dementia are the two major cognitive deficits in the elderly population. Both complicate the assessment of pain and symptoms in those with advanced illness and interfere with communication in general. When cognition and language are limited, communication becomes behavioral in nature.²¹ Contrary to current thinking, behaviors should be seen as forms of communication, rather than as unpredictable or random events with no meaning. To intervene, the palliative APRN must attempt to identify a message in the behavior.

The visual and hearing impairments common in older adults further limit verbal and nonverbal communication.²⁰ In addition to these deficits, the presence of

multiple comorbidities challenges the palliative nurse's ability to derive goals of care. The APRN should make sure the patient has hearing aids or glasses, if needed, to promote communication.

PATIENTS WITH DEPRESSION, ANXIETY, POSTTRAUMATIC STRESS DISORDER, AND SERIOUS PERSISTENT MENTAL ILLNESS

While the recommended therapeutic response to patients with psychological distress at the end of life is to listen and provide support, patients with serious persistent mental illness pose significant challenges. Here, too, the palliative APRN observes behaviors and mannerisms as means of communication, respecting the need for space and sometimes the inability to tolerate touch. For many of these patients, families are disengaged and not involved in care. This population is underserved and truly vulnerable; they may live in jails or shelters or on the streets, unable to access adequate palliative care. Goldenberg, Holland, and Schachter note that palliative patients with serious mental illness have not been studied and their prevalence is unknown.²² An appalling lack of articulation between the mental health and other healthcare systems contributes to the lack of palliative and end-of-life care for this population.²³ Baker writes that a combination of factors, including the psychiatric symptoms exhibited by these patients and providers' attitudes and feelings toward the mentally ill, influence planning for end-of-life care (Box 34.3).^{24,25} The palliative APRN, in collaboration with

Box 34.3 COMMUNICATION WITH PERSONS WITH COGNITIVE AND DEVELOPMENTAL DISABILITIES

When caring for a developmentally delayed patient at the end of life, the palliative APRN must engage family members and caregivers in discussion. The following strategies promote more compassionate care.

- Allot extra time.
- Assist parents and/or caregivers to identify unspoken wishes that may be displayed by their developmentally disabled child/adult, such as repeated self-removal of feeding tubes.
- Invite trusted family friends, physicians, and caregivers to assist parents and/or caregivers with decision-making.
- Take time to listen, talk, and develop trust and rapport with the family.
- Introduce the topic of advance directives early. Encourage parents to think about the next potential admission.
- Recognize the differences and similarities between the population of developmentally disabled persons and the general population.²⁶
- Provide more opportunities for expressions of grief.²⁷

a psychiatric nurse practitioner, can provide compassionate end-of-life care, as illustrated in the second case study.

CASE STUDY 2: CLINICAL DEPRESSION IN A PALLIATIVE CARE PATIENT

Jane was a 36-year-old woman who had been diagnosed as an adolescent with major depressive disorder. She contracted HIV as a young adult and was estranged from her family of origin and her only son. She sought services from an agency providing medical and psychiatric services as well as residential care. Jane was enrolled in a methadone maintenance treatment program in her residence. As her HIV/AIDS worsened, Jane was encouraged by staff and her psychiatric mental health nurse practitioner (PMHNP), Joann, to agree to inpatient hospitalization, where she would be able to receive palliative care. Jane adamantly refused, stating that she wanted to remain at “home” in the residence, where she was known by staff and other residents. Joann agreed to coordinate a home hospice program involving a community-based palliative APRN, Katherine, and a trained aide who would provide 24-hour care to address increasing symptoms.

Jane began to experience periods of confusion, delusional thinking, and neuropathic and nociceptive pain in her lower extremities, which was well controlled by oral methadone 5 mg/mL every 8 hours, prescribed by the APRN. Jane was at the end of life. With Joann, Jane discussed her wish to see her 16-year-old son who had lived with Jane’s sister since birth. Jane was ashamed of her diagnosis and the circumstances of her life. Yet, she firmly believed that her son was better off with her sister. However, as Jane faced the end of her life, her only wish was to see, and perhaps reconcile with, her son. Joann contacted Jane’s sister, who agreed to accompany the son to visit Jane and say goodbye. Jane died at “home” in her residence. Katherine met with residents and staff who had known and stood by Jane to assess their level of comfort, respond to questions about symptoms, listen to their sadness, and prepare for Jane’s death. Joann, in her ongoing therapy with Jane, had explored her values, wishes, and hopes. Both Katherine and Joann offered support and bereavement care to Jane’s sister and son after her death.

CONFIRMATION WHEN DEATH HAS OCCURRED

The APRN often confirms that death has occurred by assessing that there is no presence of respirations or heartbeat. In some situations, another clinician is required to verify the patient has died. In other settings, an electrocardiogram must be obtained. In many states, a professional nurse may determine and pronounce the death and even sign the death certificate. APRNs should be familiar with their scope of practice regarding death pronouncement and completion of death certificates.

Communication with families at the time of death includes notification that the death has occurred and what to anticipate when the body is viewed immediately after

Box 34.4 KEY ELEMENTS TO VIRTUAL AND TELEPHONE DEATH NOTIFICATION

1. Make the call as soon as possible after the death.
2. Prepare for the call by talking with a colleague about the deceased to review the events of the last few days.
3. Gather and verify the facts about the patient: name, gender, age, medical record number, religious denomination, and circumstances of death. Have the chart available, if possible, depending on the location where you will take the call.
4. Establish the next of kin to be notified: contact person, full name(s), address(es), relationship to the patient.
5. Arrange for a medical interpreter, if needed.
6. Review with a colleague the context of the call, the history of the care, and what you will say.
7. Take a few moments to collect and prepare oneself—with a mindfulness minute or deep breathing.
8. Find a quiet space in which to make the call.
9. Remember to talk slowly and use simple language.

Making the Call

10. Consider using technology to block personal phone telephone number or computer access such as *67 or Doximity.
11. Initiate call. If call goes to voice mail, do not leave information about the death. Leave your specific contact information such as “Martha Mark, CNS at West Hospital. Please call me back at the following number.”
12. Identify yourself and your position at the healthcare facility.
13. Ask to speak to the contact person and verify their relationship to the deceased.
14. Provide a warning shot: “I am afraid I have some serious/difficult news to share.” “Are you available to talk now or should I call you back in a few minutes?”
15. Ask if person has anyone with them or if they are driving.
16. Allow them time to get to a room with another person, call another person, or pull over on the road.
17. Check in they are ready to receive the news.

Delivering the News

18. Provide clear and direct language: “I am so sorry to inform you that X has just died.” “I am sad to have to tell you X has just died.” Do not use euphemism such as “passed on,” “expired,” or “didn’t make it” as you do not want to be ambiguous.

19. Allow time and silence for the family member/friend to take in the information.
20. Be prepared for the expression of emotions.
21. Offer simple details about what happened if the family member/loved one asks.
 - a. Explain how the patient was doing earlier and the sudden deterioration.
 - b. Explain the possible reasons for the sudden deterioration.
22. Allow the family members to ask additional questions and express feelings.
23. Provide therapeutic listening and support.

From Dahlin.²⁸

death. Box 34.4 reviews telephone notification.²⁸ Families should be aware that muscles are relaxed after death, resulting in passage of stool and urine, and relaxing of the jaw, causing the mouth to open. Presentation and care of the body after death, including cleaning, is an important nursing intervention.

DEATH NOTIFICATION VIA VIRTUAL PLATFORM OR TELEPHONE

Communication with the patient's family a video platform (e.g., Facetime, Zoom, Skype) or by telephone regarding his or her condition, prognosis, and death carries the same responsibilities for the nurse as meeting in person: assessment, listening, and providing concrete medical information (Box 34.4). Performing such calls in a private areas is still fundamental. Additionally, assuring appropriate power for any device, landline, or smart device is critical, as is a stable internet connection. Finally, it is necessary to have the facts of what occurred or is occurring. Communication virtually or over a telephone is challenging in that the clinician cannot assess the family member's safety using nonverbal clues and unsafe living arrangements or privacy. Whether by phone or virtually, the APRN must evaluate the situation and convey empathy, visually with body language and verbally with tone. Not only is conveying the information about the death important, but the APRN also must conduct an assessment of family members' coping abilities. The APRN who believes a family member is at high risk can arrange for follow-up by team members or, if more emergent, summon emergency support using 911.

Boxes 34.4 and 34.5 outline the process and steps for the APRN to follow in calling a family to notify of a loved one's death.²⁸

Box 34.5 CLOSING THE CALL

1. Offer information about next steps in terms of planning for the discharge of the body.
 - a. Ability to view the body at the facility
 - b. Basic guidance about funeral planning
2. Offer follow-up phone calls by the social worker or chaplaincy to help with memory-making (as resources allow), support, and funeral planning.
3. Provide information about follow-up telephone calls from the hospital, including the release of the body.
4. Offer condolences and a statement for having to receive this information by phone: "Again, my condolences on your loss. I wish I had been able to tell you this in person."
5. Document the call in the chart.
6. Notify the clinical team and the bereavement liaison that the call has been completed.
7. Take a moment to reflect and provide a positive affirmation for providing a difficult call with empathy.

From Dahlin.²⁸

THE ROLE OF TELEHEALTH IN COMMUNICATION DURING SERIOUS ILLNESS AND END-OF-LIFE: IMPACT OF COVID-19

Telehealth is broadly defined as the use of telecommunication technologies to support clinical healthcare. Telehealth technologies include telephone (both wired and wireless communications), remote patient monitoring (e.g., coverage of intensive care units), video conferencing, the internet, and streaming media.²⁹ Telehealth has been historically used to provide care to those in rural areas and in military health systems with forward-deployed and remote settings. Telehealth has also supported public health during emergencies such as the 2014 water crisis in Flint, Michigan, and the 2016 Zika virus outbreak in Puerto Rico, locations where telehealth clinicians were able to compensate for the inadequate supply of local providers in the affected areas.³⁰

The global pandemic caused by the novel SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2), or coronavirus disease 2019 (COVID-19), has caused millions of infections, hundreds of thousands of deaths, and caused international economic contraction. The necessity for lockdowns, quarantines, and social distancing as critical infection control measures has profoundly changed the way healthcare has been provided. The provision of palliative care has been similarly transformed (see Chapter 17, "The Palliative APRN in Telehealth"). While the role of palliative care at end of life remained focused on comfort in dying and providing

**Box 34.6 COMMUNICATION CHALLENGES
WITHIN THE COVID-19 GLOBAL HEALTH
EMERGENCY**

- Dying alone
 - Isolation increases patient and family emotional distress
 - Separation of family from patient increases provider moral distress
 - Loss of face-to-face family meetings hampers development of relationship of trust with providers
 - Dehumanizing layers of personal protective equipment (PPE) further isolates patients from providers
- Dying rapidly
 - Often rapid decompensation; patients lose capacity before values and preferences can be discussed
 - Families face abrupt decision-making, lack time to complete task of anticipatory grief
- Dying in unprecedented numbers
 - Providers face high volumes of patients in extremis, requiring difficult conversations with multiple families per day
 - High volume causes physical fatigue and compassion fatigue in providers
 - Healthcare agents often experience multiple losses in same family
 - Provider fear for personal safety and for their own family's safety from infection

emotional, psychosocial, and spiritual support for patients and families, delivery models evolved to meet radically changed practice conditions. In this context, telehealth emerged as a critical tool for palliative care providers in communicating with patients and family members.

The no-visitor policies instituted by acute and subacute facilities have presented a formidable challenge to one of the central principles of palliative care at end of life: to facilitate contact between patients and their loved ones. The prohibition on visiting dying patients in their final days has required that palliative care providers find creative ways to foster connection, provide comfort and meaning to patients, and help families in the grieving process. This context of unprecedented physical separation at end of life generated psychosocial, spiritual, and moral distress among patients, loved ones, and providers alike, thus presenting several unique communication challenges (Box 34.6).

Internationally, palliative care providers and other frontline clinicians developed a spectrum of practical applications of telehealth during the pandemic. In an acute supportive/

palliative care unit in Italy, in which family members in the pre-COVID era had been allowed to stay with the patients “8 days a week,” they employed a commercial smartphone video app to allow families to participate in daily clinical rounds.³¹ Other centers responded to the sudden and enormous demand for palliative care inpatient consult services by enlisting consultative services from palliative care specialists in other, less impacted geographic areas, utilizing telephone or video communications for goals-of-care discussions.^{32,33} Informally, and routinely, bedside providers held up bedside phones or used smartphones to access commercial video platforms to meet the simple and essential request for families to be with their loved ones before death.³⁴ Outpatient palliative APRNs were able to provide continuity of care with patients at home due to the Centers for Medicare and Medicaid (CMS) liberalization of Medicare reimbursement for telemedicine, allowing substitution of virtual visits for prescribing controlled substances.³⁵

While the emergence of COVID-19 accelerated the use of telehealth—under the most urgent of conditions—it is likely that telehealth will remain a prominent component of healthcare delivery. It is incumbent upon hospice and palliative APRNs to participate in optimizing this modality. Research is needed to investigate the most effective communication strategies for telehealth encounters while retaining our current priorities: to share information, identify needs, be fully present, and respond with empathy.³⁶ Engaging in goals-of-care conversations at end of life, under pandemic conditions, highlighted the importance of APRNs’ ongoing efforts to encourage advance care planning (ACP) completion before health crises occur.^{37,38} The high volume of cases and the highly charged clinical scenarios favor the incorporation of structured conversations in crisis encounters.^{33,39} Aiming for the best possible care that telemedicine can provide mandates that APRNs address social and healthcare disparities, working toward equitable access to telemedicine technologies for vulnerable populations.^{40,41}

FAMILIES AND LOSS

Coming to terms with death and loss is the most difficult challenge a family must confront. From a family systems perspective, loss can be viewed as a transactional process involving the dying and deceased with the survivors in a shared life cycle that acknowledges both the finality of death and the continuity of life.^{42 (p. 3)}

While palliative APRNs view both the patient and family as the focus of care, the major effort at the end of life is to prepare the patient and family for death. Bereavement care follows acknowledgment of the loss. Missing is a systematic view of the family and the impact of the loss on the family as an interactional system. This theoretical framework provides caregivers the opportunity to see beyond the number of members and roles in order to view the system as a whole in a particular phase of life-cycle development. Rolland describes three major phases in the unfolding of chronic or advanced

illness for the family member: initial crisis, chronic phase, and terminal phase.⁴³

To respect religious and cultural variations, Rolland recommends helping families during the initial crisis (or time of diagnosis) to establish open and effective disease- and treatment-related communication.⁴³ Establishing this pattern early on and knowing the ill person's wishes can benefit both patient and family. With advanced disease, where the timing of loss is ambiguous but the inevitable deterioration is not, family members will grieve at each transition. At key periods, families can be encouraged to shift their roles and responsibilities to other members.

In the crisis phase of illness, families will grieve for the loss of family life prior to the diagnosis. Family members in the chronic phase grieve for the ambiguities they must endure over the long term.⁴³ As the patient enters the terminal phase, the main question asked is how much time there will be to prepare for death and survivorship. Rolland suggests that a family's tasks at this time are as follows:

1. Completing the task of anticipatory grief and unfinished business
2. Supporting the dying member and family survivors to continue their life together for as long as they can
3. Beginning or continuing the family reorganization process⁴³

Rolland encourages the palliative care provider to "join with" the family when members are anticipating a final separation. This phase provides an opportunity for some families to experience emotional and relational healing. Relationships in highly dysfunctional families where there is a history of abuse or abandonment may not be mended. Patients who have no families or who are estranged from their families of origin may be content to be surrounded by friends and caregivers. Walsh and McGoldrick describe loss as a powerful nodal event that affects the entire family system and every member.⁴² Loss reverberates over time, starting with the threat of death and progressing to the actual approach, the immediate aftermath, and the long-term implications. The authors propose four major tasks that promote immediate and longer-term adaptation for family members and the unit as a whole:

1. Shared acknowledgment of the reality of death
2. Shared experience of loss
3. Reorganization of the family system
4. Reinvestment in other relationships and life pursuits⁴²

PALLIATIVE APRN WELL-BEING

*The grief that does not speak,
Whispers the o'er-fraught heart and bids it break.
William Shakespeare, Macbeth*

Palliative APRNs touch the fringes of family grief and are touched deeply by that grief; they must find ways to share with

colleagues and peers for sustainability. Feldstein and Gemma surveyed nurses caring for terminally ill adults and found those nurses who did not share their grief with colleagues experienced a chronic, compounded grief that interfered with their personal and professional lives and relationships. The authors posited that protracted exposure to distressing symptoms and suffering in patients and families at end of life generates a high level of stress and dysfunction in APRNs who are not vigilant about caring for themselves.⁴⁴ There are many vehicles to promote and support well-being, including sharing their grief (Box 34.7).

SUMMARY

Communication at the end of life is a complex and therapeutic transactional process between and among human beings. No more than at the end of life does it become the relational connection, the empathic link between the person whose life is ending and those who will continue to live. Communication occurs through the spoken word, the listening ear, in silence, and in action. For the palliative APRN, communication is an essential skill to be learned and practiced, to teach, model, and support. This communication, the "compassionate conversation" as a form of authentic human interaction, is not an exact science; it is shaped by the transactional process of the persons engaged in it. Ferrell suggests that palliative APRNs explore more deeply this relational aspect of communication, "What does it really mean to share bad news? Or to hear it? What is it really like to comfort a parent who holds a dying child? What does it mean to invite a patient to share their life regrets or need for forgiveness? Perhaps we have only begun to know what it means to care in serious illness. Perhaps we need deeper reflection."⁷ (p. 305) This becomes the ongoing challenge for the palliative APRN, beyond clinical competency in all aspects of care: the exploration of meaning in relational connection through communication (Box 34.8).

Box 34.7 SUPPORTING PALLIATIVE APRNS PSYCHOLOGICAL HEALTH

1. Institutional and administrative recognition of the unique stressors and challenges in caring for COVID-19 patients and families
2. Provision of evidence-based psychological support to:
 - Address psychological and safety needs
 - Engage in support of peers
 - Focus on team support interventions
 - Promote mentoring among APRN staff⁴⁵
3. Supportive workplace activity to help palliative APRNs share grief and find support
 - Discussion groups/workshops
 - Support groups
 - Remembrance services
 - Referral to mental health therapists when indicated¹⁴

Domain 6: Cultural Aspects of Care

GUIDELINE 6.1 GLOBAL

The IDT delivers care that respects patient and family cultural beliefs, values, traditional practices, language, and communication preferences and builds upon the unique strengths of the patient and family. Members of the IDT work to increase awareness of their own biases and seeks opportunities to learn about the provision of culturally sensitive care. The care team ensures that its environment, policies, procedures, and practices are culturally respectful.

CRITERIA

- 6.1.1 The IDT asks the patient or surrogate to identify and define family, which may include members of the family of origin, as well as the patient's family of choice.
- 6.1.7 Communication occurs using verbal, nonverbal, and/or symbolic means appropriate to the patient, with particular attention to cultural and linguistic considerations, cognitive capacity, the presence of learning or developmental disabilities, and the developmental stage across the lifespan.

Domain 7: Caring for the Patient Near the End of Life

GUIDELINE 7.2 SCREENING AND ASSESSMENT

The interdisciplinary team (IDT) assesses physical, psychological, social, and spiritual needs, as well as patient and family preferences for setting of care, treatment decisions, and wishes during and immediately following death. Discussions with the family focus on honoring patient wishes and attending to family fears and concerns about the end of life. The IDT prepares and supports family caregivers throughout the dying process, taking into account the spiritual and cultural background and preferences of the patient and family.

CRITERIA

- 7.2.1 The IDT:
 - a. Reviews advance directives (as applicable) and honors the patient's wishes
 - b. Provides information and support to the family and others who are providing care to the patient
- 7.2.2 For patients who have not accessed hospice, the IDT discusses the benefits of hospice with the patient and family.
- 7.2.3 Before the patient's death, the IDT discusses autopsy, organ and tissue donation, and anatomical gifts in a culturally sensitive and age-appropriate manner, adhering to applicable organizational policies and laws.

CRITERIA

- 7.3.1 With the involvement of the patient and family, a plan is developed to meet patient needs during the dying process, as well as the needs of family members before, during, and immediately following the patient's death. Cultural and spiritual preferences of the patient and family are particularly relevant when developing this plan. Reassessment and revision of the plan occurs regularly, with the frequency identified in agency or program policies.
- 7.3.2 Care of the patient at the end of life is time- and detail-intensive, requiring expert clinical, psychological, social, and spiritual attention to the process as it evolves.
- 7.3.5 In all care settings, the IDT provides education and instructions to family members and/or caregivers in preparation for the patient's death, with emphasis on whom to notify, and what to expect when symptoms change and after the patient dies.
 - a. Education and instructions are provided in accordance with the patient- and family's health literacy levels and cultural preferences.
- 7.3.6 Family expectations regarding IDT availability during the dying process are identified in advance so that staff can alleviate concerns and communicate realistic expectations.
- 7.3.7 The IDT elicits and honestly addresses hopes, fears, and expectations about the dying processes in ongoing communications with the patient and their family in a developmentally appropriate and culturally sensitive manner.
- 7.3.8 The IDT provides anticipatory grief support to the family and caregivers.

GUIDELINE 7.4 TREATMENT DURING THE DYING PROCESS AND IMMEDIATELY AFTER DEATH

During the dying process, patient and family needs are respected and supported. Post-death care is delivered in a manner that honors patient and family cultural and spiritual beliefs, values, and practices.

CRITERIA

- 7.4.1 The IDT communicates signs and symptoms of imminent death in culturally and developmentally appropriate language, taking into account the cognitive abilities of the patient and family
- 7.4.4 An IDT member supports the family before and immediately following the patient's death, assisting with cultural or spiritual practices, funeral arrangements, and cremation or burial planning.

GUIDELINE 7.5 BEREAVEMENT

Bereavement support is available to the family and care team, either directly or through referral. The IDT identifies or provides resources, including grief counseling, spiritual support, or peer support, specific to the assessed needs. Prepared in advance of the patient's death, the bereavement care plan is activated after the death of the patient and addresses immediate and longer-term needs.

CRITERIA

- 7.5.1 The IDT directly, or through referral, provides bereavement services and support to the family.
- 7.5.7 Grieving children are referred to pediatric grief specialists, programs, and camps based on their age and needs.
- 7.5.8 The IDT assesses resiliency, cumulative loss, and grief, and offers supports and services to IDT members. Emotional support services are also made available to ancillary team members involved in supporting palliative care patients.

SECTION VII

PSYCHOSOCIAL, CULTURAL, AND
SPIRITUAL ASPECTS OF CARE

CULTURALLY RESPECTFUL PALLIATIVE CARE

Helen Foley and Polly Mazanec

KEY POINTS

- Delivering culturally respectful care is a fundamental principle of nursing.
- Self-reflection on one's own cultural beliefs, values, practices and biases is essential to providing culturally sensitive palliative care.
- The palliative advanced practice registered nurse (APRN) must assess the patient's and family's cultural values, practices, and beliefs and identify their significance in the diagnosis and management of serious illness and at end of life.
- Goals of care must be established in concert with the patient's and family's cultural values, practices, and beliefs.
- Disparities in access and delivery of quality palliative care must be addressed in order to improve care for the most vulnerable.
- Essential components of palliative care, such as communication, including disclosure, prognosis, and medical decision-making; pain and symptom management; end-of-life care; and death, should be considered through a cultural lens.

CASE STUDY 1: IMMIGRATION STATUS

A palliative advanced practice registered nurse (APRN) was consulted to see Mr. S, who was admitted to the hospital for hemoptysis, weight loss, and debilitating pain in his left hip. His son brought him to the emergency room and told the staff that he had been feeling poorly, had lost 20 pounds, and had been coughing up blood for 4 months. Mr. S spoke only Spanish and had delayed seeking healthcare as he did not have US citizenship and feared deportation. Upon admission, he was diagnosed with lung cancer with bone metastasis. The palliative APRN, Mary, found him withdrawn, and the nurses reported he was refusing to take pain medication. Through the use of the hospital's interpreter service, the patient shared his fears about taking pain medication and becoming addicted. Mary ensured that there was a computer-based interpreter service every day for rounds with the patient to promote trust. The palliative APRN coordinated his pain regimen and assisted the oncology team in planning for a short course of outpatient palliative radiation that would allow him to return home with his son.

INTRODUCTION

Culture is dynamic process and its language is a cultural phenomenon subject to changing terminology. Culture influences an individual's perception about health, wellness, death, and dying and is a dominant aspect of palliative care. This chapter discusses the delivery of culturally respectful care and the integration of culture into advanced practice palliative nursing. Culturally respectful care begins with self-reflection about one's own values, practices, beliefs, and biases and their impact on the delivery of culturally respectful, sensitive, or intelligent care. Assessing for primary language and health, numeracy, and technology literacy is essential, along with implementing strategies to overcome any barriers to culturally sensitive care. The palliative advanced practice registered nurse (APRN) must use these communication strategies to elicit the patient's and family's cultural values, practices, and beliefs. Moreover, the palliative APRN must attend to the cultural disparities and racism that exist in healthcare, hospice, and palliative care.

Definitions and terms used in this chapter reflect the healthcare and cultural environment in the United States at the time the chapter was written. The chapter describes special considerations in the delivery of culturally respectful palliative care, such as supporting beliefs regarding disclosure of prognosis and medical decision-making, recognizing cultural implications of pain and symptom management, integrating cultural rituals and practices into clinical care, and dealing with cultural clashes.

OVERVIEW OF CULTURE WITHIN PALLIATIVE NURSING

It is the fabric of nursing practice to attend to culture. This component of practice is identified within the American Nurses Association (ANA) *Code of Ethics*¹ and *Nursing Scope and Standards of Practice*.² Standard 8, Culturally Congruent Practice, of the ANA *Nursing Scope and Standards of Practice*, describes the competencies needed to ensure that the nurse practices in a manner that is congruent with cultural diversity and inclusion principles.² The Hospice and Palliative Nurses Association (HPNA) emphasizes the importance of culture in *Palliative Nursing: Scope and Standards of Practice*³ and in its competency statements.^{3,4} Standard 8 *Culturally Congruent Care* emphasizes that the palliative

registered nurse has the cultural sensitivity to recognize, appreciate, and incorporate the different cultural needs of individuals with serious illness into the provision of care,³ and HPNA's *Competencies for the Palliative and Hospice Advanced Practice Registered Nurse* define cultural and spiritual competence at that level of clinical practice. Cultural competency for advanced practice palliative nursing focuses on respecting diversity, in particular race and ethnicity, spirituality, religion, gender identity and expression, sexual orientation, immigration and refugee status, social class, physical appearance, and abilities.⁴ The *Competencies for the Palliative and Hospice Advanced Practice Nurse*⁵ describe behaviors that demonstrate competency in cultural aspects of palliative care and align with the National Consensus Project for Quality Palliative Care (NCP) *Clinical Practice Guidelines for Quality Palliative Care*.⁶

Quality palliative care is clearly defined in the fourth edition of the *Clinical Practice Guidelines for Quality Palliative Care*.⁶ Cultural considerations are so essential in quality palliative care that one of the eight domains, Domain 6, is reserved specifically for Cultural Aspects of Care. The clinical implications of this domain emphasize that respecting cultural values, practices, and beliefs is an essential element in the delivery of quality palliative care. Criteria that are identified in the guidelines for palliative care practice and that are emphasized in this chapter are summarized in Box 35.1.

Box 35.1 NCP CLINICAL PRACTICE GUIDELINES FOR QUALITY PALLIATIVE CARE

Domain 6: Cultural Aspects of Care

GUIDELINE 6.1 GLOBAL

The interdisciplinary team (IDT) asks the patient or surrogate to identify and define family, which may include members of the family of origin, as well as the patient's family of choice. The IDT recognizes that:

- Quality palliative care requires an understanding of the patient's and family's culture and how it relates to their decision-making process, and their approach to illness, pain, psychological, social, and spiritual factors, grief, dying, death, and bereavement.
- Each person's self-identified culture includes the intersections of race, ethnicity, gender identity and expression, sexual orientation, immigration and refugee status, social class, religion, spirituality, physical appearance, and abilities.
- Patients and families may have experienced barriers to receiving culturally respectful healthcare, and these prior experiences may result in mistrust of the health care system.
- Culture is a strength that patients and family members bring to their plan of care.

Adapted from National Consensus Project for Quality Palliative Care.⁶

UNDERSTANDING CULTURE

The United States is a multicultural society with increasing diversity. By 2060, minority groups are expected to make up 57% of the US population.⁷ Americans have traditionally valued independence and self-reliance with an emphasis on the importance of autonomy and each individual's happiness.⁸ However, many minority groups in the diverse United States and the non-Western World value collectivism, interdependence, community, and continuity of the generations.⁸ Because of this increasing diversity, the palliative APRN must be aware of and respond to the diversity of customs, norms, beliefs, and languages.⁹ Respecting and valuing cultural diversity are key to delivering culturally appropriate palliative care.

Culture is the "learned, shared and transmitted values, beliefs, norms and life ways of a particular group that guide their thinking, decisions, and actions in patterned ways."¹⁰ Culture is shaped over time, during which the beliefs, values, and lifestyle patterns pass from one generation to another.¹⁰ The biopsychosocial and ecological organizing system within which a population of people exists is an adaptive, dynamic system, one designed to ensure survival and well-being.¹⁰ Culture is the way human beings find meaning and purpose in life and make sense out of life events. In times of crisis, culture can be a source of resilience for the individual and the family and therefore should be respected by the healthcare team.¹⁰

A commonly held misconception is that culture is synonymous only with race and ethnicity. Race and ethnicity are important components of culture because of systemic racism in today's society and subsequent racism and health disparities even in hospice and palliative care.^{11–13} It should be noted that race and ethnicity are merely sociopolitical categories determined by the US Office of Management and Budget.¹⁴ When considering culture, the NCP *Clinical Practice Guidelines*⁶ have outlined essential components which have major palliative care implications. Table 35.1 identifies key components of culture and considerations regarding the delivery of quality palliative care.^{6,15–17}

Even though an individual may belong to a cultural group, he or she may or may not adhere to its cultural norms.¹⁸ Members of cultural groups can be very similar or very diverse. Behaviors of individuals within a cultural group can range from totally adherent to group practices, values, and beliefs to completely nonadherent. It is critical that the palliative APRN not engage in stereotyping, assuming that all persons from one group will behave in a certain way.

Textbooks and respected internet websites with information on certain cultural groups may be helpful in guiding clinical practice, and they may facilitate an understanding of culturally sensitive topics in healthcare and particularly palliative care. While it is important to seek to understand the practices and values of cultural groups commonly seen in one's clinical setting, the palliative APRN must assess the values, practices, and beliefs of each patient as an individual and determine the importance of these values, practices, and beliefs to the patient and family.⁶

Table 35.1 EXAMPLES OF COMPONENTS OF CULTURE AND IMPACT ON PALLIATIVE CARE

CULTURAL COMPONENTS	PALLIATIVE CARE CONSIDERATIONS
Race	Discrimination exists regarding healthcare delivery, treatment options, and palliative and hospice care utilization among minority races when compared to non-Hispanic whites; Racism and implicit bias negatively impact equitable care.
Ethnicity	Currently more than 100 ethnic groups and more than 500 American Indian Nations in the United States; ethnic minorities are less likely to use hospice services than non-Hispanic Whites for numerous reasons including culture.
Age	Age cohorts have their own identity and culture, the very young and very old are considered vulnerable populations. Cultural attitudes of ageism can affect the care of the older adult, who may be seen as frail and unable to make decisions.
Gender identity and expression	Gender disparity in palliative care exists for those identifying as lesbian, gay, bisexual, transsexual, queer, inquiring (LGBTQI+); ethical and legal issues in decision-making and advance care planning depend on documentation of who is “family”; gender minorities have high rates of poverty, food and housing insecurities, and experience discrimination in healthcare settings (i.e., older LGBTQI+ adults in nursing facilities). ¹⁷
Sexual orientation	Respect one’s sexual orientation. Use language that is nonjudgmental. Educate patients and families about the importance of appointing a healthcare power of attorney, especially if partners are unmarried.
Immigration or Refugee status	Immigrants may face health literacy deficiencies, insurance barriers, and may lack social and financial resources depending on status. Undocumented immigrants fear deportation, often waiting until serious illness is very advanced to seek healthcare.
Socioeconomic status (measured as a combination of education, occupation, and income)	One’s physical and psychological well-being; preferences for hospice and palliative care are shaped by economic condition, healthcare access, insurance, and neighborhoods. Patients of lower socioeconomic status experience disparities across the disease trajectory of serious illness.
Religion	For those practicing a faith tradition, it may be important to integrate community clergy into healthcare team; faith and practice rituals can be a source of support and critically important at end of life.
Spirituality	Spirituality is the essence of every human being, giving life its meaning and purpose; can help transcend suffering in serious illness and at end of life.
Abilities	Those with physical disabilities often feel stigmatized because of their physical appearance. Those who are physically, emotionally, or intellectually challenged are at risk for receiving inferior care, especially if unable to speak for themselves or without an advocate.

From Cormack et al.¹⁵; Mazanec, Panke¹⁶; and Barrett, Wholihan.¹⁷

CULTURAL AWARENESS

Palliative APRNs must be aware of the impact of their own culture on their clinical practice.^{6,15,16} To provide culturally sensitive care, APRNs must reflect on their individual values, practices, beliefs, and biases. This self-reflection should occur as a review of the essential components of nursing practice and competencies required of all practicing APRNs. It is recommended that a formal self-reflection be performed and revisited regularly because one’s cultural beliefs are ever-changing and are heavily influenced by knowledge, experience, and cultural encounters.¹⁶ Box 35.2 contains an example of a self-reflection exercise that can provide great insight into one’s own worldview and how it may influence clinical care.

IMPLICIT BIAS

Within the realm of culture and racism, there is also *implicit bias*. Implicit bias refers to attitudes and beliefs that

are in one’s subconscious or are part of a person’s belief system and that they are unwilling or unable to report because they are inaccessible to one’s conscious awareness.¹⁹ Implicit bias is based on interactions and observations from childhood and formed from the ages of 2–5, and influences one’s adult actions, and decisions.¹⁹ For example, one may hold negative stereotypes about others based on age, gender orientation, race, or religion without conscious realization, which may unknowingly influence clinical practice later in life.

A collaborative research effort at Harvard University, University of Virginia and the University of Washington offers an online self-administered Implicit Association Test (IAT)²⁰ that measures implicit attitudes, stereotypes, and biases. The test is somewhat controversial because the test’s reliability, validity, and accuracy have been questioned. However, it may give insight into unconscious biases that one is not aware of and which can be unlearned once identified.

Box 35.2 CULTURAL SELF-ASSESSMENT

1. Where were you born? If an immigrant, how long have you lived in this country? How old were you when you came to this country? Where were your grandparents born?
2. What is your ethnic affiliation, and how strong is your ethnic identity?
3. Who are your major support people: family members, friends? Do you live in an ethnic community?
4. How does your culture affect decisions regarding your medical treatment? Who makes decisions—you, your family, or a designated family member? What are the gender issues in your culture and in your family structure?
5. What are your primary and secondary languages? What is your speaking and reading ability?
6. How would you characterize your nonverbal communication style?
7. What is your religion? How important is it in your daily life? What are your current religious practices? Is religion an important source of support and comfort?
8. What are your food preferences and prohibitions?
9. What is your economic situation, and is the income adequate to meet your needs?
10. What are your health and illness beliefs and practices?
11. What are your customs and beliefs surrounding birth, illness, and death? What are your experiences with death and bereavement? What are your beliefs about the afterlife and miracles? What are your beliefs about hope?
12. How have the patient and family encounters you have had over the past year influenced your values, practices, and beliefs?

Adapted from Mazanec, Panke.¹⁶

CULTURAL HUMILITY

A great deal is written about cultural competence, cultural sensitivity, and cultural humility, and confusion exists among these terms. The concept of *cultural competence* inaccurately assumes that competency is an endpoint or something to be mastered. Those striving for cultural competency recognize it is a dynamic process rather than an outcome.^{15,21} *Cultural humility*, a term coined by Trevalon and Murray-Garcia, is a desirable attribute for clinical practice.²² It is a “process of intercultural exchange, paying attention to clarifying the values and beliefs of provider and of patient and family and incorporating the cultural characteristics of healthcare professionals and individuals into a mutual balanced relationship.”²² Cultural humility requires that one enters into each new encounter with an open mind and open heart. Recognizing that our individual and professional

perspective is but one of many perspectives that will be part of the larger context we are encountering, the goal of cultural humility is to create a shared understanding.^{23–25} The NCP *Clinical Practice Guidelines* stress that the entire interdisciplinary team practices cultural humility in all clinical encounters.⁶

INTEGRATING CULTURAL ASSESSMENT INTO CLINICAL PRACTICE

Once the palliative APRN recognizes their individual cultural values, practices, and beliefs, the next step in developing a culturally respectful palliative care clinical practice is to gain skill in assessing the cultural backgrounds of patients and families. Performing a thorough cultural assessment is essential to understanding the patient’s and family’s healthcare preferences, especially in the provision of palliative care. Although many cultural assessment tools are available, some are lengthy and require a great deal of time on the part of the clinician and also the patient and family. These tools are actually long checklists, so administration not only may be burdensome but also may hinder the establishment of a trusting clinical relationship, which is the essence of culturally sensitive care.^{15,26}

In the clinical setting, presence, active listening, and strong communication skills are the best tools for assessing cultural considerations in palliative care.^{16,23} An understanding of the patient’s values and culture is likely to be revealed over time as the APRN establishes a trust relationship with the patient and family. Palliative APRNs should ask the patient and/or the family member to tell about themselves. Listening intently to their stories is the most effective way to gain an understanding of the patient’s and family’s cultural norms. Box 35.3 provides an example of open-ended assessment questions that can guide the patient and family in sharing their cultural values, practices, and beliefs and what is important to them.

THE IMPACT OF CULTURE ON COMMUNICATION

Communication is the foundation for all encounters among human beings, and this is especially true in the delivery of palliative care. Communication is an interactive, multidimensional process, often dictated by cultural norms, and it provides the mechanism for human interaction and connection.²⁴ Abiding by general communication principles for quality palliative care in a culturally sensitive manner will ensure the establishment of a trusting relationship between the clinician and the patient and family, regardless of where the interaction takes place (e.g., clinic office, hospital room, skilled care facility). Following these principles will help the APRN and the palliative care team understand patient/family norms for communication style and the giving and receiving of information (Box 35.4).^{23–26}

**Box 35.3 KEY CULTURAL ASSESSMENT
QUESTIONS**

- We want to make sure we respect how you prefer to be addressed:
 - What name do you use?
 - What sex were you assigned at birth?
 - What gender do you identify as now?
 - What gender pronouns do you use?
- Whom do you consider to be your family?
 - To whom do you go for support (family, friends, community, or religious or community leaders)?
- Where were you born and raised? (If an immigrant, how long have you lived in this country?)
- What language would you prefer to speak?
- Is it easier to write things down, or do you have difficulty with reading and writing?
- I want to be sure I'm giving you all the information you need.
 - What do you want to know about your condition?
 - To whom should I speak about your care?
- Whom do you want to know about your condition?
- How are decisions about healthcare made in your family?
 - Should I speak directly with you, or is there someone else with whom I should be discussing decisions?
- Tell me about your understanding of what has been happening up to this point. What does this illness mean to you?
- We want to work with you to be sure you are getting the best care possible and that we are meeting all your needs.
 - Is there anything we should know about any customs or practices that are important to include in your care?
 - Are you comfortable having both men and women as healthcare providers?
- Many people have shared that it is very important to include spirituality or religion in their care.
 - Is this something that is important for you?
 - Would you like me to contact our chaplain or another spiritual provider you would like to be involved in your care?
- Are there any foods you would like or that you should avoid?
- Do you have any concerns about how to pay for care, medications, or other services?

Death Rituals and Practices

- Is there anything we should know about care of the body or about rituals, practices, or ceremonies that should be performed during the dying process or at the time of death?
 - Who should be involved in the care of the body immediately after death?
 - Are there religious leaders who should be involved?
- What is your belief about what happens after death?
- Is there a way for us to plan for anything you might need both at the time of death and afterward?
- Is there anything we should know about whether or not a man or woman should be caring for the body after death?
- Should the family be involved in care?

Adapted from Cormack et al.¹⁵

**DIFFERING ABILITIES AFFECTING
COMMUNICATION**

Patients and families who are hearing- or sight-impaired face additional challenges when trying to understand communication related to their palliative care needs. One in six individuals experience impaired hearing, with impairment being more common in the geriatric population.²⁷ When caring for a patient who is completely deaf and can use sign language, use a healthcare interpreter fluent in sign language. When caring for a hearing-impaired patient, the palliative APRN can facilitate communication by (1) decreasing background noise and distractions during conversations; (2) encouraging the patient to wear eyeglasses or hearing aids during the conversation; (3) ensuring the listener can see the APRN's face; (4) speaking clearly and distinctly, but not shouting; (5) enhancing the discussion with written words and pictures to aid in explanation; and (6) asking the listener to summarize the conversation to ensure understanding.²⁷ Keep in mind that speech comprehension is more difficult for persons with hearing loss. It can be compounded by the use of protective masking which interferes with both lip movement and nonverbal cues, as became evident in the recent coronavirus pandemic.

Those who have visual impairments are usually very capable of hearing and participating in the verbal part of communication but may be unable to observe nonverbal communication, depending on the severity of the loss of sight. The American Foundation for the Blind²⁸ offers suggestions to support those with vision impairment. Avoid using nonverbal responses, such as nodding in agreement or shaking your head in disagreement as the visually impaired person may not see these responses. When entering the room, greet the patient verbally first and then offer a handshake or touch the shoulder, if appropriate. If sight is limited but present, offer written materials in large print. When the visit is over, be certain to inform the patient when you are leaving. Seek additional help from experts like the American Association for the Blind for assistance with Braille materials and other resources.²⁹

1. Select a setting that is private and as free from interruption as possible.
 - Turn off cellphones and put pagers on vibrate mode.
 - Greet the patient in a respectful, professional manner. Cultural norms related to verbal introduction and nonverbal touch or handshake should be identified early in the initial encounter to avoid making a culturally inappropriate mistake.
 - Determine the dominant language and dialect spoken and the literacy level of both the patient and the family. If there is a language difference between clinician and patient, a professionally trained interpreter of the appropriate gender, if culturally significant, should be contacted prior to proceeding with the visit.
 - Recognize that the professional's message and the understanding of the patient/family can differ, even when they share the same language. When confronted with a life-limiting illness, almost everyone experiences compromise in literacy and difficulties in processing.
2. During the initial interaction, determine how the patient would like to be addressed.
 - Some patients prefer to be called by their last name (e.g., Mr. Jones, Ms. Smith), whereas others may prefer to be called by their first names. Identify the patient's preference for gender pronouns.
 - Document the patient's preference in the medical record so that all members of the healthcare team can respect this preference.
 - Be cognizant of nonverbal communication that may be culturally insensitive.
 - Ask permission to sit down and maintain a respectful distance that does not invade private space but demonstrates empathy.
 - Introduce yourself to all present at the visit.
3. Once introductions have been made, assess patient and family cultural norms for giving and receiving information and for decision-making at the first visit.
 - Share with the patient and family that there will likely be important information about the patient's condition discussed at every visit.
 - Ask the patient with whom they would like healthcare information discussed.
 - If there are people important to the patient who cannot be present, such as a long-distance son or daughter, consider ways to use technology to share information with them and to include them in future visits using telephone or computer conferencing.
4. Find out how much information the patient and family would like to have when decisions need to be made.
 - Normalize the information-gathering process: "Some people like to hear all about the illness, its course, and treatments as well as all labs or scan results. Others prefer that we share the information needed to make decisions and limit the detail on the illness, treatment, and testing. How much information would you like us to share with you?" This may be different for patient and caregiver, and it can be challenging to respect differing needs for information.
 - Understand that accepting the family's usual process of decision-making will be critical to providing culturally respectful palliative care throughout the patient's disease trajectory.

Adapted from Mazanec, Panke.¹⁶

PREFERRED LANGUAGE, HEALTH LITERACY, HEALTH NUMERACY, AND FINANCIAL LITERACY

The NCP *Clinical Practice Guidelines*⁶ emphasize that palliative care providers should tailor communication to the patient's and family's level of literacy, health literacy, numeracy,

and financial literacy. This requires attention to the information provided orally and in written formats and consideration of an individual's or group's language preference. When there is not a common preferred language between the APRN and the patient, or when the patient and family have low health literacy and numeracy, the APRN must use culturally sensitive strategies to help them navigate the healthcare system.

PREFERRED LANGUAGE

A 2018 Census Bureau Report identified that 67.3 million people in the United States spoke a language other than English in their home.³⁰ This number has doubled since 1990 and reflects about 22% of all US residents.³⁰ The NCP *Clinical Practice Guidelines* Domain 6, Cultural Aspects of Care,⁶ defines the current standard in the criteria that outline how palliative care programs should make all reasonable efforts to provide interpreter services and written materials in the preferred language to facilitate patient and family understanding of information.

Individuals facing serious illness must receive information in a format and a language that are easily understood so they can make informed healthcare decisions. Preferred language, health literacy, and health numeracy affect the person's ability to understand complex medical information and treatment options during serious illness. Even things that seem routine and simple to healthcare providers might be confusing to the public. Literacy and language issues may compound the challenge of understanding the medical situation.

The palliative APRN should assess the environment in which they practice; this includes

- Determining the dominant languages and dialects spoken by individuals in your community and the setting where you practice.
- If the preferred language is not English, a professionally trained interpreter of the appropriate gender to the health issues should be contacted when verbal communication is required. For any interpreters, it is appropriate to ask them if a question is appropriate or how it should be asked. As of 2019, every state and the District of Columbia have enacted multiple laws addressing language access.³¹ It is important for APRNs to know the laws in their state of practice. It is important for palliative APRNs to become skilled in using the particular programs available in the setting where they work: home, hospital, clinic, long-term care facility, etc.
- Language assistive services must be provided by a qualified translator and interpreter and must be free for the patient/family. If a qualified professional interpreter is not available, access a telephone language line to assist in conversations. Examples of language lines that have interpreters for healthcare include Language Line Services,³² CyraCom International,³³ and Mobile Martti.³⁴ They offer 24-hour availability, 365 days/year for those with an account. Newer technology services, such as video-remote interpreting (VRI), allow for face-to-face interactions, especially important for those with hearing or speech impairments. Family members should only act as interpreters in an emergency.
- Family members are often uncomfortable when placed in the interpreter role, especially if sensitive topics are being addressed. Moreover, there may be challenges placed on family members depending on their gender and age for discussing gender-related issues. In some

non-Western cultures, family members have a responsibility to protect the patient from distress or worry. Therefore, family interpreters may selectively choose what and how to translate information. If the APRN is unsure if the family member is sharing accurate information with the patient, it could lead to major misunderstandings.^{15,18}

- Assessing the literacy level of the patient and family. Consider the literacy level of both the patient and the family when developing a plan of care.
- Always remaining conscious of your verbal and nonverbal communication when using an interpreter. For example, when speaking, make eye contact with the person you wish information to be directed toward, rather than looking at the interpreter. Consider tone of voice and expressions.
- Ensuring understanding by having the patient explain to you or the interpreter what he or she has heard using his or her own words.

HEALTH LITERACY

The National Academy of Medicine (formerly the Institute of Medicine) Committee on Health Literacy defines *health literacy* as the degree to which individuals can obtain, process, and understand basic health information and services needed to make appropriate health decisions.³⁵ Only 12% of adults have proficient health literacy, and 14% of adults have below-basic health literacy which negatively impacts health outcomes.^{35,36} Patients with low literacy are less likely to manage chronic conditions effectively and are more likely to be hospitalized, which may lead to poorer health outcomes and higher healthcare costs. Several key findings from National Assessment of Adult Literacy (NAAL)³⁷ underscore how important it is for the APRN to pay attention to the patient's literacy level (Box 35.5).

Box 35.5 BEHAVIORS THAT MAY INDICATE LITERACY CHALLENGES

1. Taking medications incorrectly
2. Offering an excuse when asked to read written materials (e.g., "I forgot my glasses")
3. Identifying medications by shape or color rather than name, or opening medicine bottle rather than reading the label
4. Not looking at written materials or not turning them right side up if handed materials upside down
5. Not being able to fill out simple, age- and language-appropriate forms; providing incorrect information; leaving many items blank

Adapted from Mazanec, Panke.¹⁶

Recommendations from Healthy People 2030 have added to the current understanding of health literacy by highlighting two definitions: *personal health literacy* (the ability to find and use information for decision-making) and *organizational health literacy* (to what extent the organization is equitably enabling the individual to access this information).³⁸ The palliative APRN can improve how critical information is equitably delivered, received, and understood by asking two important questions:

1. *Is the information appropriate for the individual?*
 - Identify the intended audience and determine whether materials and messages reflect the age, social and cultural background, and language and literacy skills of that audience.
 - Evaluate each individual's understanding before, during, and after delivery of information.
 - Acknowledge and respect cultural variations. Consider components of culture when developing materials or speaking with individuals (see Table 35.1). Acknowledge and respect individual and group preferences and assess for variations within groups.
2. *Is the information easy to use?*
 - Limit the number of messages being delivered at any given time. In general, no more than four messages should be conveyed.
 - Give specific recommendations and expected actions. Focusing on behavior rather than medical principles or concepts may lead to better understanding and outcomes.
 - Use plain language that is familiar to the audience. Keep it simple, and avoid long sentences and words with many syllables. Avoid acronyms and medical jargon.
 - Offer to call a family member to review instructions with them if the patient is alone and you suspect difficulty in understanding.
 - Use pictures when giving instructions. This can help individuals comprehend complicated instructions related to medical conditions, treatments, medications, and abstract concepts. Pictures should reflect the message and should not be merely decorative additions. An example is for medications: use a picture of sunrise for medications taken in the morning, high sun for medications taken in the day, moon rise for the evening, and moon in the sky for medications taken at night.

Behaviors that may indicate limited health literacy are described in Box 35.5.³⁹ Resources, instructional materials, and marketing can be made more understandable by following a few simple suggestions from the Department of Health and Human Services: use a simple 12-point font, limit line length to 40–50 characters, use headings and bullets to focus on key points, and leave plenty of white space on the paper.³⁸

HEALTH NUMERACY

Patients will receive information that involves numbers, and there is a growing recognition that attention to health numeracy is needed to help individuals who cannot fully comprehend or use the information they are given to make informed decisions about their health. Health numeracy is closely related to health literacy. Health numeracy is the degree to which individuals have the capacity to assess, process, interpret, communicate, and act on numerical, quantitative, graphical, biostatistical, and probabilistic health information to make effective health decisions.⁴⁰ Basic numeracy skills are those required to identify numbers and comprehend data without having to manipulate any figures—for example, the ability to read and understand a prescription label. We often ask patients to make treatment decisions based on percentages and averages: these data need to be put in terms that are easy to understand. An example might be saying “one in five people will respond to this treatment” instead of 20 %. While more research is needed, studies on numeracy are finding results similar to those on health literacy, in that individuals with lower numeracy skills have poorer health outcomes.

The palliative APRN should be able to assess how numerical information is received and understood by patients and families. If difficulties are uncovered, consider alternative ways of presenting important numerical information. Using pictures and plain language that describe concepts and demonstrate the desired action (e.g., how many morphine pills equal the dose ordered) may improve adherence with medical advice and lead to better outcomes. Pictures can help with the timing of medications. Illustrations of a sunrise may help identify morning medications and a sunset or full moon can signify it is time to take evening medications.

COMMUNICATING IN THE AGE OF TECHNOLOGY

The goals of digital health technology were to improve quality, safety, and efficiency of healthcare while decreasing healthcare disparities. Telehealth allows palliative APRNs to reach those in rural or underserved areas, but only if internet access and the technology is available. Patients and families must also have at least a basic level of technology literacy to be able to engage with healthcare providers. About 31.8 million adults (16% of US adults) are considered digitally illiterate.⁴¹ Those without these skills are more likely to be Black, Latinx, foreign-born, older, and less educated.⁴²

The coronavirus pandemic of 2020 has changed the way palliative APRNs and other healthcare professionals communicate with patients and families.⁴³ In many settings, patients must come alone to their medical visit or hospital stay, which complicates culturally appropriate delivery of medical information, medical decision-making, and advance care planning. For patients and families who value collective decision-making rather than individual decision-making, the family must be able to be “brought into the visit” for

Table 35.2 TECHNOLOGIES FOR VIRTUAL COMMUNICATION

TYPE OF TECHNOLOGY	STRENGTHS	CHALLENGES
FaceTime ⁴⁴	Easy to use on any iOS device Can use phone number or email; phone charges may apply depending on the phone service High-quality technology No longer needs wifi	Must have an iOS device; forward-facing camera phone or Mac computer with camera, so not available on Android or Windows
Zoom ⁴⁵	Works on Android and iOS Available in 26 countries Offers free 40-minute calls with up to 100 people As of March 2020, the #1 most downloaded app	Has had privacy and security issues; easily hacked
Skype ⁴⁶	Easy to use on any device with a Skype app “Meet now” feature allows anyone to link into a host, much like Zoom Calls are free anywhere in the world More than one person can be on the call Can record the call Can share screen if desired	Has had a history of being challenging to use because participants all must have a link; this has been recently resolved

From FaceTime⁴⁴; Zoom⁴⁵; and Microsoft Skype.⁴⁶

these discussions. Video technology, either by smart device, tablet, or computer, can help to accomplish this if the family has the equipment and technology literacy as well as internet access. It is important to make every effort to use technology that allows for face-to-face conversations. Existing commercial platforms such as FaceTime,⁴⁴ Zoom,⁴⁵ and Skype⁴⁶ are examples of useful technologies (Table 35.2). Since more than 70% of communication is nonverbal, it is helpful to be able to read body language as well as verbal responses.⁴⁷ Many patients have shown a preference for remote visits, challenging healthcare providers to find a platform that offers ease of use and full assessment and communication with the patient and family.

were able to tell her how much they loved her while the APRN held her hand in the room. The palliative APRN promised the family that she would stay with her, manage any symptoms she might have, and would make sure that a team member was with her until her death.

CULTURALLY SENSITIVE PALLIATIVE CARE TOPICS

Numerous palliative care topics (e.g., disclosure or “truth telling”; medical decision-making, including withholding and discontinuing technology; pain and symptom management; and the care of the dying and bereaved) have important cultural implications.²³ Another sensitive topic is the continued disparity in access and delivery of palliative and end-of-life care among racial and ethnic minorities.

RACIAL AND ETHNIC DISPARITIES IN ACCESS TO QUALITY PALLIATIVE CARE

Healthcare disparities in palliative and end-of-life care exist among racial and ethnic minorities. These disparities are shaped by economic conditions, insurance status, structural features of the neighborhood, knowledge, and access to care.^{23,48} Although the intention of the *Affordable Care Act* (ACA)⁴⁹ was to improve access to healthcare, safety net hospitals serving economically disadvantaged individuals and minorities still struggle with funding.⁴⁸ There is inadequate access to palliative care services, hospices, and long-term care facilities for racial and ethnic communities, negatively impacting the treatment options for care during serious illness.⁵⁰ Disparities in hospice use are evident in 2018 statistics that reflect that hospice use is less among minority groups

CASE STUDY 2: TELEHEALTH FAMILY CONFERENCING

During the COVID-19 pandemic, the palliative care team was asked to help with advance care planning and family conferencing for Ms. W. The palliative APRN met Ms. W, a 67-year-old African American woman with diabetes and moderate obesity admitted with respiratory distress after a 6-day history of fevers, nonproductive cough, and arthralgia. Ms. W was the mother of four grown children: three daughters living locally and a son in Mississippi. She was a nursing assistant employed at a local nursing home.

Within 6 hours of admission, she required intubation and sedation. The palliative APRN contacted Ms. W’s children and a virtual family meeting was scheduled. Because visitors were not allowed during the pandemic, for the last three days of her illness the family conducted daily virtual meetings with the palliative care team to receive updates on Ms. W’s condition. When Ms. W became unstable and the team was concerned that her life was short, the palliative APRN coached the family to say goodbye to their mother virtually. They sang her favorite hymns and

(82% White, 8.2% Black, 6.7% Hispanic, 1.8% Asian, 0.4% Native Americans).⁵¹

Evidence from the Health and Retirement Study explored racial and ethnic differences in end-of-life care utilization and advance care planning.⁵² The study demonstrated that people from minorities are less likely to be informed about end-of-life care options, if available, and are more likely to die in hospitals with a greater intensity of treatment at end of life. The preference for more intensive treatment may be due in part to a strong religious belief that only God can decide life and death, but it may also be due to a history of mistrust with the healthcare system and belief that any type of care other than aggressive care is of lower quality.⁵² The study also highlighted disparities in participating in advance care planning, which is known to be important for patient-centered care and cost-effective use of resources.⁵² The data from the Health and Retirement study identified that many African Americans believe they would receive poorer-quality care if they completed an advance directive and thus were less likely than Whites to do so.⁵² Lack of advance care planning may also be due in part to health literacy issues, language barriers, and mistrust of healthcare providers.^{53,54}

Palliative APRNs must address these racial and ethnic disparities in hospice and palliative care. Recommendations by Payne⁵⁴ define what is needed to make this happen: (1) acknowledge the negative effects of past and present racism, (2) learn and respect every individual's cultural and religious values, (3) commit to continuous improvement in patient-provider communication, and (4) engage in strategies with community partners to foster trust.⁵⁴

CASE STUDY 3: GOALS-OF-CARE PLANNING

The palliative care team was called in to help manage symptoms of shortness of breath and help with goals-of-care planning for a patient in the cardiac care unit. Ms. A, an African American woman, had been admitted to the cardiac care unit for the fourth time in three months due to worsening heart failure. The cardiology team recommended she transition to hospice care.

During the initial visit with the palliative APRN, Ms. Anderson reported how tired and scared she was. She was concerned about her son, who was increasingly angry about her illness, always questioning if she was getting the best care for her condition.

The palliative APRN set up a goals-of-care conversation with Ms. A and her son. During the discussion, the son became angry and accused the team of not doing everything they could for his mother. He stated, "You are not giving her the best care because she is Black—I know that is the reason." He refused any plan of care other than transfer to intensive care, despite his mother telling him that she just hated being in the ICU and was tired of all the treatment. To calm him, she agreed to ICU care.

The palliative APRN set up a meeting with Ms. A's son. She asked him to talk about his mother's care and inquired about injustices in care that had occurred in the past. They discussed the current course of treatment, her life-limiting illness, and all that could be done to manage her symptoms and provide quality care while still honoring her wishes to not return to the ICU.

DISCLOSURE OF INFORMATION AND PROGNOSIS

The *Patient Self-Determination Act* (PSDA)⁵⁵ of 1991, grounded in Western cultural values and beliefs, was written to protect individuals' healthcare preferences.⁵⁴ Western cultural preferences include the right to be informed of one's diagnosis and prognosis and the risks and benefits of treatment. *Autonomy*, as the guiding principle, assumes that the individual, rather than the family or other social group, is the appropriate decision-maker. This European-American model of patient autonomy has its origin in the present-day US dominant culture, a predominantly White, middle-class perspective that does not consider diverse cultural perspectives.^{23,56}

Some non-Western cultures believe that telling the patient they have a terminal illness strips away any and all hope, causes needless suffering, and may actually hasten death. If disclosing the patient's diagnosis and/or prognosis violates the patient's and family's cultural norms, or if the patient does not wish to receive information, doing so directly violates the patient's right to autonomy. For example, some people from indigenous populations (American Indians and Alaskan Natives) believe talking about the future is taboo.⁵⁷ Imposing negative information, such as a prognosis of a life-limiting illness, on the person who is ill is a dangerous violation of traditional Navajo values: those who adhere to Navajo traditions believe that talking about death will actually cause death. In families who adhere to Middle Eastern practices, telling the patient the diagnosis, who is perceived by the family as "vulnerable," is considered culturally unacceptable.⁵⁸ The palliative APRN may find the *Prognosis Declaration Form* helpful for assessing patient/family choice in receiving information for persons of any cultural background (Box 35.6).⁵⁹

MEDICAL DECISION-MAKING

The principle of respect for patient autonomy emphasizes the patient's right to participate in decisions about the care he or she receives. The underlying assumption of patient autonomy is that all patients want control over their healthcare decisions, yet this is not always accurate.⁵⁶ In some families, patient autonomy may not be viewed as empowering but rather as

Box 35.6 PROGNOSIS DECLARATION

- Tell me everything.
- I've not decided what I want to know about my prognosis, so ask me over the course of my treatment.
- I want to participate in my treatment, but I don't want to receive any information on my prognosis.
- I don't wish to know any information about my prognosis but I authorize you to speak with (PERSON) about my case and to answer any questions that this person may have about my likely prognosis and treatment.

From Scheier.⁵⁹

isolating and burdensome for patients who are too sick to make difficult decisions.⁶⁰ In fact, depending on patient and family cultural preferences, patient autonomy actually may violate the very principles of dignity and integrity it proposes to uphold.

In many non-Western cultures, the concept of interdependence among family and community members is valued more than individual autonomy.⁶⁰ If the palliative APRN is caring for a patient who adheres to this belief, it is culturally sensitive to include, rather than exclude, the family in decision-making. In some religious practices, it is important that the religious leaders also be included in the decision-making. Cultural groups that practice family-centered decision-making may prefer that the family, or perhaps a particular family member, rather than the patient, receive and process information (see Chapter 32, “Advance Care Planning,” and Chapter 33, “Family Meetings”).

Keep in mind that some individuals prefer to communicate their wishes verbally rather than put them in writing. They may be unwilling to sign advance directive forms because of a lack of trust in the healthcare system or a belief that God is the ultimate decision-maker over life-and-death matters.^{48,54}

DISCONTINUATION OF LIFE-PROLONGING THERAPIES

Family members may feel that by agreeing to stop potentially life-prolonging therapies they are, in fact, responsible for the death of their loved one. For families who believe that it is the duty of children to honor, respect, and care for their elders, they may feel obligated to continue futile life-sustaining interventions. Allowing a parent to die may violate the principles of “filial piety.”⁶¹

Religious beliefs may also play a role in decisions about withholding or discontinuing medical interventions. For example, some people from the Middle-East who are practicing Islam believe that potentially curative treatment should continue until the last moment of life.⁶² For those practicing Orthodox Judaism, which believes that all life is precious and only God can decide our time to die, agreeing to discontinue life-prolonging therapies may violate their beliefs.⁶³ In both examples, involving a religious leader from the family’s religious community may help the family and the healthcare team integrate religious tenets into a culturally appropriate plan of care.

All healthcare personnel should be acutely aware of the medical jargon and language they use. Many phrases, such as “do not resuscitate” and “withdrawal of life support,” have negative connotations. What is standard terminology in healthcare can get lost in translation even if the parties are speaking the same language. “Withdrawal of life support” or “withdrawal of care” may be easily confused with stopping *all* care, which is certainly not the intention. The family may feel as though the team is giving up on the patient and abandoning him or her, resulting in family suffering, isolation, and distress. Instead, use language that conveys the benefits versus the burdens of all therapies, such as discontinuing a specific

therapy and aggressively managing symptoms. Focus on what the team will do to care for the patient rather than what burdensome interventions should be stopped (see Chapter 54, “Discontinuation of Cardiac Therapies”; Chapter 55, “Discontinuation of Respiratory Therapies”; and Chapter 56, “Discontinuation of Life-Sustaining Therapies”).

PAIN AND SYMPTOM MANAGEMENT

The experience of pain and other symptoms commonly addressed in palliative care (e.g., anorexia, cachexia, nausea and vomiting, fatigue, dyspnea, and depression) must be appreciated from a cultural perspective. Pain and subjective symptoms demand a self-report of the severity and the meaning associated with them. For some, culturally learned responses to pain and symptoms may influence tolerance and behavior. Persons who have English as a second language are at risk of being unable to express pain and other symptoms.⁶⁴ It is important to remember cultural considerations and health literacy when assessing pain and symptoms. Labels like “pain” or “depression” may be culturally unacceptable for patients to self-report, so asking about a “hurt” or “ache” instead of “pain” and “a tired state” instead of “depression” may elicit a more accurate response from the patient.⁶⁵

The meaning of the pain or symptom also influences assessment and treatment.^{66,67} Religious and spiritual practices as well as ethnic values and beliefs may influence a patient’s willingness to accept treatment. Enduring pain or severe symptoms may be important to a patient who believes that suffering is necessary to achieve a good afterlife.^{65,66} Try to find a common understanding of the suffering experience and the value of pain/symptom management using a team approach, possibly including a religious leader. Finally, consider that racial, ethnic, age, or gender biases can hinder good pain and symptom management.⁶⁸ Pain is often undertreated in minorities.⁶⁹ Pain is underrated in the Latinx and African American populations, and this is associated with inadequate pain management.⁷⁰ Women, children, and elderly people are also at risk for inaccurate assessment and poor management^{65,70} (see Chapter 43, “Pain”).

Additional common signs and symptoms in palliative care that have cultural implications are anorexia and cachexia. For families who are caring for a loved one who is no longer able to eat or no longer interested in eating, anorexia and cachexia can be a source of distress. Food is seen as essential for life in all cultures.⁷¹ It is used in celebrations and rites of passage and as an expression of social relationships and connections with families, friends, and others. The intense meaning attached to food and nutrition can result in cultural and ethical conflicts over providing medically administered nutrition and hydration at the end of life. The palliative APRN must use listening and presence to understand what feeding the patient means to the family and to help the family develop alternative expressions of comfort and love. If the family’s health literacy is low, not feeding the patient may be akin to “starving him to death” or abandoning a basic human right of feeding. The APRN should provide a culturally sensitive explanation of the benefits and burdens associated with feeding.

DEATH AND DYING

A conversation about patient and family wishes during the dying process, at the time of death, and immediately after death should take place well in advance, provided it is not culturally unacceptable to discuss prior to death.^{26,72,73} In some cultures, important rituals and customs must take place prior to or at the time of death. These practices need to be identified and integrated into the plan of care. For example, those who are of the Hindu tradition may prefer to die at home, lying on the floor, close to the earth, whereas it is important for those who are Muslim that the body should be positioned facing Mecca.^{23,72–74} Care of the body after death is also important. In some traditions, it is unacceptable for the body to be cared for by someone of a different gender.^{72–74} Beliefs about autopsy or organ donation should be discussed before death. Keep in mind that some cultures and religious communities believe that organ donation and autopsy are disrespectful to the sanctity of the body.²³ The family will hold on to the memory of the patient's final days and death forever, so if cultural practices are not honored, family members may experience complicated grief after the death of their loved one.

GRIEF AND BEREAVEMENT

Grief is an emotional response to a loss with which there was an emotional attachment.⁷⁵ The experiences of loss, grief, bereavement, and mourning are guided by cultural traditions, rituals, and beliefs. The expressions of grief can vary significantly among cultures, making it important to assess expressions of grief and individuals' behavior during mourning within a cultural context. Behaviors that are acceptable in non-Western cultures may be misconstrued as inappropriate by others.^{72,75} It is important for the APRN to learn from family what are culturally appropriate practices during the mourning period in order to recognize if family members are experiencing complicated grief and need referrals for counseling and support (see Chapter 38, "Grief and Bereavement").

DIVERGENT CULTURAL VALUES AND BELIEFS

The three most common sources of cultural conflict are between the patient and family, among the healthcare team members, and among the healthcare team, patient, and family. In our multicultural society, patients and family members may have different values and beliefs that can result in conflicting opinions regarding healthcare practices. Healthcare providers, too, bring the values and beliefs of their own cultures to the clinical setting. Keep in mind that there also may be generational differences among persons from a particular ethnicity and culture. If one of the parties involved is more assimilated into the Western culture and the other aligns with non-Western values, practices, and beliefs, conflict may occur. When there is conflict over culture norms, the healthcare provider should suspend their personal beliefs and biases and focus on grasping the meaning of the message being

sent.⁷⁶ APRNs can support all parties by facilitating a family meeting with culturally appropriate discussion around the conflict. The palliative APRN may need to be the advocate for patient and family wishes. An ethics consult and family meeting may help to resolve conflict and reach a shared understanding of the goals of care; see the chapters of Section IX, "Ethical Dilemmas".

SUMMARY

With the increasing cultural diversity of the United States, the APRN must be culturally sensitive to provide quality comprehensive palliative care as delineated by nursing practice as per the ANA *Code of Ethics for Nurses*¹, the ANA *Nursing Scope and Standards of Practice*,² and the NCP *Clinical Practice Guidelines*.⁶ This requires moving beyond one's own ethnocentric view of the world to appreciate and respect the similarities and differences in others. There are many situations in which the palliative APRN is challenged to come to appreciate and understand an individual's preferences in care based on cultural values, practices, and beliefs. However, by maintaining a sense of cultural humility, caring for each patient and family member as a unique human being with unique needs, and attending to those needs with dignity and respectfulness, the APRN can provide culturally sensitive palliative care.

ENSURING QUALITY SPIRITUAL CARE

Betty Ferrell

KEY POINTS

- Assessment of spiritual needs is a component of comprehensive patient evaluation in palliative care.
- Spirituality encompasses a broad spectrum including religion, purpose and meaning, values, beliefs, and hopes.
- Advanced practice registered nurses (APRNs) provide spiritual care through communication, coordination of care, and responding to spiritual distress.

INTRODUCTION

Spiritual care becomes especially important as patients face any serious illness and at the end of life. Spirituality is closely related to culture and encompasses religious beliefs as well as a broad array of dimensions including meaning, a sense of purpose, hope, and connection.¹⁻⁴ As advanced practice registered nurses (APRNs) provide leadership, mentorship, and model expert clinical care, they act as important agents to ensure quality spiritual care. However, as with other aspects of advanced practice, APRNs need knowledge and skill development to deliver the care patients and families need.

This chapter reviews evidence-based guidelines for delivery of spiritual care with discussion of both spiritual assessment and interventions. Case examples are provided to illustrate the role of APRNs in spiritual care. The chapter also reviews spiritual assessment tools for application in advanced practice as well as suggested resources for continued learning.

The National Consensus Project identifies spiritual, religious, and existential care as one of the eight essential domains of quality care.⁵ Spiritual care is often led by the specialist member of the team, the chaplain, but all members of the team must be competent in their roles in assessment and prepared to respond to spiritual needs. As with other aspects of care in serious illness, nurses are centrally involved in the provision of this care as the most prevalent discipline across all settings of care.⁶

This textbook is devoted to advanced practice nursing, and, as is the case with areas such as complex pain or symptoms, APRNs need advanced skills in spiritual care. While all palliative nurses should be skilled in basic spiritual assessment and response to spiritual needs,²⁻⁴ palliative APRNs can be a valuable resource for complex spiritual needs. Box 36.1 presents the recommendations for Spiritual Care from the National Consensus Project *Guidelines for*

Quality Palliative Care. Some examples of complex spiritual needs might include

- Conducting a spiritual assessment for patients with less common religious affiliations or whose religious beliefs are creating ethical conflicts in care.
- Working collaboratively with the chaplain to facilitate support of spiritual distress in patients who express a sense of abandonment.
- Expert communication skills to support patients as they conduct life reviews, resolve issues of forgiveness, grasp for miracles, or in those instances when conflicting religious beliefs within families create conflicts in care.

The role of the palliative APRN has been described throughout this text as encompassing many responsibilities including that of expert clinician, educator, manager, and researcher. These roles also apply to the domain of spiritual care. Nurses work collaboratively with chaplains, and together they ensure that patients receive the spiritual care they need (Box 36.2).⁷ The APRN serves as a clinical expert in spiritual care, supported by chaplaincy, to model spiritual assessment and care. Knowledge and clinical skills are important competencies for staff education provided by the APRN to new graduates or new staff.

Nurses are also involved in the development of policies and procedures, documentation, and other structures and processes of care. Selection of spiritual care assessment tools and procedures for documenting spiritual needs and care is necessary as palliative care teams are initiated.

As with all other aspects of advanced practice nursing, proficiency in spiritual care requires life-long learning. This is especially true given the increasing diversity of the US population, which includes a vast array of religious traditions and spiritual beliefs that are critical in serious illness. See Table 36.1^{4,8-13} for mnemonic tools that may be used to guide APRNs in performing a spiritual assessment. See Table 36.2^{14,15} for spiritual care guidelines and implications for the palliative APRN.

SPIRITUAL ASSESSMENT

The importance of spiritual care rests on the foundation of key healthcare concepts such as patient-centered care, respect for the person, and culturally respectful care.^{7,10}

Domain 5: Spiritual, Religious, and Existential Aspects of Care

Spirituality is recognized as a fundamental aspect of compassionate, patient- and family-centered palliative care. It is a dynamic and intrinsic aspect of humanity through which individuals seek meaning, purpose, and transcendence, and experience relationship to self, family, others, community, society, and the significant or sacred. Spirituality is expressed through beliefs, values, traditions, and practices. Palliative care interdisciplinary teams (IDT) serve each patient and family in a manner that respects their spiritual beliefs and practices. Teams are also respectful when patients and families decline to discuss their beliefs or accept spiritual support.

GUIDELINE 5.1 GLOBAL

CRITERIA

- 5.1.1 The IDT has clearly defined policies and processes in place to ensure spiritual care is respectful of patient and family age, developmental needs, culture, traditions, and spiritual preferences.
- 5.1.2 Either directly, through referral, or in collaboration with the professional chaplain, the IDT facilitates spiritual and cultural rituals or practices as desired by the patient and family.
- 5.1.3 IDT members respect patient and family beliefs and practices, never imposing their individual beliefs on others.
- 5.1.4 The spiritual needs of family members may differ from those of the patient and are recognized and supported.
- 5.1.5 Care of children, adolescents, and their family members recognizes that spirituality is integral to coping with serious illness and is provided in a developmentally appropriate manner.
- 5.1.6 In all settings, the IDT includes professional chaplains who have evidence-based training to assess and address spiritual issues frequently confronted by pediatric and adult patients and families coping with a serious illness.
- 5.1.7 The professional chaplain is the spiritual care specialist, conducting the assessment and addressing the spiritual aspects of the care plan.
- 5.1.8 Professional chaplains develop community partnerships to ensure patients have access to spiritual care providers trained and supervised by a professional chaplain. The IDT and community spiritual care providers share information and coordinate service.
- 5.1.9 The IDT integrates the patient's and/or family's faith community into the care plan when requested.
- 5.1.10 Led by the professional chaplain, opportunities are provided to engage staff in self-care and self-reflection regarding their own spirituality.
- 5.1.11 Every member of the IDT is trained in spiritual care and recognizes the importance of the spiritual aspects of care.
- 5.1.12 Members of the IDT receive training to cultivate an openness to the spirituality of patients and families through empathic listening.

GUIDELINE 5.2 SCREENING AND ASSESSMENT

The spiritual assessment process has three distinct components: spiritual screening, spiritual history, and a full spiritual assessment. The spiritual screening is conducted with every patient and family to identify spiritual needs and/or distress. The history and assessment identify the spiritual background, preferences, and related beliefs, values, rituals, and practices of the patient and family. Symptoms, such as spiritual distress and spiritual strengths and resources, are identified and documented.

CRITERIA

- 5.2.1 All aspects of the screening, history, and assessment are conducted using standardized tools.
- 5.2.2 Spiritual screening is completed as part of every clinical assessment to identify spiritual distress and the need for urgent referral to a professional chaplain. Screening is designed to evaluate the presence or absence of spiritual needs and spiritual distress.
- 5.2.3 IDT members also include a spiritual history as part of the clinical evaluation in the initial assessment process. A spiritual history identifies patient preferences and values that may affect medical decision-making.
- 5.2.4 A spiritual assessment is triggered based upon the results of the spiritual screening and history. It is an in-depth and ongoing process of evaluation of spiritual needs, results in a plan of care, and is conducted by a professional chaplain as the spiritual care specialist, in collaboration with the faith community, based upon patient wishes.
- 5.2.5 The spiritual assessment explores spiritual concerns including, but not limited to:
 - a. Sources of spiritual strength and support
 - b. Existential concerns such as lack of meaning, questions about one's own existence, and questions of meaning and suffering
 - c. Concerns about relationship to God, the Holy, or deity, such as anger or abandonment
 - d. Struggles related to loss of faith, community of faith, or spiritual practices
 - e. Cultural norms and preferences that impact belief systems and spiritual practices
 - f. Hopes, values and fears, meaning, and purpose
 - g. Concerns about quality of life

- h. Concerns or fear of death and dying and beliefs about afterlife
- i. Spiritual practices
- j. Concerns about relationships
- k. Life completion tasks, grief, and bereavement

GUIDELINE 5.3 TREATMENT

The IDT addresses the spiritual needs of the patient and family.

CRITERIA

- 5.3.1 Spiritual elements of the plan of care are based on needs, goals, and concerns identified by patients and families, recognizing and maximizing patient and family spiritual strengths. The care plan, including religious rituals and other practices, details the expected outcomes of care.
- 5.3.2 Patient and family spiritual needs are addressed according to established processes, documented in the interdisciplinary care plan, and emphasized during transitions of care, including identification of significant practices which bring strength and comfort to the patient.
- 5.3.3 Professional and institutional use of symbols and language are inclusive of patient and family cultural and spiritual preferences.
- 5.3.4 The patient and family are supported and accommodated in their desires to display and use their own spiritual and/or cultural symbols.
- 5.3.5 Palliative care teams serving pediatric patients have expertise in honoring and meeting the spiritual needs of children and adolescents, including in situations where children or adolescents have differing values, beliefs and needs from their parents or designated decision-makers.

GUIDELINE 5.4 ONGOING CARE

Patient and family spiritual care needs can change as the goals of care change or patients move across settings of care.

CRITERIA

- 5.4.1 Throughout the trajectory of the patient's illness, the IDT performs spiritual screening to identify new or emergent issues, identifying services and supports to help navigate these transitions. Changes in prognosis and other significant transitions prompt reassessment of spirituality.
- 5.4.2 The plan of care continues to evolve based upon the changing needs of the patient and family.

Organizations addressing quality in healthcare have recognized the importance of spiritual care even before the development of palliative care. The Joint Commission (TJC), which accredits healthcare organizations, requires spiritual assessment "to determine the patient's denomination, beliefs and what spiritual practices are important."²⁰ Spiritual assessment

is closely aligned with culturally competent care, which is emphasized by many accreditation bodies since religious beliefs are very often central to cultural identity (Box 36.3).²¹

The following case study illustrates the APRN's role in spiritual assessment and how such assessment impacts care and outcomes of that care.

Box 36.2 CHAPLAINCY SERVICES

Areas of chaplaincy assessment

Grief
 Concern about death and afterlife
 Conflicted or challenged belief systems
 Loss of faith
 Concern with meaning/purpose of life
 Concern about relationship with deity
 Isolation from religious community
 Guilt
 Hopelessness
 Conflict between religious beliefs and recommended treatments
 Ritual needs

Adapted from Riba et al.⁷; and National Comprehensive Cancer Network. Distress Management (Version 2.2013). http://www.nccn.org/professionals/physician_gld/f_guidelines.asp

CASE STUDY 1: CONFLICTING RELIGIOUS BELIEF SYSTEMS

Joseph is a nurse practitioner in a 200-bed Catholic hospital. His primary position is in oncology but he is now devoting 20% of his time to the new palliative care service. He has been contacted by the intensive care unit (ICU) to assist in the care of a 70-year-old Iranian man Mr. S who was visiting his brother in the United States when he experienced a cerebral aneurysm. Mr. S is being maintained on a ventilator but is declining, and death is anticipated soon. His wife is extremely distraught, being far away from her family and friends and never having been close to the brother they were visiting. She blames the brother for insisting that her husband come to the United States to work out some family business. The patient and his wife are devout Muslims.

There are two chaplains in the hospital who support the palliative care service, but their time is very stretched between the busy emergency department and trauma center, the large

Table 36.1 MNEMONICS TOOLS TO GUIDE A SPIRITUAL ASSESSMENT

AUTHOR/S	COMPONENTS (MNEMONIC)	ILLUSTRATIVE QUESTIONS
Maugens ⁸	• S (spiritual belief system)	• What is your formal religious affiliation?
	• P (personal spirituality)	• Describe the beliefs and practices of your religion or spiritual system that you personally accept. What is the importance of your spirituality/religion in daily life?
	• I (integration with a spiritual community)	• Do you belong to any spiritual or religious group or community? What importance does this group have to you? Does or could this group provide help in dealing with health issues?
	• R (ritualized practices and restrictions)	• Are there specific elements of medical care that you forbid on the basis of religious/spiritual grounds?
	• I (implications for medical care)	• What aspects of your religion/spirituality would you like me to keep in mind, as I care for you? Are there any barriers to our relationship based on religious or spiritual issues?
	• T (terminal events planning)	• As we plan for your care near the end of life, how does your faith impact your decisions?
Anandarajah, Hight ⁹	• H (sources of hope)	• What or who is it that gives you hope?
	• O (organized religion)	• Are you a part of an organized faith group? What does this group do for you as a person?
	• P (personal spirituality or spiritual practices)	• What personal spiritual practices, like prayer or meditation, help you?
	• E (effects on medical care and/or end-of-life issues)	• Do you have any beliefs that may affect how the healthcare team cares for you?
Puchalski ⁴	• F (faith)	• Do you have a faith belief? What is it that gives your life meaning?
	• I (import or Influence)	• What importance does your faith have in your life? How does your faith belief influence your life?
	• C (community)	• Are you a member of a faith community? How does this support you?
	• A (address)	• How would you like for me to integrate or address these issues in your care?
LaRocca-Pitts ¹⁵	• F (faith)	• What spiritual beliefs are important to you now?
	• A (availability/accessibility/applicability)	• Are you able to find the spiritual nurture that you would like now?
	• C (coping/comfort)	• How comforting/helpful are your spiritual beliefs at this time?
	• T (treatment)	• How can I/we provide spiritual support?
Skalla, McCoy ^{11,16}	• M (moral authority)	• Where does your sense of what to do come from? What guides you to decide what is right or wrong for you?
	• V (vocational)	• What gives your life purpose? What work is important to you? What mission or role do you feel passionate about?
	• A (aesthetic)	• What brings beauty or pleasure to your life now? How are you able to express your creativity? How do you deal with boredom?
	• S (social)	• What people or faith community do you sense you belong with most? Do you belong to a community that nourishes you spiritually?
	• T (transcendent)	• Who or what controls what happens in life? Who/what supports you when you are ill?
		• Is there an Ultimate Other (an entity that is sacred, for example)? If so, how do you relate to It?

Table 36.1 CONTINUED

AUTHOR/S	COMPONENTS (MNEMONIC)	ILLUSTRATIVE QUESTIONS
McEvoy (pediatric context) ¹²	• B (belief system) • E (ethics or values) • L (lifestyle) • I (involvement in spiritual community) • E (education) • F (near future events of spiritual significance for which to prepare the child)	• What religious or spiritual beliefs, if any, do members of your family have? • What standards/values/rules for life does your family think important? • What spiritual habits or activities does your family commit to because of spiritual beliefs? (e.g., Any sacred times to observe or diet you keep?) • How connected to a faith community are you? Would you like us to help you reconnect with this group now? • Are you receiving any form of religious education? How can we help you keep up with it? • Are there any upcoming religious ceremonies that you are getting ready for?

From Johnston-Taylor.¹⁶

neonatal care unit, and conducting daily Mass. Joseph sees that the ICU nurses are very frustrated by Mr. S's situation. They are frustrated because of the wife's accusations that the nurses and physicians are trying to kill her husband. She refuses to have a visit by the chaplain because he is a Catholic priest. Joseph meets with the staff, communicates with the neurologist and intensivist physicians, and then organizes a family meeting. Joseph is familiar with Muslim beliefs and has arranged an ICU staff education meeting. He discusses the importance of prayer in the Muslim faith, the patient's beliefs prohibiting any discussion of death and code status, and her resistance to a do-not-resuscitate order. He also reviews the care and Muslim spiritual rituals and practices which the staff should provide as the patient dies. The hospital

chaplain connects Joseph with an imam, the Muslim spiritual leader in the community, who arranges a visit. Joseph meets with the imam when he arrives, to explain the patient's condition and plan of care. Joseph works with the ICU manager to look at the schedule for the next few days to assure the availability of a male staff member for postmortem care since only a male will be allowed to touch the body after death. Finally, Joseph collaborates with the palliative care physician and ICU staff to address the patient's symptoms, including his agitation, fevers, respiratory distress, and pain.

This case illustrates the central role of the APRN in a complex situation through proactive management of spiritual, social, and cultural care. Through his varied roles as an APRN, Joseph

Table 36.2 SPIRITUAL CARE GUIDELINES AND IMPLICATIONS FOR THE PALLIATIVE APRN

GUIDELINES REGARDING SPIRITUALITY IN PALLIATIVE CARE	APPLICATION TO APRN ROLES AND RESPONSIBILITIES
All healthcare professionals should be trained to do a spiritual screening or history.	APRN should promote, facilitate, and participate in palliative care team spiritual care education and training. Team should have consensus on which tool team will use, with input and guidance from chaplain/spiritual care provider.
Spiritual background/information should be communicated and documented and shared with interprofessional team.	APRN should assess spirituality and document finding. An appropriate referral should be made to chaplain/spiritual care provider.
Follow-up on spiritual condition changes as part of routine follow-up.	APRN should reassess spirituality as part of routine visits.
Address spiritual concerns related to psychological, physical suffering.	APRN should ensure holistic assessment of all of the domains of care and ensure spiritual interventions are holistic.
Spiritual treatment should include referral to trained spiritual care provider.	APRN should refer patients to trained spiritual care providers congruent with the patient's beliefs and religion. This may be a person on the palliative care team, the organization, or community spiritual leaders.

**Box 36.3 ITEMS FROM THE SPIRITUAL
SUBSCALE: THE CITY OF HOPE QUALITY OF
LIFE INSTRUMENT**

Spiritual Well-Being

1. How important to you is your participation in *religious activities* such as praying, going to church?
2. How important to you are other *spiritual activities* such as meditation?
3. How much has your *spiritual life* changed as a result of cancer diagnosis?
4. How much *uncertainty* do you feel about your future?
5. To what extent has your illness made *positive changes* in your life?
6. Do you sense a *purpose/mission* for your life or a reason for being alive?
7. How *hopeful* do you feel?

Adapted from City of Hope Quality of Life Instrument.²¹

ensures quality care for Mr. S and family, support for the staff, and avoidance of further cultural clash which could make this difficult situation even worse. In addition, this case demonstrates that the care is contingent on an assessment of the beliefs, practices, and values of both the patient and family. Thorough spiritual assessment is an essential aspect of quality palliative care. When cultural clashes or ethical dilemmas arise in palliative care, it is common for spiritual beliefs to be a key contributing factor.^{22–25}

SPIRITUAL CARE

The spiritual care provided to patients and families is as widely diverse as the cultures represented in our population. Palliative APRNs contribute to spiritual care provided by palliative care teams in many ways. The following three case studies are intended to illustrate the delivery of spiritual care.

CASE STUDY 2: SPIRITUAL SUFFERING

George was a 70-year-old Hispanic man diagnosed with pancreatic cancer. He was referred by his oncologist to the outpatient palliative care clinic for pain and nausea management. The palliative nurse practitioner, Jim, saw George every 2 weeks for his symptoms through alternating clinic visits with telehealth calls each week. George's symptoms improved, but he seemed very anxious and sad. Jim reviewed the initial assessment completed in the oncology clinic to identify any useful psychosocial information in the medical record. Seeing nothing documented and knowing that George was generally alone for his visits, Jim asked George about his family support and if he was depressed. George

shared that his wife, Anita, had been a cook in a local nursing home, and she had contracted COVID early in the pandemic and died. He shared that he has not attended church since her death and that he was really angry at God because he knew that, soon, his grandchildren will "lose me, too, and have no grandparents left." George told Jim that, in his family and in their close Hispanic culture, grandparents are very important for children.

This case highlights the role of the APRN in advanced disease and the need for nurses to recognize that it is common for symptom management to move beyond pharmacologic interventions and to address suffering.⁶ In this case, George is not only a patient, he is also a bereaved family caregiver. The case also illustrates the most important skill for APRNs in spiritual care: listening. Presence and listening are essential to understanding and responding to spiritual needs.

CASE STUDY 3: SPIRITUAL LONELINESS

Mary was an 82-year-old African American woman living in the South in a residential care facility. She experienced multiple symptoms from her end-stage cardiac disease and was referred to palliative care after three hospital urgent care visits over 6 weeks due to dyspnea and edema. She is now preparing for discharge after a hospital admission related to her symptoms. Mary's children live out of state, and she is described as a lonely woman, fiercely independent, and very stoic.

Mary was being seen by a master's prepared nurse, Jean, the clinical nurse specialist in the cardiac care program. Jean did a thorough assessment of Mary, including an assessment of her physical, psychosocial, and spiritual needs. When Jean asked if Mary had a church community that might offer support, Mary angrily replied that she "quit believing in God" as a child, after witnessing common hatred and racial discrimination. When asked about her life before retirement, Mary described her career as a high school science teacher, one of the first African American women to be allowed to teach science in the public school. She said she was proud to have been there at a time "when girls weren't supposed to be smart," and she became calm and proud as she told Jean about the many young women she had inspired to get an education.

Jean collaborated with the cardiology service and the palliative care team in arranging for home-based palliative care because Mary adamantly refused hospice care and insisted on returning home alone. Jean shared with the palliative care service the information she had learned from Mary about her psychosocial and spiritual needs.

This case illustrates an instance where the patient's spiritual journey, from early religious affiliation to movement away from God, becomes expressed in the final phase of life. Nursing assessment helped move beyond the religious aspect to identify positive aspects of spirituality for this patient through the meaning of her life and legacy. The literature and research related to spirituality have emphasized that spiritual care encompasses aspects beyond religious affiliation to also include life meaning, purpose, and existential needs.^{23–30}

CASE STUDY 4: SPIRITUAL CONFLICTS

Kim was a nurse practitioner on a hematology service in an urban academic medical center. One of Kim's most challenging patients was a 20-year-old Korean male, Jyen, who was admitted 40 days prior with severe graft versus host disease following stem cell transplant for leukemia. Jyen's large extended family refused to face the seriousness of his illness despite worsening renal and pulmonary complications. Jyen and his family were devout Catholics and believed in miracles. Jyen was a full code, and he and his family refused any discussion of avoiding resuscitation or life support.

Over the past few days, tensions escalated because the family believed the staff had given up on Jyen. They became angry when the nurses interrupted their bedside prayer sessions, which they believe are important for God to see they are awaiting a miracle healing. They refused palliative care. The hematology service was becoming frustrated because they believed Jyen's distress and increasing agitation was caused by his family's distress.

The family developed a good relationship with Kim, who was also Catholic. They believed that she had not given up on Jyen. Kim arranged a meeting with the family, chaplain, and social worker to both better understand the family's beliefs in miracles and their understanding of his declining status.

This case illustrates the challenges often inherent in palliative care related to spirituality. There are times when spiritual beliefs clash with clinical care goals. The APRN can be the link between the healthcare system and preserving the patient's dignity and values. Kim's action now can potentially help to avert worse conflict as Jyen's disease progresses and at the time of death.

SPIRITUAL CARE IN PEDIATRICS

There is a very significant role for nurses in pediatric palliative care to respond to the spiritual needs of children and their families.^{34–38} This requires attention to the child's developmental stage, how the serious illness has affected that stage, and the context of religious or spiritual beliefs within the family. APRNs may provide an initial spiritual assessment along with their spiritual colleagues to explore these issues.

Spiritual care in pediatrics is an example of the importance of interdisciplinary care because nurses will need the guidance of chaplaincy to understand the child's and family's religious and spiritual beliefs and practices. A child's understanding of God or a higher power and the meaning of life events is related to their developmental stage. Thus, the APRN's knowledge of childhood development is essential.^{34–38} APRNs may often be the primary providers to whom patients, siblings, parents, grandparents, and friends express their emotional responses to spiritual concerns such as anger toward God, guilt, distress, and blame.

McEvoy provides a model for assessment in pediatrics, the BELIEF mnemonic.¹²

B: Belief system (such as participation in religious activities or discussion of an afterlife)

E: Ethics of values

L: Lifestyle (such as rituals or practices related to religion)

I: Involvement in a spiritual community

E: Education to assess religious education in the family

F: Future events, including important rites and the future role of the faith community in the child's care

As stated previously, spirituality is also closely intertwined with culture, which is particularly important in pediatric care because nurses need to assess both the child's as well as the parents' and extended family's spiritual and cultural beliefs. Thus, the APRN can contribute best to the care of seriously ill children through cultural assessment, including cultural meanings of illness, traditions, rituals, and language.

RESOURCES

While the important need for APRN involvement in spiritual care may seem overwhelming, extensive resources exist. In addition to the above-cited guidelines, there are many spiritual assessment tools available for clinical use.^{39–52} The CASH tool is an example of a spiritual assessment tool that is brief to use.⁵² It includes questions on *Care*: What do I need to know about you to take better care of you; *Assistance/Help*: What has helped you most during the course of your illness; *Stress*: What are the biggest stressors in your life now; and *Hopes/Fears*: What is your biggest fear? What are you hoping for?

There are increasing numbers of textbooks and model projects advancing the domain of spiritual care. Box 36.4,^{53–56} Box 36.5,¹³ and Box 36.2^{14–15} and Table 36.1 summarize many of these resources.

Box 36.4 KEY RESOURCES FOR ADVANCED PRACTICE NURSES FOR SPIRITUAL CARE

- Johnson-Taylor E. *Fast Facts About Religion for Nurses: Implications for Patient Care*. New York: Springer; 2019.⁵⁶

Dear _____,

Your palliative care team wants to make sure you receive the physical, emotional, and spiritual care and comfort you need.

Typically, persons receiving palliative care find themselves becoming more aware of their spirituality or religion. Please help us to understand what are your spiritual care and comfort needs.

Directions: Place an "X" on the lines to show the answer that comes closest to describing your experience.

1. How important is spirituality and/or religion to you now?

/ _____

Not at all important Very important

2. Recently, my spirits have been . . .

/ _____

Awful . . . low . . . okay . . . good . . . great

What can a nurse do to nurture or boost your spirits? (check all that apply)

- pray with me
- allow time and space for my private prayer or meditation
- bring art or music to nurture my spirit
- listen to my thoughts about certain spiritual matters
- provide assistance so I can record my life story
- just be with me
- help me stay connected to my spiritual community by contacting:
 - My church/temple/mosque/local faith community's name and Location
- _____
- My clergy or spiritual leader's name (any contact information will be helpful)

Is there anything else about your spiritual beliefs or practices that the palliative care team should know about? (e.g., diet or lifestyle proscribed by your religion? Beliefs guiding your preparation for death?) Please write here (or on the back side) or tell your nurse.

From Johnston-Taylor E.⁴³

SUMMARY

Palliative care is, by its very definition and existence, based on a foundation of whole-person, comprehensive care. It is incomplete without full attention paid to the spiritual domain. Palliative APRNs contribute to this goal of whole-person care through an assessment of the spiritual needs of the entire family and application of evidence-based guidelines. Through close collaboration with chaplains and other team members, care can be respectful and inclusive of spiritual needs.

LIFE REVIEW

Jamil Davis, Mimi Jenko, and James C. Pace

KEY POINTS

- Life review has the power to heal and contribute meaning to one's life.
- Life review has its roots in life-span developmental psychology.
- Life review is a structured process that involves analytic self-evaluation.
- Life review can involve a patient/client and/or family member(s).
- Essential components of life review include active listening, a nonjudgmental attitude, superior communication skills, and firm boundaries of the therapeutic relationship.
- Life review is a spiritual intervention that creates a covenantal relationship between parties.
- Three components of life review include recontextualizing, forgiveness, and reclaiming an unlived life.
- Mindful of patient confidentiality and privacy, highlights of life review are incorporated into the electronic medical record, reflecting patient preference, decision-making, and goals of care.
- The palliative advanced practice registered nurse (APRN) works closely within the context of a team; when complex issues arise beyond the APRN's scope of practice, consultation is then requested (e.g., from board certified chaplains, mental health providers, marriage and family counselors).

the APRN summarized the major movements and accomplishments that highlighted a life fully lived. Nan remarked at the visit's conclusion that she had never taken the time to document how her life had made a difference in the lives of so many others.

INTRODUCTION

Life review as a formal concept has its roots in life-span developmental psychology.¹ According to Butler¹ and Erikson,² one's development is formed or shaped by the myriad of events and circumstances encountered throughout the entire life span. In his seminal article, Butler¹ (p. 66) conceptualized life review as

a naturally occurring, universal mental process characterized by the progressive return of consciousness of past experiences, and, particularly, the resurgence of unresolved conflicts. . . . Presumably this process is prompted by the realization of approaching dissolution and death and the inability to maintain one's sense of personal invulnerability.

Life review allows the teller of the story to recast the past in the context of the present.³ In so doing, one reviews and reexamines one's life and is given various opportunities to solve old problems, make amends, and restore any lost sense of harmony.⁴ Any form of life review involves key questions such as "Who am I?" "How did I live my life over time?" "Did I take every advantage that I could to live my life well?"

For many, there is a *distinct* difference between periodic episodes of life reminiscence and life review. Life review is not "a random sharing of pleasurable past events, but rather a structured process containing a component of self-evaluation."⁵ (p. 9) A possible end result of such a review is the chance to find new meaning in life, especially when one faces the realities of impending death.⁶

Whether conducted with the patient, the family, or both patient and family together, life review includes the outcomes of increased life satisfaction and accomplishment, the promotion of more peaceful inner feelings, and a renewed state of integrity.⁷ Consistent with Erikson's theory of development,^{2,8} the final task of ego integrity entails the acceptance of one's life as lived, an awareness of one's place in history, the gradual release of death anxiety, and a greater satisfaction with life overall. Erikson⁸ believed that the greater part of adulthood is spent finding creative and meaningful

CASE STUDY 1: THE LIFE WELL-LIVED

Nan was a 67-year-old woman recently lost her husband of 43 years and now is close to death with metastatic pancreatic cancer. During a visit with the palliative advanced practice registered nurse (APRN), she mentioned that all her life was lived through her husband (she "stood in his shadow"). Now she had nothing to show for her life now that it is reaching its conclusion. As the visit evolved, the APRN asked Nan to describe what she did as a young parent, recount where she worked while raising her children, detail her church activities where she served as the Director of the Altar Guild, and describe her hobbies (she loved to do needle-point chair coverings and crosier quilts with multiple color pieces of cloth). Once each topic was fully developed,

experiences (including one's life work/career) to avoid feeling stagnant; then, during the final stages of living, the person can look back over the years at their accomplishments and feel a sense of pride and satisfaction in the summation of the outcome(s). The alternative, ego-despair, involves the lack of pride in accomplishment, the absence of hope going forward, and the idea of stagnancy in living.²

The aforementioned end-of-life issues have sizable practice implications for palliative advanced practice registered nurses (APRNs). By 2030, older adults will outnumber children—creating the so-called “silver tsunami.”⁹ Despite generational differences between providers and clients, Byock¹⁰ asserts that caring and compassionate healthcare providers are well-positioned to listen and explore patient and family stories during those needed moments, and the outcome is a greater sense of meaning and purpose in life. When the palliative APRN *actively* welcomes and fosters these “critical opportunities,” especially in terms of interdisciplinary team interventions, the result is a more compassionate healthcare environment that promotes patient awareness, comfort, ease, and satisfaction with life.

VARIED USES OF LIFE REVIEW

LIFE REVIEW WITH THE INDIVIDUAL PATIENT

According to Jenko, Gonzalez, and Alley,¹¹ when a person's goals of care shift definitively from cure to comfort, life review provides an evidence-based approach that brings the members of a family together, alleviates suffering, and focuses specific attention on the patient's holistic care. Storytelling is an ageless form of artful human communication. It is interactive, uses both verbal and nonverbal forms of expression, and recounts a story that engages the imagination of the listener.¹² Furthermore, in reviewing one's life “story,” the storyteller is given the opportunity to find meaning that is discovered in everyday life problems along with the strengths and the depths of love and devotion that are revealed in and through one's story.^{12,13}

Storytelling is also richly explored in the nursing literature; Smith and Liehr¹⁴ proposed a mid-range nursing theory which uses story as the central feature. Story theory assists the palliative APRN in determining what “matters most” to a patient by connecting past incidents and future aspirations to the present health challenge. The health challenge is then addressed using available evidence-based literature, and the stories are integrated into the plan of care. The APRN interprets and reinterprets the story, thereby helping the patient resolve the challenge.¹⁴

LIFE REVIEW WITH THE FAMILY

Though the process of life review most often involves the exchanges between a patient and the healthcare provider, life review can also involve the family unit. In clinical situations where the patient is incapacitated, life review is conducted

with the family and often involves clarifying goals-of-care and navigating anticipatory grief.¹⁵ In these instances, an understanding of family systems is vital. Families are seen as an organized whole, comprised of both individuals and complex relationships among those individuals. When one member of a family experiences a life-limiting situation, the remaining family members struggle between processing rapidly changing contextual realities and maintaining a sense of cohesion and constancy. Families are grappling with the impending loss of a loved one as well as the realization of new family patterns and relationships.¹⁶ In addition, at the death of a loved one, the family is in a unique place to enter into dialogues about the events of the loved one's life and subsequent death. Telling these stories allows the family to maintain higher levels of emotional functioning, retain or regain hope for the future, and find a renewed passion for living.¹⁷

The literature supports storytelling as a model for patient coping with difficult and significant life stressors.¹⁸ Additionally, a systematic review conducted by Scarton and colleagues¹⁹ found families also experience emotional and spiritual distress, and the effects of supportive approaches are mostly positive.

CASE STUDY 2: THE FAMILY LIFE REVIEW

A 42-year-old man, Jack, with a large extended family suffered a massive brain injury due to a motorcycle accident. The family had made the agonizing decision to discontinue life support but were sharply divided with regard to organ donation. Their loud, arguing voices had disrupted the trauma intensive care unit, and a stalled treatment plan had prompted a “stat” palliative care consult. To set a less divisive tone, the palliative APRN first established a therapeutic milieu: an empty patient room with chairs formed in a circle. Over the next 90 minutes, the APRN evoked earlier and happier memories gained from a life richly lived. Memories of a “larger-than-life” person arose: romances with multiple women, an infectious laugh, and an adventuresome spirit. Conversations were then gently guided to philanthropic themes. Although Jack did not participate in formal nonprofit work, the family recalled that he always participated in Girl Scout cookie drives, Little League team car washes, and military veterans' events. Then the palliative APRN facilitated family agreement that Jack had a charitable giving spirit toward others; this insight led to a peaceful family consensus for organ donation.

LIFE REVIEW AS A HOLISTIC INTERVENTION

A large amount of information is shared with the provider during any given session of life review. The provider needs the luxury of time, as most patients are invested in telling detailed accounts and remembrances. As a palliative care intervention, life review is about “having conversations in human-scale time, which means you can't do it in five minutes.”²⁰ This careful, unhurried approach is a *critical* element of this intervention. When the provider engages in a session of life review, there is an unspoken covenant relationship that takes place between the patient and the healthcare provider. This notion

of entering into a covenantal relationship presupposes that two people come together; they agree on any promises, stipulations, boundaries, and/or responsibilities that are made.^{21,22} There is a bond that is being made between two equal parties for therapeutic outcomes. In the case of life review, this covenant relationship incorporates three fundamental nursing assumptions: the individual or patient agrees to enter into such a conversation, there is the promise to listen in a nonjudgmental and therapeutic manner, and there exists an unspoken pledge to intervene and address any issues of suffering that may be called forth.

Life review as a spiritual intervention, with its attending covenant relationship, presents unique opportunities to provide additional information regarding the patient's social, emotional, physical, cultural, religious, and spiritual needs. Life review calls forth the importance of the nursing process as the guide for the provision of holistic care to patients and family members. Particularly with end-of-life care, knowledge of the evolving needs of the patient and family better informs all healthcare directives and assists with advance care planning. End-of-life situations can often trigger spiritual and emotional distress, thus reducing the patient's abilities to cope, communicate, and participate in all care decisions. Knowledge of patient preferences as they evolve in these areas can be incorporated into the plan of care and further communicated to staff and the interdisciplinary healthcare team. These nursing actions help to satisfy The Joint Commission requirements for advancing effective communication, cultural competence, and patient- and family-centered care.²³

According to Kaufman,²⁴ there are 23 themes that commonly evolve from the processes of life review (see Table 37.1). With time, the experiences are seen collectively and can be woven into a cohesive whole; when this occurs, the patient's identity is further clarified and meaning-making evolves. A person not only comes to conclusions about a life lived, but is actively present when communicating that life to others.

In terms of process, the palliative APRN may want to take copious notes while listening or simply take brief notes of key topic areas. The APRN may choose to follow a set format that has worked previously for the gathering of key pieces of data as conversations evolve. Or the APRN may choose to listen

intently to the patient without paper, pencil, or computer and then summarize key points and conversation trends following the session. In any respect, the analysis of the "data" (information gathered) is extremely important in formulating an in-depth understanding of the person, the development of his or her personality, the significance of certain key life events, and how aging is playing out in terms of health, disease, distress, integrity, and decline. These data will begin to crystallize into social, psychological, historical, spiritual, and cultural life themes. In fact, the life review process shares many commonalities with qualitative research methods in that content analysis of the information gathered is essential. As content themes emerge, the meaning of the information to the patient takes shape, texture, and form. A wide range of experiences is sampled; those that require further analysis and additional work then become a part of the ongoing plan of care.

At any time during the life review process, the healthcare provider may be tipped off to an episode of a life experience needing further exploration. The patient's face may reveal a brief, fleeting glimpse of a pained affect or there may be words *not* spoken or expressed, the silence indicating a sensitive or controversial key event. This is especially true when an unspoken situation may not be socially acceptable or publicly sanctioned.

CASE STUDY 3: THE UNSPOKEN EPISODES IN
LIFE REVIEW

Bill, a 41-year-old male had been married to his partner for 4 years. Because his family did not agree with his sexual orientation, the patient had not spoken to his extended family since his marriage. Their last words were harsh and angry: "We hope we never see you again." Several years later, Bill was diagnosed with colon cancer and experienced significant complications, resulting in a lengthy hospitalization. His suffering has caused severe distress to his partner, yet his extended family remained uninformed of his deteriorating state. When Bill was given 2–3 months to live, the oncologist consulted the palliative care team.

While listening to Bill discuss his family, the palliative APRN observed a moment of hesitation in his voice. It was an elusive clue, one that could have been easily dismissed or overlooked. Yet there was something that just was "not right," so the APRN closed the door to Bill's room and said softly, "I could totally be in left field, but I think there is something you want to tell me—something that causes you great pain in the situation." After a long silence, Bill revealed that marriage had alienated his extended family. With only a few months left to live, Bill desired to both offer and receive forgiveness. After speaking with his partner, a phone call was finally arranged. Bill and his extended family had a lengthy conversation, which ultimately resulting in healing for all family members.

As providers will discover, patients often have deeply buried feelings and memories. Once brought to the surface, providers must be prepared to occasionally bear witness to intense affect, deep remorse, and searing personal pain. When facilitating a life review, the provider needs to be prepared to deal with literally anything. In instances of extremely subtle clues of suffering, one might agree with Sir Arthur Conan Doyle:

Table 37.1 MAJOR THEMES THAT EVOLVE FROM LIFE REVIEWS

Affective ties	Service
Financial status	Acquiescence
Marriage	Self determination
Work	Financial security
Social status	Religion
Community service	Disengagement
Self-reliance	Family
Industry	Achievement
Initiative	Orientation
Search for spiritual understanding/ meaning	Creativity
Discipline	Need for relationships
	Selflessness

From Kaufman.²⁴

"It has long been an axiom of mine that the little things are infinitely the most important."²⁵

LIFE REVIEW: THREE COMPONENTS

As Byock asserts, "Illness is personal; it is not just medical. People need to have services not merely to suppress suffering, but to help them in completing their lives."²⁶ To achieve this outcome, palliative APRNs need to be aware of three interconnected components to life review^{1,27}: recontextualizing, forgiving, and reclaiming unlived life.

Recontextualizing values the worth of accrued life wisdom. Life experiences, no matter what a person's chronological age, contribute to a "store" of wisdom. Recontextualizing enables the patient to recall and perhaps "reframe" self-defined mistakes and failures. Negative life events and/or situations are reframed in ways that can be positively (re)configured.¹¹ What is assumed in this process is the willingness of the patient to face the past in a different light, especially when reliving painful or unpleasant memories. Recontextualizing asserts that one is not so much a victim of the past but rather is more in control of life's experiences, having the opportunity to recast one's memories based on perceptions of the past.¹ One can reflect on past experiences and then begin the valued reparation process of those relationships and events formerly perceived as being negative. Changed perceptions can change memories, going from a sense of failure to a new-found sense of accomplishment, even success. Recontextualizing asks one to search for the deeper meanings, even to the often-elusive patterns of life events. Recontextualizing assumes that new-found meanings can heal past scars and wounds over time. One does not necessarily change the way that he or she lives, but rather begins to see life through a different filter or lens.

Recasting meanings to past events can give life a new sense of order and changes the way one sees self, others, and the world.^{1,28} Regarding the accrual of life wisdom, Baldwin²⁹ asserts that story connects one's past, present, and future, thus allowing one to live in a generational context. Often a life review serves two purposes: it helps to heal the storyteller and also begins the process of healing future generations.

CASE STUDY 4: GENERATIONAL EFFECTS OF LIFE REVIEW

Jill's life review pondered a deathbed conversation with her mother, Anna. Anna was trying to reconcile her parents' divorce in the 1940s and the challenging economic and painful emotional impact of her father's remarriage. Due to her highly unstable childhood, Anna had based her own marriage and childrearing on traditional values and low-risk choices. Jill was able to "connect the dots" of the generational impact and the limited view of life she unconsciously inherited from her mother. Jill verbalized a desire to change her own view of life; she began a new way of seeing life as abundant and filled with possibility. Cultivating additional positive, upbeat, and energizing friends helped to improve the quality of her own life while significantly impacting the lives of her own children.

Forgiveness is a voluntary choice to release retaliation, bitterness, or unfavorable judgments toward a wrongdoer and attempt to respond with a charitable spirit. Forgiveness is not necessarily predicated on reconciliation, and it does not involve minimizing or forgetting the offense. There are at least two types of forgiveness: offense-specific (which involves a particular action) and a general inclination to forgive others (which is true across settings and is stable over time).³⁰ The process of forgiveness helps to promote reconciliation between self, others, and one's higher power (where applicable).³¹ Forgiveness entails the release of anger, resentment, and feelings of being wronged, and entails the pardoning, forgiving, or absolving of the other from a debt, crime, or action.³²

Forgiveness is a central and potent theme in almost every world religion.^{33–35} The world religions can be categorized into three major groups: the *Abrahamic religions* (Christianity, Judaism, and Islam), the *Indic religions* (Buddhism and Hinduism), and *aboriginal beliefs* (tribal beliefs among indigenous groups).³⁶ The Abrahamic religions usually frame the relationship between God and human as Forgivee–forgiver and regard forgiveness as a consciously developed pattern of living. Of all the Abrahamic religions, Christianity places the strongest emphasis on an unconditional forgiveness of others. Judaism addresses forgiveness of others, yet the offender has an obligation of restitution to the offended in order to earn forgiveness. In Islamic thought, absolute forgiveness is commendable but not required. Within the Indic religions, there is an overarching theme of compassion. In Buddhism, the non-theistic notion of forgiveness is seen as the skillful means of promoting internal harmony, helping to free a person from internal regret and conflict.³³ Both Buddhism and Hinduism believe personal resentments increase suffering, both to the offender and the offended. Thus, forgiveness is a means to a higher level of mindful living for both parties.³⁶ Within aboriginal/tribal belief systems, life is seen as holistic, without a distinction between the sacred and the secular. A distinct emphasis is placed on restoration of all parties: victims are mended, transgressors are reinstated, and the community can then return to a healthy equilibrium.³⁶

Regardless of faith background, obtaining the forgiveness of a higher power is often dependent on or mutually inclusive of the way(s) that human beings first forgive self and others while asking for forgiveness in return. Restoring a sense of personal harmony allows for the quietude of the mind, which helps to foster deeper insights. A careful assessment of the patient's spiritual/religious beliefs and practices better allows the healthcare team to plan for and provide forgiveness-oriented clinical interventions.^{31,33}

Several authors^{10,36,37} agree that the final stage of life is a cherished chance to express love and gratitude between self, others, and one's higher power. Opportunities to forgive self and others yield important results at end of life. Jealousies, anger, and negativity can be redirected toward more positive thoughts and attitudes; long-standing resentments and sorrows can be released. Byock¹⁰ cautions that forgiving is not about absolving another's responsibilities, but rather provides one with a way to reframe what has been fractured, serving as the beginning steps to unfolding healing processes. The repair

work that is a part of life review does not discount the pain or the responsibilities of those involved, but does give one the tools to begin coming to terms with what was painful or unpleasant.

Reclaiming an unlived life involves reflection over one's life experiences, where a multitude of regrets are possible: educational opportunities were ignored, career aspirations and goals went unrealized, healthful living practices were minimized; romances were unfulfilled, relationships were unsuccessful, and personal disappointments seemingly overshadowed any sense of accomplishment in terms of abilities, attitudes, and behaviors. Regrets place sharp boundaries around "what should have been," leaving limitless possibilities and hopes as gradually shattered dreams, never fully realized. Unresolved conflicts can be examined in a new light and through the lens of accumulated life experience that allows for and brings forward new ways of thinking as well as problem-solving. Individual and key events can be placed into the context of one's entire life course and the "value" of the whole can expand one's sense of vision.^{11,38}

CASE STUDY 5: REFRAMING LIFE EXPERIENCES

Stephen was a 45-year-old man recently diagnosed with end-stage liver disease, with only months to live. Stephen was divorced twice and was unable to conceive a child during either marriage. Additional life disappointments included the end of a college football career following life-changing injuries after a motor vehicle accident. Upon sharing with the palliative APRN about his life, Stephen's affect was despondent and filled with anguish. Stephen tearfully emphasized his negative feelings toward failed marriages, incompleteness of his college education, inability to conceive, and his unhealthy choices of poor diet and substance abuse. Stephen continued to weep while pensively looking through old photos. Using contemplative techniques with Stephen, the palliative APRN encouraged what was previously perceived as failure and disappointment to be reframed, repaired, and/or rebuilt because reparation is always possible. Stephen was able to identify aspects of his life that brought him joy and meaning. This new awareness brought increased peace, despite his lingering regrets about what "could have been."

VARIED ELEMENTS OF LIFE REVIEW

PAIN AND SYMPTOM MANAGEMENT

Before any work can begin in regard to life review, the patient must have adequate pain and symptom management and be in a self-reported state of comfort. Once the patient's comfort is reasonably assured, life review activities can begin. The life review process assumes a therapeutic relationship between patient and provider: all of the major therapeutic elements (see Box 37.1) are present between those engaged in review and the healthcare provider who listens, draws forth, extracts, and further develops chains of thought drawn from the patient's unconscious. The healthcare provider must be comfortable with asking open-ended questions, listening

Box 37.1 ELEMENTS OF A THERAPEUTIC RELATIONSHIP

- Ensuring confidentiality and privacy of experiences shared, data collected
- Establishing trust
- Having an open attitude
- Possession of a nonjudgmental spirit
- Obtaining "consent" before any life review process begins
- Being truthful, transparent, authentic
- Maintaining boundaries and having a professional demeanor
- Clarifying meaning; restating the patient's thoughts; remembering information shared
- Watching for key verbal and nonverbal cues
- Using open-ended questions
- Being comfortable with periods of silence
- Not being in a rush to complete a session or move to the next topic
- Using self-disclosure and self-expression appropriately
- Understanding the meaning and potential importance of being culturally sensitive/humble
- Knowing about one's own spiritual and religious development/understanding
- Have a genuine sense of caring and compassion for the experiences of another

Adapted from Jenko et al.,¹¹ and Butler.³

attentively and actively, being comfortable with periods of silence and reflection, always taking care not to interrupt the patient or to interpret or attempt the completion of another's sentences/thoughts.

Life review for the healthcare provider is grounded in cultural competence, often reconceptualized as cultural humility/awareness.^{39–41} The provider is open to all ideas, viewpoints, ways of thinking, conceiving, and integrating life events. The provider remains nonjudgmental. The patient begins with free association, recall, and a personal sense of assessment. Life review has to do with a person's memory and how those memories are organized and retrieved. The patient's (and often the family's) cultural, emotional, social, and spiritual beliefs and feelings are explored and respect is duly shown throughout the entire process.

Typical topics for life review include family and friendships, loves and losses, achievements and disappointments, and adjustments made during the life trajectory. Opening questions to prompt life review can take the form of those found in Box 37.2, balancing both positive and negative aspects of life and living. If a person has difficulty remembering what occurred in the past, various prompts can be used including pictures, music, jewelry, tape-recordings, letters, or familiar personal items from the past. Memory prompting may be especially indicated with the frail elderly who may have mood or memory problems.⁴²

There is no single way to initiate a "right" life review. Healthcare providers are adept at finding the perfect teachable, reachable moment in terms of the initiation of the review process (which may take minutes, hours, weekly sessions,

Tell me when and where you were born.
What was your life like growing up?
What was school like for you?
If you have siblings, tell me about your brothers and sisters.
Tell me about a particularly enjoyable time or place that you experienced or visited.
Tell me about an event in your life that you found to be troubling or challenging.
Tell me something that you particularly remember about your childhood.
Talk to me about some of the things you remember as you grew into your teenage years.
Tell me something unique about your family or a close relationship with someone.
Did you ever marry? If so, tell me about how you met, your courtship, and how you proposed.
Tell me something about your friends, particularly your best ones.
Describe an obstacle in your life, and tell me how you were able to get through it.
Who are the people who have most influenced your life?
What is that one “most important” event you experienced in your life?
What were the most difficult deaths that you had to deal with in your lifetime?
What do you most enjoy right now?
Do you keep in touch with any of your old friends?
How did you feel (or do you feel) about retirement?
What are your thoughts about death, dying, and the possibility of an afterlife?
Who are the people that you most admire in your life?
Describe the way that a person who knows you well would describe you.
What makes you happy now?
Tell me about your work experiences; your career; your business; your vocation.
What do you think that you will really be remembered for best?
What has been the deepest regret or disappointment in your life as a child, young adult, middle or older aged adult?
How do you think you have changed over the course of your life?
What was the hardest thing you had to face as you were growing older?
What is the absolute best thing about being older?

Note: When appropriate, many find intense satisfaction in discussing significant historical/social events including the Great Depression, World Wars, political movements, and shared experiences with a community of friends, family, soldiers, members of a congregation.

Adapted from Jenko et al.¹¹; and Butler.³

lasting even up to an indefinite end place) and not press for discussions that are too intimate or sensitive for patient/family members. In every sense of the word, the storyteller is always the “hero” of the story; the provider is a nonjudgmental, open, caring, compassionate, active listener.

RELIGIOUS AND SPIRITUAL IMPLICATIONS

Humans are intrinsically spiritual, and spiritual beliefs affect healthcare decision-making and healthcare outcomes. According to the Hospice and Palliative Nurses Association (HPNA) *Position Statement on Spiritual Care*,⁴³ because human beings are intrinsically spiritual, they are in relationship with self, others, nature, and the significant or sacred. Direct clinical care entails a holistic viewpoint which addresses a cohesive and inclusive view of the patient’s overall health experience.⁴⁴ APRNs embody a holistic perspective that promotes health and wellness, assists with healing, and helps to prevent or alleviate suffering^{44,45}; this practice philosophy often leads the nurse “to greater awareness of the interconnectedness of self, others, nature, spirit and relationship with the global community.”⁴⁵ (para 1)

Spirituality may include specific religious beliefs, be completely divorced from same, or have some intermittent combinations depending on the patient’s circumstances. Religion involves specific teachings and customs, a structured approach to life, and a certain moral code as understood in or structured according to specific authoritative/holy text(s). Religion is most commonly practiced in community with others, whereas spirituality, characterized by meditation and awareness of a universal consciousness, is more of an inner search to find one’s own truth.⁴⁶ Spirituality defines those constructs that give a person strength to carry on even in the midst of life’s troubles. Spirituality provides comfort, courage, and appreciation. Spirituality encompasses a person’s beliefs, values, practices, and rituals and assumes certain spiritual needs: meaning, purpose, life satisfaction, forgiveness, love, and belonging.⁴³

It is within the practice of nursing to address the patient’s spiritual concerns: a concept of God or higher power, a source of hope and strength, significance of particular rituals or practices, and the correlation between beliefs and health.⁴⁷ Appropriate nursing interventions that help to meet the spiritual needs of patients include listening to patient/family concerns, praying with the patient upon request (when the provider feels comfortable in so doing), and reading a patient’s favorite religious materials.⁴⁷ In fact, giving attention to the spiritual dimension of patient care is one of the Joint Commission (TJC) requirements as it contributes to advanced effective communication, cultural competence, and patient- and family-centered care.²³

In facilitating life review, a patient may express themes of spiritual distress: the inability to find meaning in life⁴⁸; an impairment in connectedness, inner peace and harmony⁴⁹; or an inability to cope with multiple losses and cumulative grief.⁵⁰ Spiritual distress can be seen when a person’s spiritual beliefs are threatened through physical and/or emotional symptoms. Spiritual distress is associated with poorer healthcare outcomes including emotional despair, depression, mood disorders, anxiety, suicidal thoughts, and increased substance abuse.⁵¹ Spiritual care necessitates the ability of the healthcare provider to be fully present; identify their own boundaries, barriers, and limitations; listen nonjudgmentally; and appreciate one’s own spirituality as a lifelong companion that

informs, develops, challenges, and helps with one's personal growth. See Chapter 36 for more information about spiritual assessment.

During the process of life review, the provider seeks to recognize and respond to spiritual distress and help the patient discover deeper meaning in the experience of illness, suffering, grief, and loss.⁴³ However, spiritual distress can be extremely complicated and detrimental to a patient's overall comfort and satisfaction with life. Because the roots of spiritual distress can be extremely complicated, it is recommended that providers frequently consult with board-certified chaplains who are trained spiritual care specialists.⁴³

Holistic nursing embodies the authentic presence of the nurse, which Cumbie⁵² views as an essential component of human-to-human interaction. With this viewpoint, human beings are fundamentally good and have an inborn capacity for self-healing.⁴⁵ The APRN also recognizes and attends to multiple ways that the environment (including social, physical, financial, emotional, and spiritual aspects) impacts one's health and illness.⁴⁴ The palliative APRN strives to assist the patient to find meaning and purpose in one's life so that he or she might better find comfort, peace, and harmony.^{44,45} The

palliative APRN is uniquely educated and prepared to help patients and families find relief, support, and meaning in chronic and potentially life-threatening illness, as one's sense of spirituality may be of special concern as health deteriorates. Spiritual care, provided best through an interdisciplinary team approach, entails an assessment and monitoring of the multiple aspects involved with the spiritual dimension of living, including a life review.⁴³

The processes of life review address the spiritual components of a person, such as one's hopes, fears, purpose and meaning, guilt and forgiveness, faith community, inner sources of power, and beliefs about the possibilities of an after-life.⁴³ Empirical patterns of knowing inform the science of nursing practice through scientific data, yet personal patterns of knowing support the nurse–patient relationship through reflections, listening, and centering. This type of knowing is gathered through autobiographical stories.⁵³ The construct of life review has often been compared and contrasted with several associated constructs (see Box 37.3) including remembering, storytelling, life-review, life review therapy, and dignity therapy.^{42,54,55} The memory of one's life accomplishments, hopes, and goals has a large role in understanding emotional

Box 37.3 SELECTED DEFINITIONS RELATED TO LIFE REVIEW

Life Review:

The process of life review is much more structured than simple reminiscence. “Usually covers the entire life-span and is most often performed in a one-to-one format. Rather than simply describing past events (as in simple reminiscence), life-review focuses on the (re-) evaluation of life events and on the integration of positive and negative life events in a coherent life story.”⁵⁵ (p. 541) “Life review is the systematic and structured process of recalling past events and memories in an effort to find meaning in and achieve resolution of one's life. Although traditionally used in gerontology, life review is applicable with any person facing the end of life.”¹¹ (p. 159)

Remembering/Reminiscence Therapy:

A simple form of therapy that “encourages the patient to talk about earlier memories. It's generally offered to people in their later years who have mood or memory problems, or need help dealing with the difficulties that come along with aging . . . this treatment has a small but significant effect on mood, self-care, the ability to communicate and well-being.”⁴² (p. 1) The use of life histories—written, oral, or both—to improve psychological well-being.⁴²

Reminiscence:

“Unstructured autobiographical storytelling with the goal of communicating and teaching or informing others, remembering positive past events, and enhancing positive feelings.”⁵⁵ (p. 541) “The process of thinking or telling someone about past experiences that are personally significant . . . a therapeutic mode for promoting self-acceptance and psychological health.”⁵⁵ (p. 541)

Life Review Therapy:

Refers to the use of life review with persons with serious mental health problems, such as depression. It is characterized by linking life review to a clear theory of causal factors of depression or mental illness. . . . It often explicitly applies therapeutic techniques that have been developed in other therapeutic frameworks, such as cognitive therapy, problem-solving therapy, or narrative therapy.”⁵⁵ (p. 541)

Storytelling:

According to the National Storytelling Network,⁵⁶ storytelling is an ancient art form of human expression that uses words and actions to reveal the content of the story while encouraging the imagination of the listener. Storytelling involves five component parts: (1) interactive communication between the storyteller and the listener, (2) employing the use of words, (3) with the use of actions such as vocalization and physical motions or gestures, (4) that together present a story (narrative), (5) which encourages the imagination of the listener(s). The completed story “happens” in the mind of the listener who “co-creates” the story as seen through personal experiences, beliefs, and understandings.

Dignity Therapy:

A brief, individualized psychotherapeutic intervention designed to address psychosocial and existential distress among terminally ill patients. Such distress has often been linked to the notion of suffering and described in terms of the challenges that threaten the intactness of a person. The intervention is designed to engender a sense of meaning and purpose, thereby reducing reported suffering and distress.⁵⁷

health and well-being, as well as emotional distress and illness.⁴² For some people, life review may be painful, stressful, and possibly problematic, indicating the need for further assessment and possible therapy. For others, the process of remembering one's accomplishments, joys, and the achievements that define a life well-lived sets the stage for a peaceful death.

RESEARCH IMPLICATIONS OF LIFE REVIEW

Butler was perhaps the prime mover in the quest to discover the therapeutic effects of life review, particularly in older people.³ In evolving reviews of gerontological literature and practice, Butler³ concluded that life review demonstrated the following positive effects: having the time and ability to right old wrongs; reconciling with old enemies; coming to a more peaceful acceptance of one's mortality; and promotion of a sense of serenity, pride in one's accomplishments, and the feeling that one did the best one could in life. Older people who suffered from depression and who participated in life review reported better self-esteem and felt more positively about their life experiences than a similar group who did not participate in life review.⁴² In addition, the group who participated in life review had a more favorable view about their past experiences and had greater levels of hope for the future. Also, caregivers who participated in the sessions gained a deeper knowledge of the patient's experiences, which helped to decrease self-reported stress.⁴² Despite several limitations across studies, there was a statistically significant effect in all studies indicating that life review is an effective treatment of depressive symptoms in older adults. The effects were comparable to other well-established treatments, including antidepressive and cognitive-behavioral therapy.⁵⁸

Dignity therapy, a variation of life review, is designed to address psychosocial and existential distress in the terminally ill. Pioneered by Max Chochinov, dignity therapy involves a brief, individualized psychotherapeutic intervention that has accumulated a considerable amount of evidence for its utility and success in patients who are facing significant end-of-life concerns.^{58–60} Each "session" is designed to engender a sense of meaning and purpose and reduce the amount of suffering that a patient may be experiencing. There are seven dignity themes: generativity, continuity of self, role preservation, maintenance of pride, hopefulness, aftermath concerns, and care tenor.⁶⁰ During a session, which typically lasts between 30 and 60 minutes, the patient is asked question(s) from an interview guide based on a dignity model.⁶¹ Sessions are taped and transcribed verbatim, edited for clarity, chronology, and possible psychological harm that may be caused to others who may read the content of any given session. The edited version becomes a "written legacy document that the person shares with others important to him or her" ⁶² (p. 2) and ends with an appropriate statement of life closure (a generativity, legacy-making exercise). Several studies reported significant findings where patients reported feeling satisfied or highly satisfied with the intervention and believed that dignity therapy increased their sense of purpose, heightened their sense

of meaning, and helped increase quality of life and feelings of well-being.^{58–62}

POSSIBLE "RISKS" OF LIFE REVIEW

When one engages in past remembrances, there are risks to the patient and family, as well as to the healthcare provider who actively listens and then intervenes to improve health and well-being. For the patient, there is the risk that engaging in life review might result in psychopathological outcomes where past experiences become an obsession or in which anxiety, guilt, and/or despair are magnified.³ Excessive or obsessional "rumination" on a past event, depression, or states of panic lead to increasing rigidity rather than to increased self-awareness and flexibility.³ Tragic outcomes occur in that rare instance where a person whose increasing (but partial) insight leads to a sense of total waste.³ In this instance, just before death occurs, the patient concludes that he or she has never truly lived life as hoped and sees this clearly for the first time as he or she is about to die. In the most tragic of circumstances, a severely depressed patient might contemplate suicide.³ Another group of individuals who are prone to the risks of life review are those for whom their sense of guilt is palpable and who believe that forgiveness and/or redemption are impossible for them.³

In particularly difficult and/or vulnerable patient care situations, the APRN may personally be subject to the harmful effects of life review. The provider may feel as if they "caused" any existential angst and/or pain and suffering brought forward. If a patient engaged in this suffering later attempts suicide (successfully or not), the provider may question their role in the situation and may bear terrible feelings of guilt. In these situations, the provider must be aware of the limits of one's professional capabilities and skillsets and be able to refer to others as the need arises. The provider must also have sufficient self-care habits and emotional/physical support systems to be able to reflect, recharge, reevaluate, renew, and resume.

Additionally, the inherent nature of palliative care can create additional risks to the practitioner. In working with the dying, love and compassion are fundamental components.⁵⁷ In palliative care, the practitioner develops the ability to "see purely," meaning that one bears witness to the full range of the suffering experienced by the patient while concurrently keeping in mind each person's inherent goodness.⁶³ One must truly listen to another's story, which gives "our suffering meaning, our dying depth, and our grieving perspective."⁶⁴ (p. 66) Yet all of life is interconnected; when patients suffer, practitioners suffer. To be sustainable in the provision of palliative care, personal well-being is not "an optional indulgence but an absolute necessity."⁶⁴ (p. 93) Practitioners should be mindful of their *literal homes* (an uncluttered physical place that provides refuge) and their *inner homes* (an uncluttered spiritual place that fosters contemplation and reflection).⁶⁴

Viewing one's personal limits as a palliative APRN is vital; compassion fatigue, moral distress, and even burnout are indeed possible. Neglecting care of the self both hurts the self

and can lead to potential harm for others.⁶⁴ Whether religious or not, several authors^{65,66} stress the concept of “sabbath time.” In this spiritual practice, either for an entire day or for a portion of a day, one ceases routine, daily activity and consciously takes time off to regroup, meditate, and recharge. During sabbath time, one appreciates the normal rhythms of life—joy and sorrow, death and life, full and empty, acting and waiting. Making time to acknowledge the significant or sacred and seek personal renewal and reflection is a *crucial* life lesson for the palliative APRN, one that promotes sustainability for professional growth and ongoing clinical practice.

LIFE REVIEW AND THE ELECTRONIC HEALTH RECORD

Healthcare professionals are entrusted with the most sensitive and private information in regard to their patients and have a strong ethical responsibility to protect their patients from all types of misuse, fraud, and breaches of confidentiality.¹¹ The information gained from a life review may involve sensitive information, thus raising the issue of patient and family agreement. The agreement to initiate a life review session is best obtained verbally (rather than implied). The following statement serves as one example to gain verbal consent (or refuse it):

Based on what I now know, I believe it would be helpful for us to engage in a therapeutic process known as life review (either at that moment in time or scheduled for a later time). Life review looks at how past experiences influence what is happening to you at this moment. This process may involve up to an hour of your time for any given session with the possibility of multiple sessions. There is no charge for this time together; it is a part of your overall care. What we discover together may be very beneficial to your care, and a summary of our discussion may be included in your electronic medical record. Do you have any questions? [Then, after questions are answered] Would you like to engage in this process?

Indeed, the patient’s permission to having each and every life review that is shared become a part of their healthcare record is recommended. The healthcare provider will explain that such updates will continue to direct future interventions, actions, team communications, and ways to secure evidence-based outcomes. Additionally, data entered in the electronic health record (EHR) can be constituted of “broad brushstrokes” (e.g., “Patient spoke at length about the estranged relationship with his incarcerated son”), instead of “nitty-gritty” details (e.g., “Patient’s son serving a life sentence in the state prison for double homicide of his ex-girlfriend and his male cousin”). It is vital to remind patients and families that all data obtained are considered private and confidential and will be honored as such at all times.

There continue to be several categories that warrant higher degrees of security when it comes to entering data into

the EHR.⁶⁷ The law affords special protection in regard to patients with mental illness since EHRs contain the patient’s innermost personal communications and information. In addition, patients with HIV/AIDS and sexually transmitted illnesses constitute another category with special privacy concerns; sensitive information that may be shared in these areas must be handled cautiously and appropriately. Patients who are experiencing substance abuse and chemical dependency require special considerations over and above the categories previously described. Finally, release of the above-mentioned records to any outside source requires patient consent, and recipients must include a written statement prohibiting redisclosure of said information.

Life Review and COVID-19

Beginning in March 2020 Americans have been struggling with the coronavirus pandemic. In many instances, patients are dying alone in intensive care units or long-term care facilities, creating the possibility of “unfinished business” or incomplete, unexpressed, and/or unresolved relationship issues.⁶⁸ Researchers have identified that unfinished business takes multiple forms: *statements of affirmation and value* (such as a missed opportunity to express love or recognize worth), *missed opportunities or intentions* (such as unfulfilled plans and feeling a future absence), or *unresolved confessions and disclosures* (such as corrosive secrets that exist in families and lack of closure). Interventions for practice are varied; these are outlined in Box 37.4. Unfinished business is of particular importance for the palliative APRN, since Neimeyer asserts that “it is a big deal . . . it can account for the lion’s share of prolonged grief symptomatology of complicated grief.”⁶⁸ Practitioners can also use the 28-item Unfinished Business in Bereavement Scale, developed by Holland and colleagues,⁷⁰ with prompts such as “I should have been there when ____ died,” or “I never got to resolve a breach in our relationship.”

SUMMARY

Offering life review to a patient is a spiritual intervention that involves active listening; keen and subtle communication skills; the utmost in attentive behaviors; an open, non-judgmental, and objective frame of mind; and the luxury of time in order to allow the patient the opportunity to develop their story. It is an incredible opportunity for the patient to reflect on one’s life accomplishments, legacies, achievements, and the framing of one’s life-course. It allows the reframing of harsh memories and the celebrations of joyous events. As Myss⁷¹ asserts, “Healing does not always mean that the physical body recovers from an illness. Healing can also mean that one’s spirit has released long-held fears and negative thoughts toward oneself or others. This kind of spiritual release and healing can occur even though one’s body may be dying physically.”^(p. 7) Palliative APRNs are wise to remember this truth.

1. *Speak the name of the deceased*: Conversations about the loved one avoids a “second death” by falling silent about their life.
2. *Keep a journal*: Express both troubling and inspiring feelings via directive journaling.
3. *Connect with others*: Share your grief either within family or through online communities.
4. *Review photos*: Celebrate both low and high points in a life.
5. *Reconstruct the legacy*: Tell stories to keep memories alive.
6. *Review resilience*: Discover strengths and the possible growth through grief.
7. *Live in the now*: Avoid living in the past so much that the present is overshadowed.
8. *Conduct rituals*: Honor loved ones in symbolic events.⁶⁹

Recommended Resources

Classic books

Brussat F, Brussat MA. *Spiritual Literacy: Reading the Sacred in Everyday Life*. New York: Touchstone; 1996.

A collection of meaningful examples from contemporary books, movies, and life experiences which promote a new way of looking at and “reading” the world. Helps answer the age-old question: “How can I live a spiritual life every day?” Available on Audible and in print.

Callanan M, Kelley P. Final Gifts: *Understanding the Special Awareness, Needs, and Communications of the Dying*. New York: Bantam Books; 1992.

A classic text that describes a period of time termed “nearing death awareness.” During this time, the dying tell stories and attempt communications with friends and family members that are often misunderstood. Learning what to listen for and how to approach various situations allow the reader to respond to the dying in new and authentic ways. Available on Kindle and in print.

Frankl VF. *Man’s Search for Meaning*. New York Pocket Books; 1997.

This classic book was originally published in 1946 and is now translated into more than 24 languages. It recounts psychiatrist Viktor Frankl’s personal experience in Nazi concentration camps and his quest to discover meaning in the midst of horrific and sustained suffering. His subsequent theory, called logotherapy, explores how human beings cope with suffering by creating renewed meaning and purpose for life. Available on Audible, on Kindle, and in print.

Contemporary YouTube Videos

The active phase of dying can last days to weeks. While some patients die gently and tranquilly, others may face inevitable battles. These two videos strive to answer the question: “What would make the final moments of life best for you?”

The Guardian (2019, November 14).

Before I die: a day with terminally ill patients | Death Land #2 (14:16 minutes)

<https://www.youtube.com/watch?v=aZdDXNmD9wk>

Despite the advances in modern healthcare, aging and death continue to be inevitable. Although modern technologies have assisted us with extending life, it is easy to forget about living the remainder of our time with a higher quality. Dying can mean different things to different people. This video strives to answer the question: “What does being mortal mean to you?”

Frontline PBS. (2020, March 17), Being Mortal (54:02 minutes)

<https://www.youtube.com/watch?v=lQhI3Jb7vMg>

This documentary is based on the best-selling book of the same name, written by surgeon Atul Gawande. His reflections include the topics of age-related frailty, serious illness, and mortality. His call to action: the medical community should focus on improving quality of life and well-being, rather than just survival.

GRIEF AND BEREAVEMENT

Katharine Adelstein and Elizabeth Archer-Nanda

KEY POINTS

- Grief theories have evolved to reflect a much more nuanced individual experience, dispelling common myths that a specific timeframe exists for recovery from loss and that failing to confront one's feelings always leads to delayed grief.
- Complicated grief is relatively uncommon but left untreated it has serious health consequences.
- Palliative advanced practice registered nurses (APRNs) should pay attention to self-care around grief and bereavement, particularly while working closely with terminally ill individuals and families.

CASE STUDY 1: COMPLICATED GRIEF

Prior to his diagnosis of Parkinson disease, Jim and Louise experienced a strained relationship. Jim had a long history of alcohol use and episodes of emotionally and mentally demeaning behavior toward Louise, which caused them to grow apart rather than closer together during their “golden years.” Despite these years of abuse, Louise maintained closeness to Jim and feared life without him. She continued to seek Jim’s approval and relied heavily on him for reassurances that were more reflexive than genuine. At the onset of Jim’s diagnosis, Louise continued in her usual manner with Jim, deferring to his demands, at times feeling alone and helpless, with periods of worry that she would not be able to care for herself after Jim’s death.

Jim and Louise had three children together. Challenges within family dynamics led to strained relationships between Jim, Louise, and their children. Louise struggled to regain her own sense of self, even in the face of Jim’s progressive medical illness and end of life. After Jim’s death, Louise attempted to shift her focus toward her children. However, injured family relationships made it difficult for Louise to garner the attention and support from her children that she desired.

Although Louise anticipated it would be difficult to move through her grief, she did not foresee the inability to reconnect with her children to the level she had hoped. Although her children attempted to reach out, none could provide the level of validation and support she required. Louise felt socially isolated, empty, and filled with self-doubt. Louise struggled in the months after Jim’s death; she had not predicted it would have been so hard for her children to support her in the way she needed. Louise found herself longing for Jim. She seemed to

have difficulty recalling the challenging aspects of her relationship with Jim, often romanticizing him, which seemed to push her children further away. She struggled to find other aspects of meaning or purpose and was often numb. At times she believed things would be better if she were the one to have died. Louise slowly lost connection with friends and family. Louise gradually stopped maintaining her home. She developed feelings of guilt that if she had been a better wife and caregiver, Jim may not have died. Louise’s symptoms are consistent with *persistent complex bereavement disorder (PCBD)*. Louise would benefit from intervention for her complicated persistent bereavement.

The palliative advanced practice registered nurse (APRN) who cared for Jim at the end of his life discussed Louise’s grief with her and helped her to find a referral for a mental health provider who specialized in bereavement. Louise participated in a grief support group, sought individual therapy, and began to rebuild relationships with her children very gradually.

CASE STUDY 2: PREPARING FOR BEREAVEMENT

Ms. J was in the prime of her life at age 50 when she received her new diagnosis of multiple myeloma. A married mother of two, she and her husband were just beginning to enjoy the benefits of an empty nest. At the onset of her diagnosis, she had worked for her employer for more than two decades, enjoyed outdoor activities with her husband, and was hopeful her two adult children would someday gift her with grandchildren. Ms. J initially presented with a spontaneous fracture. She struggled to adjust to changes to her level of independence. Household chores were not up to her usual standard, and she grieved the inability to be active to her previous level of satisfaction. She was devastated that she was no longer able to care for her husband and the household to the level she had previously enjoyed.

Ms. J. maintained hope throughout several lines of chemotherapy. Unfortunately, her illness did not respond; despite aggressive intervention, her cancer continued to progress. She enrolled in a clinical trial, maintaining her willingness to have done “everything possible” to “fight” her cancer. Her efforts toward the clinical trial were to ensure that no one in her family was disappointed in her for “giving up.” During her treatment trajectory, she required hospitalization on several occasions for chemotherapy. Ms. J experienced difficulties with cognitive acuity during one of her hospitalizations. Treatment with ifosfamide led to an acute episode of delirium that was upsetting for both Ms. J and her family. She also experienced continued difficulty

with functional decline, which was perhaps more bothersome because it was an assault on her sense of personhood and created tremendous role strain.

The palliative APRN, Marcy, met with the patient and her husband for an initial consult. In preparing for the visit, the APRN decided to utilize a dignity-conserving approach to explore the patient's and her family's perspective on illness, opportunities for enhancing support, as well as the ways the patient and family can honor their grief while maintaining hope. In assessing the patient's grief, Marcy explored with the patient aspects of loss the patient might be experiencing: physical capabilities; role strain in her roles as mother, wife, employee, daughter, and sister; and challenges to personhood. During the interview, Marcy allowed space for exploration of anticipatory loss through acknowledgment of an anticipated death and the identification of supportive care that would prepare the patient and family for a "good death" that would meet both the patient and her family's goals while reducing caregiver burden. To preserve the patient's autonomy as much as possible and address aftermath concerns and foster legacy, Marcy collaborated with the embedded psychiatric team, expressive therapists, and chaplains.

INTRODUCTION

The World Health Organization (WHO) reports that 56.9 million individuals died worldwide in 2016.¹ Each death is believed to directly affect an average of five individuals.² Accordingly, an estimated 284.5 million persons experienced a bereavement in 2016. The WHO views bereavement support, even counseling, for a family as an important aspect of palliative care.³ Advanced practice registered nurses (APRNs) witness death across the life span, and palliative APRNs are uniquely positioned to encounter complications from the impact of death in their daily practice. Located at the front line of the healthcare system, palliative APRNs meet a broad range of health- and illness-related demands, including grief and bereavement assessment. Like any physical symptom in palliative care, grief and bereavement exist on a continuum and may be easy to identify and manage or may become unrelenting, making optimal relief difficult to achieve. Palliative APRNs will encounter a myriad of grief-related experiences: loss of independence and functioning, role strain or changes, disruption in relationships, and the death of an individual. To expertly manage grief and bereavement in palliative care, the APRN should (1) understand common terms, including loss, grief, and bereavement; (2) understand the application of theories related to human grief to clinical practice; (3) be able to conduct an assessment of a grieving person and distinguish normal grief from complicated bereavement; (4) know when to refer patients for psychiatric services; and (5) employ strategies for self-care.

COMMON TERMS

Common terms for death-related experiences such as grief and bereavement are sometimes used interchangeably, which

can lead to confusion.⁴ *Grief* is defined as "the primarily emotional/affective process of reacting to the loss of a loved one through death."^{5,6} Patients may also experience grief related to losses other loved ones including illness-related losses such a loss of role, loss of independence, and loss of imagined future, as well as material and other significant losses.⁷ *Mourning* is defined as "the public display of grief."⁵ While the term "grief" focuses more on the personal, internal, and emotional experience of loss, mourning refers to the outward display of grief and can be influenced by personal beliefs, religion, and culture.⁵ The broadest death-related term is *bereavement*, defined as "the objective situation one faces after having lost an important person via death."^{5,6} Bereavement can be conceptualized as a distinct state of being after a loss (Figure 38.1).⁷

Special consideration is given to different types of grief, including anticipatory, complicated, and disenfranchised. *Anticipatory grief* refers a grief reaction that occurs before an impending loss and can be defined as "the total set of cognitive, affective, cultural, and social reactions to expected death felt by the patient and family."^{5,8,9} The term "anticipatory grief" is most often used when referring to the families of a dying patient; however, the dying patient can experience anticipatory grief as well.⁵ Anticipatory grief is associated with increased distress, pain, and medical complications in the dying patients and increased overall distress in their social networks.^{5,10} Anticipatory grief and post-death grief can be regarded as two end of the same grief spectrum for family members and caregivers; thus, assessing and meeting the needs of individuals experiencing anticipatory grief can reduce the likelihood of negative outcomes at the end of life and after death.^{11,12}

Complicated grief is an overarching term that refers to various patterns of abnormal grieving including inhibited or absent grief, delayed grief, chronic grief, and distorted grief.⁵ Empirical evidence for inhibited, absent, or delayed

Figure 38.1 Overlay of Grief, Bereavement, Mourning, and Loss

grief reactions is inadequate, and there is significant debate among experts as to whether these patterns can be better described as forms of resilience.¹³ Chronic and distorted grief patterns are often referred to as complicated grief, and these patterns of grief are defined as “a chronic, impairing form of grief brought about by interference with the healing process.”¹⁴ Complicated grief was not officially recognized in the *Diagnostic and Statistical Manual of Mental Disorders*¹⁴ (DSM) until its most recent edition,¹⁵ when persistent complex bereavement disorder (PCBD) was recognized as a formal diagnosis.

Disenfranchised grief is hidden and socially marginalized such as occurs with family members who died from socially undesirable causes (e.g., suicide).⁷ Among worldwide deaths, 800,000 individuals die by suicide each year.^{16,17} Complicated grief and depression are more likely to occur in the context of sudden or violent deaths and in those experiencing disenfranchised grief.¹⁸

LOSS

Further characterization of loss provides an important framework for understanding the nature of loss and its impact on the palliative care patient. One useful description of six major types of loss is found in the pastoral care literature¹⁹ (Box 38.1).

Patients and families may experience some or all of these types of loss with advanced illness. Acknowledging the possibility that patients and families may suffer more than one type of loss related to serious or terminal illness and death can help the palliative APRN support a patient and family as they navigate a new diagnosis or worsening prognosis. Additional consideration of the categorization of loss is based on the nature of the loss: avoidable and unavoidable loss, temporary and permanent loss, actual and imagined loss, anticipated and unanticipated loss, and leaving versus being left.¹⁹

Box 38.1 MAJOR TYPES OF LOSS

Material loss: Loss of an item or an environment with particular attachment

Relationship loss: The end of opportunities to engage with others

Intrapsychic loss: Loss of an image of oneself or hopes for the future

Functional loss: Loss of control of bodily function

Role loss: Loss of an individual role in a social group

Systemic loss: Loss experienced by a system (e.g., family or workplace)

Adapted from Mitchell, Anderson.¹⁹

THEORETICAL MODELS

Human grief is a universal experience and has been observed and explored over time through many different disciplinary perspectives. The resulting theories of grief and bereavement act as a set of definitions, constructs, and assumptions that help express a systematic view of grief as a phenomenon.²⁰ Clinicians can use theories to guide their own understanding of the phenomena they witness in patients and their caregivers in order to provide more holistic grief and bereavement care.²⁰ A brief review of some of the key models of grief demonstrate that early psychological models, stage theories, and more current nuanced theoretical models contribute to an overall complex conceptual framework of grief and bereavement.

Most historic models of grief and bereavement are based in psychoanalytic theory.²¹ Foundational frameworks to our current theoretical models of grief include the ethological theory of Darwin and the psychodynamic theory of Freud.²⁰ Freud described grief as profound sadness requiring “the work of mourning” to sever ties with a loved one. This work includes a process that eventually returns the person to a fully functional, engaged state.²² In 1977, Bowlby²³ applied attachment theory to grief as an integrated interpretation of separation distress with his psychoanalytic understanding of child development.²⁰ Bowlby proposed that children and adults form attachments and that when one experiences a loss, there is constant tension between that attachment and the knowledge that the person is gone. Bowlby also introduced phases of grieving and the concept that early loss influences later loss (e.g., a person experiencing multiple losses in childhood may react more strongly to a loss in adulthood).²³

The most widely recognized model of grief was developed by Elisabeth Kübler-Ross in 1969.²⁴ Through a series of interviews with terminally patients, Kübler-Ross identified five stages of grief including denial, anger, bargaining, depression, and acceptance. She conceptualized the stages of grief with task-oriented goals necessary to achieve relief from mourning.²⁴ Though the stages of grief are well-known and recognized by the public, there is very little empirical support for this model.²⁵ Major critics of Kübler-Ross’s model suggest that the expectation that a bereaved person will or should go through these stages at all, much less in the prescribed order, can be harmful to those who do not.²⁵ Additionally, concerns regarding the conceptual clarity of the model, the lack of practical utility for development or provision of treatment, and the model’s lack of guidance in identifying those at risk for complications in the grieving process have been raised.²⁵ In 2005, Kübler-Ross reconceptualized the stages of grief to domains of grief and loosened the model to suggest that bereaved persons can move among the domains without expectation of a predefined progression, as implied by the term “stages.”^{5,26} Other theories developed using an adapted “stages of grief” model have organized grief patterns into four stages including (1) numbness/disbelief, (2) separation distress (yearning, anger, anxiety), (3) depression-mourning, and (4) recovery^{5,27}; and (1) shock-numbness, (2) yearning-searching, (3) disorganization-despair, and (4) reorganization.^{5,28–31}

Table 38.1 MAJOR GRIEF THEORIES

THEORY	AUTHOR	DATES	MAIN POINTS
Ethological theory	Darwin	1843	Grief is a natural part of having had and lost.
Psychodynamic theory	Freud	1950s	Work is to sever ties with a loved one.
Stages of grief	Kübler-Ross	1969; 2005	Task-oriented approach to achieve relief from mourning. Reconceptualization allowed for more fluidity rather than stepwise approach.
Attachment theory	Bowlby	1977	Integrated interpretation of separation distress. Tension of attachment and loss.
Dual-process model	Stroebe and Schut	1990s	Loss-oriented and restoration-oriented coping.
Meaning reconstruction	Neimeyer	2001	Ascription of meaning to death and reconstructed relationship with the deceased.
Four-component model	Bonanno	2004	Minimization of negative emotion, focus on positive experiences to cope.

References: Neimeyer,³² Borden & Kurtz Uveges,³³ Bonanno & Kaltman,³⁴ Stroebe & Schut.³⁵

More modern theories of grief emphasize that grief is an individual experience that involves integrating the loss while working to cope with negative emotions. Neimeyer's theory of meaning reconstruction³² conceptualizes bereavement as an active and ongoing process of ascribing meaning to the death and reconstructing a relationship with the deceased. In this sense the process of grief becomes less about progression toward a goal and more about finding a new relationship with the deceased that fits into a consistent life narrative.^{32,33} Other more recent models include Bonanno's four-component model³⁴ and the dual-process model outlined by Stroebe and Schut,³⁵ both of which describe a process in which the bereaved finds balance between negative and positive emotions and experience with regard to the loss and the ability to integrate and move forward with their grief. Bonanno emphasized minimizing the negative emotions associated with loss and focusing on positive experiences as a way to cope with loss. He also devised a framework of four components of grief that influence how an individual responds to loss: the context of the loss, the subjective meaning of the loss, changes in how one maintains a connection with the loved one over time, and the role of coping.³⁴ Stroebe and Schut³⁵ describe two processes—loss-oriented and restoration-oriented coping—that individuals use to adapt to loss. Loss-oriented coping involves the memories of the individual and features the loss itself, whereas restoration-oriented coping focuses on present life events (Table 38.1).

Theories of grief and bereavement have changed over time, moving from a model of psychopathology to a series of stages or tasks undertaken by the bereaved, to a process of loss integration and coping. The history of grief theory has taught us that grief is universal, complex, and difficult to describe. Grief theory draws from many different schools of thought, including neurobiopsychosocial science, social constructionism, and cognitive-behavioralism.^{7,36} Further research is needed to continue testing these models in a variety of populations and for varying types of loss.

NORMAL OR COMMON GRIEF

While the aforementioned grief theories guide our understanding that grief is a highly individualized process, it can be useful to look at the experience of acute grief as a common one with some expected findings that may help clinicians differentiate normal grief, depression, and grief complications. Generally, normal or common grief reactions are distinguished by a steady progression toward integration of the loss and maintenance of normal daily activities, though the bereaved can be counseled that daily functioning can be difficult in the early days and weeks following a loss.⁵

About 50–85% of bereaved persons will experience normal or common grief after the loss of a loved one.³⁷ Common emotional reactions after the loss of a loved one include numbness, shock, and disbelief, with much of the focus of the emotional distress relating to the anxiety of separation from the loved one.⁵ This can lead the bereaved to experience intense yearning, searching, preoccupation with the loved one, and sometimes intrusive images of death.²⁷ Bereaved persons may also experience emotions including anger, guilt, and significant periods of sadness, even despair, in the context of physical symptoms including insomnia, hypersomnia, anorexia, and fatigue.⁵ Sometimes bereaved persons even feel physical pain in relation to their loss.³⁸ The palliative APRN can reassure patients that it also is normal to experience positive emotions such as gratitude, relief, and even joy throughout the timeline of bereavement and sometimes in conjunction with negative or distressing emotions.

A frequent occurrence in bereavement is *grief pangs, bursts*, or *waves*, defined as highly intense, time-limited (20 minutes to several hours) period of distress.^{5,27} Very often these waves of grief occur in response to triggers or reminders of the deceased, including major holidays, the anniversary of the patient's death or birthday, or specific tasks associated with the aftermath of a death including estate planning, funeral preparations, choosing what to do with the deceased's special

possessions, etc.⁵ However, very often, these waves of grief may occur without warning or in the context of an unrelated activity. A modern phenomenon in grief and bereavement is the role of social media in both providing support for people going through difficult times and creating a space that can trigger grief and trauma.^{39–41}

Over time most grieving people will experience symptoms less often with shorter duration or with somewhat less intensity.⁵ While there is no specific time frame for integration of loss, most bereaved person will begin to experience some relief in their symptoms within 6 months to 1 year after their loss with occasional, more intense grief waves occurring indefinitely.^{42–44} It is important to note, however, that actual symptom improvement may be on a different time line than the outward expression of grief, which may be influenced by social, religious, or cultural factors.⁵

PROLONGED, PERSISTENT, OR COMPLICATED GRIEF

Those experiencing loss are at risk for complications resulting from grief. Family caregivers experience the burden of caring for the dying individual and are at risk for increased emotional and physical sequelae.⁴⁵ Caregivers experiencing loss are at risk for a myriad of negative outcomes, including worsening health, weight loss, and functional impairment.^{45,46} Social and emotional decline is also associated with bereavement, as is loneliness and a reduction in well-being.⁴⁷ Although most individuals will naturally start to experience a more integrated grief, allowing them to reengage in activities, including those bringing pleasure, some will go on to develop PCBD. The prevalence of PCBD is difficult to determine given that many bereft individuals do not seek help, and the specifics of the diagnosis are debated among experts; however, it is thought that approximately 1 out of every 10 bereaved adults may develop prolonged or complicated grief.^{48–50}

Complicated grief differs from normal grief not in the type of symptoms experienced by the bereaved person, but in the intensity of the symptoms and the length of time that symptoms are experienced.³ According to the DSM-5 and the *International Classification of Disease* (ICD-11), prolonged grief disorder occurs when elevated levels of grief symptoms continue after 6 months post-loss, and PCBD occurs when elevated grief symptoms continue for more than 12 months post-loss in adults and 6 months in children.^{5,15}

The hallmark of complicated grief is the level of disability or impairment it causes the bereaved person. Whereas in normal or common grief some difficulty engaging in day-to-day activities can occur immediately following the death of a loved one, those experiencing complicated grief may struggle with ruminative thoughts and extreme, persistent, and pervasive sadness that essentially disables them.⁵¹

PCBD criteria include experiencing the death of a loved one, persistent symptoms, difficulties in functioning, or a “bereavement reaction [that] is out of proportion to or inconsistent with cultural, religious, or age-appropriate norms.”¹⁵ (p. 790) While symptoms of PCBD can occur as early as the initial

months after the death, the onset of full symptoms can appear after several years.¹⁵ Individuals must have a specific number of symptoms, which range from perseverative thoughts of the deceased, rejection or denial of the death, preoccupation with the circumstances of the death, feeling that life is meaningless or empty, profound avoidance of situations where the loss will be felt, and wishing for death themselves to difficulty trusting or connecting with other people, self-blame and guilt, or an inability to make plans.^{5,15} Level of impairment is determined by observing clinically significant difficulty in social, occupational, or other important areas of functioning.^{5,15}

Risk factors for the development of PCBD include being female, having fewer years of education, preexisting or a history of depression and/or anxiety, poor physical health, and poor or maladaptive coping styles.⁵² Additional risk factors include lower perceived social support, family conflict at end of life, and difficulty accepting the death.⁵² Studies have shown that the risk for complicated grief is higher in individuals who have suffered the loss of a child or life partner. In such cases, the risk for depressive and anxious disorders is present for up to a decade after the death.^{53,54} Individuals with comorbid mood and anxiety disorders are at increased risk to develop PCBD, with associated concern for disability, poor health, and suicidality.^{55,56} Additionally, suicide loss survivors are vulnerable to feelings of shame, guilt, and stigmatization, increasing the risk for social distress and complications of grief including PCBD.¹⁷

Palliative APRNs must have a full understanding of the diagnostic criteria for PCBD so they can differentiate it from other potential diagnoses, including normal grief, depressive disorders, posttraumatic stress disorder (PTSD), and separation anxiety disorder. Shear⁴ described a primary difference between acute grief and depression as symptoms occurring *in relation to the deceased*. For example, those with depression may express a general lack of interest in others and activities, but those with acute grief will have those symptoms *because* of the death. Additionally, the DSM-V carefully outlines the hallmarks of normal grief as compared with major depression, including the waves of sadness mixed with positive emotion seen in grief as compared to the constant sadness and negative emotion seen in major depression.¹⁵ Additionally, in grief, self-esteem is usually preserved in the long run, while in major depression feelings of worthlessness are common.^{5,15} The palliative APRN should also understand the risk for comorbid major depressive disorder, PTSD, and substance abuse disorders and should refer individuals as appropriate to mental health professionals for ongoing assessment and treatment. Individuals with a history of depression or a vulnerability to depressive disorders may benefit from treatment with an antidepressant.¹⁵

ASSESSMENT

Palliative APRNs are intimately involved with individuals approaching end-of-life, as well as their caregivers. In 2002, the national practice standards from the National Organization of Nurse Practitioner Faculties (NONPF)

called for the expanded capability of nurses to identify grief responses as a health concern and to address these needs.⁵⁷ Palliative APRNs are well-positioned to assess patients who are experiencing bereavement and to facilitate the grief process through a grief assessment. A full understanding of the development of PCBD as well as an understanding of normal or common grief provides the foundation for accurate assessment and referral for treatment. Clinicians must also balance cultural, religious, and social considerations in their assessment of grief while evaluating and distinguishing symptoms that are common to both depression and bereavement.^{57,58}

For the palliative APRN, assessment of grief begins before death occurs. Anticipatory grief in caregivers is correlated with post-death grief, and significant pre-death symptoms are seen in up to 38.5% of family caregivers.⁵⁹ Anticipation of death in family caregivers very often leads to intense emotional distress, specifically separation anxiety; however, these feelings can be fluctuating because of the role of hope and uncertainty near the end of life.⁵⁹ In the context of current death-avoidant sociocultural norms, caregivers may be reluctant to think or talk about the reality of impending death in order to sustain hope and the functional capacity to continue caring for their loved one.⁵⁹ Pro-active coping with regards to anticipatory grief, however, has been shown to improve post-death outcomes in family caregivers and should be promoted by palliative APRNs.⁶⁰⁻⁶² The Anticipatory Grief Scale is a tool that may be helpful for palliative APRN's in assessing the severity of symptoms of anticipatory grief in family caregivers.⁶³

The bereavement experience is multifaceted, individual, and often occurs along with other medical illnesses, making it difficult to differentiate the symptoms of normal grief, major depression, and PCBD.⁶⁴ It is important for palliative APRNs to conceptualize bereavement care as part of their role because the consistent presence and relationship-building that occurs during the pre-death period is crucial in evaluating the level of grief in family caregivers post-death.⁴⁶ Understanding the risk factors for complicated grief and follow-up care for families is important in identifying patients who may be suffering from PCBD and may need referral to mental health resources.³⁶ Individuals who suffer from persistent bereavement are at risk for a number of comorbidities, including cardiovascular disease, cancer, depressive disorders, anxiety disorders, post-traumatic stress, and sleep impairment.²⁸ Therefore follow-up care from a trusted palliative care clinician can have an immediate impact on the health of bereaved family caregivers. Additionally, safety assessments should be conducted in individuals with higher levels of bereavement and other risk factors for suicide.

Bereavement-related stressors may be comorbid with other psychiatric disorders and can trigger major depression, post-traumatic stress, or substance use disorders.²⁸ Bereavement with comorbid depressive and anxiety disorders is associated with negative physical and mental health outcomes,⁷ making it important to fully explore differential diagnoses. Symptom overlap exists between PCBD and major depression, including feelings of sadness, decreased functional status, and suicide risk.²⁸ With the complex needs of those experiencing grief and bereavement, as well as the risk of medical complications

that can arise from PCBD, forming a network of resources among palliative care, primary care, and mental health providers is increasingly important.⁶⁵ Palliative APRNs should conceive of themselves as one part of a supportive team for bereaved persons.

There are several screening instruments to help identify individuals who need a higher level of bereavement services or a mental health referral. The Indicators of Bereavement Adaptation—Cruse Scotland (IBACS) measures severity of grief symptoms and risk of developing complications and has good evidence as a first-step in assessment of grief.⁶⁶ The most current version of a commonly used tool, the Inventory of Complicated Grief, now referred to as the PG-13, measures symptoms along four domains: separation, cognitive/emotional, social impairment, and duration.⁶⁷ The PG-13 also has a pre-loss version to use with patients prior to an expected death.⁶⁸ The Texas Revised Inventory of Grief is another screening tool commonly used in bereavement research.⁶⁹ There is empirical support for the use of grief screening tools, with one study suggesting that the use of a screening tool 6 months following the death of a loved one will predict two-thirds of cases of PCBD at 1 year.⁷⁰

STRATEGIES FOR MANAGEMENT

Strategies for management by the palliative APRN include interdisciplinary death preparation, bereavement support, and, when necessary, referral to mental health services. When death is expected, the interdisciplinary team can provide support to patients and families by providing adequate and realistic information on illness progression, supporting families in their caregiving and self-help strategies, validating grief feelings, helping families to anticipate the impending loss, and helping families to reframe and reformulate roles and relationships with the dying patient.⁵⁹ Decreasing caregiver stress, use of advance directives, and focusing on the quality of a loved one's death improve the bereavement outcomes of caregivers.^{71,72}

Involvement by hospice may also reduce the caregiver's risk for complications of grief, so, when possible and appropriate, palliative APRN's should facilitate the transition to hospice care at the end of life, bearing in mind the importance of follow-up care by the palliative APRN to promote continuity of care.^{46,73} Hospices are required by Medicare to provide bereavement services to family members for at least 1 year after the patient dies, though these services may be highly underutilized, thus underscoring the importance of continued support and follow-up from the palliative care team even if no formal bereavement services are offered by that team.^{74,75} One study identified preference of family caregivers regarding bereavement services, and they included time alone with the deceased, a quiet room to be alone after the death, sympathy cards from hospital staff, memorial services, chaplain support before/during time of death, and educational grief booklet, grief book recommendations, a check-in phone call from hospital staff, individualized counseling, and a relationship-specific support group.⁷⁶ This study also indicated the

importance of follow-up screenings for the bereaved 6–12 months post-bereavement to identify those in need of formal psychosocial support.⁷⁶

For those at low risk of complications for grief and who are assessed to be experiencing normal or common grief at the time of follow-up, there is little empirical support for the efficacy of professional intervention by medical or mental health providers.^{5,77} For individuals at risk for developing complicated grief and mental health comorbidities, professional intervention may help with their maladaptive thoughts and behaviors.⁵ Frequently these interventions focus on these maladaptive thoughts and behaviors and use cognitive-behavioral strategies to provide direct relief.⁵ Other strategies that are often incorporated into these traditional interventions include exposure therapy, cognitive restructuring, interpretive therapy, and interpersonal therapy.^{5,78–80} The format of these mental health therapies may include bereavement support groups, group therapy, individual psychotherapy, or family therapy.⁵ Sometimes the decision is made to use medications to help with symptoms of complicated grief; however, this is controversial and not well-studied, though there is some evidence that antidepressant therapy can improve specific symptoms of depression that occur in the context of grief.^{5,81} Drawing from theoretical models of grief, some newer models of grief therapy work to help the bereaved complete necessary tasks for integrating a new sense of meaning and purpose after loss.^{82,83} Important components of these therapies include helping the bereaved to find a sense of connection and belonging in the world without their loved one, as well as ways to integrate the loss into a coherent personal narrative that has personal meaning.^{82,83}

For palliative APRNs, mindfulness of individual risk factors and physical and emotional sequelae provides the foundation for helping bereaved family caregivers achieve optimal recovery after a loss.

SPECIAL CONSIDERATIONS FOR GRIEF IN CHILDREN

The vast majority of children will experience the death of someone close to them (friend or family member) at some point in their childhood, and approximately 1 in 20 children in the United States will experience the death of a parent before the age of 16.⁸⁴ Experiencing the loss of someone close to them often has profound and life-long effects on children and may result in both short- and long-term responses.⁸⁴ There are differences in the expression and experience of grief between children and adults, and attention to a child's developmental stage is crucial in providing support and guidance to a grieving child.⁵ One of the key differences between grief in children and adults is that, in children, the experience and display of intense emotional and behavioral manifestations of grief may not be continuous. This is due, in part, to the fact that children are not as able as adults to fully explore their thoughts and feelings or the long-term consequences of a loss in real time.⁵ While it may appear that children grieve for a

shorter period of time than adults, in fact their grief usually lasts longer.⁸⁵ Grief needs to be revisited by both children and their caregivers throughout their childhood at different developmental and chronological milestones.^{5,86} Expressions and explorations of grief and loss can be seen in play, artwork, schoolwork, behavior, or stories. Children may also naturally take “breaks” from their exploration of grief and appear to be immersed in usual play activities; however, this should not be taken as a sign that the child has stopped grieving.⁵ Significant life events, such as important “firsts” throughout childhood, graduation from school, marrying, and experiencing the birth of their own children, may require the child to dip back into the work of grieving, though most children will eventually achieve resolution of their grief.⁵ Factors including age, previous experiences with death, cause of death, relationship to the deceased, and stability of family life after the loss will all influence the experience, perception, and trajectory of grief for a child.⁸⁷

Taking into account the child's development stage, three major questions should be addressed with children after a loss including, “Did I cause the death to happen?” “Is it going to happen to me?” and “Who is going to take care of me?”⁸⁸ In addressing these themes it is important to provide a child with an explanation of the death. Adults should not keep difficult news from children and should encourage questions, addressing them simply, honestly, and directly. Correct language should be used when discussing death with children because euphemisms (e.g., “passed away,” “we lost him,” “she is in a better place”) can be confusing to children and lead to misinterpretations.^{5,85} Using books and children's literature is often very helpful in finding ways to explain death to a child in a developmentally appropriate way and to stimulate conversation with the child about the loss.⁸⁹ For older children, social support with other children who have experienced loss can be useful in processing and understanding their own loss. Grief Camps and other group programs have been shown to build resilience in coping with loss in children.⁹⁰ Children should be included in rituals related to death and loss. As they feel comfortable, they should be invited to participate in the planning of memorial activities and attend funerals and memorial services. Preparation for what the child might experience at these events (e.g., intense emotions of their own, seeing loved ones cry, the presence of a casket) is important to make sure this is helpful and not harmful to the child.⁵

As with adults, taking time before the death to prepare the child in developmentally appropriate ways may be protective against the development of grief complications in children.⁹¹ Offering children realistic information about their ill loved one can help begin the process of explaining and processing a death.⁹¹ Interventions including art and music therapy with a legacy-building focus can help children process their emotions around an impending loss as well as provide them with a tangible remembrance of their loved one.^{92–94}

Some children may develop grief complications, though they look different from those seen in adults. Signs of possible maladaptation to grief can include long-term changes in

behavior such as “acting out,” regressive or risk-taking behavior, loss of interest in engaging in previously enjoyed activities, or difficulty concentrating in school.⁸⁴ In these situations, or if a child appears to be at risk for harming themselves or others, expedient referral to mental health resources is appropriate.⁸⁴ Appropriate mental health resources for children may include pediatric psychiatry or psychology, bereavement support groups and camps for children, school-based programs and services, or other mental health professionals trained to counsel grieving children who are also experiencing depression, anxiety, or trauma symptoms.⁸⁴ It is important to remember that the goal of providing support for grieving children is not to take away the pain and sorrow that they are experiencing—though it can be tempting to try—but to help them integrate the loss and minimize the negative effects of loss on the child’s developmental course.⁸⁴

SELF-CARE

As nursing professionals, particularly in the field of palliative care, a substantial part of the work is bearing witness and tending to suffering.⁹⁵ Palliative APRNs and other healthcare providers are not immune to strong emotions, including grief after the death of a patient, and there is substantial evidence that they experience clinically significant grief reactions.^{38,96–98} Unacknowledged and unprocessed grief in healthcare providers can lead to burnout, which is generally defined as a state of emotional, mental, and physical exhaustion that results from prolonged periods of stress.^{99,100} In addition to burnout, healthcare providers who do not care for their own emotional well-being in the context of the stresses of their work often experience compassion fatigue (declining empathy for suffering), moral distress (a general feeling of helplessness in the context of great responsibility), and loss of personal meaning in their work, which makes them less effective at their jobs and more likely to leave the profession.^{101–103} It follows, therefore, that an important part of palliative nursing is to engage in self-care around the work of caring for patients in pain and those who may be near the end of life.

There is very little formal training in nursing and medical education around self-care practices.^{96,101,104} Several formal programs that focus on mindfulness, storytelling, self-reflection, and other contemplative practices to help healthcare providers process their emotions around death and dying have been shown to improve well-being, empathy, and job satisfaction while reducing anxiety and symptoms of burnout, though healthcare providers generally have to seek out those programs on their own.¹⁰⁴ There is also evidence to support hospital-based practices to promote processing of grief, which can be as simple as a team debrief after a death.^{96,97,105} Many healthcare providers report developing their own self-awareness and self-care plans that include such notions as focusing on “living a good life,” developing a sense of spirituality, maintaining a healthy lifestyle (healthy diet, exercise, adequate sleep), fostering hobbies and interests outside of the workplace, and prioritizing relationships with family.¹⁰⁴

Not all deaths will evoke the same amount of grief or emotional response from the healthcare team. Palliative APRNs should pay close attention to personal, situational, and patient factors that may put them at higher risk for increased emotional response to a patient death. Examples of these factors include identification with a patient or family member, a long-standing relationship with a patient, or complicated patient–family dynamics.^{38,95,98} Four ways to address complicated feelings about the loss of a patient are (1) name the feeling, (2) accept the normalcy of the feeling, (3) reflect on the emotion, and (4) consult a trusted colleague.¹⁰⁶ Using appropriate personal and team support systems; paying close attention to emotions, particularly in difficult cases; and seeking individual counseling when necessary may help prevent burnout in palliative APRNs.

SUMMARY

The field of palliative care and bereavement research continues to grow. A need exists for evidence-based interventions for the care of bereaved individuals. Wide-reaching educational efforts should focus on dissemination of best practices in bereavement care for clinicians in primary care, palliative care, psychiatry, and oncology. While the evolution of bereavement research continues along with the creation of evidence-based practice guidelines, palliative APRNs should evaluate the needs of each patient and make referrals to appropriate specialists, including mental health practitioners, to fully support patients struggling with the grieving process.

SECTION VIII

SYMPTOMS

ANOREXIA AND CACHEXIA

Robert Smeltz and Renata Shabin

KEY POINTS

- Cachexia and anorexia syndrome is present in most advanced chronic and life-limiting illnesses. The palliative advanced practice registered nurse (APRN) should be vigilant in assessing for its presence.
- Assessment of cachexia and anorexia syndrome requires subjective and objective measures and must take into account the multiple dimensions of the individual.
- Treatment of cachexia and anorexia syndrome requires a multimodal approach using pharmacologic and nonpharmacologic interventions, treating both physical and psychosocial symptoms.

CASE STUDY

RV was a 58-year-old woman with recently diagnosed ovarian cancer with peritoneal carcinomatosis. She had initiated first-line chemotherapy but was hospitalized recently for nausea, weight loss, and abdominal fullness. The palliative APRN was asked to evaluate her and assist with symptom management.

A gastrointestinal (GI) examination revealed positive bowel sounds, distended abdomen, and mild abdominal tenderness. Her height was 5-foot-1 inch and weight 105 pounds, with a 10-pound weight loss. She reported intermittent nausea, denied vomiting. Nausea occurred with eating and with the look and smell of food. She reported daily small bowel movements. She endorsed early satiety. Breakfast included a half a cup of yogurt with a small amount of fruit, with effort; she was often unable to finish due to discomfort. She did not use supplemental nutritional shakes due to their sweetness. She endorsed fatigue, which limited her ability to complete activities of daily living (ADLs). She endorsed feelings of depression and sleep disturbances. She denied pain and denied shortness of breath, coughing, and anxiety.

Psychosocial history revealed that she was married with three adult children with whom she had a close relationship. She stated that cooking and baking were one of her joys, but she no longer had the energy to cook a meal and the sight and smell of food turned her stomach. She reported being raised Catholic and was an active member of her church community.

The palliative advanced practice registered nurse (APRN) engaged in a goals-of-care conversation with RV in which eating and family meals were a focus of joy and pleasure for her and

her family. RV wanted to focus on treatment to allow her to eat with her family. She wanted to pursue disease-directed therapies, including chemotherapy. She stated that if things got worse, she would not want to be in pain and would not want to be resuscitated or intubated. She appointed her husband as her healthcare agent.

With this information, the palliative APRN prescribed oral metoclopramide 10 mg AC three times a day for nausea, oral ondansetron 4 mg every 8 hours as needed, and oral mirtazapine 15 mg every evening. A bowel regimen of oral senna, 2 tabs every evening at bedtime and polyethylene glycol each day was added. A referral to a nutritionist was initiated. A plan for daily physical activity was also created.

RV returned to clinic 2 weeks later. She stated that her appetite had not increased but she was able to join her family at meals with less nausea. She reported a weight gain of 1 pound and thought it was due to diet recommendations from the nutritionist. She reported making her own nutrition shakes at home. Her sleep had improved, and her bowel movements were regular.

INTRODUCTION

This chapter defines anorexia and cachexia and their interplay as a syndrome, as seen in most advanced stages of disease. The assessment of anorexia and cachexia is fundamental in establishing an effective treatment plan. A first step in treatment of cachexia and anorexia is setting goals and educating patients and families on the limits of reversing anorexia and cachexia in advanced disease. The use of a multimodal approach with pharmacologic and nonpharmacologic measures delivered by an interdisciplinary care team geared toward treating the whole person is the key strategy to addressing cachexia and anorexia syndrome.

Cachexia is defined as a multifactorial syndrome characterized by an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. The pathophysiology is characterized by a negative protein and energy balance driven by a variable combination of reduced food intake and abnormal metabolism.¹

Anorexia in cancer and advanced chronic illness is a decrease in nutritional intake, often accompanied by a loss of appetite. Cachexia and anorexia are often seen together, and this is referred to as *cachexia and anorexia syndrome* (CAS). CAS is seen in cancer, heart disease, kidney failure, chronic

lung diseases, and HIV/AIDS. Anorexia is seen in 40% and cachexia is seen in 51% of hospitalized patients with cancer.² Anorexia is seen in chronic obstructive pulmonary disease (COPD), end-stage renal disease (ESRD), AIDS, and Parkinson's disease in up to 67%, 64%, 82%, and 13% of patients, respectively.³ Cachexia is seen in 10.5% of patients with congestive heart failure.⁴ Anorexia is seen in 16–20% of elderly persons in the community.⁵ Anorexia, cachexia, and dementia increase in prevalence with advancing age in older populations; however, there are little data on the prevalence of CAS in patients with dementia.⁶ CAS and dehydration appear to play a role in more than one-third of deaths in dementia.⁷

CAS is a difficult symptom to treat and often becomes refractory toward the end of life.⁸ Most pharmaceuticals have limits in terms of efficacy and/or side effects. Dietary counseling seems like a logical choice with no adverse effects, but it is not clear that outcomes are improved.⁹ This chapter discusses the role of the palliative APRN in treating CAS. The pathophysiology of CAS, identifying underlying causes, and the importance of using a multimodal approach to treatment are outlined. A review of the psychosocial assessment and how CAS affects the patient and family is offered. Finally, strategies the palliative advanced practice registered nurse (APRN) can offer as part of education and support are described.

PALLIATIVE APRN CONSIDERATIONS

The palliative APRN plays an important role in the assessment, diagnosis, and treatment of anorexia and cachexia. This includes coordinating the patient's interdisciplinary care, advocating for the patient, supporting the patient, and educating the patient and family. The palliative APRN can identify the goals of care in terms of how they relate to addressing CAS and can help the family understand what is realistic within the limits of the disease at its current point in the disease trajectory.¹⁰ The palliative APRN is in a unique position to support the patient and family with the psychological impact of CAS while helping to honor the patient's dignity as a person living with CAS.¹¹ Living with CAS can cause much distress to the patient and family, and the APRN can serve as a clinical support during this time. The palliative APRN can help the family explore pharmacologic and nonpharmacologic treatment measures and identify a regimen that takes into account the patient's goals as well as caregiver burden.

PATHOPHYSIOLOGY

CAS is produced by multiple factors, including decreased appetite, alterations in metabolism, and increased catabolism. The decrease in appetite is likely multifactorial as well, resulting from decreased drive to feed, early satiety, decreased intestinal motility, and nausea. Decreased food intake results in some of the weight loss but does not explain

all of the wasting seen in CAS.¹² There are disturbances in metabolism in CAS resulting in loss of lean body mass and body fat, unlike initial stages of starvation, where initially body fat is lost.¹³

CAS is believed to be caused, in part, by pro-inflammatory cytokines (interleukin [IL]-1, IL-2 and IL-6; interferon- γ ; and tumor necrosis factor-alpha [TNF- α]) in patients with cancer. Other peptides and pathways that influence appetite and catabolism could also be affected by cancer.¹³

TNF appears to increase lipolysis and decrease synthesis of proteins. IL-6 is a pro-inflammatory cytokine, but, like TNF and the other cytokines, it is difficult to understand the specific roles in CAS since there is overlap and redundancy. It is likely that the effects of several cytokines cause CAS, and inhibiting one cytokine has little to no effect on CAS.¹³

Glucagon and other hormonal peptides and neuropeptides play a role in CAS. Specifically, glucagon administration has been shown to reduce food intake, and glucagonemia is associated with some cancers. Corticotropin-releasing factor (CRF) is seen in some cancers, and its presence decreases gastric emptying as well as food intake and appetite. There are several other neuropeptides that appear to affect feeding and weight, but their role in CAS and implications in the treatment of CAS are not known.¹⁴

Cancer cell metabolism may play a role in CAS. The uncontrolled metabolism and growth of cancer cells inhibit delivery of sufficient oxygen, which prevents creation of energy from the Krebs cycle; instead, the Cori cycle is used to create energy. This creates lactic acid, which needs to be processed in the liver, requiring further energy expenditure. This essentially helps to increase the resting energy expenditure.¹³

CAS is seen in several serious illnesses in addition to cancer. The process of aging likely contributes to CAS in the elderly population.¹⁵ Gastric emptying is decreased in older patients. Senses, including smell, taste, and sight, may be altered, which may have an impact on appetite.¹⁶ Pro-inflammatory cytokines appear to play a role in CAS older patients as well.¹⁷ CAS in amyotrophic lateral sclerosis (ALS) and dementia is not well understood. CAS in ALS is at least partially related to increased dysphagia and decreased mobility and nutritional intake secondary to the progression of the disease.¹⁸ CAS in dementia may also be related to alterations in metabolic homeostasis as well as cognitive and functional decline and dysphagia.⁶

CAS is also seen in advanced heart disease. Pro-inflammatory cytokines appear to be involved. Decreased circulation to the intestines can decrease motility and absorption, which can further contribute to anorexia and cachexia, respectively. There is an increase in muscle protein breakdown. Decreased insulin sensitivity could also play a role in CAS in patients with heart disease.¹⁹

Inflammatory responses appear to play a role in CAS in COPD. The increased work of breathing likely increases energy expenditure, contributing to CAS. Impaired oxidative capacity in COPD appears to alter protein turnover, worsening CAS further.²⁰

ASSESSMENT

The goal of assessment is to identify the presence of cachexia, weight loss, and/or anorexia. It is paramount to complete early nutrition screening to identify at-risk patients. The presence of cachexia is identified with weight loss disproportionate to or without anorexia.¹ The assessment of anorexia and cachexia includes the patient's report of appetite, disturbances in taste and smell, early satiety, and nausea. There are screening tools, but most of them are not practical for daily clinical practice, like the Mini-Nutritional Assessment tool.²¹

New tools for nutrition assessment have been developed, such as the Anorexia/Cachexia Scale (A/CS-12) for use in an outpatient setting for lung cancer patients; this tool was effective at increasing the referral of at-risk patients to nutrition consultations.²² The cancer patient's food intake should be assessed at the start of treatment and routinely during active cancer treatment.²³

For all patients with CAS, the number of meals the patient eats per day and the size or the percentage of the meals eaten should be recorded. A variety of tools can be used. The patient can keep a food diary or use applications on computers or handheld devices for tracking food consumption, or healthcare providers can do a calorie count. Tools such as the Patient Generated Subjective Global Assessment (PG-SGA), the Nutritional Risk Screening (NRS), and the Malnutrition Screening Tool (MST) are most frequently referenced. The PG-SGA requires specially trained staff, the NRS considers patients weight loss and food intake, and the MST applies to outpatient oncology patients based on weight and appetite loss. The MST is a quick tool that consists of two questions regarding appetite and weight loss, and the PG-SGA is practical for outpatient oncology patients.²⁴

Other causes of reduced food intake should be assessed. These include pain, stomatitis, constipation, dyspnea, depression and anxiety, fatigue, dry mouth, and poor dietary habits.²⁵ More information on the assessment and treatment of these symptoms can be found throughout this textbook.

The patient's weight should be monitored. Fluid retention should be considered when evaluating weight changes. Body mass index (BMI) is associated with the patient's weight and height. Muscle loss is associated with decreased functional status. Muscle loss, an important end point for assessing cachexia interventions, can be determined through muscle strength and muscle mass. Muscle strength can be assessed using handgrip strength (handgrip dynamometry) and upper extremity and lower extremity strength testing. Muscle mass, a component of lean body mass, is assessed through the mid-upper arm muscle area.^{26,27}

Laboratory tests and imaging can be used to measure nutritional status, inflammation, and body composition. Prealbumin is one of the better measures for assessing malnutrition. A low prealbumin level indicates low protein stores, indicative of chronic anorexia. C-reactive protein (CRP) measures systemic inflammation which can be seen in cachexia¹ but cachexia can be present without an increase in C-reactive protein (CRP).²⁵ Cross-sectional imaging (computed

tomography [CT] or magnetic resonance imaging [MRI]), dual energy x-ray imaging (DEXA), anthropometry (mid-arm muscle area), and bioimpedance analysis are tests that can measure muscle mass. One study compared these techniques but found the diagnosis of cachexia was limited.²⁶

The palliative APRN must assess the patient's functional status. This can be accomplished through patient report on activities or provider assessment using the Karnofsky scale, the Palliative Performance Scale, or similar measures.²⁴ In addition, the psychosocial effects of anorexia and cachexia should be assessed. Lack of food intake may alter energy levels and subsequently affect mood.

CACHEXIA AND ANOREXIA MANAGEMENT

Identifying the goals of care and how they relate to management of CAS is important. The palliative APRN can initiate a goals-of-care discussion so that they can inform the patient and family of what is realistic and within the limits of the disease. The patient and family may want to treat CAS to increase body mass, weight, and functional status or to improve appetite for the sake of the pleasure of eating, or they may be simply looking for a way to help the patient. An understanding of the natural progression of disease and the pharmacologic and nonpharmacologic measures (Table 39.1) used to treat CAS will help the patient and family to clarify and meet their goals.

PHARMACOLOGIC MANAGEMENT

Megestrol acetate (MA) is a synthetic progestin used as an antineoplastic agent and to stimulate appetite.²⁸ MA increases weight by a small amount, but with an increase in adverse events across a variety of serious illnesses when compared to placebo; however, there is no defined optimal dose to maximize weight gain and minimize adverse events.²⁹ Earlier studies have shown similar results, with an increase in thromboembolic events and mortality.³⁰ Currently, MA is the most studied and effective pharmaceutical for increasing weight in CAS, but patients should be aware of the side effects and limits of the drug before they start taking it.²⁹ The typical dosage of MA is 800 mg once a day, or 625 mg with the concentrated formulation.²⁸ However, there is not enough evidence to support the most effective dosage of MA.²⁹ MA reaches peak plasma concentrations in 1–5 hours. It is metabolized by the liver and excreted by the kidneys and in the feces.²⁸

The American Geriatric Society recommends avoiding MA in older adults.³¹ The current evidence for MA in the elderly is mixed, showing some benefit in some and no benefit in other studies.³² Currently, there is insufficient evidence to recommend megestrol for CAS in heart failure.³³

Dronabinol and other cannabinoids have been used to improve appetite in CAS resulting from multiple etiologies. Dronabinol, a synthetic cannabinoid, has been approved to

Table 39.1 CACHEXIA AND ANOREXIA SYNDROME (CAS) MANAGEMENT

	INTERVENTION	IMPLEMENTATION	COMMENTS
Pharmacologic	Megestrol	800 mg PO qd	Shown to improve appetite and weight. Increased risk of blood clots and increased mortality. Patients should be aware of this potential adverse effect before implementing.
	Dronabinol	Starting dose is 2.5 mg PO bid (qd in older adult).	Treats anorexia in HIV/AIDS, treats therapy-related nausea in cancer patients
	Glucocorticoids	Starting dose: dexamethasone 4 mg PO qd	Use of this regimen is limited due to side effects. Used often to treat anorexia and cachexia near the end-of-life.
Nonpharmacologic	Dietary counseling	Refer to dietitian in complex cases. Provide instruction to reduce size of meals but increase frequency.	No evidence that this will result in sustained weight gain or improved quality of life in advanced cancer patients. Patients with COPD did benefit from nutritional counseling in terms of increased oral intake, weight gain, and increased strength.
	Oral care	Oral hygiene can prevent oral infection. Keeping the mouth moist can improve mastication and prevent infection.	Low-risk and low-cost interventions

treat anorexia related to HIV/AIDS.³⁴ There is no evidence to support the use of dronabinol and cannabinoids in CAS related to cancer,³⁵ but dronabinol is approved to treat cancer treatment–related nausea that is refractory to first-line antiemetics.³⁴ Research for a similar medication, nabilone, supports its effectiveness in lung cancer; however, more and larger studies are needed before it can be recommended in treating cancer-related CAS.³⁶ Nabilone is currently only recommended as a cancer treatment–related antiemetic when first-line therapies have failed, with no indication for use in any disease-related CAS.³⁷

The starting dose for dronabinol is 2.5 mg before lunch and supper; however, 2.5 mg once daily should be considered for geriatric patients and in patients who experience side effects with more frequent daily dosing. The maximum dosage is 20 mg per day in divided doses.³⁴ The most common side effects involve the central nervous system and include feeling high, somnolence, and confusion. The initial half-life is 4 hours, but the terminal elimination half-life is 25–36 hours. Steady-state plasma levels are reached in 2 weeks.³⁴

Glucocorticoids have shown some efficacy in improving appetite and weight gain, but no better than MA and with a worse toxicity profile.³⁸ The toxicity may be limited if the drug is given for short periods of time; however, the beneficial effects wear off after the steroids are stopped.³⁸ The efficacy of glucocorticoids on appetite could depend on patients' baseline status, showing improvement in appetite in patients with higher functional status and without drowsiness.³⁹

Mirtazapine is known to produce increased appetite in 17% and weight gain in 12% of patients as a side effect.⁴⁰ Although it has been studied, there is currently insufficient evidence to support the clinical use of mirtazapine in treating CAS related to cancer⁴¹ or in the elderly.³² Nonsteroidal anti-inflammatory drugs (NSAIDs) have been studied for their effectiveness in managing CAS. The drugs studied include

celecoxib, ibuprofen, and indomethacin. Currently, there is insufficient evidence to recommend their use in clinical practice.⁴²

Thalidomide is thought to work by anti-inflammatory mechanisms, blocking cytokines or cytokine production and thereby treating the underlying causes of cachexia. Insufficient evidence exists to support the use of thalidomide, and its use is not recommended due to toxicities in the absence of efficacy.⁴³

The fatty acids, linoleic acid and icosatetraenoic acid, have been studied to determine their efficacy. It is thought they can reduce the inflammatory factors involved in CAS. Linoleic acid may increase self-report of appetite and daily caloric intake in patients with COPD associated anorexia; however, no change in weight was seen.⁴⁴ There currently is insufficient evidence to support the efficacy of eicosapentaenoic acid (EPA), an omega-3 fatty acid, but early studies show promise.⁴⁵ Further research will need to be done to determine if fatty acids are effective.

Ghrelin, a peripheral hormone that is secreted from the stomach, is being studied as a treatment for CAS. The release of ghrelin stimulates the release of growth hormone and stimulates orexigenic neurons in the hypothalamus, which is known to increase appetite. Ghrelin has been shown to increase appetite in healthy subjects.⁴⁶ Ghrelin has been shown to increase food intake, but its effect on other outcomes is unclear. Given insufficient evidence on efficacy and safety, ghrelin is not recommended for use in treating anorexia and cachexia in patients with serious illness.⁴⁷

L-Carnitine given with celecoxib was compared with L-carnitine with celecoxib and MA. Both treatments were effective in increasing lean body mass and increasing physical daily activity. However, it was not compared to placebo, and the number of people finishing the study was fewer than 60.⁴⁸ Another study looked at five types of treatment, with more than 300 patients enrolled. The only group that showed a

statistically significant increase in lean body mass was the one taking a combined medication regimen including L-carnitine, MA, EPA, and thalidomide.⁴⁹ Despite the limitations of these studies, they suggest that multiple-drug regimens should be looked at more closely, but cannot yet be recommended for clinical practice.

NONPHARMACOLOGIC MANAGEMENT

The palliative APRN is in a unique position to help patients with CAS. Aside from the emotional support provided, APRNs can assess the patient's symptom burden that could be contributing to CAS and prescribe a nonpharmacologic approach that includes engagement of an interdisciplinary team including pharmacists, dieticians, and physical therapists.⁵⁰

Dietary counseling can play an important role in patients with anorexia and cachexia. Dietary counseling includes education on modifying familiar or favorite foods to match patients' changing tastes and needs, adding nutritional supplements, and decreasing the size and increasing the frequency of meals.⁵¹ Standard nutrition supplements alone may not be able to reverse the effects of CAS.⁵² There is some evidence to support dietary counseling in patients with COPD. With therapy mainly in the form of nutritional supplements, patients with COPD experienced increased caloric intake, increased weight, and increased grip strength.⁵³

Current evidence does not clearly support increased survival, significant weight gain, or improved quality of life with dietary counseling in cancer patients; however, since the risks are low, patients and families may value this kind of support. Dietary counseling should start early with additional nutritional support alongside palliative care.⁵²

Providing good oral care to reduce the risk of mucositis and oral mucosal infections can prevent some causes of decreased oral intake.⁵⁴ This includes good oral hygiene and a multimodal approach to oral care. Patients at risk (those with reduced immunity, receiving radiation therapy, or receiving chemotherapy) or with mucositis should use a mouth rinse, like bicarbonate solution or a bland mouth wash, regularly.⁵⁴ Using sucralfate-based saliva substitutes can provide needed moisture to the mouth to aid with mastication and prevent dryness. Using an antifungal or antibiotic agent in the presence of oral infection should be considered.⁵⁴

Exercise has shown some benefit in improving symptoms related to CAS. One randomized controlled trial found that exercise tracked on an electronic tracker, ActivPal, led to increased compliance.⁵⁵ Exercise can be beneficial in a multimodal approach because it can help regulate hormones and improve strength and quality of life.⁵¹ A recent Cochrane review found insufficient evidence demonstrating the effectiveness of exercise on cancer cachexia patients, but there is little harm in incorporating this approach.⁵⁶ More evidence is needed to make recommendations on the types and quantity of exercise that work best, but it is likely this could be tailored to the patient. It is important for patients to avoid exercise

that causes pain or is too strenuous; safety is always the first consideration.

It has also been determined that patients and families may benefit from psychosocial support while living with CAS and undergoing rigorous cancer treatment. Poor body image can play a significant role in emotional well-being.⁵¹ Assessment of quality of life and mood should be part of standard treatment; one study demonstrated that living with cachexia led to worse quality of life scores than in non-cachectic patients.⁵⁷

MEDICALLY ADMINISTERED NUTRITION AND HYDRATION

Decisions regarding medically administered nutrition and hydration are challenging. Enteral nutrition is utilized when the cancer patient is unable to have adequate oral intake but has a functioning gastrointestinal (GI) tract.⁵⁸ Parenteral feeding can be considered in cancer patients if the patient does not have a functioning GI tract, has active cancer treatment options, and has a prognosis of at least 3 months.⁵⁸ Parenteral feeding is often used temporarily prior to treating the gut dysfunction. If prognosis is uncertain, or there is hope of reversing an acute condition, a time-limited trial of medically administered nutrition can occur with clearly outlined treatment goals.⁵⁹

The decision to proceed with enteral feedings and tube placement is multifactorial. Patients with advanced cancer and a poor prognosis likely will not see benefit from enteral or parenteral nutrition and are apt to have more complications.⁸ The American Society of Parenteral and Enteral Nutrition (ASPEN) does not recommend medically administered nutritional support to be used for most patients undergoing chemotherapy or radiation, especially in end-stage cancer patients.⁹

In patients with advanced dementia, medically administered nutrition does not improve survival, increase mobility, reverse malnutrition, or prevent aspiration pneumonia and is therefore not recommended.⁶ Medically administered enteral feeding is often used in severe dysphagia associated with stroke, when the patient's oral intake is expected to remain impaired for at least 30 days and realistic goals of care are established.⁶⁰ Also, patients with head and neck cancers who have lost the ability to swallow as a result of the disease or treatment and are experiencing malnutrition can benefit from enteral feeding through a percutaneous endoscopic gastrostomy (PEG) tube.⁶¹ (See Chapter 56).

MULTIMODAL APPROACH

CAS is a multifactorial syndrome with multiple components contributing to the symptoms, so it is reasonable to suspect that several modes of treatment, including nutritional, pharmacologic, nonpharmacologic, and exercise measures, will be needed to address the CAS.⁵⁶ There are no definitive studies that would allow recommendations to be made for specific treatment regimens (including an exercise program); however,

available evidence suggests a trend showing that a multimodal approach could help.⁵⁵

Identifying the patient's goals of care related to treating CAS is an initial step in using a multimodal approach. This will help tailor the interventions and will determine if using a pharmaceutical like MA is prudent. The goals will also inform the instructions provided during nutritional counseling. If patients want to maintain weight during disease-directed therapies, they should eat small meals several times a day, paying attention to the nutritional content of the food. However, if goals are geared toward comfort, instructing patients and families to focus on comfort feeding is important.⁶²

PSYCHOSOCIAL SUPPORT

CAS not only affects the body but also has psychosocial implications for patients and families.⁶³ This is because food is the essence of life. It not only sustains life, but it also plays a central role in most cultures, traditions, and celebrations. Moreover, preparing food is one way we show love and take care of the ones we love. Therefore, food symbolizes life, love, and nurturing. The perception of patients who cannot or do not want to eat can be seen as rejecting that love. The inability to eat over time is a visible reminder of the imminence of death.

The psychosocial dimensions of anorexia and cachexia also result in social isolation. Patients may avoid social situations to avert the rituals of eating if it caused physical distress such as nausea or anxiety around eating. The patient may try to please family and friends and attempt to eat and families may pressure or contently remind the patient to eat, but this can strain relationships.⁶⁴ Family members often experience a sense of rejection, guilt, or helplessness when the patient refuses offers of food.⁶⁵

Patients with CAS and their family members may express concern about the patient's decreased appetite, changing appearance, prognosis, and changes in social interactions.⁶⁴ Addressing these concerns is important to patients and families,⁶⁴ but healthcare professionals may not have the knowledge or training to do so.⁶³ APRNs specializing in palliative care need to develop expertise in addressing the physical and psychosocial sequelae of CAS.

The palliative APRN can arrange a family meeting to discuss the role of food in the patient's care. This will create an opportunity for the patient and family to discuss their views about eating food in light of the patient's condition and disease. The APRN can establish goals of care as they relate to nutritional intake. This becomes a good time to educate both the patient and family on the impact that progressive illnesses have on appetite and weight loss.

END-OF-LIFE CONSIDERATIONS

During the final days to hours of life, it is not uncommon for patients to eat and drink little to nothing. The family may make requests at this time to address the patient's poor

nutritional intake or weight loss. This often includes requests for medically administered nutrition and hydration. It is likely the family is seeking a way to provide care to their loved one. Finding meaningful ways for family members to provide care introduces hope that may not have been realized.

Providing the family with education regarding the risks and limited benefits of medically administered nutrition may be helpful.⁶⁶ Some studies demonstrated increased symptoms due to increased fluid burden and no improvement in quality of life, while others stated that hydration is a human right and that it will alleviate thirst.⁶⁶ Overall, the use of medically administered nutrition is not recommended at end of life due to increased risks of adverse effects and little to no benefit.^{8,67} The body increasingly becomes unable to properly process food due to an underlying inflammatory response and catabolic state. Providing medically administered nutrition is unable to reverse these processes.⁸ The APRN can identify the values, preferences, and beliefs influencing these decisions in honest goals-of-care conversations.^{8,59} The patients previously stated wishes regarding nutrition and hydration at end of life must be reviewed. If there is a disagreement between family wishes and previously documented goals, hospital policies may need to be referenced.⁵⁹

When goals of care are directed toward treating symptoms and promoting comfort, it is helpful to provide foods in small portions that are easy for the patient to consume and tolerate. Easing diet restrictions and allowing diet modifications can greatly increase food enjoyment at end of life.⁶² Any food provided should be the right consistency, texture, and amount.⁶² Sometimes a taste is all that is needed; this is referred to as *pleasure feeding* or *eating*. Safety always needs to be considered, along with goals and comfort; patients should not be force fed or made to feel judged regarding their lack of desire to eat.⁸

It is important for families to see the hope they provide to their loved ones by their presence and commitment to care. Having some useful routines of care that family members can provide at the end of life goes a long way in comforting both the patient and the family. The family can utilize aromatherapy, massage, music therapy, and other more advanced options depending on the care site to aid in comforting and nurturing their loved one at the end of life.⁶⁸

SUMMARY

CAS comprises a complex set of symptoms that are difficult to manage; best outcomes can be achieved with early identification and intervention. The cause of CAS can be related to treatment, but, as the end of life nears, it is almost always a manifestation of the progression of disease. Since reversal of this progression is often not possible, alleviating or slowing CAS is difficult, if not impossible. Identifying goals of care for nutrition and weight loss is important. Educating family members and primary care providers about CAS as part of the natural progression of disease is necessary. The palliative APRN can utilize screening tools early to identify nutritional deficiencies and help the patient and family identify a

multidisciplinary regimen (pharmacologic and nonpharmacologic) that will maximize the patient's comfort and help slow the development of CAS.⁶⁹ Though a palliative care focus cannot eliminate CAS, the palliative APRN can help improve some of the symptoms and can align care with the patient's values to optimize quality of life.⁶⁹

BOWEL SYMPTOMS

Kimberly Chow and Lauren Koranteng

KEY POINTS

- Constipation, diarrhea, and malignant bowel obstruction are highly prevalent and distressful symptoms in advanced illness.
- The palliative advanced practice registered nurse (APRN) plays a vital role in assessing, treating, educating, and supporting patients and families with a high symptom burden from bowel dysfunction throughout the disease trajectory.
- Bowel symptoms do not occur in isolation from other symptoms, and proper management requires a global understanding of the patient's experience.

CASE STUDY: CONSTIPATION

AJ was a 40-year-old woman diagnosed with myelodysplastic syndrome 3 years prior. She declined initial curative treatment with standard hypomethylating agent and allogeneic stem cell transplantation. She had a past medical history significant for anal warts, for which she underwent a rectal dilatation with a post-procedure course complicated by pyoderma gangrenosum.

AJ maintained close follow-up with her oncologist for more than 2 years, requiring red blood cell transfusions approximately twice per month. When her disease progressed to acute myeloid leukemia (AML), she agreed to stem cell transplantation. Unfortunately, she relapsed 3 months later, which was indicative of an overall poor prognosis. Despite multiple lines of disease-directed therapies, her AML continued to progress with extensive bone marrow involvement causing severe hip pain. A palliative advanced practice registered nurse (APRN) was consulted to assist with pain management and psychosocial support.

Upon initial consultation, AJ reported not only bone pain, but severe rectal pain with bowel movements that was even more distressing. She expressed frustration that her care providers and family did not focus as much on these symptoms despite her struggles to use the bathroom every morning. The palliative APRN sensitively performed a comprehensive assessment of her bowel history, beginning with the diagnosis of pyoderma gangrenosum and her worsening symptoms over the course of AML therapy. AJ's bowel patterns fluctuated between diarrhea and constipation. Most recently, she reported sensations of incomplete stool evacuation that required at least three consecutive trips to the bathroom to feel fully relieved. By the third attempt, her pain would escalate to 8 out of 10

on the numeric rating scale due to repeated irritation. AJ took only a stool softener out of fear that laxatives would result in diarrhea, which exacerbated rectal inflammation. She became tearful, expressing awareness of her limited life expectancy and inability to participate in anything that she enjoyed due to pain and bowel anxiety. She was unwilling to take opioids due to risk of exacerbating her constipation. In addition to her post-transplant medications, AJ was taking prednisone for the past year for possible graft-versus-host-disease. Her physical exam was significant for erythema and superficial skin tears around the anus. Digital rectal exam was not performed due to pancytopenia and her immunocompromised state. Her abdominal examination was unremarkable.

The palliative APRN worked with AJ to develop a detailed plan of care that addressed both her bowel patterns and pain. A low-dose stimulant laxative was added to the stool softener with a plan to gradually titrate to achieve the goal of more efficient bowel movements in fewer attempts. In collaboration with the transplant team, her steroids were tapered to allow for better tissue healing. AJ's bowels started to normalize within a few days, and she was willing to initiate opioids for pain relief. Unfortunately, she developed opioid-induced constipation despite ongoing titration of laxatives. She was unwilling to add stronger osmotic laxatives due to past experiences with severe diarrhea but was amenable to a trial of low-dose naloxegol that specifically targeted opioid-induced constipation. With this bowel regimen, AJ's bowels and pain remained well controlled as she considered her limited options for further disease-directed therapies. She requested that her palliative APRN participate in ongoing goals-of-care discussions involving her family and primary oncology team because she felt that management of her symptoms in order to actively and comfortably participate in her life was her main priority.

INTRODUCTION

This chapter discusses three common bowel symptoms that are highly prevalent and distressful for palliative care patients: constipation, diarrhea, and obstruction. These symptoms rarely occur in isolation from other clinical manifestations of disease and can affect a person's quality of life and eligibility for treatment; they may even be life-threatening. The palliative advanced practice registered nurse (APRN) must approach care with a global understanding of the patient's individual needs, primary illness, disease-related complications, and past and current treatments. Assessment and

management are always provided with respect for the patient's culture, privacy, and goals of care.

CONSTIPATION

Constipation remains a largely subjective symptom that is often quantified by individuals based on what they perceive to be their normal bowel function.¹ Four suggested domains for clinical diagnosis are (1) life-long history of constipation using the Rome Criteria; (2) clinical changes causing or exacerbating constipation; (3) subjective symptoms, including bloating or incomplete defecation; and (4) objective changes, such as frequency and consistency of stools.² Constipation is a highly distressing symptom for patients, families, and providers and can lead to a multitude of physical signs and symptoms, including anorexia, nausea, vomiting, abdominal pain, distention, and obstruction.³⁻⁵ In addition to the physical distress, patients also feel the psychological and social effects such as irritability, loss of independence, embarrassment, and social isolation from not wanting to be far from a bathroom.⁴

The American Gastroenterology Association defines constipation as “difficult or infrequent passage of stool, at times associated with straining or a feeling of incomplete defecation.”⁶ The identification and management of constipation in palliative care have historically been complicated by the lack of a universal definition as well as by disparities between patient and provider opinions on the extent and frequency of the symptom.^{5,7}

INCIDENCE

Constipation is one of the most frequently encountered and bothersome symptoms in patients with serious chronic illness.⁸ Approximately one-third of older adults experience some degree of constipation.⁴ Specific to the palliative care population, estimated prevalence across recent studies remains highly variable and ranges from 7% to 90%.^{1,8} Constipation is one of the most common nonmotor symptoms that occur in patients with Parkinson's disease and can affect between 50% and 80% of the population.⁹ For those on opioid therapy, an estimated 72–87% of patients will report constipation at some point during treatment.⁸ Despite its high prevalence in acute and chronic illness, constipation often remains unrecognized, underreported, and undertreated by providers at every level, with the consequence of unnecessary distress, anxiety, and even hospital admissions.^{2,10,11}

PATHOPHYSIOLOGY

Potential causes of constipation may be related to structure, disease, or personal factors and are grouped into primary or secondary causes.¹² Primary (e.g., idiopathic or functional) constipation occurs without an identifiable underlying cause.¹³ Gastrointestinal motility is often intact, with reports of difficulty evacuating, hard stools, or dysfunction of the

Box 40.1 SECONDARY CAUSES OF CONSTIPATION

- Medications (e.g., opioids, anticholinergics)
- Personal factors (e.g., time, privacy, diet, activity, fluid intake)
- Endocrine/Metabolic disorders (e.g., diabetes, hypercalcemia, hypothyroidism)
- Cancer-related (e.g., tumor obstruction, spinal cord compression, electrolyte imbalances, cerebral tumors)
- Neurologic disease (e.g., cerebrovascular disease, Parkinson's disease)
- Psychologic disorders (e.g., anxiety, depression, somatization)

pelvic floor muscles or anal sphincter.^{5,12-14} Opioid induced constipation (OIC) is mostly associated with delayed colonic transit due to the binding of opioid agonists to mu-opioid receptors located in the enteric nervous system.^{10,15}

Secondary causes of constipation (Box 40.1) are the result of medications, personal factors, or disorders that may be structural, metabolic, or neurologic in nature. In advanced illness, constipation is often multifactorial from decreased activity, anorexia, polypharmacy, older age, side effects of disease and treatment, and psychological effects of disease.^{12,16-20} Current recommendations support treating the multiple contributing factors rather than single risk factors, and the palliative APRN should be aware of the common etiologies.

ASSESSMENT

A subjective assessment requires a thorough history of current and past bowel patterns. The palliative APRN should document stool volume, frequency, and appearance, along with the presence of accompanying symptoms, such as flatus, nausea, vomiting, and anorexia.^{1,3}

The palliative APRN may want to consider the elements of the *Constipation Assessment Scale* (CAS), a quick, reliable, and validated tool commonly used in palliative care.⁸ It assesses for eight symptoms that measure the severity of constipation: (1) abdominal distention or bloating, (2) change in amount of gas passed rectally, (3) less frequent bowel movements, (4) oozing liquid stool, (5) rectal fullness or pressure, (6) rectal pain with bowel movements, (7) smaller stool size, and (8) urge, but inability to pass stool.^{21,22} Medication reconciliation can help the APRN to identify common medications (Table 40.1) that may contribute to constipation.^{22,23}

It is important to note that several studies emphasize the disconnect between provider assessment and the patient and family experience with constipation.^{4,7,11} One exploratory, qualitative study on the experience of constipation assessment and management by palliative care specialists revealed a heavy focus on physical assessment with very little attention paid to the psychological and social impacts of impaired bowel patterns.⁴ Patients and families expressed frustration that the

Table 40.1 DRUGS/DRUG CLASSES ASSOCIATED WITH CONSTIPATION

DRUGS/DRUG CLASS	EXAMPLES
Antacids	Calcium carbonate
Anticonvulsants	
Antidepressants	Amitriptyline, doxepin
Antihistamines	Diphenhydramine
Antiparkinsonian agents	Benzotropine, bromocriptine
Barium sulfate	
Calcium channel antagonists	Verapamil
Cholestyramine	
Clonidine	
Diuretics	Furosemide, hydrochlorothiazide
Nonsteroidal anti-inflammatory agents	Ibuprofen, naproxen
Opioids	Morphine, hydromorphone
Serotonin receptor antagonists	Ondansetron, granisetron
Phenothiazines	Promethazine
Polystyrene sodium sulfonate	
Vinca alkaloids	Vincristine

From Mooney et al.²²; Richter.²³

primary approach was often focused on reactive medication management, rather than lifestyle factors, nonpharmacologic options, and preventive measures. Subjective assessments must include the anxiety, fear, embarrassment, caregiver distress, and social isolation often associated with constipation. Patients and families should be asked about the lifestyle and dietary changes they have implemented and their personal preferences and goals for symptom management to ensure a unified team approach to care. In fact, a growing body of literature is supporting the use of patient reported outcomes (PROs) to incorporate the patient's and family's voice into the regular assessment of palliative care symptoms.^{4,24}

When conducting a physical exam, the palliative APRN should always be mindful of privacy and cultural sensitivity. Such an assessment may need to be done with another person present for a sense of safety and comfort. Assessment includes looking for oral lesions and thrush, which can affect diet and nutrition. The abdomen should be assessed for bowel sounds, distention, tenderness, and organomegaly. Fecal masses may be palpable on rectal exam. Box 40.2 lists the differential diagnoses to consider when patients present with constipation. Unless the patient is immunocompromised, rectal exams help rule out fecal impaction, impaired sphincter tone, anal fissures, tumor, and/or hemorrhoids.^{14,22,25}

Box 40.2 DIFFERENTIAL DIAGNOSIS OF CONSTIPATION

Psychologic disorders (e.g., anxiety, depression)
Irritable bowel syndrome
Colonic obstruction (e.g., malignant, nonmalignant)
Surgical adhesions
Electrolyte Imbalance
Ileus
Spinal cord compression

From Sharma, Rao¹⁴; Mooney et al.²²; Prichard, Bharucha.²⁵

Further workup of constipation should be dictated by life expectancy and may include complete blood count, comprehensive metabolic panel, thyroid levels, and abdominal radiograph.^{22,23} For palliative care patients, extensive imaging and bloodwork may be costly and provide little benefit.²⁶ Results may lead to unintentional findings that can complicate the clinical picture and delay care transitions. Thus, any workup should match the patient's goals of care.

MANAGEMENT

PHARMACOLOGIC MANAGEMENT

Optimal pharmacologic management of constipation involves a combination of effective and appropriate prophylactic and treatment doses. Table 40.2 offers prophylactic options to consider.^{27,28} Because there is a lack of rigorous data to strongly support the use of one laxative over another, the choice of agents should be influenced by factors such as cost, patient preference, availability, and side effects.²⁸

Developing an individualized bowel regimen requires careful thought and monitoring by the palliative APRN as

Table 40.2 OPTIONS FOR PROPHYLACTIC MANAGEMENT OF CONSTIPATION

Start with a basic regimen based on the patient status and preference and titrate to effect.	
Patients on opioid therapy should be on constipation prophylaxis unless contraindicated.	
Option 1	Senna 17.2 mg at bedtime or 17.2 mg oral (PO) twice daily if taking opioids. Consider stool softener (Docusate 100 mg PO twice daily) if indicated
Option 2	Polyethylene glycol 17g PO once daily
Option 3	Lactulose 30 mL PO once or twice daily
Option 4	Bisacodyl 1 tablet PO once daily

From National Comprehensive Cancer Network²⁷; Candy et al.²⁸

even the most benign-appearing laxatives carry risks if not prescribed properly. For example, caution should be taken with over-the-counter laxatives, suppositories, and enemas as they may be contraindicated or duplicates of an already prescribed regimen.²² Before initiating stimulant laxatives, palliative APRNs should assess for partial or complete bowel obstruction because prescribing medications to increase intestinal motility could be life-threatening.^{29–31}

Palliative APRNs should also be mindful of minimizing pill burden for patients and especially those with advanced illness. One prospective randomized controlled trial demonstrated that docusate plus sennosides was no more efficacious than sennosides alone in managing constipation in hospice patients.³² Table 40.3 contains the various classes of laxatives and bowel preparations, initial and maximum daily doses, and special considerations for the palliative APRN.^{21,22,33–38}

Table 40.3 MEDICATIONS FOR CONSTIPATION

GENERIC NAME (<i>BRAND NAME</i>)	INITIAL DOSE	COMMENTS
Bulk-Forming Agents: Absorb liquid in the gastrointestinal tract and increase the bulk consistency of stool. <i>Not recommended if unable to tolerate large volume of liquids.</i>		
Psyllium (<i>Metamucil</i>)	2.5 g PO 1–3 times daily	Drink with 8 ounces of liquid Separate dose by at least 2 h from other medications Onset of action: 12–72 h
Methylcellulose (<i>Citrucel</i>)	2 g 1–3 times daily as needed MDD: 6 g	Caution in dehydrated patients Onset of action: 24–48 h
Stimulant Laxatives: Stimulate myenteric plexus and initiate peristaltic activity and inhibit water absorption		
Senna (<i>Senokot</i>)	17.2 mg PO at bedtime MDD: 68.8 mg	Previously used in combination with docusate May cause cramping Onset of action: 6–12 h
Bisacodyl (<i>Dulcolax</i>)	5 mg PO <i>or</i> 1 suppository <i>or</i> enema (10 mg) PR once daily MDD: 15 mg PO	May cause cramping Onset of action: 6–8 h (oral); 0.25–1 h after rectal administration
Castor Oil (<i>Emulsoil</i>)	15–60 mL PO once daily as needed MDD: 60 mL	May cause cramping Onset of action: 2–6 h
Surfactant/Detergent Laxatives: Lower surface tension of stool to allow mixing of aqueous and fatty substances; alter intestinal mucosal permeability		
Docusate salts (<i>Colace</i>)	50–300 mg PO in single or divided doses MDD: 240 mg PO for docusate calcium; 360 mg PO for docusate sodium	Onset of action: 24–72 h Recent study suggests no significant benefit of docusate with sennosides versus sennosides alone; should consider use on an individual basis.
Osmotic Laxatives: Cause fluid retention, distending the colon to increase peristalsis		
Lactulose (<i>Kristalose Chronulac, Constulose, Enulose</i>)	15–30 mL once daily MDD: variable	Mix with beverage to improve flavor Costly May cause flatulence and cramping Onset of action: 24–48 h
Sorbitol (<i>Arlex</i>)	30–45 mL (27–40 g) PO once daily MDD: 45 mL PO; 120 mL PR	Less expensive than lactulose May cause abdominal pain, cramping and diarrhea Onset of action: 0.25–1 h
Magnesium citrate (<i>Citroma</i>)	150–300 mL PO as a single or divided dose MDD: 300 mL PO as a laxative	Chill to improve taste May cause cramping Onset of action: 3–6 h
Magnesium hydroxide (<i>Milk of Magnesia</i>)	15–60 mL PO daily, preferably at bedtime MDD: 60 mL	May dilute with water prior to administration Onset of action: 0.5–8 h
Magnesium sulfate (<i>Epsom Salt</i>)	10–30 g PO as single or divided doses MDD: N/A	Dissolve in a full glass of water prior to intake May use lemon juice for taste Onset of action: 3–6 h
Polyethylene glycol (<i>Miralax</i>)	17 g daily MDD: 34 g PO daily	Mix with 8 ounces of water, juice, coffee, or tea Onset of action: 24–96 h

Table 40.3 CONTINUED

GENERIC NAME (<i>BRAND NAME</i>)	INITIAL DOSE	COMMENTS
Lubricant Laxatives: Penetrate and soften stool and interferes with reabsorption of water in the colon		
Mineral oil (<i>Fleet Mineral Oil</i>)	45 mL PR as single dose MDD: 45 mL	Avoid oral formulation due to risk of lipid pneumonitis if aspirated Adverse effects: mild abdominal pain, fecal urgency, cramps Onset of action: within 0.25 h
Other Agents		
Linaclotide (<i>Linzess</i>)	145 µg PO once daily MDD: 290 µg	Take on empty stomach at least 0.5 h before the first meal of the day May cause diarrhea
Lubiprostone (<i>Amitiza</i>)	24 µg PO twice daily MDD: 48 µg	May experience nausea, diarrhea, headache, abdominal pain, distension, flatulence Take with food and water
Methylnaltrexone (<i>Relistor</i>)	Administered SC based on weight: ≤38 kg: 0.15 mg/kg/day; 38 to <62 kg: 8 mg/day; 62–114 kg: 12 mg/day	For opioid-induced constipation; high cost of administration Onset of action: 0.5–1 h
Naloxegol (<i>Movantik</i>)	25 mg PO once daily	For opioid-induced constipation Time to peak <2 h Reduce dose to 12.5 mg if unable to tolerate recommended dose

MDD, Maximum daily dose.

From Sharma, Rao²¹; Mooney et al.²²; Sykes³³; Wald³⁴; Viscusi et al.³⁵; Jamal et al.³⁶; Fukudo et al.³⁷; Naloxegol.³⁸

NONPHARMACOLOGIC INTERVENTIONS

A nonpharmacologic approach is a key part of the care plan and considers personal factors to promote optimal bowel function. Examples include routine upright positioning, increasing activity, and an effective combination of fiber and fluid intake when appropriate. Toileting should allow privacy and ample time. Unless completion of assessment is urgent, the palliative APRN should not interrupt the patient's toileting to complete assessment.^{4,5,12,28} Smaller studies have suggested the potential benefits of gentle abdominal massage and acupressure by trained professionals as a nonpharmacologic approach to constipation.^{39,40}

MANAGEMENT INTERVENTIONAL TECHNIQUES

Evidence supports the use of digital rectal examination (DRE) in order to exclude fecal impaction if a patient has not had a bowel movement in more than 3 days or if they report feelings of incomplete evacuation.^{8,11} Disimpaction can cause severe pain, so proper premedication should be provided. Additionally, any rectal interventions should be used with caution in immunocompromised patients.²²

PATIENT AND FAMILY EDUCATION

Participating in his or her own plan of care can be extremely helpful to ensure compliance. This approach empowers the patient to detect changes and communicate them to the care team. Education on the nonpharmacologic interventions mentioned here should be reviewed, and caregivers should also be educated about the physical, psychological, and social impact that constipation can have on the patient. Patients and caregivers should understand proper bowel prophylaxis and signs of constipation to report. They can benefit from being aware of and participating in self-care activities, increasing physical activity, and keeping food diaries.

DIARRHEA

Diarrhea has commonly been classified as an increase in stool frequency and liquidity; for the majority of the general population, it is self-limited and does not require medical attention.⁴¹ The objective definition is the passage of three or more unformed stools within a 24-hour period.³⁴ Acute diarrhea occurs within 24–48 hours of exposure to the offending agent or event and usually subsides within 1–2 weeks.²² Most cases have a short duration and are

infectious in nature. For chronic diarrhea, onset may not occur immediately and can persist for more than 30 days.³⁵ The goal of management is to determine and treat the underlying etiology while simultaneously providing supportive care.

Subjectively, patients may describe any change in stool frequency, volume, or consistency as diarrhea; this should be clarified.⁴² When bowel movements are intense and variable, patients may have discomfort, anxiety, and experience social isolation. Uncontrolled, persistent diarrhea can cause increased weakness, malnutrition, dehydration, and electrolyte imbalances that may be debilitating and even life-threatening.⁴¹ In patients continuing to receive active treatment, severity of symptoms may result in dose reduction or even discontinuation of disease-targeted therapies. The palliative APRN should be mindful of treatments that commonly cause diarrhea in order to provide prompt evaluation and intervention.

INCIDENCE

The incidence of diarrhea in the palliative care population varies by disease and treatment modalities. In HIV-positive patients, diarrhea has been reported in 28–60% of the population treated with combination antiretroviral therapy.⁴³ In older, frail adults, approximately 10–60% of patients receiving enteral feedings will suffer from diarrhea.⁴⁴ While significantly less prevalent than constipation in the palliative care population, diarrhea is a highly distressing symptom, with both physical and psychosocial effects.

Diarrhea occurs frequently throughout the cancer treatment trajectory and has been seen across all treatment approaches, including systemic therapies, radiotherapy, surgery, and even from the primary malignancy itself. Malignancies of the gastrointestinal system, such as pancreatic and colorectal cancers, have the highest frequency of tumor-associated diarrhea, and diarrhea is seen in approximately 20% of these cases.⁴¹ The incidence and severity of chemotherapy-induced diarrhea vary based on the agent and dose, with rates as high as 50–96% with certain regimens.^{41,45} Radiation-induced diarrhea has been mostly associated with treatment that involves the lower gastrointestinal tract, with incidence of diarrhea of any level reported in up to 70% of patients and more moderate to severe cases seen in 20–40% of this population.^{22,41,46,47}

PATHOPHYSIOLOGY

The pathophysiology of diarrhea is described by the specific cause or causes of increased stool water content and output. Potential causes are listed in Table 40.4 and include increased fluid secretion, decreased fluid absorption, or bowel hypermotility.^{22,48,49}

Table 40.4 PATHOPHYSIOLOGY OF DIARRHEA

TYPE	CAUSES
Increased fluid secretion- (Most difficult to control and often not preventable)	Inflammation Hormones Enterotoxins Chemotherapy, radiotherapy
Decreased fluid absorption	Medications (i.e., antibiotics) Hyperosmolar preparations/enteral feedings Laxative overuse Dietary: high sorbitol diet, lactose intolerance Fistulas
Bowel hypermotility	Gastrointestinal malignancies Adhesions, fistulas Biliary/pancreatic or bowel obstructions Chemotherapy

From Mooney et al.²²; McQuade et al.⁴⁸; and Sauk, Richter.⁴⁹

ASSESSMENT

A careful history and assessment are crucial. The palliative APRN should assess the frequency, appearance, and number of stools and the temporal correlation with medications, treatment, or meals. Secondary effects of diarrhea, such as fatigue, weakness, abdominal pain or cramping, dehydration, dizziness, weight loss, and skin breakdown, should also be identified. Constipation with a sudden onset of diarrhea is suspicious for fecal impaction or obstruction with overflow diarrhea.^{16,22} Medications should be reviewed for offending agents, such as laxatives, antibiotics, and chemotherapeutic agents.⁴²

Specific signs of dehydration that palliative APRNs should be assessing in patients with moderate to severe diarrhea include dry oral mucosa, skin appearance, and changes in mental status. The physical assessment includes looking for oral candidiasis, hyperactive or hypoactive bowel sounds, abdominal distention, and tenderness. A rectal examination is performed if there is concern for fecal impaction.¹⁶

Additional testing may include stool specimen examination for pus, blood, fat, ova, or parasites as appropriate. Cultures and sensitivity testing can rule out opportunistic infections, such as *Clostridium difficile* or other gastrointestinal infections that should be on the APRN’s differential diagnosis (Box 40.3).^{22,49,50} For high-volume output, stool specimens should be collected before suppressing output, and patients should be evaluated for electrolyte imbalance. Severe diarrhea with rapid dehydration can lead to acute renal injury and, in extreme cases, shock. If obstruction is suspected, an abdominal radiograph may be indicated.^{16,42} While symptoms of diarrhea may be quite distressing for patients, palliative APRNs must take time to thoroughly assess their patients in

Box 40.3 DIFFERENTIAL DIAGNOSIS OF DIARRHEA

Viral (e.g., noroviruses, rotaviruses)
Bacterial (e.g., *Salmonella*, *Shigella*, *Escherichia coli*, *Listeria*, *Clostridium*)
Protozoal (e.g., *Giardia lamblia*, cryptosporidium)
Medication (e.g., antibiotics, magnesium-containing agents, laxatives, chemotherapy)
Inflammation (e.g., ulcerative colitis, Crohn's disease)
Functional (e.g., irritable bowel syndrome, diverticulosis, anxiety)
Malabsorption syndromes (e.g., sprue, pancreatic insufficiency, lactase deficiency)
Treatment-related (e.g., post-gastrectomy dumping syndrome, fistulas)

From Mooney et al.²²; Sauk, Richter⁴⁹; and Jump et al.⁵⁰

order to implement safe prescribing techniques and identify clinical scenarios that may warrant further evaluation, including hospitalization.^{27,41,49}

MANAGEMENT

Management first considers treatment of the underlying cause. If this does not lead to resolution of diarrhea, symptom management to thicken stool and slow peristalsis may be necessary. Adequate hydration should be ensured, and modification of medications or dietary factors should be considered.³⁵

PHARMACOLOGIC MANAGEMENT

Identifying the cause of diarrhea guides pharmacotherapy. Treatment for specific causes of diarrhea may include pancreatic enzymes for steatorrhea or pancreatic insufficiency, cholestyramine for excess fecal bile acids or radiation-associated diarrhea, histamine antagonists for carcinoid syndrome, antibiotics, and mesalazine for ulcerative colitis.¹⁸ Various non-specific medications (Table 40.5) can be used for the general treatment of diarrhea and unless contraindicated, may help control the extent of symptoms.^{21,51,52}

NONPHARMACOLOGIC INTERVENTIONS

Nonpharmacologic interventions begin with dietary modifications, including a focus on oral rehydration, as tolerated. Bowel rest or consuming clear liquids and simple carbohydrates can often give the gastrointestinal tract a much-needed rest. Proactive management should be provided for patients undergoing treatments highly associated with diarrhea.

Keeping a food log to help determine any food sensitivities is encouraged. Common products that are irritating to normal bowel function are dairy products, caffeine, and high-fiber, spicy, and high-fat foods.^{16,22}

MANAGEMENT INTERVENTIONAL TECHNIQUES

For patients with limited mobility, fecal incontinence and persistent diarrhea in the acute care setting may warrant consideration of rectal catheter placement to divert stool away from both impaired and healthy skin. Patients on anticoagulation and antiplatelet therapy have an increased risk of gastrointestinal hemorrhage with rectal tubes and should be monitored closely.²² The palliative APRN should advocate for appropriate treatments that are in line with the patient's goals of care and improve quality of life as defined by the patient.

PATIENT AND FAMILY EDUCATION

Persistent diarrhea can be quite debilitating and distressing for patients and their families. Implementing changes in the home environment may help the patient feel more secure and comfortable. The goal is to minimize or prevent accidents by attempting to plan and time activities based on predictable bowel patterns. Access to the bathroom should be unobstructed, and the availability of a commode may be helpful to reduce the risk of injury. Beds can be protected with padding, which may be more dignified for the patient compared to wearing diapers. Meticulous skin and perineal care are essential and should be emphasized to patients and caregivers. Application of skin ointment may help with irritation, and odor management with aromatherapy may be soothing for the patient.

BOWEL OBSTRUCTION

INCIDENCE AND DEFINITION

A malignant bowel obstruction (MBO) is defined as an obstruction beyond the ligament of Treitz that is related to an intra-abdominal primary cancer with incurable disease or from a non-intra-abdominal primary cancer with clear intraperitoneal disease.^{53,54} MBO occurs in approximately 5–51% of women with ovarian cancer and 10–28% of patients with advanced gastrointestinal cancers.⁵⁵ Depending on the type of malignancy, median survival after onset varies between 30 and 90 days; awareness of median survival can aid in prognosticating and decision-making.^{47–49}

PATHOPHYSIOLOGY

MBO can occur at single or multiple levels and can be classified as mechanical or functional, partial or complete.⁴⁸

Table 40.5 PHARMACOLOGICAL MANAGEMENT OF DIARRHEA

GENERIC NAME (<i>BRAND NAME</i>)	INITIAL DOSE	COMMENTS
Bulk-forming agents: Absorb liquid in the gastrointestinal tract and increase the bulk consistency of stool		
Methylcellulose (<i>Citrucel</i>)	2 g 1–3 times daily as needed MDD: 6 g	Take with water to reduce risk of choking Caution in dehydrated patients Onset of action: 24–48 h
Cholestyramine (<i>Questran</i>)	2–4 g 2–4 times daily MDD: 24 g	Bile acid-binding resin For chologenic diarrhea
Opioid agents: If cause of diarrhea is unknown and low suspicion for infection		
Codeine	10–60 mg PO 2–4 times daily MDD: Variable	Avoid use in diarrhea caused by poison or bacteria
Diphenoxylate/ Atropine (<i>Lomotil</i>)	5 mg/0.05 mg (2 tablets) PO, then 1 tablet (2.5mg/0.025 mg) after each loose stool MDD: 20 mg	Avoid use in diarrhea caused by poison or bacteria Onset of action: 0.75–1 h
Loperamide (<i>Imodium</i>)	4 mg PO initially, followed by 2 mg after each unformed stool. MDD: 16 mg	Avoid use in diarrhea caused by poison or bacteria
Opium tincture	50 mg/5 mL solution Take 0.6 mL PO 4 times a day MDD: 6 mL	25 times stronger than paregoric or camphorated tincture of opium Range: 0.3–1 mL per dose Monitor stools Do not abruptly discontinue after prolonged use
Camphorated tincture of opium (<i>Paregoric</i>)	2 mg/5 mL solution. Take 5–10 mL PO 1–4 times daily MDD: N/A	Monitor stools Do not abruptly discontinue after prolonged use
Adsorbents: Naturally occurring minerals that have adsorptive capacities		
Kaolin-pectin mixture	15–30 mL PO after each loose BM MDD: 120 mL per 12 h	May decrease the absorption of drugs that chelate with aluminum Onset of action: 24–48 h
Polycarbophil (<i>Fiber-lax</i>)	1,000 mg PO 1–4 times daily MDD: 6,000 mg PO	Some products may contain calcium Onset of action: 12–72 h
Salicylates: May have antisecretory, antimicrobial, and anti-inflammatory effects		
Bismuth subsalicylate (<i>Pepto-Bismol</i>)	524 mg PO every 30–60 minutes, as needed. MDD: 4.2 g	For nonspecific acute diarrhea Avoid if salicylate hypersensitivity FDA approved for proctitis and ulcerative colitis May discolor stool
Somatostatin Analogues: Inhibit diarrhea caused by hormone-secreting tumors of the pancreas and GI tract		
Octreotide (<i>Sandostatin</i>)	300–600 µg/day SC in 2–4 divided doses	May cause diarrhea, abdominal pain, nausea, and drowsiness High cost of administration
Other agents		
Ranitidine (<i>Zantac</i>)	150 mg twice daily MDD: 300 mg	May be given with pancrelipase Reduces gastric acidity
Pancrelipase (<i>Creon</i>)	Dose varies by brand	Individualize dose; may be given with ranitidine or other H ₂ blocker
Vancomycin	125 mg daily for 10 days	Diarrhea due to <i>Clostridium difficile</i>
Metronidazole (<i>Flagyl</i>)	400 mg 3 times daily for 10–14 days	Diarrhea due to <i>Clostridium difficile</i>
Cyproheptadine (<i>Periactin</i>)	4 mg 3 times daily	Carcinoid syndrome diarrhea

MDD, Maximum daily dose.

From Sharma, Rao²¹; Bharucha et al.⁵¹; and Lamberts, Hofland.⁵²

It can affect bowel function significantly and is considered an oncologic emergency due to the risk of perforation, sepsis, or necrosis.

Intra-abdominal tumors may be intraluminal or intramural. They can impair bowel function by occluding the lumen, causing intussusception or impairing peristalsis. Malignant adhesions can create multiple points of obstruction as they kink the bowel from an extramural site.^{46,48} Duodenal obstruction is most related to cholangiocarcinoma and pancreatic malignancies, while distal obstruction is largely associated with primary colon and ovarian carcinomas.⁴⁸ In rare cases, obstruction is treatment-related from nonmalignant adhesions following surgery or radiation.

ASSESSMENT

A combination of subjective and objective findings often aids in diagnosing the presence and level of obstruction. The palliative APRN should understand the different characteristics of the location of the bowel obstruction. Duodenal obstruction presents with severe vomiting and emesis often containing undigested food. Pain or distention will often not be noted on examination. Obstructions of the small and large intestine both present with hyperactive bowel sounds with borborygmi. Nausea and vomiting will be more severe with obstruction higher along the gastrointestinal tract, whereas obstructions of the large intestine will produce delayed emesis with abdominal distention and colicky pain.^{22,53,55} As part of the initial subjective assessment, palliative APRNs should assess the primary goals of patients with MBO receiving palliative care, and their family, which often includes time at home, avoidance of surgery, and minimizing symptom sequelae.⁵⁵

Radiologic imaging should be employed only if suspected findings can be treated. There tends to be an overreliance on abdominal x-rays, which are more cost-effective but less accurate than contrast radiographs. Computed tomography (CT) scan is the gold standard for diagnosis, with an accuracy of 94% in identifying the etiology of obstruction, and can help the clinician rule out other diagnoses such as ileus, pseudo-obstruction, Ogilvie syndrome, or intrabdominal sepsis.^{22,56}

MANAGEMENT

Symptoms associated with MBO have historically been difficult to manage, as nausea, vomiting, colic, and abdominal pains can be quite persistent and bothersome. A number of medical and surgical interventions exist, but the best treatment remains undetermined and should always be based on the patient's goals of care, symptom burden, and prognosis.^{22,54,57-59}

PHARMACOLOGIC MANAGEMENT

The goal of pharmacologic management in obstruction is to provide symptomatic relief while minimizing the adverse effects of medications. Individualized treatment approaches may include analgesics, antisecretory drugs, glucocorticoids,

and antiemetics. These pharmacologic management options are listed in Table 40.6 and may be the sole treatment or used for symptom relief while anticipating surgical interventions.^{54,60,61} For persistent pain, opioid analgesics are recommended but may exacerbate colicky pain. Anticholinergic agents may offer additional pain relief in these scenarios.⁵⁴ Given the challenges with oral medications, parenteral, sublingual, and transdermal routes should be considered. The palliative APRN should also keep in mind that while combination regimens can improve quality of life, they often require inpatient admissions due to cost and lack of availability in the community. Treatment approach remains guided by the patient's larger goals of care and unique needs.

NONPHARMACOLOGIC INTERVENTIONS

During the workup and evaluation of potential treatment options, patients should avoid oral intake of food and fluids that may worsen symptoms and increase the risk of perforation with complete obstruction. The palliative APRN may prefer a period of bowel rest to avoid unnecessary surgical interventions. Thirst and the desire for oral intake may be highly distressing, and support as well as meticulous mouth care should be provided.⁵⁹

MANAGEMENT INTERVENTIONAL TECHNIQUES

Multiple factors are associated with the selection of intervention, and several options exist. Initial management often consists of fluid resuscitation, electrolyte repletion, and placement of a nasogastric tube for decompression. Care should be taken when rehydrating patients as excess fluid may worsen bowel edema.⁵⁴ Surgical intervention in advanced cancer is controversial and is determined by performance status, extent of disease, level of obstruction(s), presence of ascites, and goals of care.^{53,56,59,62} Patients with progressive cancer despite tumor-directed therapy pose the greatest risk for surgeons and often the risk of surgery outweighs any potential benefit, which may be difficult for patients and families to understand and accept.^{54,59,63}

Endoscopic procedures, such as gastric or colonic stenting, present a less invasive option and have been associated with quicker recovery in patients with a single focus of obstruction or locally advanced disease.⁶⁴⁻⁶⁶ Stenting is contraindicated in patients with already established perforation or for rectal tumors as symptoms of tenesmus and incontinence may worsen. Risks include stent migration and perforation.⁶⁶⁻⁶⁸

Management in patients with a poor prognosis, overt ascites, and carcinomatosis with multiple levels of obstruction is primarily supportive; placement of a venting gastrostomy tube can help to relieve symptoms. This may or may not allow the patient to tolerate some oral intake for pleasure and decreases pressure in the abdomen.^{66,69,70} Nasogastric tubes are often used as a temporary bridge to surgery and can be quite

Table 40.6 PHARMACOLOGICAL MANAGEMENT OF OBSTRUCTION

GENERIC NAME (<i>BRAND NAME</i>)	INITIAL DOSE	COMMENTS
Chlorpromazine (<i>Thorazine</i>)	10–25 mg q4–6h as needed MDD: 1,000 mg	To control nausea and vomiting Sedating Monitor for extrapyramidal symptoms (EPS) Onset of action: 0.5–1 h
Haloperidol (<i>Haldol</i>)	0.5–1 mg q12h <i>or</i> q4–6h as needed MDD: 100 mg PO	To control nausea and vomiting Monitor for EPS Onset of action: 0.5–1 h
Metoclopramide (<i>Reglan</i>)	10 mg q6–8h MDD: 60 mg PO; single dose not to exceed 20 mg	Prokinetic; avoid in definitive or complete obstruction May cause sedation, fatigue, and restlessness Onset of action: 0.5–1 h
Prochlorperazine (<i>Compazine</i>)	10 mg PO q4–6h as needed <i>or</i> 25 mg PR q6–12h as needed MDD: 50 mg/day PR; 40 mg/day PO <i>or</i> IM	EPS especially at high doses Onset of action: 0.5–1 h
Hyoscyamine (<i>Levsin</i>)	0.25–0.5 mg IV <i>or</i> SQ q6h as needed <i>or</i> 0.125–0.25 mg PO <i>or</i> SL q4h as needed MDD: 1.5 mg	May cause blurred vision, confusion, constipation, dizziness, drowsiness, ileus, mydriasis, nausea/ vomiting, nervousness, palpitations, sinus tachycardia, urinary retention/hesitancy, weakness Onset of action: IV: 2–3 minutes; PO: 20–30 minutes
Octreotide (<i>Sandostatin</i>)	50–100 µg IV/ SQ q8h MDD: Variable	High cost of administration May cause diarrhea, abdominal pain, flatulence, nausea, constipation Onset of action: 0.5 h
Scopolamine Transdermal Patch Scopolamine Hydrobromide (<i>Transderm Scop</i>)	1.5 mg transdermal q72h; 0.3–0.6 mg IV <i>or</i> SQ q4h as needed MDD: 2.4 mg IV 1 transdermal patch q72h	May cause drowsiness, or somnolence Onset of action: Transdermal, 4 h; IV, 15–20 minutes
Dexamethasone (<i>Decadron</i>)	4 mg 1–2 times daily MDD: Variable	Long-term use not recommended

MDD, Maximum daily dose.

uncomfortable. These tubes provide short-term symptomatic relief in patients who do not qualify for a gastrostomy tube due to severe ascites or tumor infiltration of the stomach.^{54,58,63}

PATIENT AND FAMILY EDUCATION

Patients and caregivers should be taught about the signs and symptoms of obstruction early in the disease course, especially in gastrointestinal and gynecologic malignancies, where obstruction is highly prevalent.⁵⁸ Patients may feel that lack of bowel movements is expected in the setting of decreased food and fluid intake and may go weeks without reporting early or late signs of obstruction. MBO is often indicative of the late stages of disease, and access to psychoeducation and support for both patients and caregivers cannot be emphasized enough.

SUMMARY

Bowel symptoms do not occur in isolation and are often accompanied by decreased appetite, fatigue, and general

malaise. Patients may experience loss of dignity that can lead to social isolation if not addressed. Adequate support and education can empower patients to play an active role in their disease process and can help build trust between the patient, the family, and the palliative APRN. The palliative APRN must understand conditions, medications, and situations that induce bowel symptoms in order to provide appropriate care throughout the disease trajectory. Crafting an individualized plan of care tailored to specific patient needs is an essential piece of quality care and promotes quality of life.

FATIGUE

Shila Pandey

KEY POINTS

- Fatigue affects 48–78% of patients receiving palliative care and is most prevalent in advanced cancer.¹
- Palliative advanced practice registered nurses (APRNs) have the specialized training to synthesize data so they can provide care that is centered on patients' goals in the areas of health, quality of life, and function.^{2,3}
- Palliative APRNs are positioned to integrate palliative care into their work environment as they collaborate with interdisciplinary colleagues to address the many needs of patients and family members.

CASE STUDY

Carmen was a 78-year-old African American woman with newly diagnosed acute myeloid leukemia (AML) who presented to the cancer center for treatment options. Her past medical history included Pager's disease in the left breast (status post lumpectomy and radiation 9 years prior), obstructive sleep apnea, gastroesophageal reflux disease, peptic ulcer, refractory lymphedema, hyperlipidemia, depression, and claustrophobia. She had an episode of chest and back pain approximately 2 months ago with a negative cardiac workup. Computed tomography (CT) and magnetic resonance imaging (MRI) showed multiple lytic lesions involving the ribs, T11 vertebral body with a pathologic fracture, and a thyroid nodule measuring 1.7 cm. Abdominal ultrasound showed mild hepatomegaly with a dominant 5.7 × 5.6 cm cyst at the junction of the left and right hepatic lobes. Carmen was admitted for leukocytosis and expedited treatment. Initial presentation showed labs with a blast population of 12% with a white blood count of 21.7. Her hospital course was significant for a bone marrow aspirate and biopsy that confirmed AML, and she was initiated on azacitidine and venetoclax. She received transfusions for anemia and thrombocytopenia.

Review of systems was negative except for diarrhea from the leukemia treatments and fatigue. Physical exam confirmed hyperactive bowel sounds and dry mucous membranes. Several lab values were abnormal, including a hemoglobin of 7.0 g/dL. Carmen had received multiple transfusions, and the plan was to continue with treatment for leukemia. It was deemed that Carmen was not a candidate for future hematopoietic cell transplantation. After a chest wall nerve block, her pain was well controlled, but she rated her fatigue at 10/10. Eastern Cooperative Oncology Group (ECOG) performance status was 2. Additional

medications included hydroxyurea, antidepressant, β -blocker, antiviral, pregabalin, and several vitamins.

Carmen was retired from a government research coordinator position, which remained a source of pride. Carmen was married for more than 50 years before becoming a widow 5 years prior. She had three adult children, aged 50, 48, and 45, each with whom Carmen had distinctive relationships. The family dynamics had changed after the death of her husband. Her eldest daughter, Gina, an internal medicine physician, was most involved her in care. Carmen's children and friends stopped by throughout the week to visit or bring a meal. Her hobbies included reading, drawing, and painting.

Carmen stated that she had very poor quality of life. She reported crying frequently, having little energy to do much of anything around the house or go out with friends, and a diminished appetite. In addition, she admitted to feeling complacent, more anxious, and rather negative. Carmen noted she "just couldn't seem to get moving" and she had "never been this tired in my life." She loved visits and spending time with her children and friends. However, she was relieved when they left so she could lie down and take a nap.

Carmen was referred to palliative care. Prior to the meeting, Carmen's case was reviewed with the palliative care team. At the appointment, the palliative advanced practice registered nurse (APRN) reviewed the purpose of the meeting with Carmen and her daughter Gina. During the consultation, Carmen explained her understanding about the AML. Gina also shared her views of what her mother had been going through. Carmen and her daughter expressed understanding about the ultimate outcome of her disease and that treatment would not provide a cure. She knew she needed to complete an advance directive, but stated, "I can't bring myself to think about it yet." She said, "I'm just so very tired." Gina stated that she was at a loss as to how to help her.

The palliative APRN explained to Carmen and Gina that fatigue is a common symptom of both treatment and cancer. A consult with physical therapy (PT) and occupational therapy (OT) was recommended so that Carmen could learn how to maximize her activity through exercises and other techniques. Meetings with social work and chaplaincy were suggested to work on reframing her disease and creating her legacy. Carmen also agreed to meet with the nutritionist about her decreased appetite and with integrative medicine for massage and other integrative therapies. Carmen was started on methylphenidate 5 mg PO twice daily at 8 AM and 1 PM after she expressed inability to engage in exercise due to fatigue. Her oncologist agreed to a 2-week trial of the drug, which did help her increase physical

activity and improved fatigue scores and so it was continued upon discharge.

Over the next 3 months, Carmen saw some improvement in her fatigue levels. Her energy never returned to baseline; she was unable to complete any books or artwork. However, she was able to carry on with most of her activities of daily living. Carmen stated that the appointments with physical and occupational therapy were most helpful, teaching her strategies to walk and conserve energy. The social worker discussed with her ways to reframe her outlook on life in coping with fatigue as well as the disease overall. She was also able to teach her three children ways to support Carmen both emotionally and around the house, in addition to taking care of themselves. Gina found social work and chaplaincy especially helpful in dealing with the role changes.

As expected, Carmen became more ill and was no longer able to continue disease-targeted therapies or the oral methylphenidate. When Carmen was ready, the APRN set up a home hospice visit. Carmen died a peaceful death 3 weeks later on hospice. Gina and her siblings expressed deep gratitude for all that was done for their mother. They were thankful that she did not suffer at the end of her life.

INTRODUCTION

Fatigue is a common symptom experienced by patients with serious conditions and illnesses. For patients receiving palliative care, the prevalence of fatigue ranges from 48% to 78%.¹ The number of people living with three or more chronic diseases is expected to rise from 30.8 million in 2015 to 83.4 million in 2030.⁴ In addition, the population continues to age, with the number of people aged 65 or older reaching 23.5% by 2060.⁵ In older adults with chronic illnesses the prevalence of fatigue ranges from 40% to 74%.⁶ People living with multiple comorbidities tend to have a higher symptom burden, unaddressed symptoms, poor quality of life (QoL), and unmet palliative care needs.⁷ These burdens on the population, including economic, are expected to rise by 2030.⁸ It is essential that palliative advanced practice registered nurses (APRNs) understand how to manage fatigue in individuals throughout the life span and across illnesses.

See and colleagues⁹ conducted a cross-sectional study to investigate symptom burden of patients admitted to a palliative care unit. They found patients with both malignant and nonmalignant illnesses were more likely to have fatigue, pain, and psychological or spiritual symptoms. As people transition to the end of life, symptom burden usually worsens.¹⁰ Fatigue is one of the most reported, severe symptom experienced by patients with cancer due to the disease and its treatment.¹¹ Its prevalence in patients with advanced-stage cancer ranges from 62% during treatment to 51% during treatment.¹² Adolescents and young adults with cancer have a higher prevalence of severe fatigue when compared with population-based controls.¹³ Fatigue is also prevalent in cancer survivors and may be associated with disability.¹⁴ In fact, many breast cancer survivors experience fatigue that may last from months to years.¹⁵

For patients with heart failure (HF) and cardiovascular disease, shortness of breath and fatigue are the two most commonly reported symptoms, with fatigue as one of the first symptoms of HF.^{16,17} In 2019, fatigue was reported as one of the most common symptoms for patients with chronic obstructive pulmonary disease (COPD), with its prevalence at 77% and its severity significantly affecting QoL, causing functional impairment and frequently associated with pain and dyspnea.¹⁸ For patients with chronic kidney disease (CKD), fatigue is the most common symptom irrespective of hemodialysis status.¹⁹ Patients with neurological and autoimmune disorders, such as multiple sclerosis (MS), systemic lupus erythematosus (SLE), diabetes, Sjögren's syndrome, amyotrophic lateral sclerosis, and Parkinson's disease also experience fatigue as one of the most prevalent and debilitating symptoms.^{20,21,22,23} After a stroke, fatigue is a common consequence, with the prevalence of post-stroke fatigue reported as high as 85%.²⁴

Other chronic conditions such as chronic liver disease, inflammatory bowel disease, chronic graft versus host disease (GvHD), and endometriosis also have a high burden of fatigue.^{25,26,27,28} People living with human immunodeficiency virus (HIV) are at elevated risk of fatigue given the hematologic and metabolic changes that result from HIV infection, affecting nearly 90% of this population.^{29,30} Fatigue is a symptom that may overlap with many psychiatric illnesses. In major depressive disorder, fatigue is more common in women than men and reported in 95% of patients.³¹

DEFINITIONS OF FATIGUE

Fatigue is a symptom of overwhelming tiredness or malaise associated with many diseases and disorders; in some cases no specific causes can be found.³² Definitions of fatigue are varied given the complexity of this symptom.³³ Clinical fatigue has been defined by three major features: (1) generalized weakness, resulting in limitations in some activities; (2) easy fatigability and reduced capacity to maintain performance; and (3) mental fatigue resulting in impaired concentration, loss of memory, and emotional lability.³⁴ The National Comprehensive Cancer Network (NCCN) defines cancer-related fatigue (CRF) as "a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning."³⁵ Fatigue in advanced illnesses other than cancer is often called *nonmalignant fatigue*.³⁶ Chronic fatigue syndrome (CFS) or myalgic encephalomyelitis (ME) is characterized by profound fatigue, reduction in ability to perform usual activities, unrefreshing sleep, postexertional malaise, and cognitive dysfunction for more than 6 months.³⁷ CFS is usually a diagnosis of exclusion and an extreme version of fatigue in the palliative care population and may not be associated with an underlying serious illness. For these reasons and others, CFS is beyond the scope of this chapter. While there is no one agreed-upon definition of fatigue, a common theme is that fatigue affects the patient's

physical function, cognition, emotions, and daily activities and is beyond the norm.

PATHOPHYSIOLOGY OF FATIGUE

There are several descriptions in the literature on the pathophysiology of fatigue, with most of the research coming from CRF. The pathophysiology of fatigue is multifactorial and involves a complex interaction of cognitive, emotional, psychosocial, and somatic factors, resulting in highly variable clinical expressions.³⁸ Matura and colleagues³⁹ conducted a systematic review of 26 studies to describe the biological mechanisms of fatigue in cancer and chronic illnesses. They synthesized the current state of the literature describing inflammation and alterations in the hypothalamic–pituitary–adrenal (HPA) axis and the autonomic nervous system as possible mechanisms of fatigue in patients with cancer, HF, MS, COPD, CKD, and rheumatoid arthritis (RA). Additional causes of CRF include metabolic or neuroendocrine dysfunction and genetic influence.⁴⁰

Fatigue can also be described as peripheral or central.^{37,41–43} Peripheral mechanisms include hypotheses about adenosine triphosphate (ATP) and muscle contractility properties.³⁷ *Peripheral fatigue* refers to muscle fatigability caused by disorders of muscle and the neuromuscular junction, such as myasthenia gravis and McArdle's disease. Chronic conditions such as cancer damage the sarcoplasmic reticulum and dysregulation of ATP can lead to lower protein synthesis or metabolite production, which causes increased intracellular calcium levels as well as impaired mitochondrial mechanisms for regeneration of skeletal muscle. Hence, this can compromise the individual's ability to perform physical tasks.³⁷

Central fatigue is a result of either failed transmission of motor impulses or an inability to perform voluntary activities.^{37,41,43} Central mechanisms include hypotheses about cytokines, HPA axis, circadian rhythm, serotonin, and vagal afferent nerve dysfunction. These biological processes affect the body physically and cognitively, thus impairing concentration and energy.³⁷ Cytokine dysregulation causes a pro-inflammatory state characterized by elevated levels of circulating cytokines, such as c-reactive protein (CRP), interleukin-6 (IL-6), interferons (IFNs), and tumor necrosis factors (TNFs) and is a main driver of fatigue in cancer and chronic illnesses including irritable bowel syndrome (IBS) and Parkinson's disease.^{36,41} Central fatigue mechanisms for fatigue are key to presentations of fatigue in autoimmune diseases, such as SLE, MS, type 1 diabetes, celiac disease, CFS, and RA.⁴² Autonomic nervous system impairments are pathologic to fatigue in MS and Parkinson's' disease and can present as orthostatic intolerance.^{43,44} Interestingly, the severity of central fatigue does not always correlate with the severity of the underlying disease. For example, a patient with MS may experience fatigue in one limb caused by a sustained motor task. Magnetic resonance imaging (MRI) is the primary procedure used to rule out other factors, along with a neuropsychological assessment if cognitive impairment is suspected.

Box 41.1 CONTRIBUTING FACTORS TO FATIGUE^{30,37,38}

- Inflammation/cytokines
- Metabolic and neuroendocrine alterations
- Autonomic dysfunction
- Dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis
- Genetic influences
- Adenosine triphosphate (ATP) dysregulation
- Deconditioning
- Dehydration
- Chemotherapy/radiation
- Polypharmacy
- Comorbidities of major organs
- Mental health disorders
- Paraneoplastic syndromes

Conditions that cause fatigue often have both central and peripheral mechanisms at work to cause this symptom.

Muscular, cardiac, and pulmonary deconditioning increases the risk for chronic fatigue. Prolonged hospitalization, treatment-related adverse events, or critical illness can decrease exercise tolerance which further exacerbate fatigue. Highlighted in Box 41.1 are multiple other conditions that contribute to fatigue. Iron deficiency anemia and aplastic anemias are known to manifest fatigue and other symptoms due to low hemoglobin.^{45,46} Chronic infections lead to an inflammatory state which can persist after resolution of an infection.⁴⁷ Cancer-directed treatments such as chemotherapy and radiation are also offending causes of fatigue.⁴⁸ Predisposing risk factors such as history of depression or anxiety, sleep disturbance, pain severity, or lower levels of physical activity may increase risk of fatigue in those with cancer and chronic illnesses.^{49,50}

IMPACT OF FATIGUE ON QUALITY OF LIFE

Fatigue affects not only a patient's physical well-being but also psychological, social, and spiritual well-being.^{51–54,56,59,60–65} Studies exploring CRF have shown a decrease in functional status, interference with activities of daily living, and limits on quality of life, especially in the elderly. CRF can negatively affect health-related QoL at the time of diagnosis and may last for years in adults and adolescents, including those in remission.⁵¹ Higher severity of fatigue often leads to worse reports of QoL.⁵² QoL may remain poor despite stage of cancer or presence of metastasis.⁵³ Cancers where fatigue occurs in symptom clusters, such as with lung cancer, have strong negative

associations with QoL.⁵⁴ Akin and colleagues⁵⁵ conducted a descriptive-correlational study to investigate the relationship among fatigue, self-efficacy, and QoL in cancer patients who were receiving chemotherapy. They observed significant correlations between fatigue and QoL, with worse fatigue causing lower ratings of QoL. For cancer patients and survivors, long-term fatigue is associated with an increase in depression, sleep disturbance, and neuropathy.⁵⁶ Severity of fatigue and its effect on QoL and mental function can play a role in predicting when someone with cancer will return to work.⁵⁷ Non-cancer patients report fatigue as one of the worst symptoms they experience and describe it as a feeling of tiredness, having little energy, and as a main barrier to functioning.^{58,59}

Fatigue experienced by people living with chronic illnesses such as COPD is also negatively associated with QoL.^{58,60} Negative impacts of fatigue include alterations in daily life functioning leading to high mental burden, challenged coping, loss of joy in life, and, in some cases, loss of the will to live.⁶⁰ For patients with MS, fatigue and depression are closely associated with QoL.⁶¹ However, physical fatigue may have the strongest influence on overall QoL, emotional well-being, role limitations, social function, and other measures of health-related QoL in patients with MS.⁶² For older adults, fatigue related to chronic illness is associated with poor physical performance and negative outcomes such as hospitalizations, increased health care utilization, disability, and mortality.⁶³ Fatigue in neurological diseases not only decreases QoL and functioning but also can be a reason for earlier retirement.²² Fatigue can also be demoralizing because it robs patients of who they were, leading to grief over loss of roles and responsibilities.^{59,64}

Overall, fatigue can negatively impact one's sense of self, cognitive performance, physical function, family care, and social interaction.⁶⁵ Figure 41.1 summarizes areas of QoL

affected by fatigue. The burden of fatigue extends into the area of spirituality. Hirsh and Siros⁶⁶ examined the association between hope and fatigue across three chronic illnesses (arthritis, IBD, and fibromyalgia) and found that those with greater hope reported less stress and consequent fatigue. However, this may be less true for CRF.^{67,68} Cancer patients and non-cancer patients alike experience the profound effects of fatigue. Due to medical advances, people are living longer with these serious illnesses; hence, palliative APRNs should continue to assess QoL.

ASSESSMENT OF FATIGUE

Like pain, fatigue is a subjective experience, requiring dependence on self-report to assess its presence and severity. The assessment of fatigue can be complex given its varied etiology and definitions. Although objective testing may assist with the management of fatigue, patient-reported outcomes remain the gold standard for fatigue assessment.⁶⁹ Screening for fatigue in seriously ill patients should be part of a comprehensive assessment by the palliative APRN. It is recommended that patients with cancer and survivors be screened for fatigue at the initial visit, at appropriate intervals during and following treatment, and as clinically indicated.^{35,70} This approach can be taken with other serious illnesses including HF and COPD. A common and easy to use assessment is measurement of fatigue by a single-item number scale, using a 0 as “no fatigue” and 10 as “severe fatigue.” Similarly, a single-item scale such as the Visual Analogue Scale for Fatigue (VAS-F), which uses a 10 cm, 0–100 mm horizontal line is useful for quick screening.⁷¹

In addition to the patient's self-report of fatigue, palliative APRNs should use a holistic, patient-centered approach to obtain information to assist in management of this symptom. Fatigue assessment tools may be unidimensional or multidimensional. Unidimensional assessment tools measure the physical impact of fatigue, whereas multidimensional tools assess the physical, mental, and emotional dimensions of fatigue.¹ Multidimensional tools are much longer than unidimensional ones and may be more time-consuming. Shorter form versions have been created for some such as the Multidimensional Fatigue Symptom Inventory-Short Form (MFSI-SF) to address this problem.⁷² Other tools, such as the Edmonton Symptom Assessment System (ESAS)^{73,74} and the Symptom Distress Scale⁷⁵ are single- and multiple-item measures with fatigue items embedded in other scales and are often used in palliative care settings. Palliative APRNs must select the assessment tool that is most appropriate for their patient population.

Multidimensional tools are often used in palliative care since fatigue usually affects other aspects of well-being that cannot be measured in single-item or unidimensional tools. Table 41.1 provides unidimensional (Brief Fatigue Inventory [BFI],⁷⁶ Functional Assessment of Chronic Illness Therapy-Fatigue [FACIT-F],⁷⁷ Fatigue Severity Scale [FSS],⁷⁸ Profile of Mood States Fatigue subscale [POMS-F]⁷⁹) and multidimensional tools (Multidimensional Fatigue Inventory [MFI],⁸⁰

Figure 41.1 Areas of quality of life affected by fatigue.^{51,55,60,66}

Table 41.1 FATIGUE ASSESSMENT TOOLS

UNIDIMENSIONAL FATIGUE ASSESSMENT TOOLS		MULTIDIMENSIONAL FATIGUE ASSESSMENT TOOLS	
INSTRUMENT	DESCRIPTION	INSTRUMENT	DESCRIPTION
Brief Fatigue Inventory (BFI)	9 items Measures intensity or severity (present, usual, worst fatigue during past 24 hours) 0–10 scale (0 = no fatigue, 10 = fatigue as bad as one can imagine) Average of 9 items provides a global fatigue severity score (1–3 mild, 4–6 moderate, 7–10 severe)	Multidimensional Fatigue Inventory (MFI)	20 items Likert scale ranging from 1 to 7 Evaluates five dimensions of fatigue: general fatigue, physical fatigue, reduced motivation, reduced activity, and mental fatigue Validated in cancer and chronic fatigue syndrome
Functional Assessment of Chronic Illness Therapy–Fatigue (FACIT-F)	13 items Measures self-reported level of fatigue and its impact during activities of daily living over the past week Likert scale ranging from 0 to 4 0 = “not at all” and 4 = “very much” Score ranges from 0 to 52 with a score <30 indicating severe fatigue	Fatigue Symptom Inventory (FSI)	14 items Evaluates multiple aspects of fatigue Primarily validated in cancer 11-point Likert scale (0–10) 0 = “not at all fatigued” and 10 = “as fatigued as I could be” Global score obtained from all items
Fatigue Severity Scale (FSS)	9 items Designed to differentiate fatigue from clinical depression 1–7, total score divided by 9; 1 indicates “strongly disagree” and 7 indicates “strongly agree.” The minimum score = 9 and maximum score possible = 63	Fatigue Questionnaire (FQ)	11 items Assesses mental fatigue and physical fatigue Likert-type scale ranging from 0 (“less than usual”) to 3 (“much more than usual”) Higher scores indicate more fatigue
Profile of Mood States Fatigue subscale (POMS-F)	7 items Used in cancer and non-cancer population Five-point scale ranging from “not at all” to “extremely”	Fatigue Assessment Scale (FAS)	10 items Likert-type scale ranging from 1 (“never”) to 5 (“always”) Total scores can range from 10 (lowest level of fatigue) to 50 (highest level fatigue)

References: Chen et al., 2016⁷⁶; Montan et al., 2018⁷⁷; Ozyemisci-Taskiran et al., 2019⁷⁸; Minton, Stone, 2019⁷⁹; Hinz et al., 2020⁸⁰; Hann et al., 1998⁸¹; Chilcot et al., 2016⁸².

Fatigue Symptom Inventory [FSI],⁸¹ Fatigue Questionnaire [FQ],⁸² Fatigue Assessment Scale [FAS]⁸³) that have been developed. Both types of screening tools for fatigue have been studied for validity and reliability.⁸⁴ For example, the Fatigue Assessment Scale (FAS) displayed good internal consistency and test-retest reliability to assess fatigue in patients with SLE.²⁰

Once screening for fatigue is completed, a focused evaluation will be needed based on the severity of the fatigue. For moderate to severe fatigue, a more detailed history and physical exam is warranted.^{35,70} Assessment of fatigue should include a detailed health history of its onset, duration, severity, aggravating and alleviating factors, effect on function, and associated psychosocial effects. A comprehensive review of systems and physical exam should be conducted. A detailed physical exam including a cognitive, neurological, and musculoskeletal evaluation may help to rule out other confounding factors of fatigue. Comorbidities that may cause fatigue include hypo- or hyperthyroidism, HF, infections, COPD, sleep apnea, anemia, autoimmune disorders, IBS, and cancer.⁸⁵ A review of medications and potential side effects, nutritional status, and stage of illness

may help identify potentially reversible causes of fatigue.⁷⁵ Ordering laboratory tests to detect for anemias, electrolyte abnormalities, or other diagnostics should depend on the goals of care. Furthermore, assessment of functional status can help explain symptom severity and prognosis in palliative care patients.⁸⁶ Table 41.2 summarizes key components to consider when assessing fatigue.

Effective fatigue assessment and management can be hindered due to patient, professional, and system barriers. A survey of palliative care providers, mostly nurses, found a lack of confidence in assessing fatigue and completing an individualized management plan.⁸⁷ A total of 77.2% of participants did not find fatigue an easy symptom to manage, and fewer than half felt confident assessing and managing it. Although patients may report fatigue as a common symptom, they may not seek help for the symptom.⁸⁸ Patients may believe fatigue is to be expected with their illness or age and be hesitant to report the symptom or accept help. These patient and provider factors add to the challenges in treating this common but complicated symptom. Fatigue may be associated with disease progression, and the fear associated with this may be a barrier to patients reporting fatigue to their providers. In

Table 41.2 COMPREHENSIVE ASSESSMENT OF FATIGUE

PHYSICAL EXAM	LABORATORY	CONCERNING COMORBIDITIES	DIAGNOSTICS
Functional status - Karnofsky performance status (KPS) - European Cooperative Oncology Group (ECOG) criteria	Complete blood count (includes white blood cells, hemoglobin, hematocrit, platelet counts)	Malignancy Hypo or hyperthyroid HF Infection COPD, CHF, HIV, CVA	Chest X-ray Electrocardiogram Echocardiogram Computerized tomography scan (CT)
General appearance Weight, BMI, vital signs	Basic metabolic profile (includes creatinine, blood urine nitrogen, electrolytes)	Sleep apnea Anemias Autoimmune disorders	Magnetic resonance imaging (MRI)
Systems: Skin, hair, nails: Alopecia, rashes, growths, pallor Head and neck: Thyroid exam, oral cavity Cardiac: Heart sounds, edema Lungs: Respiratory rate and effort, lung sounds Gastrointestinal: Jaundice, organomegaly, tenderness Renal: Change in urine color or output Musculoskeletal: Muscle atrophy, joint appearance, range of motion Neurological: Mental status, sedation, motor and sensory function Psychological: Orientation, alertness, affect	Hepatic profile (includes alkaline phosphate, transaminases) Albumin Total protein Thyroid stimulating hormone Urinalysis Vitamin B ₁₂ , thiamine, folate, vitamin D levels Basic natriuretic peptide	Irritable bowel syndrome Poor nutritional status Chronic liver disease Parkinson's Disease Renal disease or injury Depression, anxiety	Positron emission tomography (PET)

CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CVA, cerebrovascular accident; HF, heart failure.

addition, patients get fatigued with questionnaires and assessment forms during their interactions with healthcare systems. System barriers still exist despite repeated recommendations from healthcare societies. These barriers include lack of supportive care referrals, lack of healthcare reimbursement that affects the availability of medications and prescription practices, lack of consistent assessment and documentation between clinical settings, and lack of time to obtain a consult order for supportive services.⁷⁰

MANAGEMENT OF FATIGUE

In the palliative care setting, effective fatigue management requires addressing symptoms that contribute to fatigue and preventing secondary fatigue by maintaining a balance between restorative rest and restorative activity.⁸⁹ The primary goal of managing fatigue is to treat any underlying contributory factors (e.g., pain, anemia, medication side effects, emotional distress) that are reversible with pharmacologic and/or nonpharmacologic interventions. When that is not possible, mitigating the effects of fatigue through palliation to maximize energy levels becomes the goal. Often a combination of both pharmacological and nonpharmacologic approaches is needed.⁹⁰

PHARMACOLOGIC MANAGEMENT

For patients whose fatigue is a major hindrance on function and quality of life, there are limited nonspecific pharmacologic options for the management of fatigue. The evidence for the use of psychostimulants, corticosteroids, antidepressants,

and supplements continues to evolve. Table 41.3 summarizes options for pharmacologic management of fatigue.

Psychostimulants

Psychostimulants have been used to help patients with fatigue. Psychostimulants act to increase cortical function by interacting with neurotransmitters and receptors in the brain. These drugs include methylphenidate, modafinil, or dexamphetamine. Different types of psychostimulants work differently in the brain to produce short-term increased energy levels and psychomotor activity.⁶⁵ Medications like methylphenidate affect the brain in several areas, whereas modafinil, another type of stimulant, specifically affects the excitatory histamine projections to the hypothalamus, promoting wakefulness.⁹¹ The NCCN³⁵ reports “some evidence” for using medications for fatigue, but randomized controlled trials (RCTs) have also shown a significant placebo effect. In light of these findings, the NCCN recommends the use of psychostimulants, specifically methylphenidate, for cancer patients undergoing active treatment after other causes of fatigue have been excluded.

In 2015, Mücke and colleagues⁹² performed a review of pharmacologic treatments for nonspecific fatigue in patients with advanced cancer and other advanced chronic diseases receiving palliative care. After screening more than 1,645 publications, data from 45 studies, 18 drugs, and 4,696 patients were analyzed. Studies used in the meta-analysis were those that investigated medications (amantadine, pemoline, and modafinil) for patients with MS-related fatigue and for those with advanced cancer and fatigue (methylphenidate and modafinil). Even though methylphenidate for patients with cancer or HIV and amantadine for MS patients showed

Table 41.3 PHARMACOLOGIC INTERVENTIONS FOR FATIGUE

INTERVENTION	CONSIDERATIONS	EXAMPLES WITH COMMON STARTING DOSAGES	AVERAGE COST FOR 1-MONTH SUPPLY
Psychostimulants	Methylphenidate may be used for fatigue associated with cancer and other serious illnesses in carefully selected patients	Methylphenidate 5 mg PO every morning or bid (8 AM and 1 PM)	\$\$
	Modafinil can be used in patients with Parkinson disease, obstructive sleep apnea, and HIV but is not recommended for chronic renal failure (CRF)	Modafinil 50 mg PO every morning	\$\$\$
	Amantadine is primarily used in multiple sclerosis-related fatigue	Armodafinil 100 mg PO bid	\$\$\$
	Caution with use in elderly, severe hypertension, untreated hyperthyroidism or glaucoma, and uncontrolled cardiac arrhythmia	Dextroamphetamine 10 mg PO every morning	\$\$\$
Corticosteroids	Consider a time-limited course	Dexamethasone 4 mg PO daily every morning	\$\$
	Reserve long-term use for end of life or terminally ill	Betamethasone 4 mg PO daily every morning	\$\$
	Monitor for multisystem side effects including hyperglycemia	Methylprednisone 32 mg PO daily	\$\$
		Prednisone 7.5 mg PO daily	\$
Antidepressants	Insufficient evidence on the use of selective serotonin reuptake inhibitors (SSRIs) for fatigue in cancer and multiple sclerosis	Bupropion 150 mg PO daily	\$\$
	Assess for other symptoms and depression Consider long half-life and side-effect profile of drugs before use		
Supplements	Insufficient evidence for the use of L-carnitine	L-Carnitine 500-1,000 mg PO daily	\$
	Ginseng may have therapeutic effects for CRF	Ginseng 800 mg PO daily	\$
	More research is needed for the use of vitamin D or zinc supplementation	Coenzyme Q10 500 mg PO daily	\$
		Zinc 8 mg PO daily	\$
		Vitamin D 15 µg to 1,200 µg PO daily based on vitamin D levels	

References: National Comprehensive Cancer Network (NCCN), 2021³⁵; National Institute of Health (NCI), 2021⁶⁵; Mücke et al., 2015⁹²; Fabi et al., 2020⁹³; Miller, Soundy, 2017⁹⁸.

superior effect, the authors concluded that no specific medication could be recommended for treating fatigue in patients receiving palliative care. Given this evidence, organizations such as the European Society for Medical Oncology (ESMO) are not able to reach a consensus on the use of psychostimulants.⁹³ Other reviews have also found mixed results on the efficacy of methylphenidate^{94,95} and modafinil⁹⁶ for CRF and for MS-related fatigue.⁹⁷ Use of modafinil for MS fatigue is cautioned until larger clinical studies are conducted.⁹⁸

Dose of stimulant and length of therapy may be important factors to its utility.^{92,99} A prospective, controlled, double-blind, placebo-controlled study found that when methylphenidate was used as needed there was a significant decrease in fatigue after 2 hours ($P = 0.004$) and 5 hours ($P = 0.001$), respectively, in patients with advanced cancer.¹⁰⁰ Methylphenidate can be combined with other interventions such as erythropoiesis-stimulating agents or complementary alternative medicine.^{101,102,103} The use of erythropoietin is associated with risks and should be carefully considered. At the end of life, there may be little benefit of psychostimulants.¹⁰⁴ Palliative APRNs should be aware of the contraindications for psychostimulant use. These include comorbid

advanced arteriosclerosis, cardiac arrhythmias, severe hypertension, untreated hyperthyroidism, or glaucoma.

Corticosteroids

Corticosteroids are used to treat various clinical conditions and have multiple effects on the body.¹⁰⁵ They are used in endocrine disorders, pulmonary conditions, autoimmune disease, infection, and musculoskeletal conditions, and in the form of injections for pain relief. Glucocorticoids such as dexamethasone decrease fatigue by decreasing the inflammatory response and HPA axis function, which are associated with fatigue. The NCCN³⁵ recommends limiting the use of corticosteroids to the terminally ill, patients with fatigue and concomitant anorexia, and patients with pain related to brain or bone metastasis. Similarly, the ESMO⁹³ clinical practice guidelines recommend the short-term use of dexamethasone or methylprednisolone for the control of CRF in metastatic cancer patients. Dexamethasone appears to be the most studied glucocorticoid for management of fatigue.

Results of a 2015 Cochrane review⁹² revealed a lack of research studies investigating the use of corticosteroids for

fatigue, even though this is a common clinical practice. A review by Begley and colleagues¹⁰⁶ also reported varied results of corticosteroids on CRF and recommended more rigorous research. Similarly, Tomlinson and colleagues¹⁰¹ conducted a meta-analysis and found corticosteroids were not associated with improvement in fatigue in patients with cancer or recipients of hematopoietic stem cell transplantation. Dexamethasone is often used to treat more than one symptom, such as nausea, pain, and fatigue. Yennurajalingam and colleagues¹⁰⁷ performed a secondary analysis of a previously conducted RCT to examine the effects of dexamethasone on symptom clusters in patients with advanced cancer. They found a significant improvement in the fatigue/anorexia-cachexia/depression cluster scores compared with placebo at day 8 and day 15 of treatment. A retrospective review on the effect of prophylactic use of an oral dexamethasone on fatigue during regorafenib treatment in patients with metastatic colorectal cancer found the incidence of fatigue was significantly lower with dexamethasone than without dexamethasone ($P = .022$).¹⁰⁸ Steroids may be most helpful for patients with fatigue who are in the terminal phases of serious illness. A retrospective review examined the use of 4 mg per day of betamethasone in 87 hospitalized cancer patients at the end of life.¹⁰⁹ Betamethasone was effective in 42 out of 87 patients, suggesting steroids can have a sufficient effect on CRF for at least 2 weeks in terminally ill patients.

It is well-known that long-term use of steroids is associated with negative side effects, so future studies are warranted, keeping in mind the risk–benefit ratio. Some serious illnesses may require the long-term use of steroids. In such conditions, careful monitoring for adverse effects, particularly those affecting quality of life is essential.¹¹⁰ Multiple systems can be affected, leading to a wide range of side effects including osteoporosis, myopathy, hyperglycemia, peptic ulcer formation and gastrointestinal bleeding, hypertension, delayed wound healing, mood changes, psychosis, predisposition to infection, oral thrush, and others.¹¹¹ For the cancer patient, the palliative APRN should collaborate or consult with the primary oncologist before initialing therapy since corticosteroids may impact the effectiveness of immune-based systemic cancer treatments such as immunotherapy.¹¹² Palliative APRNs should consider prognosis before initiating long-term use of corticosteroids for management of fatigue. Regular monitoring for clinical response is needed, and one may discontinue or taper the steroid if there is no clinical benefit.

Antidepressants

Fatigue and depression are highly comorbid in people living with serious illnesses. Individuals with either fatigue or depression have an approximately twofold increased risk for comorbid presentation of both traits compared to the general population.¹¹³ Given some similarities in presentation, it may be challenging to differentiate the two diagnoses. Antidepressants have also been used to mitigate fatigue.

Generally, antidepressants affect the serotonin or norepinephrine system or both. Those affecting the serotonin system (selective serotonin reuptake inhibitors [SSRIs]) include fluoxetine, paroxetine, escitalopram, and sertraline. Agents affecting the norepinephrine system include bupropion and mirtazapine. Agents like venlafaxine and duloxetine affect both systems.¹¹⁴ The SSRIs have been shown to improve depression and anxiety in cancer patients, but studies have failed to reveal improvement in fatigue.^{92,115,116} A 2015 Cochrane review on the pharmacologic agents for fatigue in palliative care patients could not find therapeutic effects of paroxetine or fluoxetine for this symptom in COPD, cancer, and other chronic illnesses.⁹² Similarly, a review conducted by Miller and Soundy⁹⁸ could not find enough data to evaluate the use of antidepressants for MS-related fatigue. Hence, the NCCN and ESMO do not recommend the use of antidepressants for the control of CRF.^{35,93}

Bupropion, a norepinephrine/dopamine-reuptake inhibitor antidepressant, has been shown to be more effective for patients with CFS, but there are mixed reviews as to its efficacy in patients with CRF.^{35,116} Ashrafi and colleagues¹¹⁷ conducted a randomized, double-blind, placebo-controlled trial on the effects of bupropion on patients with cancer fatigue. The primary endpoint was change in average daily fatigue from baseline to week 4 using the FACIT-F questionnaire. Cancer patients who received 150 mg bupropion daily had a significant improvement in fatigue and QoL compared to the placebo group ($P = 0.000$). Similar results were observed by Salehifar and colleagues¹¹⁸ in a double-blind randomized placebo-controlled clinical trial conducted on bupropion versus placebo in 30 patients with cancer and fatigue. Results showed a significant difference by the end of week 6 ($P = 0.006$) in the intervention group. Despite the lack of evidence for antidepressants in the management of fatigue alone, these medications may be beneficial for patients with fatigue and depression.

Palliative APRNs should consider the risks and benefits of using antidepressants in the seriously ill. These medications may take 4–6 weeks to take effect. Selection of antidepressants should be based on side-effect profile and patient characteristics. The effectiveness of antidepressants can be evaluated by assessing the degree of symptom reduction and the occurrence of any adverse effects.¹¹⁹ One must also consider the cost of these medications. Generic and brand names of antidepressants may be expensive or unaffordable for some. In addition, availability of insurance coverage and out-of-pocket costs should be assessed before starting therapy. Patients may fear stigma with antidepressant use, for which the APRN can provide education and counseling.

Supplements

Other supplements have been the subject of evaluation for fatigue, with mixed results. Vitamins have not proven to be effective at reducing CRF.⁶⁵ L-Carnitine is thought to be helpful in treating CRF due to its ability to decrease pro-inflammatory cytokines. This nutrient can be depleted

from chemotherapeutics. However, studies have not been able to support its effects.⁹² Marx and colleagues¹²⁰ conducted a meta-analysis to evaluate the effectiveness of L-carnitine supplementation for CRF. The review of 12 studies showed no significant difference in fatigue with carnitine use ($P = 0.45$). Similarly, two separate reviews of carnitine for MS fatigue found insignificant results and insufficient data to support its use in this population.^{98,121} Another systematic review of commonly used supplements, guarana, acetyl-L-carnitine, and co-enzyme Q10, could not confirm any statistical benefit for fatigue in patients with breast cancer.¹²²

Ginseng has also been evaluated for treating fatigue. In 2017, Yennurajalingam and colleagues¹²³ conducted a prospective, open-label study with 30 patients with CRF. Participants received high-dose *Panax* ginseng at 800 mg orally daily for 29 days. The primary endpoint was change in fatigue scores using the FACIT-F. Results showed a significant reduction in mean FACIT-F scores at baseline, day 15, and day 29 with use of *Panax* ginseng ($P < 0.001$). These promising results were replicated in a systematic review conducted by Arring and colleagues¹²⁴ of 10 studies on the use of ginseng as a treatment for fatigue in serious illness. They reported significant results and a modest effect of 800–2,000 mg of American and Asian ginseng on fatigue with no reported adverse effects in any of the studies.

Supplementation with other vitamins has also been studied for management of fatigue. Coenzyme Q10 is one of the most popular dietary and nutritional supplement on the

market.¹²⁵ Sanoobar and colleagues¹²⁶ conducted a randomized, double-blinded, placebo-controlled trial to determine the effect of 500 mg per day of coenzyme Q10 supplement versus placebo for 12 weeks on fatigue in 45 patients with MS. Results showed a significant decrease in fatigue for the intervention group ($P = 0.001$). A prospective, randomized, double-blinded, placebo-controlled study conducted in Portugal found zinc supplementation prevented fatigue and maintained quality of life of patients with colorectal cancer on chemotherapy.¹²⁷ Research on vitamin D supplementation for patients with cancer is still evolving. Low vitamin D levels may be associated with higher levels of self-assessed fatigue in men but not women.¹²⁸ Supplements are often combined for management of fatigue. However, these studies have limited generalizability, with mixed results.^{129,130} The ESMO and NCCN guidelines do not recommend the use of CoQ10, guarana extract, American ginseng, L-carnitine, or other supplements for CRF.^{35,93} Patients who are interested in the use of supplements for fatigue should be properly counseled, and potential side effects with disease-targeted treatments should be reviewed.

NONPHARMACOLOGIC INTERVENTIONS

All patients should receive general education on treatment-related fatigue due to chemotherapy and radiation therapy (Table 41.4). General nonpharmacologic strategies include balancing rest and activity, conserving energy, preventing weight loss, optimizing nutrition, and using distraction (e.g.,

Table 41.4 NONPHARMACOLOGIC INTERVENTIONS FOR FATIGUE

INTERVENTION	CONSIDERATIONS	EXAMPLES
Physical activity	Assess functional status, risk of bleeding, orthostatic blood pressure Caution with bone metastasis, fractures, or anemia Consult rehabilitation specialists for patients who are severely deconditioned Therapies should be tailored to patient needs and abilities Review costs and insurance coverage with patient and family and seek discounts with insurance if present.	Walking, biking, aerobics, resistance exercises, swimming Tai Chi High-intensity interval training Yoga Physical therapy Occupational therapy Gym memberships, community health centers, YMCA
Integrative therapies	Review risk of bleeding, history of bleeding disorders prior to engaging in acupuncture Adverse effects of acupuncture may include needling pain, hematoma, bleeding, orthostasis, or more serious conditions such as vasovagal reactions Risks of massage may include infection, bruising, risk of fracture, reactions to lotions, or dislodging thromboses	Acupuncture Acupressure Reflexology Reiki Massage
Psychosocial therapies	Consider home-based sessions using telehealth to increase compliance to therapy These therapies may be delivered with other nonpharmacological or pharmacologic interventions Use interpreters or culturally appropriate modifications for non-English-speaking patients	Cognitive behavioral therapy Behavioral therapies Relaxation techniques Mindfulness based stress reduction Music therapy Art therapy Hypnosis Biofeedback Patient education and counseling

References: National Comprehensive Cancer Network (NCCN), 2021³⁵; National Institute of Health (NCI), 2021⁶⁵; Mücke et al., 2015⁹²; Fabi et al., 2020⁹³; Hilfiker et al., 2018¹³³.

listening to music, taking short naps, reading).^{35,65,93,98,131} Teaching patients how to monitor their fatigue by using a diary increases awareness of when levels vary and allows them to plan their day accordingly.¹³² The NCCN guidelines organize nonpharmacologic interventions into three groups: physical activity (e.g., exercise, yoga), integrative therapies (e.g., massage, acupuncture), and psychosocial intervention (e.g., cognitive-behavioral therapy [CBT]).³⁵ Although important to a comprehensive fatigue management plan, access to nonpharmacologic therapies may be limited in accessibility, availability, and affordability. A limited number of cancer centers have coexisting integrative medicine centers. In addition, not all insurance companies may provide coverage or reimbursement for integrative or complementary therapies. However, APRNs can partner with patients and families to find community programs or community health centers such as the Young Men's Christian Association (YMCA). APRNs may also need to collaborate with insurers to appeal for coverage of these services.

Physical Activity

Research studies have shown exercise to be the most effective intervention for managing fatigue.^{56,88,133,134,135} If the patient's functional status permits, there are several activities, such as walking, biking, aerobics, and swimming, that may prove beneficial. Empirical evidence for exercise guidelines is lacking.⁹³ In 2017, Mustain and colleagues⁹⁰ conducted a meta-analysis of 113 unique studies to compare pharmaceutical, psychological, and exercise treatments for CRF. Although all intervention types showed significant moderate improvements in CRF, studies that intervened with exercise demonstrated the largest overall improvement ($P < .001$). The role of exercise in CRF has been studied in specific tumor populations as well. Zhou and colleagues¹³⁶ conducted an RCT on the effects of Tai Chi after chemoradiotherapy in patients with in nasopharyngeal carcinoma. Results showed Tai Chi reduced fatigue scores on multiple subscales of fatigue ($P < 0.01$ for general, physical, and emotional fatigue). Several studies, including meta-analyses, have shown exercise reduces CRF significantly in men with prostate cancer.^{137,138,139}

Hilkiker and colleagues¹³³ conducted a systematic review and meta-analysis of 245 studies on the effects of exercise for CRF during and after treatment. During cancer treatment, aerobic and resistance training (alone or combined), and yoga had moderate to large effect sizes compared with usual care. After cancer treatment, yoga showed a large effect size for the reduction of CRF, while combined aerobic and resistance training, Tai-Chi, and aerobic or resistance training alone showed moderate effect sizes. Exercise as an effective intervention for fatigue in breast cancer patients and survivors has been well-studied.^{140,141,142} Juvet and colleagues¹³⁴ conducted a meta-analysis on the effects of exercise during and after treatment on physical functioning and fatigue in breast cancer patients. Of the 25 RCTs in the review, 17 addressed the efficacy of exercise on fatigue.

Results showed exercise reduced fatigue during (standard mean difference [SMD] = -0.19 , 95% confidence interval [CI] = $-0.31, -0.07$) and after chemotherapy or radiotherapy (SMD = -0.52 , 95% CI = $-0.96, -0.09$). A reduction of fatigue was observed at 6 months of follow-up, and greater effects were seen after cancer-directed treatment. Patients with advanced cancer can benefit from exercise as well. An RCT conducted on patients with advanced cancer receiving palliative care and physical therapy for 2 weeks found a significant reduction in fatigue scores.¹⁴³ The intervention consisted of 30-minute active exercises, myofascial release, and proprioception neuromuscular facilitation for 2 weeks.

Effects of exercise have also been studied in CFS. Galeoto and colleagues¹⁴⁴ conducted a systematic review, and results showed rehabilitation programs that promote physiotherapy techniques such as exercise, mobilization, and body awareness are the most effective in reducing medium- and long-term fatigue severity in CFS patients. A 2019 Cochrane review of eight RCTs concluded that exercise therapy reduces fatigue in CFS; however, long-term effects are unclear.¹⁴⁵ For patients with MS, an individualized and supervised exercise program with aerobic training, resistance training, flexibility, and balance exercises is part of a multimodal approach to improve function and QoL.¹⁴⁶ Exercise has been shown to be effective in improving MS-related fatigue and other dimensions of well-being in several RCTs.^{147,148,149,150} Other chronic illnesses including CKD, COPD, and SLE may benefit from exercise programs to address bothersome fatigue.¹⁵¹⁻¹⁵⁴ All programs should be tailored to the patient's needs and adjusted as the functional status changes. Caution should be taken with exercise interventions when patients have bone metastases, thrombocytopenia, anemia, fever or active infection, or any limitations secondary to other illnesses.³⁵ Physical therapy consultations should be made when patients have comorbidities (e.g., heart disease, COPD), recent major surgery, functional or anatomical deficits, or substantial deconditioning.³⁵

Physical therapists (PTs) offer methods to manage fatigue with instruction to patients on proper body mechanics, paced breathing, and activity modification to decrease physical exertion.¹⁵⁵ Occupational therapists (OTs) assess and analyze patients' functional problems. In the case of CRF, OTs can teach patients practical interventions, such as energy conservation and lifestyle management.^{152,153} The most common interventions provided by OTs include mobility, self-care skills, upper extremity strength and function, educational needs, home management skills, and need for assistive devices.¹⁵⁴ PTs and OTs can adapt activities according to the effects of fatigue on patients' functional abilities and ensure that proper equipment is accessible so patients can maintain as much independence as possible. This, in turn, empowers patients to continue making their own healthcare decisions and, at the same time, preserves their dignity.^{154,155} Palliative APRNs are in a key role to assess the severity of fatigue and offer

recommendations and referrals to appropriate exercise therapies.

Integrative Therapies

Acupuncture and Acupressure

Integrative therapies, such as acupuncture and massage therapy can be effective in managing a wide range of symptoms in patients with cancer.¹⁵⁵ The NCCN recommends acupuncture for those who have completed treatment and recommends massage therapy for patients with fatigue who have completed cancer treatment or are on active treatment.³⁵ The Pan-Canadian Practice Guidelines¹⁵⁶ and the ESMO guidelines⁹³ both could not reach a consensus on the use of acupuncture for CRF. However, the American Society for Clinical Oncology (ASCO) and Society for Integrative Oncology recommend acupuncture for patients who have completed cancer therapy.^{157,158} These therapies along with reflexology and Reiki are often used in hospice and palliative care to provide comfort.¹⁵⁹ Evidence from systematic reviews shows promising results using acupuncture in conjunction with patient education to reduce CRF and improve quality of life.^{160,161} Zhang and colleagues¹⁶¹ conducted a meta-analysis of 116 RCTs with 1,346 participants to evaluate the effect of acupuncture on CRF. Results showed acupuncture delivered in 20- to 30-minute sessions 1–3 times a week for 2–6 weeks had a significant reduction on fatigue ($P < 0.01$). Participants included those who were receiving cancer-directed treatments and those where not. Seven studies in this review reported the occurrence of adverse events. The effects of acupuncture on fatigue were found to depend on the number of sessions, not the duration, frequency, or length of sessions.

Cheng and colleagues¹⁶² conducted a randomized, double-blind, placebo-controlled pilot trial to evaluate the clinical effect of acupuncture on CRF in lung cancer patients. Twenty-eight patients with CRF were randomly assigned to active acupuncture or placebo. The intervention group received acupuncture twice per week for 4 weeks followed by 2 weeks of monitoring. The primary outcome was fatigue scores on the Brief Fatigue Inventory. Results showed a significant reduction in fatigue scores at 2 weeks in the 14 participants who received active acupuncture compared with those receiving the placebo ($P < 0.01$). At week 6, symptoms improved further ($P < 0.001$). There were no significant differences in the incidence of adverse events in either group ($P > 0.05$). Integrative therapies can be used in non-CRF. In patients with CKD, acupuncture can improve symptoms fatigue, pain, and other symptoms.¹⁶³ It is thought acupuncture affects the regulation of sympathetic nerves and the activation of bioactive chemicals to provide this benefit. However, a Cochrane review on acupuncture for symptoms of CKD suggests that further evidence is needed to make clear recommendations for this population.¹⁶⁴ Integrative therapies such as acupuncture are frequently used in patients with MS for relief of fatigue and other symptoms.¹⁶⁵

Acupressure has been studied to be effective in the relief of CRF as well.^{166,167,168} Zick and colleagues¹⁶⁹ conducted a Phase 3 randomized, single-blind, clinical trial on the effects of acupressure for fatigue in 424 breast cancer survivors. The intervention group received 6 weeks of daily self-administered relaxing acupressure or stimulating acupressure. The primary outcome was change in the Brief Fatigue Inventory score from baseline to weeks 6 and 10. At week 6, significant results were seen in the number of participants who achieved normal fatigue levels with relaxing acupressure and stimulating acupressure ($P < 0.001$). Significant results were also seen at week 10 ($P < 0.002$). Acupressure is often delivered with or without essential oils.¹⁴⁴ Patients who are interested in acupuncture should be screened for thrombocytopenia or bleeding disorders to avoid adverse events.

Massage

Massage, Reiki, and therapeutic touch are common non-pharmacological interventions used to provide comfort to patients in palliative care settings.¹⁷⁰ Similar to acupuncture, massage studies have shown clinical significance in improving fatigue, but larger-scale trials are needed to substantiate its efficacy.^{171,172} Kinkead and colleagues¹⁷³ conducted an early-phase, randomized, single-masked, 6-week investigation on 66 women who were Stage 0–III breast cancer survivors who had received surgery plus radiation and/or chemotherapy with CRF. They compared weekly Swedish massage therapy, light touch, and waitlist control. The primary outcome was scores on the Multidimensional Fatigue Inventory. Results showed a statistically significant 6-week reduction in total fatigue scores within the Swedish massage therapy and light touch groups ($P < 0.0001$) and a significant increase in fatigue scores within the wait list control group.

A more recent open-label, parallel-group, quasi-randomized controlled pilot study with 46 cancer patients receiving chemotherapy found aromatherapy massage reduced CRF.¹⁷⁴ Primary endpoints included fatigue scores on the Piper Fatigue Scale. Patients in the intervention group received 40-minute hand and foot massage three times per week for 6 weeks during home visits. The control group received standard medical care. Median fatigue scores did not change during weeks 2–6. However, at week 8, the fatigue scores were significantly lower in the intervention group ($P < 0.005$). Similar results were replicated in a RCT studying effects of foot massage to control CRF in patients with colorectal cancer who were receiving chemotherapy.¹⁷⁵ Results showed significant reduction in fatigue levels in those who received reflexology or classical massage compared to controls in the third ($P = 0.030$), fourth ($P < 0.001$), and fifth weeks ($P = 0.036$) of therapy. More research is needed on the effects of massage for fatigue related to MS.¹⁷⁶ Massage as an intervention can be delivered in hospitals, clinics, or in patient's homes. Massage therapy should be provided by certified practitioners who can tailor therapies to the patient's medical condition. Caution should be taken for patients with fractures, deep vein thrombosis, open skin wounds, or bleeding disorders.

Psychosocial therapies are aimed at helping patients cope with their fatigue. These therapies teach patients how their thoughts can influence feelings and behaviors. Cognitive-behavioral therapy (CBT) has been shown to be effective for both non-cancer and cancer patients.^{177,178,179,180,181} Use of psychosocial interventions in palliative care has been widely studied.¹⁸² The NCCN, ESMO, and Pan-Canadian Practice Guidelines recommend the use of psychosocial interventions such as CBT, mindfulness-based stress reduction, psycho-education therapies, educational therapies, and supportive expressive therapies.^{35,93,158} Poort and colleagues¹⁸³ conducted a reviewed of 14 RCTs on psychosocial interventions for fatigue during cancer treatment. Some studies showed psychosocial interventions such as CBT, support group therapies, and energy conservation approaches improved physical functioning directly after the intervention and may improve fatigue at first follow-up. However, this 2017 Cochrane review could not provide clear evidence to support or not support the use of psychosocial interventions for reducing fatigue in this population.

In an RCT, Mendoza and colleagues¹⁸⁴ studied fatigue in cancer and cancer survivors to determine the effects of waking hypnosis with CBT compared to education control. Forty-four participants completed questionnaires before and after the intervention. The instruments included Patient-Reported Outcomes Measurement Information System (PROMIS), Medical Outcomes Survey Sleep Problem Index, the Patient Health Questionnaire Depression Scale (PHQ-8), Pain Catastrophizing Scale (PCS), and the Cancer Treatment Distress Scale. The intervention group received the combined hypnosis and CBT intervention. Results showed significantly greater improvements in sleep problems, fatigue, and average pain intensity ($P < .001$) with the intervention group compared to the control. Secondary outcomes also resulted in significant differences for depression, cancer distress, pain interference, and pain catastrophizing. Effect sizes for all measures were larger following the waking hypnosis with CBT intervention. At follow-up at 3 months, treatment gains remained for all symptoms ($P \leq .001$). Overall results conclude that CBT as an evidenced-based intervention provides extended benefits in helping to control fatigue and other symptoms.

For MS fatigue, CBT provides short-term relief.¹⁸⁵ Use of combined approaches with CBT and therapies known to improve fatigue is recommended in patients with MS.^{43,186} More research is needed to evaluate longer term effects of CBT on MS-related fatigue. Mindfulness-based interventions can be effective in reducing fatigue in patients with advanced COPD¹⁸⁷ and chronic HF.¹⁸⁸ These psychosocial interventions can be delivered at place of residence or with the use of telehealth to increase adherence to therapy.^{189,190,191} Palliative APRNs should provide appropriate referrals to interdisciplinary specialists who can provide these psychosocial interventions, including nurses and social workers, and provide education to all patients suffering from fatigue.

Fatigue is an almost universal symptom for people with serious illness receiving palliative care. This symptom clearly affects function and quality of life, often occurring with other bothersome symptoms. Palliative APRNs are in a key position to assess for fatigue and provide evidence-based pharmacologic and nonpharmacologic interventions. Careful consideration of disease trajectory, prognosis, and goals of care will guide treatment strategies. A patient-centered approach in management of fatigue, including education of the patient and family unit, is essential to alleviate the burdens of fatigue. Fatigue affects physical, psychosocial, emotional, and other aspect of well-being. The palliative APRN can partner with the interdisciplinary team to identify, assess, and manage fatigue holistically throughout the disease trajectory.

NAUSEA AND VOMITING

Katherine E. DeMarco

KEY POINTS

- Nausea and vomiting are different symptom burdens that require the palliative advanced practice registered nurse (APRN) to perform a comprehensive assessment to determine appropriate and personalized interventions for the individual patient.
- When antiemetics are used as part of the management plan, the palliative APRN must consider the etiology of symptoms and use one medication from a pharmacologic class. The simultaneous use of more than one agent from each class is generally avoided to prevent overlapping side effects/toxicities.
- The use of nonpharmacologic interventions as per evidence-based benefits and the patient's condition and values are part of the palliative APRN's approach to the management of nausea and vomiting.

lead to feelings of social isolation. The burden of uncontrolled symptoms may lead to feelings of hopelessness and depression. Caregivers may be distressed by their inability to nourish patients. The cost of medications and other direct and indirect care may contribute to distress. If the symptoms are thought to be related to disease-modifying treatments, patients may decide to prematurely stop potentially beneficial therapies. The palliative advanced practice registered nurse (APRN) can positively impact the patient's quality of life and reduce the risk of physical sequelae through a symptom management plan that is based on an understanding of the physiology and pathophysiology of N/V, comprehensive symptom assessment, and formulation of a symptom diagnosis that will direct the use of antiemetic therapies.¹⁻³ Using national palliative care guidelines, such as the National Consensus Project for Quality Palliative Care *Clinical Practice Guidelines* and the National Comprehensive Cancer Network *Palliative Clinical Practice Guidelines in Oncology* can support the palliative APRN in creating evidence-based and patient-personalized care plans.^{4,5}

CASE STUDY: NAUSEA AND VOMITING IN CANCER AND PARKINSON'S

Chad was a 75-year-old man with metastatic gastric carcinoma involving his liver and lungs. His past medical history included Parkinson's disease, hypertension (HTN), and gastroesophageal reflux disease (GERD). He reported intermittent nausea and dizziness over the past month and 1–2 episodes of vomiting in the past 3 days. The palliative advanced practice registered nurse (APRN) considered whether his symptoms were due to changes in gastrointestinal (GI) function related to tumor growth in or adjacent to the GI tract (liver metastasis), possible increased intracranial pressure from an undetected central nervous system (CNS) tumor, GERD, constipation, dehydration, reactions to medications, or anxiety.

DEFINITIONS

Although nausea and vomiting are separate symptoms, they are often viewed as a single entity in practice and in the literature. Either may be experienced acutely, chronically, spontaneously, or in response to specific events, such as eating, activity, or medication use. *Nausea* is a subjective unpleasant sensation experienced in the back of the throat and epigastrium and is associated with a perceived need to vomit. Patients may describe queasiness or an upset or unsettled stomach or may use other terms. Nausea may be continuous or intermittent and may have a more negative impact on quality of life than vomiting.^{2,6} *Vomiting* is the expulsion of gastric contents through the mouth. It may occur as a single episode or be recurrent. *Retching* or *dry heaves* refers to spasmodic contractions of abdominal muscles and diaphragm that do not result in vomiting.^{2,6}

Acute nausea occurs within minutes or hours of a specific event, such as chemotherapy. Temporal co-occurrence of cluster symptoms or delayed N/V occurs at least 24 hours after the stimulus and lasts for 3–7 days.¹ N/V associated with an event may trigger a learned response to similar events in the future, causing anticipatory N/V.⁷ Refractory N/V occurs when the symptoms continue to occur even when

INTRODUCTION

Both adult and pediatric individuals who have serious or advanced illness can experience nausea and vomiting (N/V). The symptom(s) of N/V affect all the dimensions of quality of life, particularly if the symptoms are protracted.^{1,2} Dehydration, electrolyte imbalances, malnutrition, fatigue, and aspiration are common physical sequelae of N/V. Concerns about eating and declining physical function may

medications and other interventions are completed.³ There is no formal definition for chronic nausea. However, in academic research, nausea that last longer than 4 weeks is often considered chronic nausea.¹

PREVALENCE AND RISK FACTORS

Much of the research and literature on N/V focuses on the experience and management of these symptoms in oncology practice. Up to 80% of adult oncology patients undergoing chemotherapy and/or radiation therapy experience N/V.⁸ Nausea is more frequently experienced than vomiting. The prevalence rates vary depending on specifics of disease, chemotherapeutic agents used, and anatomic sites of radiation therapy.⁷ In oncology patients with advanced disease who are no longer receiving active anti-cancer therapies, the prevalence rate is about 60% for nausea and 30% for vomiting.⁷

N/V is also frequently experienced by patients with other life-limiting or life-threatening illnesses and conditions (Table 42.1). N/V may burden patients with progressive neurological conditions, such as multiple sclerosis and Parkinson’s disease.^{3,9} As patients near death, the overall prevalence of N/V is 19%, with a range from 8.4% to 70%.⁶ A literature review identifies that about 40–70% of individuals experience moderate to severe nausea in the final weeks of life.^{10,11} The risk of developing N/V in advanced disease may be higher in patients who are female, are younger, and have a history of low alcohol intake.⁷ Other risk factors include treatment with chemotherapy, opioids, antibiotics, and digoxin and the presence of hypercalcemia; fluid and electrolyte imbalances; hepatic, renal, gastrointestinal (GI), and central nervous system (CNS) pathologies; and anxiety.^{7,12}

PHYSIOLOGY

The research surrounding chemotherapy-induced N/V (CINV) advanced our understanding of the basic physiology of vomiting. Nausea involves more cerebral involvement and consciousness compared to vomiting,¹⁰ whereas vomiting is a protective reflex designed to rid the body of ingested toxins. Vomiting is controlled in the brainstem by the vomiting center (VC) in the medulla and the chemoreceptor trigger zone (CTZ).^{1,10} A number of neurotransmitters and their receptors play an important role in coordination of the reflex. Dopamine/dopamine receptors, γ -aminobutyric acid (GABA), serotonin/5-HT₃ receptors, and substance P/neurokinin-1 receptors have the best-described roles.^{6,7,10} Cannabinoids and their related receptors, present in the CNS and the GI tract, may also play a role, with synergistic effects on dopamine, serotonin, and neurokinin-1 receptors.⁶ Mechanoreceptors in the CNS may also cause N/V symptoms as these receptors are responsive to pressure from stretching and irritation of the meninges.¹⁰

The vomiting center responds to input from afferent pathways that include the CTZ, the vagus nerve, the cerebral cortex, and the vestibular system. The CTZ is a highly vascular area located in the fourth ventricle of the brain. The lack of a blood–brain barrier at the CTZ allows direct exposure to various drugs, toxins, and metabolites circulating in the blood or cerebrospinal fluid. Dopamine, histamine, serotonin, and substance P are the major neurotransmitters in this pathway.^{2,6,7} Studies suggest that there may be synergistic activity between 5-HT₃ and neurokinin-1 receptors.⁶ In addition, the CTZ responds to signaling from the vagal afferents mediated by the release of serotonin from gastric enterochromaffin cells in response to injury or inflammation of the GI tract, changes in GI motility, and the chemistry of the luminal contents. Oropharyngeal irritants signal the CTZ via the pharyngeal

Table 42.1 PREVALENCE OF NAUSEA AND VOMITING IN NON-ONCOLOGY POPULATION

DISEASE	NAUSEA RATE (%)	VOMITING RATE (%)	NAUSEA AND VOMITING RATE (%)
Liver failure	50		50
Heart failure	50	24	2–48
End-stage renal disease			8–52
HIV/AIDS			41–57
COPD	18	4	4
Motor neuron disease	No data found		
Parkinson’s	9.8	4.1	
Dementia			8
Multiple sclerosis	10–40	2	2–78
COVID-19	10–27	8–16	

From Chow et al.⁶; Lee et al.⁹; Higgson et al.¹³; Levinthal et al.¹⁴; Moens et al.¹⁵; Elshazli et al.¹⁶; Dorrell et al.¹⁷; and Elmunzer et al.¹⁸

branch of the vagus nerve, with histamine and acetylcholine thought to be the major neurotransmitters. The vagal afferents may also directly stimulate the vomiting center.¹⁰

The cerebral cortex signals the VC via the midbrain. The primary neurotransmitter may be GABA. Stimuli include anticipation, fear, and memories (e.g., anticipatory vomiting) as well as signals from the senses, such as disturbing sights, smells, or pain. The VC also responds to vestibular input via the inner ear, mediated by histamine and acetylcholine. Motion, certain medications, and changes in intracranial pressure may trigger this pathway. With threshold stimulation of these afferent pathways, the VC triggers the efferent pathways that coordinate the complex sequence of powerful and sustained contractions of the abdominal muscles and diaphragm and relaxation of pyloric and duodenal sphincters that forces expulsion of gastric contents via the mouth.^{2,3,12,13}

Physiologic pathways and the central processing of nausea are still poorly understood. At one time, nausea was thought to be caused by subthreshold stimulation of the vomiting pathways, but recent research suggests that the physiology of nausea is different.^{14–19} While vomiting is a reflex controlled by lower brain structures, nausea seems to require consciousness and cerebral function.¹⁰ Studies suggest that nausea may be associated with the morphology of the subcortex, along with changes in gastric myoelectrical activity and neuroendocrine responses mediated via the autonomic nervous system and cerebral cortex.¹⁹ The changes in gastric motility are accompanied by a decrease in gastric acid levels and release of cortisol, β -endorphins, epinephrine, and norepinephrine, causing nausea, pallor, cold sweats, tachypnea, tachycardia, and increased salivation.^{7,10} The CTZ plays a role in the development of nausea through its effect on GI motility, taste aversion, and food intake.⁷

These different physiological pathways may explain why N/V does not always respond to the same symptom interventions. An example is the continued higher incidence of post-chemotherapy nausea despite the reduced incidence of chemotherapy-induced vomiting with the use of research-based antiemetic guidelines.²⁰

ETIOLOGY

Nausea, vomiting, and retching are distinct phenomena that may be experienced acutely, chronically, independently, simultaneously, or sequentially. In palliative care, the etiologies of N/V are often multifactorial and may be related to underlying disease and/or comorbidities, treatment effects, or debility.^{1,6,21} Most often, a primary etiology of N/V can be identified and should always be explored.²¹

N/V is often experienced in relation to other symptoms. Clusters of two or more symptoms that consistently occur concurrently may share a common etiology and be synergistic.²² Studies of N/V in oncology describe clustering of nausea, vomiting, loss of appetite, taste changes, weight loss, and fatigue.^{20,22} While not all concurrent symptoms are clusters, the palliative APRN's attention to other symptoms is part

of the comprehensive assessment and may suggest etiologies for N/V.

Gastroparesis, occurring in 34–45% of cases, is a common etiology in palliative care that is suggested by intermittent nausea, early satiety, and postprandial bloating relieved by vomiting.^{2,21,23} Gastroparesis occurs due to slowed or delayed gastric emptying. Upper GI symptoms such as dyspepsia, N/V, constipation, and gastric outlet obstruction can occur with gastroparesis. Commonly etiologies include a variety of causes, such as diabetic neuropathy, postsurgery of the GI tract, and postinfectious gastroparesis. Lesser common etiologies include stroke, Parkinson's disease, paraneoplastic syndrome, and opioid or anticholinergic medication classes. Since 2000, gastroparesis prevalence has increased in the United States.²⁴

Bowel obstruction, occurring in a range of 3% to 30% of cases, may be suggested by the presence of N/V, abdominal pain, altered bowel function, and abdominal distention.^{21,25} Bowel obstructions, such as malignant obstructions, occur in 3–15% of individuals with cancer.^{25,26} Malignant obstructions can be due to tumor burden or mechanical or functional obstruction, which can occur due to abdominal carcinomatosis, tumor infiltration of the GI musculature, myenteric plexus, or a combination of both. Patients who are diagnosed with ovarian cancer and colon cancer have a higher incidence of bowel obstruction, 20–50% and 10–29%, respectively.^{25,26}

Pharyngeal stimulation is suggested by vomiting and gagging associated with cough and difficulty clearing secretions.²¹ Persistent nausea unaccompanied by or unrelieved by vomiting may suggest a metabolic and drug-related cause. Opioid use in patients without a previous history of nausea may cause constipation, gastroparesis, and/or stimulation of the CTZ, resulting in a 40% incidence of N/V. Early-morning vomiting associated with headache may suggest increased intracranial pressure. Nausea related to movement may suggest a vestibular component.²¹

Anti-neoplastic interventions are common palliative interventions and are known to have the risk of N/V. It is estimated that 50–80% of patients who receive chemotherapy, immunotherapy, and/or radiation have treatment-induced N/V.^{8,27} Chemotherapy, immunotherapy, and radiation therapy can induce N/V acutely and with delayed onset. Radiotherapy-induced N/V (RINV) is identified as an underestimated and underrecognized symptom burden.²⁸ Anti-neoplastic-induced N/V can impact the patient's ability to continue disease-directed or palliative-focused cancer treatments.

Other etiologies, both acute and chronic, also need to be considered by the APRN in formulating a differential diagnosis and approach to symptom management. In patients with chronic obstructive pulmonary disease (COPD), N/V may be reactions to antibiotics, theophylline, or steroids; steroid-induced GI irritation; gastropathy from circulatory overload; or infection (e.g., thrush, cough and secretions, fatigue, and anxiety). Heart failure may trigger N/V related to cardiac ischemia, digitalis and other medications, congestive gastropathy, impaired renal and/or hepatic function causing hyponatremia, dehydration from diuretics, cough, and anxiety.^{2,10,21} Table 42.2 outlines common etiologies of N/V to be considered in formulating a differential diagnosis.

Table 42.2 COMMON ETIOLOGIES OF NAUSEA AND VOMITING

Gastrointestinal	Drug-induced
Ascites	Anesthesia
Adhesions	Antibiotics
Biliary obstruction	Anticonvulsants
Cholecystitis	Aspirin and NSAIDs
Constipation	Chemotherapy
Gastric irritation/distention	Digoxin
Gastroparesis	Cannabis/marijuana
Gastric outlet obstruction	Immunotherapy
Gastric reflux	Iron supplements
Hepatitis	Opioids
Hepatic capsular distention	Theophylline
Intestinal obstruction	Buprenorphine/naloxone
Irritable bowel	Radiation-induced
Intra-abdominal cancers:	Esophagus
Colon, pancreas, ovarian,	Abdominal
gastric, esophageal	Pelvic
Peritoneal carcinomatosis	Brain
Pancreatitis	
Gastric or duodenal ulcers	
Metabolic	Increased intracranial
Fluid and electrolyte imbalances:	pressure
Hypercalcemia	Cerebral edema
Hyper-/Hyponatremia	Intracranial tumor
Dehydration	Intracranial bleeding
Adrenocortical insufficiency	Skull metastases
Liver failure	Carcinomatous meningitis
Renal failure	
Diabetic ketoacidosis	
Pregnancy	
Infections	Psychological
<i>Candida</i> esophagitis	Fear
Gastroenteritis	Anxiety
Sepsis	
Vestibular	Pharyngeal
Motion sickness	Chronic cough
Ménière syndrome	Oropharyngeal secretions
Vestibular problems

ASSESSMENT

The palliative APRN's comprehensive symptom assessment includes data from multiple sources, including the patient, family, and caregivers; medical and surgical history; medication history and current utilization of medications, including herbs, vitamins, and cannabis; physical examination and clinical observation; the medical record; and diagnostic tests. The assessment data describe the clinical personhood, the individual's health status, the individual's symptom experience, and other patient-specific factors that will affect the symptom management plan. This includes an understanding of the patient's prognosis, overall goals of care, and specific goals for symptom relief.¹⁰

A synthesis of the patient-specific data and the palliative APRN's knowledge and understanding of the health problems forms the differential diagnoses and likely cause(s). In conjunction with patient-specific goals, this guides potential further diagnostic testing for therapeutic decision-making and the selection of therapeutic interventions to eliminate or modify the cause of the symptom, if possible, and to alleviate symptom distress related to N/V.

Identifying the presence of the symptom(s) is the first step in assessment. The subjectivity of nausea is expressed by the patient and therefore varies from patient to patient.¹ The patient's report of N/V, either spontaneously or in the clinical interview, is a frequent method of symptom identification. Some patients may be reluctant to report either symptom in the belief that nothing can be done or that symptom management will detract from disease-directed therapies. Palliative APRNs should remain aware that N/V can have associated cluster symptoms and/or multifactorial etiology; symptom assessment is therefore multidimensional.¹ Routine screening for common symptoms using symptom inventory tools, such as the Memorial Symptom Assessment Scale or the Edmonton Symptom Assessment System, is another method of symptom identification.^{11,31}

Understanding the patient's experience of N/V begins with the patient's description of the symptom to clarify its nature. The patient's experiential, linguistic, cultural, ethnic, and geographical background may influence the expression and meaning of N/V for the individual. Characteristics of onset, frequency, duration, intensity or severity, and pattern of occurrence; triggering and alleviating factors, such as use of prescription or over-the-counter medications or herbal preparations, exercise or activity, and changes in eating and drinking patterns; and associated symptoms help delineate possible etiologies and therapies. The effects of the N/V on the patient's function, including performance status and quality of life, are essential parts of the assessment. N/V symptoms often change eating patterns and are accompanied by diminished physical functioning and self-care capacity. In turn, social isolation, uncertainty, and concern about how N/V affects the patient's lifestyle, medical therapies, family caregivers, and survival add to symptom distress.^{1,10}

If aligned with the patient's personalized medical care plan, clinical evaluation and diagnostics may be beneficial. Analysis of renal, liver, and pancreatic function, along with assessing for metabolic abnormalities (e.g., hyponatremia, hypokalemia, and hypercalcemia) could be necessary. In addition, diagnostics, such as computed tomography (CT) of the brain, abdomen and pelvis, and/or radiographs of the abdomen may assist clinically to connect to the patient's N/V experiences.¹

In addition to the clinician assessment and history, patient diaries and journals may aid in understanding the patient's perception of and response to N/V.³ There are also specific assessment tools for evaluating N/V. The *Morrow*

Assessment of Nausea and Vomiting (MANE) and the *Rhodes Index of Nausea and Vomiting* (INVR) enhance the patient's report of the symptom characteristics. Other tools (e.g., the *Functional Living Index-Emesis* and the *Osborn Nausea and Emesis Module*) describe the effect of the

symptoms on function and well-being.^{6,20} Research investigating novel technology approaches, like machine learning to assess and predict an individual's nausea susceptibility, is being conducted and will likely impact the future of clinical care¹⁹ (Table 42.3).

Table 42.3 ASSESSMENT OF NAUSEA AND VOMITING

General	<i>Clinical Personhood</i> Demographics: Age, gender, race, employment, education, place of residence, socioeconomics, health insurance Spiritual: Values/beliefs, faith community, practices, rituals, restrictions Psychosocial: Marital status, sexual preference, culture, coping, social supports, substance use concerns, financial, past experience with health-related issues Current quality-of-life concerns Consider a symptom journal that the patient maintains and shares with palliative APRN	
Health status	Current diagnosis, prognosis, functional status, disease course, and trajectory, including past and current therapies, patient's understanding of disease status, goals of care Medication history; recent history or present anti-neoplastic interventions; current medication list/reconciliation. Herb, substance use; including cannabis and illicit drug history and current use. Assessment for polypharmacy and drug interactions. Past symptom burden history, including history of nausea or vomiting and effective therapies.	
	NAUSEA	VOMITING
Symptom experience	Patient description: Nausea, upset stomach, queasiness, sick stomach, other	Description of “throwing up,” “upchucking,” “barfing”; volume, color, content of emesis
Severity	0 none–10 worst; mild/moderate/severe intensity; episodes per day/week/month; intermittent or constant	Frequency per day/week; volume of emesis, intensity of vomiting
Duration and pattern	Onset; pattern and timing of occurrence	
Modulating factors	What makes your nausea or vomiting better or worse (e.g., time of day, medications, eating, activity, bowel function)?	
Distress/Impact	<i>Meaning of symptom; interference with function and quality of life:</i> What and how much are you able to eat or drink? What concerns you most about the nausea and/or vomiting? What worries do you have about what is causing it? Do you have an inability to eat or drink? Are you able to eat with family/friends? When you do eat, how soon do you become full or satisfied? Is this a change compared to prior? What effects does it have on energy and activity? Are there family concerns? What have been the effects on treatments? Have you had concerns about your appetite/weight in the past? Overweight? Underweight? History of anorexia/bulimia?	
Associated symptoms	Fever, cough, oropharyngeal secretions, dizziness, headaches, vision changes, anorexia, dysgeusia, hyperosmia, dysphagia, abdominal pain, bloating, abdominal distention, heartburn, hiccups, constipation, diarrhea, weight changes	
Physical examination	Temperature Weight: If available serial weights, comparison to past weights is helpful Neurological: Level of consciousness; cognition, balance, cranial nerve deficits Oropharynx: Mucositis, secretions, infection, obstruction Blood pressure and pulse: Sitting, lying, standing to assess for postural hypotension from fluid imbalance Abdomen: Distention, bowel sounds, tenderness, masses, ascites Rectal exam: Fecal impaction	

(continued)

Table 42.3 CONTINUED

Diagnostic tests as indicated by:	Laboratory tests for renal and hepatic function, electrolytes, calcium, sodium, potassium
• History and physical findings	Complete blood count
• patient's health status	Blood or urine cultures if infection is suspected
• goals of care	Therapeutic drug level monitoring, if appropriate (digoxin, theophylline, tricyclic antidepressants, etc.)
	Radiological studies:
	Computed tomography (CT) or magnetic resonance imaging (MRI) of brain if CNS pathology suspected
	Chest radiograph if pneumonia suspected
	Plain film of abdomen to assess for obstruction or constipation
	CT scan of abdomen to assess for obstruction, ascites, other pathologies
	Endoscopic evaluation to assess for reflux, esophagitis, obstruction

CASE STUDY: NAUSEA AND VOMITING
(CONTINUED)

Chad described persistent, worsening, continuous, moderate-level (5–6/10) nausea in the past 4 weeks. Over the past 3 days, the nausea was accompanied by vomiting of moderate amounts of regurgitated food/liquid or green, sour liquid once or twice each day. Vomiting did not relieve the nausea. He noticed the symptoms were worse when he ate, so he restricted his oral intake, resulting in a 6-pound weight loss in the past month. His bowels were normal for him, having a bowel movement every 2–3 days. He noted some abdominal bloating, which he attributes to gas and “not eating much.” He felt abdominal pressure and had an increased abdominal pain, 6/10 at best and 9/10 worst intensity. He periodically modified his normal activities around the house and declined social activities because of worsening tremors and increasing fatigue.

Chad’s medications included carbidopa 25 mg/levodopa 100 mg tablet 4 times per day, long-acting morphine tablets 60 mg orally every 12 hours for malignant pain (in the lung and liver), immediate-release morphine 15 mg tablets every 4 hours as needed for moderate to severe pain, senna 2 tablets taken at night, prochlorperazine 10 mg tablet every 6 hours as needed for nausea and/or vomiting, and omeprazole 20 mg tablet daily in the morning. He was opioid-tolerant and had increased the immediate-release morphine due to worsening pain the past 2 weeks. He was in between his chemotherapy cycles at this time.

Chad’s assessment and physical exam revealed weight loss; increased upper extremity and hand tremor; abdominal distention, with palpation tenderness to the right upper quadrant of the abdomen; pain at 6/10; and nausea. Restaging scans completed 6 weeks earlier showed stable liver metastasis. His laboratory studies were unremarkable. The symptom diagnosis was N/V likely related to increased morphine use and opioid-induced constipation. There was a concern for worsening performance status as well.

MANAGEMENT STRATEGIES

The goal of antiemetic therapy is to modify or alleviate the patient’s experience of N/V by reducing the incidence and severity of both, addressing symptom-related distress, and

modifying or eliminating the cause if possible. Broad categories of interventions include patient and family education, psychosocial and spiritual support, behavioral and lifestyle changes, medications, invasive procedures, and etiology-directed therapies. The suspected cause of the N/V, the patient’s general condition, comorbidities, current medications, prognosis, goals of care, and the patient’s preferences and available resources guide selection of interventions. Table 42.4 summarizes management approaches.

INTERVENTIONS

If the etiology of N/V is diagnosed, it is beneficial to treat the underlying cause(s). The corrective action of the symptom burden treats the patient with enhanced medical optimization.¹ Multimodal management of N/V is often viewed as the mainstay of therapy. When medications are being considered, the personalized medication administration route is a thoughtful patient- and APRN-shared decision. Alternative to the oral route, medication administration that can be considered include sublingual, oral dissolvable tablets, intravenous, subcutaneous, transdermal, suppository, and rectal. The palliative APRN’s multimodal and holistic approach encompasses nonpharmacologic and integrative interventions which are safe and personalized to the individual. For all interventions that are considered, the palliative APRN should be mindful to assess accessibility and financial burdens to the patient. Patient and family education centers on causes of N/V for the individual, realistic goals for symptom control, and implementation of the symptom management plan. This may include specific instructions regarding how and when to use medications, other therapies, and self-monitoring journals.³ Patients and families also receive support and education about how to contact the care team for unexpected or emergent situations.

Nonpharmacologic Interventions

Psychosocial and spiritual support centers on acknowledging the quality of life and functional concerns as well as symptom distress; it that focuses on the meaning and implications of the symptom for the patient. Nursing’s presence and understanding the symptom control plan help to decrease the patient’s

Table 42.4 APPROACHES TO MANAGING NAUSEA AND VOMITING IN PALLIATIVE CARE

Identification and management of etiology and contributing symptoms	
Patient and family education	Likely causes of nausea and vomiting for this patient Functional and exercise goals for symptom management Directions re: specific interventions and self-monitoring, including emergent situations (e.g., symptom journal) Information about how to contact clinical care team
Psychosocial and spiritual support	Acknowledge the psychological, social, cultural, and religious impact of nausea and vomiting as appropriate for patient and family. Refer to social worker, chaplain, or psychiatric support, if needed.
Nutrition counseling	Mouth care ^a Small, frequent meals or snacks ^a Maintain fluid intake but limit fluids with meals ^a Pleasant eating environment ^a Eat bland, cool temperature foods ^a Avoid salty, sweet, spicy foods ^a Use enriched and fortified foods to increased calories and protein. Use of commercial oral liquid nutritional supplements Consultation with qualified nutritionist
Cognitive-behavioral therapies	Includes relaxation, imagery, distraction, self-hypnosis ^b
Integrative therapies	Acupuncture ^b Acupressure ^c Ginger ^c Aromatherapy ^c Music therapy ^c Acupressure bands and relaxation music ^c
Metabolic abnormalities	Correct if possible: hypercalcemia, hypokalemia, hyponatremia.
Medications	Antiemetics see Table 42.5. Medication routes to be evaluated and considered by APRN; risk, burden vs. benefit Constipation management (see Chapter 40, “Bowel Symptoms”)
Medically administered hydration and nutrition	May benefit patients with early-stage disease who have temporary limitations in oral intake or those with GI malfunctions but high-performance status. Generally, not tolerated or beneficial in patients who have end-stage disease. Individualized goals of the therapy need to be considered.
Therapeutic Radiation	Radiation therapy for brain metastasis and other CNS conditions
Invasive procedures	For obstructions: Nasogastric tube to suction, surgery, venting gastrostomy tubes, stents

^a Expert opinion;

^b Limited data to support use;

^c Mixed or no data to support use.

From Dalal¹; Chow et al.⁶; Tipton⁷; Glare et al.²¹; McKenzie et al.²⁷; Gyi^{32,33}; Peoples et al.³⁴; Uster et al.³⁵; Zeng et al.³⁶; Wei et al.³⁷; and Holmer Pettersson, Wengstrom.³⁸

and family's sense of loss of control and uncertainty. Involving social workers, a chaplain, and/or psychiatric support may also be helpful. Expert opinion and some research have shown that cognitive therapy is a psychological modality that eases the burdens of N/V.¹ However, due to Grade B research, best practice recommendations include using clinical judgment when referring a patient to cognitive therapy or relaxation therapy.³² Psychotherapy or counseling may be particularly helpful if medically administered nutrition and hydration, as well as invasive procedures to bypass obstructions, are being considered. Behavioral interventions, such as relaxation, progressive muscle relaxation, and guided imagery, reduce the incidence and intensity of anticipatory chemotherapy-related

N/V.³² These techniques can be taught to patients and may increase their sense of control and decrease distress.^{6,7,21}

Lifestyle changes center on self-care activities dealing with physical activity and oral intake. One study reveals that when nutrition and physical exercise are completed systematically, individuals experience a decrease in N/V intensity.³⁶ Expert opinion suggests that oral care; recommendations on the amount, types, and frequency of intake; and maintaining an environment free of emetogenic sights, sounds, and smells are key points.⁶

The use of integrative therapies has grown, although few studies have been done in palliative care populations.³⁴ In general, integrative interventions may also help with anxiety

and overall stress reduction. Most of these therapies are relatively nontoxic and can be suggested based on N/V evidence in other populations. However most are not covered by insurance. Some studies have highlighted music therapy to ease distress related to N/V. A systematic review and meta-analysis revealed that music interventions can ease anticipatory N/V, chemotherapy-induced vomiting, and other N/V burdens, but these data were mixed and limited.^{36,37}

Some studies demonstrate a reduction in the incidence of postoperative and acute CINV through acupuncture.^{1,38} Acupressure reduced acute chemotherapy-induced nausea. The use of acupressure wristbands produced mixed results.³⁶ Specifically, acupuncture, electroacupuncture, acupoint stimulation, acupressure, and transcutaneous electrical nerve stimulation were determined to all ease postoperative N/V.³⁹ Both acupressure and acupuncture could be considered within a multimodal care plan.

Interest in the spice ginger as an antiemetic exerting weak inhibition on 5-HT₃ receptors led to studies and reviews of its use in motion sickness and pregnancy- and chemotherapy-related nausea. Formulations and doses varied, as did reported side effects of heartburn, diarrhea, and bruising. The mixed study results demonstrate no clear evidence of efficacy.^{6,29} It is recommended that the APRN considers ginger as part of a multimodal approach with standard antiemetic medications.³³

If N/V is moderate to severe, recurrent, or prolonged, as with recurrent or persistent GI obstructions, the use of medically administered nutrition and hydration, electrolyte balance, or enteral or parenteral nutrition may be considered. For patients in advanced or terminal stages of disease, the use of these therapies beyond the acute phase of management is a highly individual decision based on goals of care, prognosis, and the perceived benefits, burdens, and outcomes of the interventions.⁴⁰

Pharmacologic Interventions

There are eight classes of drugs used in antiemetic therapy: dopamine receptor antagonists, including prokinetics and neuroleptics (antipsychotics), corticosteroids, serotonin receptor antagonists, NK1 receptor antagonists, cannabinoids, anticholinergics, antihistamines, and benzodiazepines (Table 42.5). There are potentially other medications not used as commonly which may be worth consideration when nausea or vomiting proves intractable (e.g., hydroxyzine). Drug selection may be guided by either a mechanistic or etiological approach or by an empiric approach. The mechanistic approach is evidence-based, utilizing an understanding of the neurotransmitters and neuroreceptors involved in the different emetic pathways and the use of drugs to block their activation/effect.¹ The empiric approach leaves antiemetic selection to the preference of the clinician. Due to limited randomized trials and low-quality studies, there is no clear evidence that one approach or antiemetic class is more effective in palliative care, particularly where the etiology of N/V may be unknown or multifactorial, and only limited studies on antiemetic efficacy in this population exist.⁴¹ Understanding the action and

side effects of the different antiemetics may guide medication selection.^{1,10,21} Regardless of the approach, if initial therapies are unsuccessful, adding or rotating to a different class of antiemetics may be beneficial. In the situation of intractable or refractory N/V, combination therapies may be considered.²¹

Dopamine receptor antagonist (D₂) antiemetics are active at the CTZ and in the gut.⁴² Commonly used drugs in this class are metoclopramide and neuroleptics such as prochlorperazine, chlorpromazine, haloperidol, and olanzapine. Metoclopramide is the drug of choice for patients who have advanced cancer and a patent GI tract.^{5,43} Except for haloperidol, most drugs in the class also block other receptors in the emetic pathway.²¹ Haloperidol is commonly prescribed for N/V and is administered via the oral, intravenous, or subcutaneous route. It should be noted that haloperidol is not absorbed through the transdermal route, relegating transdermal gel preparations such as lorazepam, diphenhydramine, and haloperidol (known as ABH Gel) ineffective and dangerous for older adults since these medications all cause significant extrapyramidal effects.^{42,44} Dopamine receptor antagonist agents may be most useful for N/V related to chemical or metabolic causes.

Extrapyramidal side effects that range from mild to moderate akathisia (subjective sense of restlessness to motor restlessness), parkinsonian-like changes (masked facies, resting tremor, cogwheel rigidity, shuffling gait, bradykinesia), dystonia (involuntary contraction of major muscles [e.g., torticollis, oculogyric crisis]), and tardive dyskinesia (characterized by lip smacking, rhythmic tongue and/or body movements, grimacing) may be associated with dopamine receptor antagonist use. Management of extrapyramidal symptoms includes discontinuing the drug or reducing the dose. Co-administering a benzodiazepine, a β -blocker, or an anticholinergic may temporarily reduce akathisia and dystonia.⁴⁵

Olanzapine, a second-generation atypical antipsychotic, targets HT₃ and histamine receptor sites. Due to the common side effect of drowsiness, olanzapine is recommended as a short-term course for N/V.⁴⁶ It is recommended to consider olanzapine when the etiology of nausea is unknown, or when refractory or chronic nausea occurs, or EPS symptoms are present.^{8,10} More research is needed to identify its benefit and risk profile when treating anti-neoplastic-induced N/V.⁴⁶

Selective 5-HT₃ (serotonin receptor subtype) receptor antagonists (e.g., ondansetron and granisetron) work on receptors in the GI tract, the CTZ, and the VC. In the palliative oncology setting, 5-HT₃ receptor antagonists are considered primary intervention for N/V caused by chemotherapy and radiation therapy that affects the digestive system organs.^{28,47} Granisetron extended-release can be beneficial with treating delayed-onset CINV.⁴⁸ The antiemetic class of 5-HT₃ receptor antagonists can also be beneficial for treating postoperative N/V, gastroparesis, and N/V related to bowel obstruction, where chemical and mechanical intestinal stimulation causes release of serotonin from enterochromaffin cells.^{9,23,48} They should also be considered if dopamine antagonist agents are ineffective or not tolerated. Constipation and QT prolongation are potential side

Table 42.5 COMMONLY USED ANTIEMETICS

DRUG	SUGGESTED DOSES AND ROUTE	PRIMARY NEURORECEPTOR AFFINITY	COMMON USE	SIDE EFFECTS/ COMMENTS
DOPAMINE RECEPTOR ANTAGONISTS				
Prokinetic agent (Metoclopramide)	Oral, ODT, IV: 10–20 mg, q6–12h	Moderate D ₂ (primarily in GI tract) Low 5-HT ₃ (only at high doses)	Gastroparesis Ileus or partial bowel obstruction	EPS; esophageal spasm; colic in GI tract obstruction; prolonged half-life in renal failure. QT prolongation. Do not use in complete bowel obstruction. Do not co-administer tricyclic antidepressant as it reverses the prokinetic effect.
Butyrophenone (Haloperidol)	Oral: 0.5–5 mg q8–12h IV: 0.5–1 mg q6–8h Caution with subcutaneous route due to risk of haloperidol crystals Not absorbed via transdermal route	High D ₂	Chemical and/or metabolic nausea Bowel obstruction	Less sedating than phenothiazines. May cause QT prolongation, EPS, or neuroleptic malignant syndrome. Dose reduction may be needed in hepatic insufficiency. Safe in renal failure.
Phenothiazine (Prochlorperazine)	Oral: 5–10 mg q6–8h PR: 25 mg q12h IV: 10 mg q6h Max dose: 40 mg/24 h	Moderate D ₂ Low H ₁	Chemical and/or metabolic nausea	EPS; headache; dry mouth; hypotension, drowsiness; QT prolongation Low oral absorption
Chlorpromazine	Oral: 10–25 q6h IV: 12.5–25 mg q6–12h	Moderate D ₂ Low H ₁	Chemical and/or metabolic nausea	More sedating than prochlorperazine; EPS; QT prolongation
Atypical antipsychotic (Olanzapine)	Oral: 2.5–10 mg q12–24h	D ₁₋₄ , 5-HT ₃ , H ₁	Refractory nausea/vomiting	Sedation; hyperglycemia; reduced seizure threshold. Associated with weight gain and improved appetite. Lower risk of EPS QT prolongation
CORTICOSTEROID				
Dexamethasone	Oral: 2–4 mg q6–24h IV: 2–4 mg q6–24h	Possibly reduces release of serotonin or activation of corticosteroid receptors in the CNS	Cerebral edema Intracranial tumors Chemotherapy-induced nausea Bowel obstruction	Insomnia; anxiety; euphoria; perirectal burning with IV administration; GI upset; metabolic effects: glycemic changes; infection risk Abrupt discontinuation can cause rebound N/V
Methylprednisolone	See dosing per immunotherapy guidelines.	Anti-inflammatory glucocorticoid used in replacement therapy of adrenocortical deficiencies	Recommended for use of immunotherapy induced N/V and other immunotherapy side effects	Hypertension; body fluid retention; HF; euphoria. Metabolic effects: glycemic control, infection risk. Do not abruptly discontinue; can cause rebound N/V.

(continued)

Table 42.5 CONTINUED

DRUG	SUGGESTED DOSES AND ROUTE	PRIMARY NEURORECEPTOR AFFINITY	COMMON USE	SIDE EFFECTS/ COMMENTS
SEROTONIN ANTAGONISTS				
Ondansetron	Oral/ODT/IV: 4-8 mg q8–12h	High 5-HT3 Both peripherally and centrally	Chemotherapy-induced nausea; delayed-onset of chemotherapy induced N/V Abdominal radiation therapy Postop GI irritants	Constipation Headache Diarrhea Mild sedation QT prolongation
Granisetron	Oral/IV: 1 mg q12h or 2 mg q24h Transdermal patch: 3.1 mg/24 h (lasts 7 days)			
NK1 RECEPTOR ANTAGONISTS				
Aprepitant	125 mg PO chemo day 1, 80 mg PO on chemotherapy day 2 and day 3; give 1 hour prior to chemotherapy Oral capsule, oral suspension, and IV formulations are available. See NCCN guidelines. Dose and frequency of medication are dependent upon risk category of emetogenic chemotherapy and chemotherapy schedule.	P/neurokinin 1 (NK1) receptor antagonist with high selectivity and affinity	Chemotherapy-induced nausea and vomiting, for highly emetogenic and moderately emetogenic chemotherapy Postoperative nausea and vomiting	Hypotension; constipation; diarrhea, asthenia; abdominal pain.
Fosaprepitant	150 mg IV, given with dexamethasone 12 mg orally 30 minutes prior to chemotherapy day 1 and concurrent 5-HT3 receptor antagonist. See NCCN guidelines. Dose and frequency of medication are dependent upon risk category of emetogenic chemotherapy and chemotherapy schedule.	Pro-drug of aprepitant, which is a selective, high-affinity antagonist of human substance P/ neurokinin 1 (NK-1) receptors	Chemotherapy-induced nausea and vomiting, for highly emetogenic and moderately emetogenic chemotherapy	Diarrhea; fatigue; neutropenia; infusion reaction; Stevens-Johnson syndrome.
Rolapitant	180 mg PO within 2 hours of chemotherapy, day 1 and every 2 weeks. Concurrent use of dexamethasone and 5-HT3 receptor antagonist. See NCCN guidelines. Oral capsule and IV formulations are available. Dose and frequency of medication are dependent upon risk category of emetogenic chemotherapy and chemotherapy schedule.	Selective and competitive P/ neurokinin 1 (NK1) receptor antagonist with antiemetic activity. Crosses the blood–brain barrier and occupies brain NK1 receptors	Chemotherapy-induced nausea and vomiting, In combination with other antiemetic agents; including highly emetogenic chemotherapy	Decrease in appetite; neutropenia; dizziness; hiccoughs.
Netupitant/ Palonosetron	300 mg/0.5 mg PO 1 hour prior to chemotherapy on day 1; administration of dexamethasone day 1–4 of chemotherapy. See NCCN guidelines. Dose and frequency of medication are dependent upon risk category of emetogenic chemotherapy and chemotherapy schedule.	P/neurokinin 1 (NK1) receptor antagonist, and palonosetron, a selective serotonin-3 (5-HT3) receptor antagonist	Chemotherapy-induced nausea and vomiting, Acute and delayed	Headache; fatigue; erythema; constipation; indigestions; asthenia; serotonin syndrome.

Table 42.5 CONTINUED

DRUG	SUGGESTED DOSES AND ROUTE	PRIMARY NEURORECEPTOR AFFINITY	COMMON USE	SIDE EFFECTS/ COMMENTS
Fosnetupitant/ Palonosetron	235 mg/0.25 mg IV over 30 minutes, starting 30 minutes prior to chemotherapy. administration of dexamethasone day 1–4 of chemotherapy. See NCCN Guidelines. Dose and frequency of medication are dependent upon risk category of emetogenic chemotherapy and chemotherapy schedule. Decadron also given prior to chemotherapy.	Active metabolite of Fosnetupitant is a selective substance P/neurokinin 1 receptor antagonist. Palonosetron is a 5-HT3 receptor antagonist	Chemotherapy-induced nausea and vomiting, Acute and delayed, associated with highly emetogenic chemotherapy	Headache; fatigue; asthenia; constipation; indigestion; erythema; hypersensitivity reaction; serotonin syndrome.
CANNABINOIDS				
Dronabinol	2–10 mg q8–12h Contains sesame oil	CB ₁	Second-line antiemetic	Sedation; dizziness; disorientation; concentration difficulties; euphoria; dysphoria; hypotension; dry mouth; tachycardia.
Nabilone	1–2 mg q8–12h (max dose 6 mg/day)	CB ₁	Second-line antiemetic	
ANTICHOLINERGICS				
Hyoscyamine	Oral/IV: 0.125–0.25 mg q4h as needed up to 1.5 mg/day	mAChR (in the vomiting center and peripherally)	Intestinal obstruction Peritoneal irritation, Increased intracranial pressure	Dry mouth; ileus; urinary retention; blurred vision; agitation.
Scopolamine	Transdermal: 1.5 mg q72h (lasts 72 h)		Excess secretions Motion sickness	Onset of effect is up to 24 h. Crosses the blood-brain barrier: common side effects are confusion and sedation.
ANTI-HISTAMINES				
Promethazine	Oral, PR, or IV: 12.5–25 mg q6–8h (max dose 100 mg/day)	High H ₁ Low D ₂ Low mAChR	Motion sickness Increased intracranial pressure	Drowsiness Sedation Dry mouth Constipation Dizziness Confusion Blurred vision
Cyclizine	Oral: 25–50 mg q6–8h (max dose 200 mg/day)	H ₁		
Diphenhydramine	Oral/IV: 12.5–50 mg q6–8h			
BENZODIAZEPINE				
Lorazepam	Oral/IV: 0.5–1 mg q6–24h	GABA	Anxiety Not FDA approved as antiemetic	Sedation; amnesia; delirium. Depression. Reduce dose in renal or hepatic insufficiency. Not FDA approved as an antinausea or antiemetic.
OTHER				
Octreotide (somatostatin analogue)	SC: 100–150 mg q8h IV continuous infusion: 0.2–0.9 mg/day IM depot: 20–30 mg q3–4 weeks	Somatostatin receptors in brain, pituitary, GI tract	Bowel obstruction. Reduces peristalsis and intestinal secretions	Pain at injection site; worsening GI symptoms. Reduce dose in renal or hepatic insufficiency.
Mirtazapine (antidepressant)	Oral: 7.5–30 mg at bedtime	5-HT ₃ , H ₁ , mAChR	Gastroparesis	Increased appetite; weight gain, somnolence.

ODT, oral disintegrating tablet; D₂, dopamine; H₁, histamine; 5-HT₃, serotonin; CB₁, cannabinoid; mAChR, muscarinic acetylcholine receptors; EPS, extrapyramidal side effects.

effects.^{7,20,47,48} Insurance coverage may be a factor in access to these medications.^{7,47}

Antihistamines block H₁ receptor activity at the CTZ and the VC. They are primarily used to manage N/V caused by vestibular stimulation (e.g., motion sickness, raised intracranial pressure). Promethazine, cyclizine, meclizine, and diphenhydramine are commonly used agents. Sedation and anticholinergic side effects may limit use, particularly the potential for falls and delirium in older adults.^{7,21}

Anticholinergic agents are primarily used as antiemetics in combination with other antiemetics for control of N/V associated with dizziness and movement and bowel obstruction.^{4,32} They block muscarinic acetylcholine receptors (mAChR) in vestibular nuclei and the autonomic nervous system, resulting in decreased peristaltic tone and movement and reduced intestinal secretions.^{4,35} Hyoscyamine and scopolamine are commonly used drugs in this class.

Corticosteroids are often used in antiemetic regimens for CINV, RINV, symptom management in bowel obstruction, and in treatment of raised intracranial pressure. The antiemetic mechanism of these agents is not known. Theorized actions include anti-inflammatory and antisecretory activity and altered permeability of the blood-brain barrier with reduced effect of potential chemical and metabolic stimuli. Dexamethasone with ondansetron, a 5-HT₃ receptor antagonists, has been shown to treat RINV.²⁷ Concerns about gastric irritation, glycemic control, infection risk, proximal muscle weakness with long-term use, and dysphoria and/or delirium may limit their use.²⁰

Cannabinoids' activity at the CB₁ receptors in the central and peripheral nervous systems is thought to be the basis of their antiemetic effect. Dronabinol and nabilone are approved by the US Food and Drug Administration (FDA) for use in CINV.^{35,36} Cannabinoids are not recommended as first- or second-line antiemetic interventions.^{49–51} The effectiveness of other cannabinoid formulations, such as medicinal or recreational state programs, are not established. Cannabis remains a schedule 1 substance despite legalization for medical and recreational purposes in some states. When considering medicinal cannabis, the palliative APRN should implement shared decision-making with the patient. It is recommended to consider financial burdens, state legislation, and patient preferences.⁵⁰ Reports of cannabinoid hyperemesis syndrome (CHS) with chronic cannabis use raise the need for further study of this antiemetic class.⁵²

Neurokinin-1 receptor antagonists are FDA approved for use in acute and delayed CINV and in the postoperative setting. Drugs in this class are aprepitant, fosaprepitant, and netupitant. Neurokinin-1 receptor antagonists are recommended in conjunction with other antiemetics. Combination therapy is recommended to treat moderate to high-risk emetic anti-neoplastic-associated interventions.⁵³ A combination of NK1 receptor agonists, such as aprepitant, and a 5-HT₃ receptor agonist, such as granisetron, has been shown to relieve chemotherapy- and radiation associated N/V.^{27,28} Other multi-class emetic medications, such as netupitant and palonosetron (NEPA), have also been found to ease CINV. Research is still being conducted to evaluate the routine clinical use of NEPA.⁵⁴

Benzodiazepines act on GABA in the cerebral cortex. They are effective in managing anxiety associated with N/V but do not have antiemetic activity.^{12,35} Side effects of sedation and amnesia may limit use. Mirtazapine, a tetracyclic antidepressant, has activity as a 5-HT₃, H₁, and muscarinic receptor antagonist. Reports of its antiemetic effect in diabetic gastroparesis and idiopathic nausea are indicative of a prokinetic effect that needs further study in the palliative care population.²¹

CASE STUDY: NAUSEA AND VOMITING (CONTINUED)

Initial interventions for Chad's presumed opioid-induced constipation focused on his bowel regimen: senna 2 tablets twice a day and lactulose 30 mg solution 1–3 times a day, with a goal of a bowel movement at least every other day. Due to the increasing duration and intensity of the N/V, his antiemetic was changed. Prochlorperazine was discontinued and replaced by mirtazapine 7.5 mg tablet at night, for its pro-kinetic effect, which enhanced the bowel regimen. This antiemetic rotation was aimed to benefit Chad's performance status because the prochlorperazine could have been interacting with his Parkinson's disease medications, carbidopa/levodopa.

MANAGEMENT OF GASTROPARESIS-INDUCED N/V

Concurrent treatment for the primary etiology of gastroparesis and gastroparesis-induced N/V is recommended. Evidence has found that transdermal granisetron eases N/V and other associated symptoms such as postprandial fullness, upper abdominal pain, early satiety, and loss of appetite.²³ Motility agents such as metoclopramide or mirtazapine can be considered. Specifically, the pro-motility effect of metoclopramide on the upper GI tract and its activity at the CTZ make it a useful first-line antiemetic.⁵⁵ However, it should be avoided in patients with complete bowel obstruction.²¹

MANAGEMENT OF OPIOID-INDUCED N/V

There is limited evidence to guide management of opioid-induced N/V.^{56,57} These symptom burdens may result from gastroparesis, constipation, CTZ stimulation, and/or vestibular stimulation. Some experts observe that opioid-induced N/V may be time limited, with symptoms easing within 5–7 days of starting the opioid.⁴¹ In the acute setting, concurrent or preemptive use of metoclopramide to ease morphine-induced N/V was not recommended. With use of metoclopramide, there was an increase in dizziness without reducing morphine-induced N/V.⁵⁸ A preliminary study retrospectively identified that administering naldemedine tosylate, a peripheral acting nonselective opioid receptor antagonist, could have secondary benefits and help ease early-onset opioid-induced N/V.⁵⁹ Given limited evidence, managing associated symptoms, such as constipation and anticipatory N/V, by preemptively treating the symptoms

can still be considered. Although there are no specific recommendations in the literature, opioid rotation also seems reasonable.^{41,57} Higher quality research is needed to guide management of opioid-induced N/V.

CASE STUDY: NAUSEA AND VOMITING
(CONTINUED)

After 7 days, Chad's tremors improved and he was able to better participate in his usual activities. He started to have more frequent but liquid bowel movements. His nausea intensity lessened to 3–4/10 after episodes of vomiting. He associated vomiting with oral nutritional intake.

Physical exam revealed increased abdominal distention, and, upon palpation, abdominal pain extended from the right upper quadrant to the right lower quadrant. His bowel sounds were infrequent and periodically high-pitched. A CT scan of his abdomen showed partial bowel obstruction secondary to disease progression.

MANAGEMENT OF
CHEMOTHERAPY-INDUCED
NAUSEA AND VOMITING

Chemotherapy-induced N/V (CINV) is a common adverse and stressful side effect that individuals experience. Both acute- and delayed-onset N/V are associated with anti-neoplastic treatments. The American Society of Clinical Oncology (ASCO) and National Comprehensive Cancer Network (NCCN) are the clinical organizational leaders that provide best practice and expert opinion and compile evidence-based antiemetic guidelines.^{22,60} Updated research and clinical guidelines support using a multiple classes of antiemetic medications to prevent and ease CINV. Considering the high emetic risk, a combination of an NK-1 receptor antagonist and a 5-HT₃ receptor antagonist, along with dexamethasone and olanzapine were found to prevent, treat, and overall ease CINV.⁸ Cannabinoids have insufficient evidence and are therefore not recommended to treat CINV.⁴⁹ Some findings have reported undermanagement of CINV events.⁶¹ It is best practice for the palliative APRN to develop an antiemetic care plan that is personalized to the patient and aligned with the known emetic risk profile of the chemotherapy being administered.⁸

MANAGEMENT OF CANNABINOID
HYPEREMESIS SYNDROME

CHS has become more common as medicinal and recreational laws have increasingly been passed by state legislatures. A systematic review of literature identifies that management of CHS can be difficult. The palliative APRN should provide CHS education about the etiology and treatment of CHS. Recommendations to treat CHS include the individual decreasing or eliminating the use of cannabinoids and consideration for the use lorazepam as an anticipatory antiemetic or haloperidol or topical capsaicin to relieve vomiting.⁵² In general, the prevalence of cannabis use is likely to increase

so additional high-quality research is needed to establish evidence-based guidelines.

MANAGEMENT OF BOWEL OBSTRUCTION

Bowel obstruction requires immediate intervention. Decisions about surgical, interventional, and/or medical management are based on the etiology of the obstruction and the patient's condition and goals of care. Symptom management in bowel obstructions focuses on relief of pain, N/V, and abdominal distention. Surgical interventions for bowel obstructions are intended on removing or minimizing the tumor burden. Postsurgical morbidity, mortality, and reobstruction are all common risks and burdens.²⁶ If the bowel obstruction is deemed to be inoperable, the palliative APRN should review illness severity, trajectory, prognosis, and other recommended interventions with the patient.²⁵

If surgical options are not appropriate, the use of venting gastrostomy tubes or stents may offer symptom relief. If the patient has a high-performance status, life expectancy greater than 30 days, and an obstruction at the gastric outlet, proximal small bowel, or colon, then insertion of self-expanding metal stents placed via endoscopy or interventional radiology may be considered. Although often successful in relieving symptoms, stents may cause perforation and bleeding; if the stent migrates, reobstruction may occur.^{26,62} Prolonged nasogastric intubation is possible to relieve distention and vomiting but is limited by discomfort from nasal and pharyngeal irritation and/or infections, difficulty clearing oral secretions, and aspiration pneumonias. An alternative is a venting gastrostomy tube (g-tube) that is placed surgically or percutaneously during an endoscopic procedure to allow drainage of gastric contents. With a venting g-tube in place, limited oral intake may be tolerated, which can be psychosocially satisfying for both the patient and family. Large-volume ascites, carcinomatosis, and tumor infiltration of the stomach may preclude g-tube placement. Complications include pain at the insertion site, leakage of gastric fluid with resulting skin irritation, and the need for periodic replacement if used in long-term therapy^{62,63} (see Chapter 40, "Bowel Symptoms," for further information).

CASE STUDY: NAUSEA AND VOMITING
(CONTINUED)

Acutely, Chad's new diagnosis of partial bowel obstruction was managed with a nasogastric tube (NGT) to intermittent wall suction and bowel rest. In addition, he received intravenous dexamethasone 6 mg in the morning, prior to breakfast, and intravenous ondansetron 4 mg every 6 hours for breakthrough nausea and/or vomiting. He also received octreotide, which he initially received as subcutaneous injections followed by a depot/long-acting form to prevent recurrent obstructive symptoms. Short-acting doses were continued while it took effect. With consultation from Chad's neurologist, intravenous metoclopramide, for its prokinetic effect was considered. However, it was not administered as his symptoms improved.

Chad resumed palliative chemotherapy to treat the tumor. He continued his optimized bowel regimen and opioid pain management plan, as well as oral mirtazapine and depot octreotide to minimize recurrent symptoms.

SUMMARY

N/V is highly distressing that many palliative care patients experience as a result of disease or therapies, even those that are palliative- or symptom-focused. The palliative APRN provides expert, compassionate clinical care while contributing to the expanding evidence base for managing these symptoms in palliative care. Successful management of these complex symptoms requires that the APRN conducts an ongoing comprehensive assessment to describe the patient's experience and associated factors, formulate a symptom diagnosis based on an understanding of likely etiologies, and use appropriate nonpharmacologic and pharmacologic management strategies based on best evidence, expert opinion, and patient acceptability.

PAIN

Judith A. Paice

KEY POINTS

- Expert assessment skills, including highly developed history-taking and physical examination skills, are essential to effective pain management in palliative care
- Palliative advanced practice registered nurses (APRNs) with comprehensive knowledge of pain management options can prescribe appropriate therapies, educate patients and families regarding safe and effective medication use, and consult colleagues who might provide other essential interventions, such as physical or occupational therapy, interventional techniques, cognitive-behavioral strategies and integrative therapies.
- Safe prescribing practices are vital for patients, families, and society at large.

hydrocodone/acetaminophen was changed to oxycodone to reduce potential toxicities associated with excess acetaminophen. After consistent use of oxycodone, a fentanyl patch was added to provide a baseline level of relief. Radiotherapy was consulted for palliation of bone metastases. A home palliative nurse was consulted to ensure his environment was safe, provide ongoing assessment of pain, and reinforce teaching. Transition to hospice occurred when disease progressed, and he died peacefully.

INTRODUCTION

Pain is greatly feared by those experiencing a life-threatening illness. In most cases, patients and their loved ones can be reassured that this symptom can be relieved, but in some cases pain can be extremely challenging to control. This is in part because the subjectivity of the pain experience, along with the absence of specific laboratory or imaging markers, complicates assessment and management. The biopsychosocial model of pain provides a framework that can guide palliative APRNs in understanding the many variables that contribute to the experience of pain (Figure 43.1).^{1,2} Biological, psychological, social, and spiritual factors should be considered part of a complete assessment and serve as a guide for development of a comprehensive plan of care.

The palliative advanced practice registered nurse (APRN) is in a unique position to provide this “whole-person” care. Blending knowledge of the common pain syndromes seen in life-threatening illness, sophisticated assessment skills, and awareness of interventions used to relieve pain while employing stellar education and communication strategies, the APRN can provide safe and effective pain relief for the majority of palliative care patients with pain.

GOALS OF PAIN MANAGEMENT

The goals of comprehensive and effective pain management include prevention of pain, relief of pain, improved function and quality of life, safety, and the prevention of adverse societal effects (such as diversion). In a perfect world, all pain would be prevented. Yet acute pain serves as an important warning sign. Therefore, although preventing acute pain is neither reasonable nor desired in all circumstances, there are situations in palliative care where the APRN can work to

CASE STUDY

Mr. J was a 66-year-old African-American man with metastatic non-small-cell lung cancer for whom a full pain assessment was conducted. He recently developed right hip pain and was found to have a pathologic fracture of the right femur, which was treated with open reduction and internal fixation and x-ray therapy (XRT) 3 months prior. This pain had resolved, but he then presented with low back pain and right rib pain these were consistent with sites of metastatic disease on his positron emission tomography (PET) scan. The back pain was distributed over the low lumbar area, described as aching without radiculopathy. The intensity was 2 at rest but 8 when standing for more than a few minutes. The rib pain was also aching and throbbing and was worse when lying on that side or taking a deep inspiration. He had been given hydrocodone/acetaminophen with little relief, although he took less than the prescribed dose. He denied adverse effects. Further investigation revealed no personal history of substance misuse, but his son had died from a heroin overdose. He was extremely worried about becoming addicted and anxious regarding constipation. Review of the prescription drug monitoring program revealed only a few refills of small amounts of hydrocodone, all prescribed by his oncologist. Urine toxicology was negative except for opioids.

Extensive education provided by the palliative advanced practice registered nurse (APRN) reassured Mr. J about safe medication use and storage. Constipation prevention and management were discussed and a bowel program was initiated. The

Figure 43.1 The biopsychosocial model of pain.

From Sutton LM, Porter LS, Keefe FJ. Cancer pain at the end of life: A biopsychosocial perspective. *Pain*. 2002;99(1–2):5–10¹; and Syrjala KL, Jensen MP, Mendoza ME, Yi JC, Fisher HM, Keefe FJ. Psychological and behavioral approaches to cancer pain management. *J Clin Oncol*. 2014;32(16):1703–1711.²

develop strategies to prevent pain. Procedural pain, such as that experienced with bone marrow aspiration or other interventions, can be reduced or prevented with adequate local and/or systemic analgesics, education, and preparation. There is ample evidence that unrelieved postoperative pain correlates with chronic pain syndromes, such as post-mastectomy pain.³ Thus, prevention of acute pain may preclude or limit persistent pain syndromes.

When pain cannot be prevented, relief is imperative. This requires a balance among analgesia, increased function, and safety, and these goals are based on the state of the patient's illness. For the actively dying, the scale may tip toward analgesia, with less emphasis on function. For the patient who is a long-term survivor, the goal of enhanced function supersedes complete pain control.⁴ Regardless of the patient's overall stage of disease, safety needs are paramount. Adverse effects must be prevented, minimized, or controlled. Medications must be used by the patient, and only the patient, in a manner that will limit untoward events. This includes preventing access to controlled substances by family, friends, caregivers, or others for inappropriate use (sharing with others or selling the medications).^{5,6}

PAIN SYNDROMES IN PALLIATIVE CARE

An awareness of common pain syndromes seen in life-threatening illness assists the APRN in identifying the etiology and guides treatment.^{7,8} Differentiating acute from chronic syndromes will help determine the course and treatment options. Specific pain syndromes common in those with cancer have been identified, but unfortunately the types of pain associated with other life-threatening illnesses have not been fully categorized (Table 43.1).^{9–11} Understanding the

Table 43.1 SELECTED CANCER PAIN SYNDROMES

Tumor-Related Pain Syndromes

- Bone metastases
- Hepatic capsule distention due to metastases
- Plexus involvement by tumor

Treatment-Related Pain Syndromes

Surgical Pain Syndromes

- Post-amputation phantom pain
- Post-thoracotomy pain
- Post-mastectomy pain

Radiation-Related Pain Syndromes

- Chest pain/tightness
- Cystitis
- Enteritis
- Fistula formation
- Myelopathy
- Osteoporosis
- Osteoradionecrosis
- Pelvic fractures
- Peripheral nerve entrapment
- Plexopathies
- Proctitis
- Secondary malignancies

Chemotherapy-Related Pain Syndromes

- Chemotherapy-induced peripheral neuropathy
- Osteonecrosis from corticosteroids

Stem Cell Transplant-Mediated Chronic Graft-versus-Host Disease

- Scleroderma-like skin changes
- Eye pain and dryness
- Oral pain and reduced jaw motion
- Dysuria
- Dyspareunia, vaginal pain
- Paresthesias
- Arthralgias, myalgias

Hormonal Therapy-Related Pain Syndromes

- Osteoporotic compression fractures
- Arthralgias

Pain Unrelated to Tumor or Treatment

- Comorbid conditions, such as diabetic neuropathy, arthritis

From Paice⁴; Paice et al.^{6,11}

etiology may lead to treatment options beyond analgesic therapies, such as radiotherapy for new bone metastases or surgery to repair joints affected by avascular necrosis (discussed later in this chapter).

Another strategy for grouping pain syndromes is by their quality: somatic, neuropathic, visceral, or mixed.⁸ Understanding the quality of the patient's pain informs the analgesic regimen. One paradigm is as follows:

- *Somatic pain*: Usually managed by non-opioids and opioids
- *Neuropathic pain*: Treated with adjuvant analgesics and opioids (little or no response to non-opioids)
- *Visceral pain*: May be controlled by opioids and, in some cases, corticosteroids or other adjuvant analgesics

PAIN ASSESSMENT

The APRN is uniquely trained to obtain a comprehensive pain assessment in palliative care. This includes a thorough history, a careful physical examination, and, in some cases, interpretation of laboratory values or imaging results.^{12–14} The history can be guided by the biopsychosocial model, considering all components of the pain experience. Box 43.1 provides a sample template for a comprehensive pain assessment.

While conducting a thorough history, it is useful to consider those patients at risk for inadequate assessment and management of pain (Box 43.2).^{15–17} The use of tools designed for special populations can improve the accuracy of assessment findings. Table 43.2 provides a list of instruments designed to assess pain in adult populations at risk for inadequate assessment.¹⁸

The physical examination begins when first meeting the patient. Observing the patient's gait while they approach the examination room or evaluating posture while sitting or lying in bed provides essential information. Pay special attention to nonverbal cues of pain. This is followed by close inspection of painful sites, evaluating areas of trauma, skin breakdown, changes in bony or joint structures, and trophic changes, such as reduced hair growth or thickened nails. Palpate areas for tenderness or masses (including signs of obstipation). Perform range of motion in affected extremities to determine if there are contractures or disorders of the joint that elicit pain. Auscultation can reveal crackles, rhonchi, or decreased breath sounds that may signal painful respiratory complications (such as pneumonia) or hyperactive bowel sounds, suggesting bowel obstruction. Percussion can assist in revealing fluid accumulation in ascites. A careful neurological evaluation can identify allodynia, dermatomal distribution of pain, and other sensorimotor changes.

Coupled with a thorough physical examination, radiographic studies and laboratory evaluation may be useful in identifying the etiology of pain. However, these tools may not be readily accessible in all settings, they may place the patient at risk for discomfort (e.g., lying on a hard table

Box 43.1 TEMPLATE FOR COMPREHENSIVE PAIN HISTORY DOCUMENTATION

Chief Report

Mr. J is a 56-year-old African-American male diagnosed with metastatic non-small-cell lung cancer (NSCLC) after experiencing a chronic cough that did not resolve with antibiotic therapy; we were asked to see him by Dr. Washington for concerns related to back pain. Briefly, he was diagnosed with NSCLC 8 months ago and underwent 4 courses of chemotherapy (carboplatin and pemetrexed). He recently developed right hip pain and was found to have a pathologic fracture of the right femur that was treated with open reduction and internal fixation and x-ray therapy (XRT) 3 months ago. He now presents with low back pain and right rib pain which are consistent with sites of metastatic disease on recent positron emission tomography (PET) scan.

Pain History

Location(s), referral, radiating pattern
Duration
Intensity (last 24 hours, at rest, with movement)
Quality
Timing
Aggravating/alleviating factors
Other symptoms associated with pain
Functional changes/interference with daily activities

Current Therapies

- Medications duration, response
- Radiation therapy
- Other nerve blocks, kyphoplasty/vertebroplasty, physical therapy (PT)/occupational therapy (OT), acupuncture, etc.

Prior Treatment, Response, Adverse Effects, Reason for Discontinuing

- Medications dose, duration, adverse effects
- Radiation therapy (sites)
- Other nerve blocks, kyphoplasty/vertebroplasty, PT/OT, acupuncture, etc.

Past Medical History

The PMH includes *relevant* serious illness, chronic diseases, surgical procedures, and injuries the patient has experienced.

Social History

Marital status/partnered
Children/grandchildren
Type of home (access), who lives in home, who provides support
Work history, education

Substance Use History

Smoking
Alcohol consumption (ETOH)
Cannabis medical card, adult use
Recreational drug use
Family history of addictive disease
Physical, emotional or sexual abuse, especially as preteen or teenager; post traumatic stress disorder (PTSD)

Medication History

Current medications, including prescription and nonprescription medications, name and dosage for each.

Review of Systems

Perform a review of symptoms (ROS) that may occur along with pain. May use Edmonton Symptom Assessment Scale (ESAS) or other symptom assessment tool in place of ROS. The following is the ROS for Mr. J.

GENERAL: Endorses fatigue, sleep

HEENT: Xerostomia, denies dysphagia

CV: Denies chest pain

RESP: Denies SOB, cough

GI: Last BM x days ago, consistency x , appetite [poor/good], nausea and vomiting

GU: Denies urgency, frequency, incontinence, or dysuria

MS: Denies tripping or falls

NEURO: Denies neuropathy

SKIN: Denies rash or open wounds

PSYCH: Endorses feeling sad/depressed, finds strength through [name the focus, strategy, or intervention]

Performance Status

May use ECOG, Karnofsky, Palliative Performance, Scale or other tool. This helps determine function and prognosis and track change over time.

Physical Exam

List the physical assessment findings that are “remarkable” or contribute to understanding the pain experience and/or etiology.

Patient Goals

What the patient hopes to achieve if pain is relieved (e.g., return to work, play with grandchildren, go to church).

Impression/Recommendations

PHARMACOLOGIC MANAGEMENT OF PAIN

There are three broad categories of medications used to relieve pain: non-opioids, opioids, and adjuvant analgesics. In most cases, a strong analgesic regimen employs multimodal therapies, including more than one pharmacologic agent along with nonpharmacologic strategies. The palliative APRN with prescribing privileges must adhere to safe prescribing principles as well as bearing in mind financial and regulatory concerns.

NON-OPIOIDS

Acetaminophen (also called paracetamol) is analgesic and antipyretic and is found in a variety of combination prescription and over-the-counter compounds. These may include admixtures with opioids (e.g., acetaminophen with codeine, hydrocodone, or oxycodone), or over-the-counter cold, sinus, or sleep remedies (e.g., acetaminophen with diphenhydramine). Hepatic toxicity can result from excessive use, and a firm limit on daily consumption has not been established.^{20,21} Some sources recommend no more than 2,000 mg per day, while others suggest up to 3,000 mg may be safe. This needs to be tailored to the patient. Altered hepatic function, excessive alcohol intake, and other comorbid factors may place some patients at elevated risk, and these individuals should be advised to avoid acetaminophen. Renal toxicity is another potential adverse effect of this agent. Acetaminophen is available in oral formulations (including liquids), suppositories, and an injectable formulation which has been used to treat pain and fever.²² The adult dosage (adults weighing >50 kg) is 1 g given intravenously every 6 hours with a maximum of 4 g per day; patients with renal or hepatic disease should be given a decreased dose or should avoid this drug. The price may preclude use in many palliative care settings.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are analgesic, antipyretic, and anti-inflammatory. They are generally useful for nociceptive or musculoskeletal pain syndromes.^{22–24} Adverse effects include gastrointestinal bleeding (which can be prevented with the addition of a prostaglandin analog or a proton pump inhibitor), renal dysfunction, platelet aggregation abnormalities (generally reversible when stopping the drug, except for aspirin, which has an irreversible effect on platelets), and cardiovascular events, such as myocardial infarction and stroke in those at risk.^{25–27} Most NSAIDs are available in oral formulations, some in liquids or suppositories. Ketorolac is available for parenteral use and is highly potent; however, prolonged use is contraindicated due to an elevated risk of adverse effects. Topical formulations, including gels, patches, and creams, of several NSAIDs are now available over the counter or with a prescription. These formulations are generally considered to be safe with little systemic absorption.²⁸

OPIOIDS

Opioids are useful in treating nociceptive and neuropathic pain, although higher doses are generally required to relieve nerve pain.^{29,30} A wide array of opioids is available, allowing

rotation when one opioid is ineffective or produces uncontrolled adverse effects. Immediate-release agents provide faster onset to provide rescue when breakthrough pain occurs, and controlled-release products allow more constant control of pain. Various routes of administration allow personalized care when oral delivery is not feasible. Table 43.3 lists opioids available in the United States.^{8,29,31} Prevention and management of adverse events is crucial, as is education of patients, family members, and caregivers regarding safe use of these agents.³²

There are significant differences between opioids. Codeine is a prodrug and must be metabolized to morphine by the action of the CYP2D6 enzyme.^{33,34} Inadequate analgesia can result in patients who are poor metabolizers, while increased toxicity and overdose have been reported in individuals (or a breastfeeding baby) who are ultra-rapid metabolizers of this enzyme.^{35,36} Tramadol is a weak opioid agonist and a serotonin-norepinephrine reuptake inhibitor. Due to this dual action, it has a ceiling of 300 mg per day, and naloxone will not completely reverse overdose.³⁷ Tramadol should be avoided in patients with seizure risk or suicidal ideation. Dizziness is the most common adverse effect. Tapentadol is also an opioid agonist and norepinephrine reuptake inhibitor, with little action on serotonin reuptake.³⁸ Caution is warranted when adding antidepressants that act on the serotonin system to either tramadol or tapentadol to prevent serotonin syndrome. As with tramadol, naloxone will not completely reverse the effects of overdose with tapentadol.

Methadone can be a highly effective analgesic: it may prevent or limit hyperalgesia, it appears to be useful for neuropathic pain, it can be crushed and used via enteral tubes while retaining its long-acting property, and it is inexpensive.^{39,40} Several challenges complicate the use of methadone, and several guidelines recommend a palliative care consultation when considering its use. As a result, palliative APRNs must be highly skilled in the use of this opioid. Specific issues in methadone use include the long and variable half-life, which complicates dose escalation and conversions; the prolonged QTc that can result; lack of clarity on equianalgesic ratios; and many drug–drug interactions.^{40–42} Box 43.3 provides guidelines for use of this drug.^{29,42} Table 43.4 lists potential drug–drug interactions with methadone involving medications commonly employed in palliative care.^{39,41,43} Box 43.4 lists chemotherapeutic agents that can result in prolonged QTc when given in combination with methadone.⁴⁴

When analgesia is incomplete despite appropriate titration of the opioid, or when adverse effects persist despite aggressive management, opioid rotation is warranted.^{13,41–48} Box 43.5 provides general guidelines for opioid rotation. An excellent handbook is available to guide the APRN who is new to equianalgesic dosing: *Demystifying Opioid Conversion Calculations: A Guide for Effective Dosing*.³¹ Although online calculators are available, the palliative APRN must thoroughly understand the calculations to provide safe dosing and to teach other colleagues how to use them appropriately.

ADJUVANT ANALGESICS

Adjuvant analgesics include agents that have other purposes but have been found to be analgesic, primarily in the management of neuropathic pain. Table 43.5 includes common agents, starting doses, and potential adverse effects.^{8,13,41,49,50} Because

these agents act via different mechanisms, patients with complex pain may require multimodal therapy that includes one agent from each drug class. There are few studies exploring the efficacy of these drugs in the palliative care setting, and results often conflict with observations from clinical practice.

Box 43.3 METHADONE PRESCRIBING RECOMMENDATIONS

- Opioid-naïve
 - Start at 2–7.5 mg oral methadone per day, usually every 12 hours dosing
 - Increase no more than 5 mg/day, no more often than 5–7 days
- Opioid tolerant in terms of oral morphine equivalents (OME)
 - <60 mg OME use naïve dosing
 - 60–199 mg OME and patient <65 years of age, use 10:1 conversion (10 mg OME:1 mg methadone)
 - ≥200 mg OME and/or patient >65 years of age, use 20:1 conversion (20 mg OME:1 mg oral methadone)
 - Increase no more than 5 mg/day, no more often than 5–7 days (may be more aggressive in some settings)
 - Usually given in divided doses (q8h or q12h)
- Provide breakthrough medications not methadone.
- Use caution when combining with benzodiazepines or other sedating drugs, especially at night, in patients with sleep apnea, respiratory infection.
- Consider potential drug–drug interactions when modifying treatment plan

From McPherson et al.⁴¹

Corticosteroids are important adjuvant analgesics for the relief of neuropathic pain as well as some visceral pain syndromes that involve inflammation around masses (e.g., ovarian or gastrointestinal malignancies).^{51,52} These agents can be highly effective in reducing the tumor burden of lymphoma, which can open airway or gastrointestinal obstructions from this malignancy.

From Kreutzweiser, Tawfic³⁹; McPherson et al.⁴¹; Hanna, Senderovich⁴³; and Edmonds et al.⁴⁴

Added benefits of corticosteroids include improved appetite for approximately 2 weeks, and activation, which can relieve fatigue and possibly depression.⁵¹ Systematic reviews find the evidence for analgesia associated with corticosteroids to be generally weak despite anecdotal clinical experiences suggesting these agents can provide efficacy in some settings.^{52,53} Study design issues, including inclusion criteria, limit the extrapolation of these findings to most people with cancer pain. Important drug–drug interactions with dexamethasone are listed in Box 43.6.

Lidocaine and other local anesthetics have been limited by the lack of an oral formulation. Topical solutions and patches may relieve more superficial pain syndromes. Spinal delivery, either alone or in combination with opioids and other agents, can be useful, but administration requires specialists to insert catheters and potentially complicated and/or expensive delivery systems (e.g., catheter care, external or implanted pumps). Infusions of parenteral lidocaine, particularly in the face of intractable neuropathic pain, may be effective.^{54,55}

Box 43.5 OPIOID ROTATION/SWITCHING OPIOIDS

Step 1

- Calculate the equianalgesic dose using a standard table or online calculator.
- Reduce dose by 25–50% to account for incomplete cross-tolerance between opioids.

Step 2

- Consider an additional increase or decrease of 15–30% based on medical and psychosocial characteristics.
- Consider adverse effects, risk of withdrawal.
- Frequently reassess and titrate.
- Provide an oral rescue dose of 10–20% of 24-hour dose.

From Fallon et al.¹³

Table 43.5 ADJUVANT ANALGESICS

DRUG CLASS	USUAL ADULT DAILY STARTING DOSE	ROUTES OF ADMINISTRATION	ADVERSE EFFECTS
Antidepressants	Nortriptyline 10–25 mg qhs	PO	Anticholinergic effects
	Venlafaxine 37.5 mg bid	PO	Nausea, dizziness
	Duloxetine 30 mg qd		Nausea
Antiepilepsy drugs	Gabapentin 100 mg tid	PO	Dizziness
	Pregabalin 50 mg tid	PO	Dizziness
	Clonazepam 0.5–1 mg qhs, bid, or tid	PO	Sedation
Corticosteroids	Dexamethasone 2–20 mg qd	PO/IV/SQ	“Steroid psychosis” Dyspepsia
Lidocaine	Lidocaine patch 5% qd (also 4% patch over the counter along with creams/gels) Lidocaine infusion	Topical IV/SQ	Rare skin erythema Perioral numbness, cardiac changes
N-Methyl-D-aspartic acid antagonists	Ketamine (see following text section on ketamine for dosing)	PO/IV	Hallucinations

From Swarm et al.⁸; Fallon et al.¹³

Ketamine is an N-methyl-D-aspartic acid antagonist that is thought to be useful in relieving neuropathic pain, in reducing opioid doses when high doses appear ineffective, or in the management of opioid-induced hyperalgesia.^{56,57} Yet clinical trials have not supported the benefits of ketamine for pain control in palliative care. In a controlled trial of ketamine versus placebo in neuropathic cancer pain, ketamine was equivalent to placebo.⁵⁸ Case reports suggest this agent may be useful for refractory depression at the end of life.⁵⁹ Box 43.7 provides a sample protocol for use in palliative care. Palliative APRNs with prescribing privileges should check state and institutional rules regarding their ability to prescribe this medication. Additional well-controlled studies are needed to evaluate the role of ketamine for those with central sensitization who might be experiencing neurotoxicity and hyperalgesia to opioids at the end of life, as well as the efficacy in treating severe depression and suicidal ideation in those with serious illness.

The role of cannabinoids in relieving pain is often questioned, and palliative APRNs will be asked by professionals, patients, and the public about the use of these compounds.^{60,61} Research is limited, in part because of inadequate funding and lack of availability of an approved study drug.⁶² Possible harms include hyperemesis syndrome (seen more often with inhaled cannabis) and psychiatric or cardiovascular effects (seen more frequently with edible cannabinoids).⁶³ As the APRN reviews current literature, it is helpful to understand the different formulations of cannabinoids. This is particularly important as more states approve either medical or adult use (formerly called recreational use) of cannabinoids.⁶⁴ Box 43.8 clarifies the variety of formulations of cannabinoids.^{65,66}

**NONPHARMACOLOGIC
INTERVENTIONS FOR PAIN**

The biopsychosocial model clarifies the need for both pharmacologic and nonpharmacologic techniques to relieve pain. The findings from the complete pain history and physical examination help the palliative APRN in designing a treatment plan that incorporates appropriate interventions. Many of these interventions require the expertise of specialists and other team members, including radiologists, surgeons, psychologists, physical therapists, chaplains, social workers, and many others. Close communication with these consultants and team members will ensure continuity of care and will increase the chances of meeting the patient’s goals for pain relief. Education is an essential component of all successful pain relief regimens.⁶⁷ Table 43.6 lists selected nonpharmacologic interventions.^{2,68–70} Challenges to the incorporation of these interventions into the treatment plan include lack of reimbursement, limited access to practitioners with expertise in these interventions, and reluctance on the part of some patients and family members to accept these techniques.⁷¹

Box 43.7 KETAMINE PROTOCOL FOR ORAL OR PARENTERAL ADMINISTRATION IN PALLIATIVE CARE

Purpose

This is an adjunct medication often considered for pain refractory to opioids or intractable side effects from opioids, particularly if the pain is neuropathic in nature or if a high degree of morphine tolerance is suspected.

Definition

Ketamine is an N-methyl-D-aspartate receptor (NMDA) agent that may be opioid-sparing.

Protocol

ORAL DOSING

- The typical starting dose is 10–15 mg PO every 6 hours. Reversal of morphine tolerance may occur at low doses such as this, while management of neuropathic pain is likely to require higher doses.
- There is no commercially available oral product. The injectable product may be diluted from its standard concentration of 50 mg/mL or 100 mg/mL with cherry syrup or cola to mask the bitter taste when given orally.
- Consider decreasing long-acting opioid by 25–50%.
- Dosing may be increased *daily* by 10 mg every 6 hours until pain is relieved or side effects occur. Do not increase doses more frequently than every 24 hours.
- Major side effects include dizziness, a dreamlike feeling, and auditory or visual hallucinations. If intolerable side effects occur, ketamine should be decreased to the previous dose or discontinued. Resolution may not occur for 24 hours.
- Oral doses as high as 1,000 mg per day have been reported in the neuropathic pain literature, with average oral doses of 200 mg per day in divided doses required for pain relief.

IV DOSING

- Ketamine may be given intravenously or subcutaneously if the oral route is not available.
- Some facilities allow a ketamine challenge. A trial of 10 mg IV can be considered, which may be repeated in 15–30 minutes.
- The starting infusion dose of 0.2 mg/kg/h can be increased by 0.1 mg/kg/h q6h, with upward titrations to 0.5 mg/kg/h or 800 mg in 24 h.
- Consider decreasing long-acting opioid dose by 25–50%.
- The injectable solution is irritating and the subcutaneous needle may need to be changed daily.
- For side effects of hallucinations or a dreamlike state, benzodiazepines can be given prophylactically or Haldol can be given when the effects occur.

Box 43.8 FORMULATIONS OF CANNABINOIDS

Endocannabinoids

- Endogenous neurotransmitters arachidonic acid derivatives (e.g., anandamide)

Phytocannabinoids (Also Called Botanical Cannabis)

- Compounds found in *Cannabis sativa* plant (e.g., THC, CBD, many others)
- Primarily smoked, vaporized, ingested or applied topically

Synthetic Cannabinoids

- Laboratory-produced congeners of THC, CBD
- Dronabinol (Marinol) tablet, approved in United States for chemotherapy-induced nausea and vomiting and AIDS-associated anorexia
- Nabilone (Cesamet) approved in United States for chemotherapy-induced nausea and vomiting that has not responded to traditional treatments
- Nabiximols oral spray indicated for neuropathic pain, spasticity (not yet approved in United States)
- Cannabidiol (Epidiolex) a oral solution approved in United States for drug-resistant seizures

SAFE PRACTICES

Pain management in palliative care will include the use of drugs with a high potential for abuse. To provide safe and effective pain control, palliative APRNs must work to prevent misuse and diversion.

SAFE STORAGE

Education of patients and their family members regarding safe storage and disposal is essential. Studies suggest that patients, including oncology and palliative care patients, are not employing these practices.^{80,81} Medications should be kept locked, not stored in the medicine cabinet or out on the kitchen counter. Medications should never be shared and should be used only for pain relief. Many find that these medications enhance sleep, improve mood, and relieve anxiety, particularly during initial exposure, in part due to the sedating effect. But tolerance quickly develops to the soporific or sedative effect, and patients will find the need to escalate doses to obtain the original response. Dose escalation can lead to serious complications, including oversedation or other toxicities as the dose is increased. Compounding this is the stigma held by many about taking psychotropic medications, which are more appropriate in managing anxiety, depression, sleep issues, or other mood disorders.⁸²

SAFE DISPOSAL

Safe disposal of medications prevents access by others (e.g., children, pets, individuals with intent to use the drugs recreationally or sell these agents) and limits impact on the environment.⁸¹ Municipalities are detecting medications in the water supply, in part as a result of drugs being flushed into the sanitary system. The Environmental Protection Agency advises against flushing medications (<https://www.epa.gov/hwgenerators/collecting-and-disposing-unwanted-medicines>), preferring incineration.

The Drug Enforcement Agency (DEA) offers a twice-yearly National Prescription Drug Take-Back Program and allows collection receptacles in places such as law enforcement stations, hospitals, and pharmacies, the locations for which can be found at DEA website (<https://apps2.deadiversion.usdoj.gov/pubdispsearch/spring/main?execution=e1s1>).

The Food and Drug Administration (FDA) recommends that if a take-back program is not available, medications (except for opioids) should be mixed with moistened kitty litter or used coffee grounds, placed in a sealed plastic bag, and thrown away in the trash. Empty pill bottles or other packaging should be blacked out so that the drug or individual cannot be identified. However, the FDA still requires that if a take-back program is not available, opioids must be flushed down the sink or toilet due to safety concerns (https://www.fda.gov/drugs/safe-disposal-medicines/disposal-unused-medicines-what-you-should-know#Flushing_list).

SAFE PRESCRIBING

Because there is no absolute predictor for who might misuse medications, chronic pain management experts recommend the use of “universal precautions.” Although studies are ongoing regarding their efficacy, particularly in palliative care, many prescribers are adopting all or some of these recommendations.^{83–86} Box 43.9 outlines key aspects of universal precautions.⁸⁷ Numerous tools are available to screen for misuse or high-risk behaviors (e.g., CAGE, Current Opioid Misuse Measure [COMM], Opioid Risk Tool [ORT]). Few have been validated in a palliative care population.

Random urine drug testing through toxicology screening can help determine if patients are taking illicit drugs or not taking the drugs prescribed.^{88,89} However, caution is advised in the interpretation of these results; false negatives and positives abound (see Table 43.7). For example, a patient receiving transdermal fentanyl will have a test result that is negative for opioids. The palliative APRN obtaining random urine toxicology must seek expert advice regarding interpretation of the results before making decisions regarding whether a patient should no longer be prescribed an opioid.

Statewide prescription drug monitoring programs (PDMPs) are now available in 49 states (Missouri has a modified program). Although the information provided by each state varies, most allow prescribers to view the controlled substances that have been prescribed for a particular patient, the date and number of tablets/patches dispensed, the method of payment (insurance vs. self-pay), the pharmacy where the drug was dispensed, and the name of the prescriber.⁹⁰ Many state PDMPs can access data from other states. Although sometimes viewed as a method to “catch” offenders, more often these programs help identify the medications taken by patients who do not bring in their medications or do not know the name of the drug (e.g., the “blue pill”). Several states and institutions have mandated review of the PDMP prior to prescribing a controlled substance. The palliative APRN must be aware of the associated regulations to appropriately and safely prescribe.

Box 43.9 UNIVERSAL PRECAUTIONS

Assess

- Pain and function
- Risk for addiction/diversion

Opioid management agreements or “contracts” have limited evidence in palliative care.

Adherence Monitoring

- Urine drug testing
- Pill counts
- Prescription drug monitoring programs

From Arthur, Bruera.⁸⁷

Table 43.7 URINE DRUG TESTING

TEST	TYPE OF TEST	GENERAL PURPOSE	INTERPRETATION ISSUES: EXAMPLES
Brief Screen	Immunoassay More rapid results usually within hours Less expensive	Detects the presence of drugs: amphetamines, barbiturates, benzodiazepines, cocaine, opiates, phencyclidine, δ -9-tetrahydrocannabinol (THC)	False negatives: Cannot detect synthetic opioids such as oxycodone May not detect ketamine, clonidine, non- benzodiazepine hypnotics (e.g., zolpidem) False positives: Selective serotonin reuptake inhibitor (SSRI) intake positive benzodiazepine Ephedrine positive amphetamines Nonsteroidal anti-inflammatory drugs (NSAIDs) positive barbiturates
Confirmation	Liquid or gas chromatography/mass spectrometry May take days for results More expensive; not all insurance covers	Can identify specific opioids and other controlled substances along with their metabolites	Timing of collection may alter results: A delay from ingestion to sampling may produce negative results for hydrocodone and positive results for hydromorphone (a metabolite of hydrocodone) Consider the metabolites of each opioid during interpretation

Table 43.8 CONTROLLED SUBSTANCES SCHEDULES

SCHEDULE	EXAMPLES SELECTED	APRN ABILITY TO PRESCRIBE
Schedule I	Heroin Lysergic acid diethylamide (LSD) Marijuana (cannabis)	No currently accepted medical use in the United States; available only for research purposes
Schedule II/IIN (2/2N)	Schedule II Amphetamine Cocaine Codeine Fentanyl Hydrocodone Hydromorphone Methadone Meperidine Methamphetamine Methylphenidate Morphine Opium Oxycodone Pentobarbital	Allowed by national DEA registration. Each state has its own statutes as to whether APRN can prescribe. Transmucosal immediate-release fentanyl products (TIRF REMS) require REMS (https://www.tirfremssaccess.com/TirfUI/remis/home.action)
Schedule III/IIIN (3/3N)	Buprenorphine Codeine/acetaminophen Ketamine Testosterone	Allowed by national DEA registration. Each state has its own statutes as to whether APRN can prescribe. Buprenorphine requires medication-assisted therapy (MAT) for treatment of opioid use disorder; requires specialized waiver (see https://www.samhsa.gov/medication-assisted-treatment)
Schedule IV	Tramadol Alprazolam Clonazepam Diazepam Lorazepam Midazolam	Allowed by national DEA registration. Each state has its own statutes as to whether APRN can prescribe.
Schedule V	Cough preparations containing not more than 200 mg of codeine per 100 mL or per 100 grams	Allowed by national DEA registration. Each state has its own statutes as to whether APRN can prescribe.

Adapted from <http://www.deadiversion.usdoj.gov/schedules/#define>

Another component of safe prescribing is the provision of naloxone, an opioid antagonist, in the event of an accidental overdose by the patient or loved ones (e.g., a grandchild finding and eating a tablet, thinking it is candy).⁹¹ Naloxone is available as a nasal formulation, an auto-injector, or in vials for intravenous administration. Long used by first responders to treat opioid overdose, nasal naloxone is now available as a generic formulation, by prescription, although many national retail pharmacies will provide it without a prescription. Additionally, although initially costing patients approximately \$150, most insurance companies now cover this charge. To save costs, some settings have used improvised atomizers to deliver naloxone; however, there is concern this does not deliver a full dose of the medication and must be avoided. Patients and family members require education about the symptoms of an opioid overdose, including inability to wake the person verbally or by shaking them, very slow or shallow breathing, and fingernails or lips turning blue. In addition to explaining how to use the nasal naloxone, they should be informed to call 911 after administering naloxone as the duration of effect is from 30 to 90 minutes, much shorter than most opioids. Although co-prescribing with opioids is recommended, it is unclear how often this medication is currently provided to those receiving palliative care in the home. For more information about delivery systems, patient teaching and access, see <https://www.drugabuse.gov/drug-topics/opioids/opioid-overdose-reversal-naloxone-narcan-evzio>.

Palliative APRNs must also be aware of the DEA schedule system so they can comply with prescribing regulations in their own state and institution. Table 43.8 lists substances that may be used in palliative care for pain and symptom control. Lack of awareness of any changes to an agent's schedule can result in delays in patients obtaining needed medications. For more information, see <https://www.dea.gov/drug-scheduling>.

Risk evaluation and mitigation strategies (REMS) have been instituted to advance safe prescribing of a variety of substances. Two of these strategies involve opioids and have implications for APRNs who might prescribe these agents. Use of the strategy for transmucosal immediate-release fentanyl products (TIRF REMS) (<https://www.tirfremssuccess.com/TirfUI/remss/home.action>) is required for prescribers of these products. An online educational module and exam can be completed for provider enrollment in this program. When these medications are prescribed for an individual patient, he or she signs an online agreement affirming that he or she understands appropriate use of these products. The strategy for extended-release and long-acting opioid analgesics is highly recommended to improve the knowledge of both providers and patients (<http://www.er-la-opioidremss.com/lwgUI/remss/home.action>).

Despite all of these measures and safeguards, there may be times when patients exhibit what seems to be aberrant drug-taking behavior. The palliative APRN must assess further requests for early or frequent refills. Box 43.10 describes the differential diagnosis for these requests so that the underlying problem can be appropriately addressed^{92,93} (see Chapter 47, "Patients with Substance Use Disorder and Dual Diagnoses").

Box 43.10 DIFFERENTIAL DIAGNOSIS OF ABERRANT DRUG-TAKING BEHAVIOR

Addiction (Substance Use Disorder)

PSEUDO-ADDICTION (INADEQUATE ANALGESIA)

- Amount of drug ordered too low dose, number of tablets
- Partial fill provided by pharmacy
- Insurance limits, prior authorization

OTHER PSYCHIATRIC DISORDERS

- Chemical coping
- Mood disorders (anxiety, depression)
- Encephalopathy
- Borderline personality disorder

INABILITY TO FOLLOW A TREATMENT PLAN

- Low literacy
- Use of pain medication to treat other symptoms (sleep, anxiety, depression)
- Misunderstanding regarding "prn" or as needed dosing
- Fear of pain returning

CRIMINAL INTENT

From Yennurajalingam et al.⁹²; and Arthur, Hui.⁹³

SUMMARY

Effective pain management in palliative care requires knowledge of common pain etiologies, as well as skill in conducting a thorough assessment. The palliative APRN who is devising a treatment plan must consider the available pharmacologic and nonpharmacologic therapies, using the biopsychosocial model as a guide. Consulting with other team members is imperative to provide optimal control including pain services for interventions such as a neurolytic block, radiation oncology for radiation, and surgery for kyphoplasty or vertebroplasty. Safety is crucial: the palliative APRN must use tools such as prescription drug monitoring programs and urine toxicology. Education of patients and families regarding appropriate use, storage, and disposal of pain medications is essential.

RESPIRATORY SYMPTOMS

Ember S. Moore and Kathleen Broglio

KEY POINTS

- Dyspnea and cough are symptoms that affect individuals with advanced diseases and may worsen toward the end of life.
- The advanced practice registered nurse (APRN) should assess dyspnea and cough using a biopsychosocial approach, with the understanding that these symptoms affect the entire person.
- The APRN should actively seek opportunities to participate in research to extend the current body of evidence related to dyspnea and cough.

CASE STUDY: SHORTNESS OF BREATH

Carey was a 64-year-old woman with past medical history of chronic obstructive pulmonary disease (COPD), hypertension (HTN), and severe osteoarthritis woman who quit smoking 15 years ago. Three months ago, after a 30-pound unexplained weight loss, she was diagnosed with adenocarcinoma of the lung with metastases to the liver. She initiated chemotherapy and was referred to palliative care for assistance in management of her dyspnea and cough. The palliative advanced practice registered nurse (APRN) performed an assessment to elicit information about her respiratory status. Prior to her diagnosis, she was able to walk around her neighborhood with her dog, about one-half mile without having to stop to rest. Carey reported she was unable to ambulate 50 feet without becoming short of breath. Additionally, her chronic cough has worsened over the week, and it exacerbated the pain in her right upper quadrant of the abdomen. Carey reported taking ipratropium bromide/albuterol inhaler as well as guaifenesin as needed, which did not help her shortness of breath or cough. She wondered if having oxygen at home will help her feel better.

INTRODUCTION

Dyspnea and cough are two common symptoms that often contribute to decreased quality of life (QoL) and can be exceptionally distressing symptoms near end of life for individuals and their caregivers. Each can be associated with several underlying acute and chronic disease states or develop as symptoms of a new disease process or acute complication of treatment, such as a malignant pleural effusion or chemotherapy induced pneumonitis. Although very common

in palliative care, dyspnea and cough have relatively limited research dedicated to understanding the effects of these symptoms on the total person. This may be due to the difficulty of appreciating and measuring the different severity of symptoms. As an example, a person may say “I can’t catch my breath” or “I’m suffocating!” but has oxygen saturations within normal limits and no observed work of breathing.¹

Dyspnea and cough may exacerbate or influence each other as well as symptoms such as anxiety, pain, and depression.² These relationships highlight the need to better understand and address the complexity of interactions between physiologic, psychological, environmental, and interpersonal factors that affect the quality of life—and the quality of death.^{3,4} (In lieu of robust research and treatment guidelines in palliative care, much of the evidence is extrapolated from research of these symptoms in the general population as well as specific populations such as those with chronic obstructive pulmonary disease [COPD] or congestive heart failure [CHF]).

Although individuals often present with both symptoms, dyspnea and cough are two distinct symptoms, each with complex pathophysiology. Advanced practice registered nurses (APRNs) must accurately assess the situation, treat the underlying cause when possible, and manage dyspnea and cough much like managing “total pain”⁵ to enhance the person’s QoL and alleviate suffering.

DYSPNEA

DEFINITION

Dyspnea is a medical term for a symptom or sign usually associated with an underlying condition. It has been defined by the American Thoracic Society as “a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity.”⁶ (pp. 436–437) The group adds that the “experience of dyspnea derives from interactions of physiological, psychological, social, and environmental factors and may induce secondary physiological and behavioral responses.”⁶ (pp. 436–437) Bausewein et al. (2018) differentiate the medical term “dyspnea” from the common term “breathlessness,” “a unique and subjective experience to the individual reflecting the patient’s perspective based on the daily experience.”⁷ (p. 48) *Breathlessness* can better encompass the many dimensions of a person’s experience of dyspnea, and breathlessness may persist as a chronic symptom despite optimal treatment of underlying conditions.⁷

Dyspnea is a symptom that often arises from physiologic impairment from a disease process or subsequent therapies, and it may be independent of physiologic signs of respiratory compromise, such as tachypnea. The person experiences physical sensations that are commonly described as “suffocating,” “can’t get enough air,” or being “out of breath”⁸ that can be rated in degree of unpleasantness as well as the reaction to these sensations.⁹ The reactions, an affective response of the central nervous system, are associated strongly with other symptoms such as depression, fear, and anxiety.¹⁰

Neuroimaging study results demonstrate the relationship between the affective response and reported symptom severity. Additionally, these neuroimaging studies have shown the effect that opioids have in altering the affective response.^{1,8,10,11} This new information may increase the understanding of why some individuals who experience dyspnea over time, such as those with COPD, may have different experiences of dyspnea during different time periods of disease course.

A person with COPD may have chronic experiences of activity intolerance or exacerbations of dyspnea. These experiences may be due to increased anxiety and fear related to a learned affective response compared to those with cancer, where dyspnea tends to occur toward end of life and is more limited to episodic events.^{12,13} Individuals with COPD tend to rate their symptoms of dyspnea worse than those with cancer or CHF. This may be due to anticipatory responses learned over time mediated by the amygdala and hippocampus.^{1,10,14} Understanding this relationship can help target treatments and future study to better palliate all aspects of dyspnea.

Descriptive qualities of dyspnea have been separated into three categories (air hunger, work, and tightness); each may arise from different pathophysiologic processes such as COPD, CHF, advanced cancer, lung fibrosis, and neuromuscular disease and may indicate the need for different management approaches.⁴ Acute dyspnea and chronic breathlessness can also be differentiated. Although acute dyspnea can be considered a palliative care emergency, it is important to differentiate it from the chronic experience that many individuals with serious illness experience.¹⁵ Chronic breathlessness may be viewed as a syndrome that is associated with anxiety, depression, and declining activity tolerance. It has been “defined as “breathlessness that persists despite optimal treatment of the underlying pathophysiology and that results in disability.”¹⁶ (p. 1)

PREVALENCE

Dyspnea may be experienced by up to 2.9% of the general population.^{15,17} The majority of people living with COPD experience some dyspnea, and 80% frequently experience moderate to severe dyspnea.^{18,19} Dyspnea is also experienced by 51% of individuals with lung cancer^{12,20} and up to 52% of those with dementia at the end of life.^{12,21} Activity-related breathlessness is twice as high in woman compared to men and is likely explained by the general gender difference in absolute lung volume.^{19,22}

Although the recorded prevalence in these special populations is relatively high, the percentage of seriously ill

individuals experiencing dyspnea may be underappreciated secondary to challenges in measuring dyspnea and consistently documenting it as a symptom.⁹ Underappreciated symptoms may be most significant in populations that have historically experienced significant dyspnea burden such people with COPD, CHF, advanced local or metastatic cancer, idiopathic lung disease, pulmonary hypertension, and motor neuron disease/amyotrophic lateral sclerosis. Individuals may not be aware that there may be better treatment for this pervasive symptom.^{7,23} The individual may experience frustration, vulnerability, and shame related to dyspnea and may not appreciate that symptoms of anxiety, insomnia, and depression may be rooted in their experience of dyspnea. Therefore, the palliative APRN should be keenly aware that individuals may underreport the impact or the decreased QoL related to dyspnea.^{20,24}

The quality and intensity of dyspnea may vary across disease states.²⁵ In a qualitative study of individuals with cancer, COPD, CHF, and motor neuron disease, there were individual variations in the experience of dyspnea.²⁶ Those with COPD had higher levels of breathlessness over time, whereas those with lung cancer experienced worsening dyspnea toward the end of life.²⁵ In a consecutive cohort hospice study, dyspnea was worse in those with non-cancer diagnoses but increased significantly for individuals with cancer in the last 8–10 days of life.^{12,27} Among individuals with advanced cancer, those with metastases to lung, liver, and lymph nodes were strongly predisposed to more severe dyspnea,²⁸ pointing to the need for the palliative APRN to personalize treatment.

ETIOLOGIES

The APRN must understand the multifactorial etiologies of dyspnea to design the best treatment plan. Pulmonary causes of dyspnea can be from malignant or nonmalignant sources, whereas cardiac causes of dyspnea are generally related to nonmalignant pathology. Dyspnea may occur related to increased respiratory effort in obstructive processes, increases in ventilatory requirements, restrictive processes, ventilatory mismatch, fatigue, or musculoskeletal weakness.^{11,29} Systemic causes of dyspnea may be secondary to advancing disease as well as the side effects of treatments. Psychological states including mood and expectation influence the experience of and can also provoke dyspnea¹¹ (see Table 44.1).

PATHOPHYSIOLOGY AND MECHANISMS

The sequences of pathophysiological mechanisms that result in the symptom of dyspnea are not completely understood. Studies to date have led to the development of several constructs of physiologic mechanisms and affective states that interact in the whole person.^{11,29,30} A person with COPD may have dyspnea at rest and severe exertional dyspnea and anxiety and related depression due to decreased functional ability, while a person with CHF may have severe exertional dyspnea with disease exacerbation with mild anxiety and no depression (see Box 44.1).

Table 44.1 POTENTIAL CAUSES OF DYSPNEA IN ADVANCED DISEASE

PULMONARY	CARDIAC	SYSTEMIC	TREATMENT-RELATED	PSYCHOLOGICAL
Airway obstructions	CHF	Cachexia	Surgical	Anxiety
Carcinomatosis	Ischemia	Steroid myopathy	Lobectomy	Panic
Chest wall infiltrations	Pericardial effusion	Hepatomegaly	Pneumonectomy	
COPD	Pulmonary hypertension	Ascites	Chemotherapy	
Interstitial lung disease		Anemia	Pulmonary or cardiac toxicity	
Effusions		Metabolic abnormalities	Radiation side effects	
Embolism		Obesity	Pneumonitis	
Pneumonia		Hyperventilation	Fibrosis	
Pneumothorax		Neuromuscular abnormalities	Pericarditis	
Superior vena cava obstruction				
Tumor				

This is only a partial list of more common causes.

Adapted from Chan et al.³⁰

It is generally accepted that the experience of dyspnea emanates from changes in activity in central and peripheral chemoreceptors, imbalance in feedback between efferent and afferent signals from sensory receptors in the body to the brain's respiratory processing centers (thought to be in the medulla and cortex), and the effects of increased activation of affective

response to these changes in the limbic and paralimbic brain areas. This results in a sensation of "unpleasantness."²⁹

Independent of changes in respiratory activity, levels of hypoxia, and hypercarbia have been shown to generate equivalent levels of air hunger in humans and can induce a sense of "unpleasantness" or "air hunger."³¹ Changes in mechanoreceptor and ergoreceptor activity in the lung, chest wall, upper airway, and facial receptors can also contribute to dyspnea by relaying feedback to the somatosensory cortex.^{29,32,33} It is hypothesized that these neuromechanical changes drive many responses, such as changes in breath rate and depth and affective response. Affective responses may lead to modification of overall activity.

Over time, limitation of physical activity to avoid these triggers leads to muscle deconditioning that has at least two further effects that contribute to dyspnea in chronic conditions.²⁹ First, it can contribute to overall muscle deconditioning, including that of the diaphragm, which can affect the ability to respond with optimal lung volumes for inspiration. This may cause changes to mechanoreceptor stimulation and decrease overall spirometry. Second, increased anaerobic muscle metabolism may result from global deconditioning. This may cause increased systemic acidosis with muscle activity that may increase chemoreceptor stimulation, thus further driving the cycle of dyspnea.^{29,31} Dyspnea can arise from a sense of increased work of breathing in those with fatigue, weakened respiratory muscles, or obstructive diseases. Neuromechanical dissociation, a mismatch between incoming information from the respiratory system and outgoing commands from the brain center, can also cause dyspnea.^{29,34}

Results of neural imaging studies have demonstrated that the limbic and paralimbic areas of the brain are active when a person experiences dyspnea and are known to be active in people experiencing fear and reaction to learned responses.^{11,29} In imaging studies of opioids used for activity-induced dyspnea, brain activity in the limbic and paralimbic areas was interrupted.^{1,35} This finding offers one explanation of the affective mechanisms and experience of dyspnea. Further investigation may lead to a better understanding of the central processes involved in the perception of and response to

breathlessness, which are not fully explained by currently accepted mechanisms.¹¹

CASE STUDY: SHORTNESS OF BREATH (CONTINUED)

Carey was worried that time was limited due to the progression of disease seen on recent imaging and that she was not a good surgical candidate for tumor resection. She hoped to walk down the aisle in 1 month to see her son married. She felt her dyspnea was currently limiting her ability to participate in this important event. Carey's oxygen saturation was 95% on room air after ambulating to exam room. Her cough was moist, nonproductive, and intermittent, and she was grimacing and splinting the right upper quadrant of her abdomen. Her breath sounds were very diminished in the right middle and bilateral lower lung fields. A chest radiograph showed minimal bilateral pleural effusions and a normal cardiac silhouette.

Carey was offered a trial of low-dose opioids for her dyspnea. The palliative APRN prescribed 4 mg oral liquid morphine every 4 hours as needed for dyspnea with instructions to take it 30 minutes prior to planned activity. A follow-up visit was planned for 1 week to evaluate her response to the morphine.

CLINICAL ASSESSMENT

The palliative APRN should ensure that a routine assessment of dyspnea is incorporated fully into practice in a similar routine to that of pain.⁷ Many people with serious illness may not appear in distress yet experience acute or chronic dyspnea. They and their caregivers may not volunteer to report symptoms of chronic breathlessness, and, without routine assessment, symptom distress may be underappreciated and undertreated.³⁶ McCaffery's (1968) original description of the subjectivity of "pain as being what the person says it is when experienced"³⁷ (p.95) implies the complexity of the pain experience and the need first to assess symptoms in a similarly robust manner based on the implications of that experience. Similarly, the subjectivity of dyspnea needs to be recognized as a combined mind and body phenomenon.³⁶

The palliative APRN's clinical assessment of dyspnea initially focuses on eliciting the underlying pathology, either from previous consultations or by appropriate assessment and diagnostic workup. A biopsychosocial assessment is imperative because the individual's experience and interpretation of dyspnea and preferences for treatment may vary and change with disease progression.^{7,9,26}

Experts recommend dyspnea assessment and tracking over time.^{6,36} The APRN can adapt the PQRST mnemonic for pain assessment to guide dyspnea assessment.³⁸

- Provoking/palliating factors
- Quality/characteristics
- Relationship to other symptoms, such as fatigue, anxiety, and depression
- Severity, using a unidimensional scale
- Timing (constant or intermittent)

In individuals with cancer, the APRN should assess not only the effects of tumor burden, but also the post-treatment effects of radiation, chemotherapy, and immunotherapies that may contribute to dyspnea. In individuals with cardiac, pulmonary, or motor neuron diseases, the palliative APRN should inquire about the appropriate use of disease-modifying therapies that affect the respiratory system. Lifestyle factors should be explored because exposure to environmental toxins like tobacco smoke may contribute to dyspnea.

Multiple dyspnea assessment tools have been developed, yet many are unidimensional or disease-specific or do not address dyspnea's affective component or dyspnea in advanced disease.³⁶ The American Thoracic Society and the American College of Chest Physicians have not endorsed the use of any specific scale.⁶ The modified Borg Scale,³⁹ visual analogue scale (VAS),⁴⁰ and numeric rating scale (NRS)⁴¹ are unidimensional scales that measure dyspnea severity but do not elicit affective components of dyspnea. Although they are simple, these tools have been validated and are indicated in initial and follow-up assessments as part of a short dyspnea assessment. For assessment of individuals who have cognitive challenges, the categorical verbal descriptor scale (VDS) using "none," "mild," "moderate," and "severe" has shown good correlation with the VAS and NRS scales and may be ideal for continued assessment in certain individuals.²³ Individual self-assessment tools in those with advanced disease such as the Memorial Symptom Assessment Scale (MSAS)⁴² and the Edmonton Symptom Assessment System (ESAS),⁴³ measure the severity of multiple symptoms. Psychometrically valid tools, such as the Dynspnoea-12, tested in those with CHF, COPD, and interstitial lung disease (ILD),⁴⁴ and the Cancer Dyspnea Scale (CDS), tested in those with cancer,⁴⁵ address both the physical and affective components of dyspnea. For individuals who cannot self-report, the Respiratory Distress Observation Scale (RDOS) is a validated, simple-to-use tool that may help the clinician to evaluate the trend and response to treatment.^{46,47} However, this seems to be used mostly in the intensive care unit and at end of life. Caregivers' reports, through use of unidimensional scales such as NRS or VDS, may be useful if the individual cannot report the severity of dyspnea. It is important for the APRN to use the above-mentioned tools when appropriate and reassess at regular intervals.^{36,48}

The clinical interview and the use of psychometrically validated tools for dyspnea assessment should be coupled with physical examination and diagnostic testing as appropriate. In considering the choice of diagnostic testing for evaluating dyspnea, the palliative APRN should understand potential causes for dyspnea related to the disease state. Further diagnostic testing should be coupled with consideration of the goals of care and the effects of additional information on the management of disease or symptom (see Box 44.2).

MANAGEMENT

The palliative APRN must ensure optimal management of both the disease and the dyspnea. Disease-specific therapies should be optimized to decrease dyspnea when the benefit

Clinical Interview

outweighs the risk and if consistent with goals of care. Toward the end of life, dyspnea management may preclude the treatment of the underlying pathology.⁴

Although there has been progress in understanding the mechanisms of dyspnea, the treatment of dyspnea has not progressed significantly. Despite the lack of high-quality studies and gaps in evidence for recommended therapies, the palliative APRN can manage dyspnea and improve QoL.^{3,4,49} Regardless of the state of disease, the APRN should utilize pharmacologic, nonpharmacologic, and psychoeducational strategies as well as breathlessness services, if available, to decrease symptom distress.^{3,7,49,50}

Dyspnea management in the palliative care population may vary considerably related to the underlying diseases, phase of advanced disease, and individual treatment preferences related to goals of care. The palliative APRN role is vital to assess and acknowledge a distressing symptom that may be underreported in a person who has lived with serious illness prior to palliative care involvement. The APRN discusses goals of care to frame management recommendations. In this population, the palliative APRN utilizes therapies that may not be used in the general population to best control symptoms as end of life approaches (see Table 44.2 and Table 44.3).

Pharmacologic Management

Opioids

Dyspnea has been compared to pain in terms of the need to address it as a basic human right for treatment—the evidence is there for opioid therapy—and to deny it is to deny a human right.⁵¹ Opioids are the first-line pharmacologic treatment for dyspnea. Low-dose opioids may reduce dyspnea by decreasing the respiratory drive without inducing respiratory depression even in individuals who are opioid-naïve.^{4,35,49} It is thought that the positive effect on the “unpleasantness” of dyspnea from low-dose opiates is due to the suppression of respiratory system signaling in the brainstem as well as higher brain centers. This is thought to interrupt the affective response and may be of most importance when considering opioid’s therapeutic use.^{1,10} There is strong evidence for the treatment effect of opioids on COPD; even a single dose of morphine may improve exertional dyspnea ratings.⁵² Consensus on optimal dose, route, and how opioids may relieve dyspnea in some populations, such as CHF and ILD, remains less defined.³⁵

Morphine, the most widely studied opioid, has been shown to be effective for dyspnea.^{35,53–55} In a systematic review and meta-analysis of 26 randomized controlled trials (RCTs) ($n = 526$), dyspnea improved with opioid therapy compared to placebo.⁵⁶ Recent evaluation of that meta-analysis noted selection bias and recommended reassessment and a revised recommendation of a moderate level of evidence for the use of opioids to relieve dyspnea.⁵⁷ A few small studies have demonstrated the efficacy and safety of buccal fentanyl compared to immediate-release morphine for rapid relief of episodic dyspnea in cancer.^{58,59}

In a multisite RCT of patients with chronic dyspnea, 54% of participants had COPD and were treated with extended release once-daily morphine (10–30 mg), which remained

Table 44.2 SELECTED PHARMACOLOGIC TREATMENT OPTIONS FOR DYSPNEA IN SERIOUS ILLNESS

MEDICATION	COMMENT
Opioids (IV, SC, PO)	May be considered first-line treatment for dyspnea related to cancer, COPD May consider in CHF Optimal dosing not determined; start low dose and may titrate more rapidly for severe dyspnea Adult starting morphine doses range from 2.5 mg to 5 mg orally (or IV/SQ equivalent) q4h as needed Other opioids may also be effective if morphine is contraindicated Consider low dose, extended release opioid if tolerating immediate release opioids
Benzodiazepines (IV, PO)	Not a first-line recommendation Consider as second or third line or combination with opioids for refractory dyspnea at end of life. Potentially useful for refractory dyspnea and dyspnea-associated anxiety
Furosemide	Nebulized furosemide cannot be recommended due to equivocal evidence May be useful in COPD
Corticosteroids (IV, PO, INH)	May be beneficial and well-tolerated in cancer associated dyspnea May reduce airway inflammation and edema leading to dyspnea.
Oxygen	Beneficial in hypoxemia Beneficial in ILD to support activity related hypoxemia Questionable benefit in absence of hypoxemia, trial is warranted
Noninvasive ventilation (NIV)	Long term use effective in dyspnea associated with neuromuscular or restrictive thoracic diseases Benefits not clear long-term in stable COPD Benefits shown when combined with opioid therapy in hypercarbic COPD For patients foregoing intubation yet with hope for more time, may be beneficial in combination with opioid therapy for short-term survival
High-flow nasal therapy	May provide benefit to reduce work of breathing and respiratory rate May improve exercise tolerance especially with combined opioid therapy

CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; ILD, interstitial lung disease.

From Ambrosino, Fracchia³; Pisani et al.⁴; Johnson, Currow³⁵; Strieder et al.⁴⁹; Simon et al.⁶⁰; Ekstrom et al.⁶¹; Faverio et al.⁶²; Rochwerg et al.⁶³; and Koyauchi et al.⁶⁴

effective over time.⁵³ There is a call to consider oral extended-release low dose (10–30 mg per day) opioids for the treatment of dyspnea standard in care as the risks are relatively low and side effects such as constipation, nausea, and vomiting can be controlled.^{35,65}

The potential for improvement in health-related QoL should be of high value in palliative care.^{1,11} Common barriers in prescribing opioids for dyspnea have been their association with respiratory depression or lack of provider experience in prescribing opioids for the treatment of dyspnea.⁵⁰ Results from studies of individuals with COPD,⁶⁶ cancer,⁶⁷ or CHF⁶⁸ evaluating the use of opioids for dyspnea failed to demonstrate a relationship between opioids and respiratory compromise.

Limited studies have been conducted to confirm the opioid dose needed to manage dyspnea. This is partially due to the inherent difficulty of conducting RCTs in vulnerable populations and the heterogeneity of the populations with dyspnea. The proposed starting dose of morphine for opioid-naïve individuals with acute dyspnea in the acute care setting is 1–2 mg intravenous (IV) every 15 minutes with titration until dyspnea improves.⁴ In those who can take oral medications, the recommended dose is 2.5–5 mg oral morphine (or morphine equivalent) every 4 hours as needed.⁶⁹ In individuals who can take medications orally with chronic breathlessness, experts recommend starting with 10 mg of extended-release oral morphine daily, with titration to control symptoms to 30 mg daily,³⁵ combined with 2 mg immediate-release oral morphine every 4 hours as needed for dyspnea.

Based on the variation of proposed doses, APRNs should use the same approach as when treating pain: “start low and go slow.” There is an exception when managing dyspnea toward the end of life in an acute care setting, where opioids may be given IV and the dose rapidly titrated. The palliative APRN should anticipate and prevent opioid-related side effects such as nausea, vomiting, and constipation, and the dose may need to be adjusted for those who are older and frail with multiple comorbidities and as disease progresses.⁵⁵ Although there are limited studies on the use of other opioids for dyspnea, the APRN can use opioids other than morphine for those with renal dysfunction due to accumulation of morphine metabolites M-3-glucuronide and M-6-gluconoride, which may add to the adverse effects of opioids.³⁸

Nebulized opioids may be attractive to individuals who may not want to take oral medications, yet the evidence of the effects of nebulized opiates are equivocal due in part to the low-quality evidence to date.^{4,56} Therefore, the use of nebulized opioids should be evaluated on a case-by-case basis^{70,71} but may be considered if oral or parenteral opioids fail to provide benefit.

Benzodiazepines

Benzodiazepines have been used for dyspnea and may treat the affective response to dyspnea. In a systematic review (eight studies in advanced cancer and COPD) benzodiazepines were not of significant benefit regardless of type, dose, or route.⁶⁰ Anxiolytics (including benzodiazepines) have not been recommended by the American and Canadian thoracic societies for dyspnea in individuals with COPD.^{6,72} However, benzodiazepines have been shown to be effective in some small studies.^{73–75}

Although quality studies are needed to further evaluate their potential efficacy, benzodiazepines may be used for dyspnea refractory to opioids or other nonpharmacologic

Table 44.3 NONPHARMACOLOGIC AND INTERVENTIONAL THERAPIES FOR DYSPNEA IN SERIOUS ILLNESS

INTERVENTIONAL	
Tunneled catheter	May provide almost immediate relief of dyspnea in malignant and non-malignant pleural effusions More consistent success compared with pleurodesis Infection rate similar to pleurodesis
Pleurodesis	May decrease dyspnea due to pleural effusions High failure rate Tunneled catheter has better success rate
Bronchial stenting	First line for to re-establish airway patency in obstructions and relief of dyspnea if aligned with individual's goals
NONPHARMACOLOGIC	
Rehabilitation	Breath training COPD and HF may have benefit Low risk, low cost Pulmonary rehabilitation Usually combination of physical and respiratory therapy over several weeks; Strong evidence for improvement in chronic dyspnea, health related quality of life in COPD, Some evidence in cancer and ILD Not possible in severe dyspnea and at end of life
Psychoeducational	Counseling, education, relaxation, Internet-based self-management May increase self-efficacy May be included in holistic breathlessness services May have positive effect on affective component of dyspnea
Fans	May be beneficial Low-risk and low-cost treatment
Acupuncture	May be beneficial, some inconsistent evidence

COPD, chronic obstructive pulmonary disease; HF, heart failure; ILD, interstitial lung disease.

From Brighton et al.²; Ambrosino, Fracchia³; Pisani et al.⁴; Bausewein et al.⁷; Kako et al.³²; Strieder et al.⁴⁹; Vitacca et al.⁷⁶; Frost et al.⁷⁷; Bausewein et al.⁷⁸; Bittencourt et al.⁷⁹; and Gysels et al.⁸⁰

measures, especially in those who have anxiety.⁶⁰ Midazolam is recommended in the symptomatic hospitalized patient at end of life due rapid onset of action, short half-life, and ease in IV titration to desired effect.⁸¹ In non-acute situations, it is reasonable to consider low-dose oral lorazepam due to the relatively short half-life and availability in liquid form. Dosing can start at 0.5 mg orally or sublingually every 4 hours. Individuals with significant anxiety, who may not be approaching the end of life, may also benefit from treatment of anxiety with agents such as selective serotonin reuptake inhibitors.⁴

Furosemide

In individuals with dyspnea secondary to lung congestion, as in CHF, or in those who have had lymph destruction from therapy such as radiation, IV furosemide and diuretics may be helpful in treatment. In a review of nebulized medications for dyspnea, furosemide showed potential benefit in those with dyspnea related to COPD.⁴ Yet, in a recent double-blind randomized crossover trial, no relief of exercise-induced dyspnea was noted in healthy men using nebulized furosemide.⁸² In a systematic review of the use of furosemide for dyspnea in cancer, only two small RCTs were identified, and nebulized furosemide was not beneficial for dyspnea.⁸³ Given the paucity of studies, the use of nebulized furosemide should be reserved for those who do not respond to first-line therapies.^{3,4}

Corticosteroids

Although corticosteroids are often used in palliative care for many symptoms, there is conflicting evidence on their efficacy in treating dyspnea.^{3,4} However, in RCTs, dexamethasone was well-tolerated and reduced severe dyspnea symptoms in individuals with cancer.^{84,85} Due to limited evidence, steroid use for dyspnea may be considered in disease processes involving inflammation and in those with malignancy.^{4,84}

Oxygen

Standard Supplemental Oxygen Therapy. Oxygen is generally the first treatment clinicians consider when someone is dyspneic. The use of oxygen is warranted if dyspnea is related to a physiologic event limiting the delivery of necessary oxygen to the body, such as for those with COPD^{3,4,49,61} and fibrotic lung diseases.⁶² However, in advanced disease, the oxygen saturation and carbon dioxide status may not correlate with the perception of dyspnea. Abernethy and colleagues (2010) compared the effects of oxygen versus room air delivered by nasal cannula in those with advanced disease in a multisite RCT and found that the subjective feeling of dyspnea was relieved in those who were treated with air by nasal cannula at the same rates as those treated with oxygen therapy, thus questioning the need for oxygen therapy and calling for ongoing evaluation of alternative strategies.⁸⁶ Ekström and colleagues (2016) concluded that there is modest evidence that dyspnea with activity was improved with the use of oxygen therapy in those with COPD who were mildly hypoxemic or not hypoxemic and would not have qualified for home oxygen therapy.⁶¹

Oxygen use in ILD is standard practice although there is little evidence of improvement of dyspnea. However, oxygen may improve health-related QoL and exercise tolerance in this population.^{62,87} There have not been any high-quality studies assessing the efficacy of oxygen use in those with CHF, yet for those with comorbid obstructive sleep apnea, nocturnal oxygen may improve QoL.^{88–90}

Despite wide use of oxygen for those with dyspnea in many advanced disease states, most results from systematic reviews do not support its long-term use in individuals without hypoxemia.^{61,88,91} The palliative APRN's best approach may be a time-limited trial of oxygen therapy to evaluate the

response in dyspneic individuals with advanced disease who are not hypoxemic or only mildly hypoxemic.

Noninvasive ventilation. Noninvasive ventilation (NIV) delivers assisted airway pressure through the upper airways by a face mask or pronged nasal mask. NIV is able to provide this oxygen support without the use of oropharyngeal or tracheostomy tubes. NIV has commonly been used to provide continuous positive airway pressure (CPAP), and/or for those who need lower expiratory airway pressure for better tolerance, bilevel positive airway pressure (BiPAP). This ventilation is provided in and out of the hospital setting for treatment of obstructive sleep apnea and illness states with hypoxemia. NIV has been established in international guidelines as treatment for respiratory distress and dyspnea in acute COPD exacerbation, acute pulmonary edema, chest trauma, and postoperative weaning or post-extubation respiratory distress.^{61,63,88,91} NIV combined with exercise training and pulmonary rehabilitation has been shown to improve dyspnea and health-related QoL measures in those with heart failure.⁸¹ Vitacca and colleagues (2018) found that in individuals with COPD and restrictive thoracic diseases, NIV improved exercise endurance but not dyspnea symptoms.⁷⁶

In a systematic review of NIV in palliative care, there is strong support for its use in treating dyspnea in many illnesses including acute exacerbations of COPD and end-stage neuromuscular diseases yet equivocal and limited evidence on the effects on NIV on dyspnea at end of life. The widespread use of NIV at end of life may be more related to specific goals of care such as treating dyspnea and achieving short-term survival goals while avoiding oral intubation at end of life.⁹² The treatment of dyspnea related to motor neuron diseases poses additional challenges. Individuals must make decisions related to the use of both noninvasive and invasive ventilation not only to manage dyspnea but also to prolong life. Based on lack of evidence on the treatment of dyspnea in a wide variety of advanced disease and end of life, the American Thoracic Society was unable to provide a firm recommendation for the use of NIV as a palliative care tool yet was able to note the possibility of use as a therapy for certain disease states.⁶

High-Flow Nasal Therapy. Compared to traditional nasal cannula oxygen delivery that is usually limited to 15 liters of oxygen flow, high-flow nasal therapy (HFNT) is a type of NIV delivered through nonocclusive nasal cannulation that allows for delivery of warmed and humidified gas flow up to 100% the fraction of inspired oxygen (FiO₂). Up to 60 liters of oxygen per minute can be delivered while also providing some positive end expiratory pressure (PEEP) and providing washout of carbon dioxide in physiologic dead space. The warmed and humidified therapy may contribute to individual's increased ability to mobilize secretions. The physical apparatus allows for the individual to better communicate and tolerate oral intake compared with NIV that uses face masks. HFNT has not been provided out of the hospital setting, mostly due to high oxygen use demands that usually are not able to be delivered in most home settings as most home oxygen concentrators deliver only up to 10 liters per minute.

In recent decades, HFNT has been shown to provide a number of beneficial effects such as decreased work of

breathing and reduced respiratory rate.⁹² It has been used for prevention and treatment of acute respiratory failure in individuals with CHF and pneumonia.^{3,4,93} HFNT improves respiratory distress by decreasing respiratory rate and work of breathing in CHF,⁹⁴ cystic fibrosis,⁹⁵ and ILD,^{62,64} and by counterbalancing auto-PEEP in those with COPD.⁹⁶

Although the study of HFNT in all illnesses has not consistently demonstrated decreased dyspnea, it has been shown to decrease work of breathing by reducing the respiratory rate in many disease states.^{62,96} For individuals seeking to avoid intubation at the end of life who also want symptoms of respiratory distress managed and short-term life prolongation, HFNT may be well-tolerated.^{62,93-95} HFNT will likely be more widely used in palliative care as technology changes, which may enable its use in the home care setting. Until that time, palliative APRNs should discuss the goal of the HFNT, especially if lung disease will not enable the individual to transition to oxygen therapy that is available at home or in a skilled or assisted living facility. A potential scenario may be that HFNT would be utilized to allow family or friends to visit the individual prior to discontinuation to allow natural death.

Pisani and colleagues (2018) highlight the need for the palliative APRN to address symptom management in the context of individual goals of care to guide decision-making when considering oxygen therapy, HFNT, and NIV.⁴ NIV may be indicated in individuals who do not want intubation but are seeking symptom relief mainly from dyspnea. If that individual will not be able to live without continued ventilatory support, yet wishes to maintain cognition and prolong life, NIV in combination with pharmacologic agents may support these combined goals as the individual approaches the end of life.⁴ In acute situations and near end of life, the individual may wish to utilize these therapies in the short term to achieve certain goals, such as seeing family members prior to their death.

Interventional Therapy

The palliative APRN may consider referrals for interventional therapies to reduce dyspnea if consistent with the individual's goals of care. Disease-modifying therapies that may reduce dyspnea, such as chemotherapy and radiation therapy, should be explored as first-line treatments for obstructions secondary to tumor burden.⁹⁷ Mechanical or chemical pleurodesis may reduce dyspnea secondary to pleural effusions. For those with more advanced disease, the placement of a tunneled catheter for management of pleural effusions has been shown to be the most effective option.^{77,98} For those with malignant airway obstruction, interventional bronchoscopy as well as or instead of stenting may provide benefit.⁹⁹ However, the increased risk of infection secondary to stenting should be balanced against the possible benefit of decreased feelings of dyspnea.

Nonpharmacologic Management

Treatment for dyspnea is best managed using an individualized multimodal approach. When considering the inclusion

of pharmacologic and nonpharmacologic treatments, it is important to consider the individual's beliefs, the perceived relevance, insurance coverage, short-term benefits, convenience in administration, and caregiver involvement, as well as the stage and trajectory of the disease.^{99,100}

Therapies

A Cochrane review assessed various therapies used for breathlessness. There was high-level evidence for the use of neuromuscular electrical stimulation (NMES) applied to quadriceps for dyspnea improvement over several weeks in individuals with COPD. Chest wall vibration also improved dyspnea in individuals with COPD and in one study for those with neuromuscular disease. In malignant and non-malignant disease states, walking aids and breath training had a moderate level of evidence to support their use, and acupuncture showed improvement in dyspnea symptoms with low quality of evidence.⁷⁸ There is a paucity of studies of these therapies on those with ILD and therefore these therapies can only be recommended with weak evidence.⁶²

Pulmonary Rehabilitation

There is strong evidence for the use of pulmonary rehabilitation (PR) to improve QoL and dyspnea in individuals with COPD,^{101–103} CHF,^{104,105} and ILD.¹⁰⁶ These programs may be safe for individuals who are not in acute respiratory distress or failure and may be combined with other therapies such as NIV or a combination of breath training with aerobic training to have maximal benefit.^{76,79} In a prospective RCT of individuals with CHF, inspiratory muscle training (IMT) with computer-assisted measurement and guidance was added to standard PR aerobic training. Both groups in PR showed improvement in exercise tolerance and dyspnea, yet individuals who had IMT with standard PR showed significantly higher improvement in exercise tolerance and dyspnea symptom reduction at peak exercise.¹⁰⁴ It is important to recognize that improvement in exercise tolerance, dyspnea symptoms, and QoL may be gradual as many of these programs take place over many weeks or months. The study of PR in individuals with cancer is sparse, yet there are many areas of potential for the possibility of improving QoL, exercise tolerance, and perhaps dyspnea with PR, thus much more research is needed to answer these questions.¹⁰⁷

Psychoeducational Interventions

The authors of a systematic review on noninvasive interventions for lung cancer concluded that nursing intervention programs may improve dyspnea.¹⁰⁸ Counseling, education, exercise, and relaxation techniques to manage breathlessness have been beneficial in individuals with various serious illnesses and most effective when combined with PR to extend the effectiveness of training.² In a RCT of an internet-based self-management support program compared to face-to-face care and general health education for individuals with COPD, dyspnea was not reduced, but there was satisfaction with participation in the program and increased self-efficacy.¹⁰⁹ Cognitive-behavioral interventions have been shown to have a positive effect on anxiety and depression.

Doyle and colleagues (2017) demonstrated that the addition of volunteer-based neutral befriending conversations in addition to standard cognitive training demonstrated improved and longer-lasting reduction of anxiety in those with COPD versus cognitive training alone.¹¹⁰ A common theme in these programs is the inclusion of education, social support, and empowerment of individuals who may be isolated by their illness, which may increase self-efficacy and improve self-management of dyspnea.²

Breathlessness Intervention Services

In those with serious illness, the effects of breathlessness on a person's life may compromise their dignity or feelings of self-respect or worth. Targeting holistic treatment to illness-related concerns can benefit the individual's breathlessness symptoms and dignity.^{2,26,109,111} A newer concept in the treatment of dyspnea, *holistic breathlessness services*, may increase understanding and self-efficacy, decrease feelings of isolation and distress, and optimize person-centered care. This comprehensive approach to treating dyspnea includes combining palliative care specialists and respiratory physiotherapists as holistic breathlessness services who work together to manage dyspnea and reduce distress in individuals with advanced disease.⁸⁰

An RCT (2014) of individuals with refractory breathlessness and breathlessness at rest were treated with usual care or seen by a holistic breathlessness service for 6 weeks. The service combined palliative, respiratory, occupational, and physical therapy. Those who participated with holistic services had about 16% improvement in rating mastery of breathlessness over those in standard care group. Although findings were not significant, anxiety rating were more improved in the intervention group.¹¹² Ultimately, optimizing person-centered care has the potential to treat and maintain dignity for individuals with breathlessness and serious illness.^{80,112} Although these services may not be available to the palliative APRN working in rural settings, working to collaborate and include respiratory physiotherapists in the assessment and management of dyspnea may improve outcomes.

Fans

The use of fans has been advocated for the relief of dyspnea because airflow has been shown to relieve dyspnea.³³ It has been hypothesized that cool air on the nasoreceptors decreases the subjective feeling of dyspnea. In a randomized controlled crossover trial evaluating the use of a handheld fan on the leg and face, results showed a positive effect on dyspnea with the use of the fan on the face.¹¹³ Results from a meta-analysis demonstrated that fan therapy was effective in treating dyspnea in individuals with terminal cancer.³² Due to its low risk and cost, a trial of a fan is warranted, except for those with facial pain secondary to trigeminal neuralgia or a neuropathic process that may be aggravated by the air on the face. At the time of this writing, with the prevalence COVID-19, an airborne virus, the use of fans may not be appropriate due to the risk of infection spread. These are a cost-effective intervention for patients in residential, home

settings, in hospice programs, and who live in less resourced areas.

Acupuncture

Acupuncture has been shown to be beneficial for dyspnea symptoms in people with advanced disease, yet many studies have been small and heterogeneous or lacked a control group.¹¹⁴ Results from a recent RCT in individuals with lung cancer undergoing chemotherapy demonstrated significant improvement in dyspnea symptoms in the acupressure group.¹¹⁵ If available without undue burden to the individual, acupuncture may be a consideration as part of a multimodal therapeutic approach.

Management at the End of Life

Dyspnea may worsen in both pulmonary and nonpulmonary disease states toward the end of life. The palliative APRN should optimize pharmacologic management at this time to relieve suffering. In the acute care setting, the use of an opioid infusion may treat both dyspnea and pain and may be rapidly titrated. Benzodiazepines in combination with opioids may improve moderate to severe dyspnea when opioids alone have failed.^{3,4} Although there may be concern that opioids and benzodiazepines may hasten death, the principle of the double effect justifies their use to relieve dyspnea at the end of life.⁶⁷ In home care settings, use of sublingual or rectal routes of opioids and benzodiazepines may alleviate dyspnea at end of life. For a select few who experience intractable dyspnea, the use of palliative sedation may be a consideration if dyspnea cannot be controlled with opioids and benzodiazepines (see Chapter 57, “Palliative Sedation”).

At the time of this writing, there is a worldwide pandemic secondary to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2 or COVID-19). Due to the acute and potentially chronic injury to the pulmonary system, the individual may experience resulting chronic dyspnea. Depending on the individual’s physiologic status, underlying comorbidities, and goals of care, treatment focus may preclude the ability to reverse the disease trajectory. In these cases, the focus will shift to the management of dyspnea to relieve suffering, and methods utilized in other disease states would also be used in this setting.

CASE STUDY: SHORTNESS OF BREATH
(CONTINUED)

Carey was able to attend her son’s wedding. She took an average of morphine 4 mg about 8 times a day for her dyspnea and was transitioned to extended-release morphine 15 mg two times daily with 4 mg morphine available every 2 hours as needed. After 2 months, she returned to the clinic in a wheelchair with a 15-pound weight loss, and worsened and more painful cough. She felt that the morphine wasn’t helping her dyspnea as it had in the past. Her lung sounds were very diminished throughout the right lung fields, and she described extremely thick yellow sputum with

her cough. On chest radiograph she had a large right pleural effusion and a small left pleural effusion.

After discussion about her goals in care, she shared that she was hoping that she and her family could have hospice support to help her remain at home with her family as much as possible and enjoy time outside during the warm weather. With those goals in mind she agreed to referral to interventional radiology for palliative pleural drainage catheter placement with the hope of managing the pleural effusion at home.

COUGH

Acute and chronic cough secondary to multiple etiologies, including premorbid conditions, medical therapies, and advanced diseases, can be a debilitating symptom. Individuals seek medical attention for cough due to concerns about serious illness, sleep disturbances, difficulties with tasks such as speaking on the phone, urinary incontinence, and the impact on family, friends, and co-workers who may be disturbed by the cough.¹¹⁶ Cough as a primary symptom can also create and exacerbate other symptoms and is often part of a symptom cluster that includes pain, dyspnea, and lack of appetite.¹¹⁷ The additive effect of multiple distressing symptoms can impact the individual’s QoL, thus highlighting the need for the palliative APRN to possess the skills to manage multiple related symptoms in the individual with serious illness.

Cough due to viral infections of the respiratory system is one of the leading causes of visits to medical providers.¹¹⁸ The prevalence of chronic cough, which is defined as cough that persists for longer than 8 weeks, is estimated to be 10% worldwide, with higher prevalence in Oceania, Europe, and America.¹¹⁹ Internationally, cough is more predominant in women; two-thirds of the individuals seeking medical care for chronic cough were women in their 60s.¹¹⁶

Although cough is a major symptom seen in those with serious illness, there is a dearth of high-quality studies conducted in the palliative care population.^{117,120} The mainstay of cough management in palliative care is extrapolated from the guidelines for the management of cough in the general population.^{116,118,121–123}

CASE STUDY: SHORTNESS OF BREATH
(CONTINUED)

Carey was assessed by the hospice nurse. Her dyspnea was better controlled with the pleural catheter placement; however, it was more difficult to clear her thick secretions. She reported the constant presence of cough since her teenage years.

PHYSIOLOGY

Cough is a complex protective neuronal reflex that protects the lungs from chemical and thermal irritants, clears

secretions, prevents aspiration, but also spreads infectious disease. The complex physiology, which is still not completely understood, is outlined briefly here. Cough receptors (nerve endings of sensory vagal nerves) innervate the pharynx, trachea, carina, and bronchi. Mechanical and chemical stimuli and inflammatory mediators (tachykinins, bradykinin, and prostaglandins) activate the cough receptors located in the epithelium of larynx, trachea, and bronchi. These receptors detect the stimuli and transmit the signal to the cerebral cough center via the myelinated A-delta (fast-adapting and slow-adapting mechanoreceptors) and the nonmyelinated C-fibers.

Cough is then generated by motor neuron reflexes under the influence of the neurons in the medulla oblongata. The influence of the brain on cough is seen with cough suppression, idiopathic or refractory cough, and the absence of cough during anesthesia. The cough reflex can also be activated via extrapulmonary sources such as rhinosinusitis, even though vagal nerves are not located in the nose or sinuses. The current thought is that, in these cases, trigeminal nerve fibers are involved in the activation and relief of cough.

The cough reflex can be modulated by blocking multiple transient receptor potential (TRP) ion channels, N-methyl-D-aspartate (NMDA) and γ -aminobutyric acid (GABA), which provides opportunities for treatment strategies. To add to the complexity of cough pathophysiology, hypersensitivity of the cough reflex may occur through peripheral sensitization and central neuronal changes, thus leading to chronic idiopathic or refractory cough.^{118,124} Chronic refractory, idiopathic cough, more commonly referred to as *cough hypersensitivity syndrome* (CHS), has been likened to neuropathic pain, which often has central neuronal changes.¹²⁵ With this emerging understanding related to the physiology of cough, the possibilities of treatment can be expanded to include agents that are utilized in the treatment of neuropathic pain.

It is helpful to think of the cough event in three separate phases: (1) the inspiratory phase to produce enough volume for the cough; (2) the compression phase, where the larynx closes and the chest wall, diaphragm, and abdominal wall muscles contract, thus increasing intrathoracic pressure; and (3) the expiratory phase, during which the glottis opens, and there occurs an expiration of air that may dislodge mucous or foreign materials.¹²⁶

COMMON ETIOLOGIES

Cough has been classified based on its duration into three phases: acute 1–3 weeks, subacute 3–8 weeks, and chronic cough greater than 8 weeks. Recurrent acute cough is that which recurs several times yearly and lasts up to 3 weeks¹¹⁸ (see Table 44.4).

Acute Cough

Acute cough is most commonly associated with viral infections of the respiratory tract and generally resolves within a

Table 44.4 ETIOLOGIES OF COUGH IN THE GENERAL POPULATION

Acute (1–3 weeks)	Viral infections Asthma Inhalation intoxication Pulmonary embolism Pneumothorax Acute congestive heart failure
Subacute (3–8 weeks)	Viral infection Postviral rhinosinusitis Pneumonia Pleuritis
Chronic (>8 weeks)	Upper airway cough syndrome (UACS) Cough variant asthma Nonasthmatic eosinophilic bronchitis GERD Chronic bronchitis secondary to COPD ACE inhibitors Obstructive sleep apnea Chronic idiopathic cough or UCC/CHS

COPD, chronic obstructive pulmonary disease; CHS, cough hypersensitivity syndrome; UCC, unexplained chronic cough.

From Morice et al.¹¹⁶; Kardos et al.¹¹⁸; Lai et al.¹²¹; Gibson et al.¹²³; Spanevello et al.¹²⁷; and Song, Morice.¹²⁸

few weeks without specific treatment. The various causes of acute cough include not only viral infections, but also asthma and inhalation intoxication such as from smoke, as well as acute lung pathologies, such as pulmonary embolism, pneumothorax, or acute CHF exacerbation.¹¹⁸

Subacute Cough

Similar to acute cough, the most common reason for subacute cough that persists from 3 to 8 weeks is a viral infection. The cough may also be a result of postviral rhinosinusitis due to bronchial hyperreactivity or may be secondary to lung pathology such as pneumonia and pleuritis.¹¹⁸

Chronic Cough

Cough lasting more than 8 weeks, labeled chronic cough, has many potential causes. Airway diseases responsible for chronic cough include chronic upper airway diseases; chronic bronchitis secondary to COPD; cough variant asthma, including nonasthmatic eosinophilic bronchitis; obstructive sleep apnea; lung cancer; cystic fibrosis; and environmental irritants (smoke); as well as systemic disease with lung involvement or rare diseases of the tracheobronchial system. Extrapulmonary diseases that can cause chronic cough are gastroesophageal reflux disease (GERD), angiotensin-converting enzyme (ACE) inhibitors, and cardiac diseases that produce lung congestion and endocarditis. Chronic idiopathic cough, also termed *unexplained chronic cough* (UCC), is also a consideration if diagnostic workup is negative for the just listed pathologies.^{118,123,127} Emerging evidence suggests that chronic cough even in some of the above-mentioned disease states may be due to CHS.^{116,127,128}

BRIEF OVERVIEW FREQUENT CAUSES OF COUGH

Upper Airway Cough Syndrome

Upper airway cough syndrome (UACS), which has also been referred to as *postnasal drip syndrome*, *rhinitis*, or *rhinosinusitis* has been assumed to be one of the most common cause of chronic cough. With the evolution in the understanding of chronic cough, some question whether the cough that has been attributed to UACS may actually be cough secondary to CHS.¹¹⁶

Cough Variant Asthma/Nonasthmatic Eosinophilic Bronchitis

Asthma is characterized by chronic or recurrent respiratory symptoms associated with airway inflammation and variable airflow obstruction. Most individuals experience wheeze, dyspnea, and cough. Some individuals with asthma who have cough-predominant symptoms without signs of bronchial obstruction can be classified as having cough-variant asthma.^{116,118} A third disorder classified under asthma that causes a chronic cough, not secondary to bronchoconstriction or hyperresponsiveness is nonasthmatic eosinophilic bronchitis.¹¹⁶

COPD

Cough is a common symptom for those with COPD who have chronic bronchitis. Variations of cough in COPD types may not be fully understood and appreciated. Cough secondary to bronchitis is generally defined as cough that has occurred for at least 3 months a year for 2 years and is not attributable to other causes. Madison and Irwin (2020) have raised concerns that other potential causes of chronic cough in those with COPD such as UACS, GERD, and asthma may be overlooked and thus further diagnostics and treatments could be missed.¹²⁹

GERD

Chronic cough secondary to GERD has been one of the most frequently cited.¹²⁷ At present, GERD is viewed as one of the possible triggers for chronic cough due to hypersensitivity of the cough reflex.¹¹⁸ There is also controversy about the role of reflux in chronic cough and the possibility that esophagopharyngeal reflux may be the actual problem.¹¹⁶

ACE Inhibitors

Cough associated with ACE inhibitors, which is a class effect, was first reported with the medication captopril in 1985.¹³⁰ The incidence of cough secondary to ACE inhibitors varies from 3.9% to 35%. Approximately 20% of individuals discontinue ACE inhibitors due to cough. The cough tends to be dry, is not dose-related, and time to onset varies; it can occur within hours or months after starting treatment and can persist for months after discontinuation of treatment.¹³¹

UCC and CHS

Chronic idiopathic or refractory cough, also termed UCC, was a category utilized to define chronic cough that did not seem to be associated with the conditions known to cause cough.¹²³ A relatively new paradigm, CHS, has been proposed to describe unexplained cough that may arise from increased sensitivity to chemical, thermal, mechanical, or emotional triggers. CHS is thought to arise from dysregulation of the neural pathways that regulate the cough reflex and neural alterations that regulate cough processing. Clinical measurement tools are lacking and antitussives may not be effective, whereas agents that work centrally, such as gabapentinoids and opioids, may be helpful.^{127,128}

ETIOLOGIES OF COUGH IN INDIVIDUALS WITH SERIOUS ILLNESS

In the palliative care population, cough may be a common symptom seen in those individuals with ineffective swallowing, malignancies (most commonly lung and surrounding structures), and infections in those with diseases such as COPD and cystic fibrosis. Common causes of cough such as UACS, viral infections, and GERD can also occur in those with serious illness and may not be related to the life-limiting illness.¹³² Consideration for aspiration as a causative factor of cough should be considered in those with dementia,^{133,134} neuromuscular diseases,¹³⁵ and Parkinson's disease¹³⁶ as there may be decreased cough sensitivity which results in aspiration.^{133–136}

In individuals with cancer, cough is most commonly associated with primary cancers arising from the airways, lungs, pleura, and other mediastinal structures as well as primary tumors metastasizing to the mediastinum.^{117,137} Indirect causes include pulmonary embolism, atelectasis, pleural effusion, pericardial effusion, and infections such as pneumonia or empyema.¹³² Radiation therapy has also been known to cause fibrosis of the lung, which can cause chronic cough.¹¹⁷

Targeted agents such as immunotherapies utilized in advanced lung cancer are known to cause pneumonitis, in which cough and dyspnea are the predominant symptoms. At the time of this writing, COVID-19 infection is a worldwide pandemic. Lung involvement, with bilateral pneumonia has been reported in up to 80% of symptomatic individuals. Given similar symptomatology (dyspnea and cough), it may be challenging to initially determine the causative factor¹³⁸ (see Table 44.5).

ASSESSMENT

The palliative APRN's comprehensive assessment will help guide symptom management. In an individual with serious illness and cough, the APRN may already have some ideas about the causative factor of the cough based on the underlying disease. However, determining the etiology of cough in an individual with serious illness can be challenging. Multiple etiologies need to be considered given the likelihood of chronic

Table 44.5 ETIOLOGIES COUGH IN INDIVIDUALS WITH SERIOUS ILLNESS

Pulmonary	COPD Cystic fibrosis Interstitial lung disease
Neurologic	Amyotrophic lateral sclerosis Cerebrovascular disease Dementia Multiple sclerosis
Cardiac	CHF
Systemic	HIV Tuberculosis
Cancer	Direct Causes Tumor/tumor microemboli Pulmonary parenchymal involvement Lymphangitic carcinomatosis Intrinsic or extrinsic airway obstruction Pleural effusion Indirect Causes Chemotherapy, targeted therapy Radiation therapy GERD infection Paraneoplastic syndrome Pulmonary embolus Smoking

This list is not exhaustive. Consider etiologies of cough in general population in addition to those listed.

CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; GERD, gastroesophageal reflux disease.

From Molassiotis et al.¹¹⁷; Spanevello et al.¹²⁷; von Gunten, Buckholz¹³²; and Harle et al.¹³⁷

comorbidities. The APRN should differentiate between acute versus subacute versus chronic cough, infectious versus noninfectious cough, life-threatening versus non-life-threatening causes, and cancerous versus noncancerous or chronic conditions.

By conducting a comprehensive assessment, the palliative APRN may be able to differentiate between the acute or new pathology and comorbid conditions contributing to cough (see Table 44.6). Assessment of cough begins with a thorough review of the individual's medical history, review of systems, and current medications. The APRN should inquire about environmental factors such as current and past occupation, tobacco or cannabis use, exposure to secondhand smoke or other irritants or allergens known to cause cough. A review of medications will help determine if the individual is taking medications that may cause cough (i.e., ACE inhibitors) and which medications have been ineffective in controlling cough.

The APRN should conduct a thorough individual evaluation of the cough, including the intensity and quality of the cough (wet, dry, productive), its temporal onset (acute, subacute, chronic), frequency, precipitating, aggravating and alleviating factors, accompanying symptoms, and the resulting emotional stress. Assessment should include inquiry into potential red flags (fever, weight loss, vocal changes) that may

Table 44.6 COUGH ASSESSMENT

Clinical interview	Onset, duration, severity, productive/non-productive, exacerbating/alleviating factors Use of disease-modifying therapies that could induce/control cough Lifestyle factors: Smoke exposure, environmental triggers
Assessment tools	The Leicester Cough (LCQ) Questionnaire Cough-Specific Quality-of-Life Questionnaire (CQLQ) Visual analogue scale (VAS)
Physical examination (tailored to potential cause of cough)	General: Observation type/frequency of cough Ears, nose, and throat: Signs of rhinitis/pharyngitis, swallow and gag reflex Pulmonary: Respiratory rate and quality, lung sounds, sputum production Cardiac: Heart sounds, jugular venous pressure, edema
Diagnostic testing (if indicated to assess for etiology)	Asthma Spirometry, methacholine challenge, induced sputum GERD 24-hour pH testing, esophageal manometry UACS Sinus radiography or computed tomography, laryngoscopy, videofluoroscopic swallow evaluation; nasopharyngoscopy Cardiopulmonary Chest radiograph, computed tomograph (CT) scan of the chest/neck, bronchoscopy, echocardiogram Esophageal Modified barium swallow, endoscopy

GERD, gastroesophageal reflux disease; UACS, Upper airway cough syndrome.

From Morice et al.¹¹⁶; Kardos et al.¹¹⁸; Lai et al.¹²¹; Spanevello et al.¹²⁷

indicate a new concerning pathology or infection. Changes in environmental triggers should also be assessed as a potential cough trigger.^{125,139}

For those with acute cough, the APRN should first consider the most common causes of cough, such as rhinoviruses, especially in those reporting nasal congestion and rhinitis or postnasal drip. Assessment for GERD should be considered when there are reports of acid regurgitation or retrosternal pain. Acute respiratory infections should be considered if the individual reports cough with purulent sputum production.^{121,123}

The palliative APRN should focus questions related to the organ system that is most likely associated with the cough. For example, in individuals with COPD, the APRN should inquire about the presence of fever/chills, productive or nonproductive sputum, hemoptysis, and increased dyspnea. The APRN should ask individuals with CHF about

weight gain, increased edema, orthopnea, activity intolerance, and increased use/need for oxygen.^{121,125} The APRN should consider the use of cough assessment tools such as the Leicester Cough (LCQ) Questionnaire¹⁴⁰ and the Cough-Specific Quality-of-Life Questionnaire (CQLQ),¹⁴¹ which are valid and reliable for use in adults. Although widely used, the Visual Analogue Scale (VAS) has insufficient data to support its use.^{116,142}

In individuals with chronic cough, the APRN should consider if there may be more than one etiology of the cough, especially in individuals with multiple comorbidities. To consider appropriate management, the APRN may need to consider if the source of cough in an individual with lung cancer is secondary to the tumor, the treatment, or a comorbidity such as COPD or GERD.

When conducting the physical examination, the palliative APRN should take into consideration the individual's medical history and the clinical interview. Consideration should be given to several different organ systems that may be the etiology of the cough; this includes examination of the ears, nose, throat, heart, and lungs.¹²¹ The APRN may also assess the individual's swallowing and gag reflex to assess for possible presence of aspiration that could be contributing to the cough. However, in the frail individual, such as the person with dementia, the cough reflex may be impaired or even absent and thus contribute to the development of repeated aspiration pneumonia.¹³³

DIAGNOSTIC EVALUATION

With the information obtained from the interview and physical examination, the APRN can determine what type of diagnostic evaluation may be necessary. In the population without life-limiting illnesses, workup of some of the most common causes of cough include the following:

- Asthma: Spirometry, methacholine challenge (a drug used to induce bronchoconstriction that can be measured by spirometry), and induced sputum test
- GERD: Twenty-four-hour ambulatory pH monitoring, and esophageal manometry
- UACS: Plain sinus radiography and CT of the sinuses^{118,125}

Normal chest radiography usually excludes bronchiectasis, persistent pneumonia, sarcoidosis, and tuberculosis.¹²⁵ If aspiration is suspected, a clinical assessment and tests such as the modified barium swallow can determine the degree of dysphagia.¹⁴³

In those with serious illnesses, such as cancer or advancing COPD, the APRN should consider whether more comprehensive diagnostic tests such as CT scans are warranted. If the APRN is in a consultative role, involvement of the primary specialists (oncologists, pulmonologists, cardiologists) may help tailor the type of evaluation needed and avoid the possibility of duplicate diagnostic evaluations.

CASE STUDY: SHORTNESS OF BREATH (CONTINUED)

Although Carey had previously declined medications for cough, she was interested in a retrial of guaifenesin 600 mg extended-release every 12 hours to help thin her pulmonary secretions. She occasionally utilized 4 mg of oral morphine about 2–3 times daily for severe cough with dyspnea, but she preferred to avoid sedating medications. Carey also utilized relaxation techniques that not only helped her cough but also her dyspnea.

Four weeks after placement of a pleural catheter and hospice admission, Carey developed a fever and worsening dyspnea after her grandson who lived out of state visited her. He later tested positive for COVID-19. Carey's cough and dyspnea worsened, and she developed a fever. She did not want to seek any further medical workup. Carey was able to stay at home with the priority of comfort over alertness at the end of her life. Her oral morphine dose was titrated up and lorazepam was utilized to manage her dyspnea and cough. She died peacefully with her family around her.

MANAGEMENT

Palliative APRNs play an instrumental role in the care of individuals with life-limiting illnesses. Management of cough in this population may vary considerably from that of the general population. In the general population, managing cough is directed at treating reversible causes. Although the diagnostic workup and treatment may include some modalities seen in the general population, those same methods may not be feasible for individuals with advanced disease if they are approaching the end of life.

Pharmacologic Therapies

The goal of cough management is to treat the underlying cause and either help promote cough (expectorants) or suppress cough (antitussives). For acute cough related to the common cold, individuals often use antihistamines, decongestants, nonsteroidal anti-inflammatories, and over-the-counter cough suppressives. However, due to the paucity of high-quality studies, there are no specific recommendations.¹⁴⁴ For those with subacute cough (3–8 weeks), individuals often use over-the-counter antitussives and inhaled corticosteroids. However, results of studies do not support the use of any pharmacologic agents for subacute cough not related to COPD or asthma.¹⁴⁵

Targeted therapy should be considered in individuals with chronic cough related to conditions that affect the general population, such as UACS, asthma, GERD, and chronic bronchitis, with the primary aim being the treatment of the underlying cause of the cough. For these conditions medications such as expectorants and inhaled corticosteroids (UACS), antacids (GERD), inhaled/oral corticosteroids (asthma/bronchitis), and bronchodilators (bronchitis) may be the mainstay of treatment for cough.^{116,118,143} With the recent

evolution in the understanding of UCC and CHS, treatment may include neuromodulatory agents utilized to treat neuropathic pain such as gabapentinoids and tricyclic antidepressants.¹²³ Medications are in development that target the cough reflex pathway, which may change treatment options for those with UCC.^{128,146}

It is important to recognize that, for many individuals receiving palliative care, cough may be related to a comorbid condition that is not the life-limiting illness. The palliative APRN may have the opportunity to provide guidance for treatment of the cough to the clinician managing these comorbid conditions. In individuals receiving palliative care, there is a lower threshold for empiric treatment to manage the distressing symptom of cough especially if the overall care is directed toward alleviating distressing symptoms. A pragmatic approach has been proposed that includes stepwise treatment, much in the same way as pain is treated based on severity.¹⁴⁷ In the case of worsening cough and advancing disease, opioids may be the medication class of choice if the cough is severe and not responsive to other measures.¹¹⁶ A brief description of pharmacologic agents will help the palliative APRN determine the best treatment in those with serious illness (see Table 44.7).

Expectorants

Expectorants decrease the viscosity of mucus, allowing for improved expulsion. This can be helpful for the individual with excessive or thick mucus production. Guaifenesin, the only expectorant available in the United States, is utilized in many over-the-counter products for cough and cold. However, it can also be utilized in conditions where mucus hypersecretion and cough are present, such as in chronic bronchitis. It is relatively safe, well-tolerated, and is available in both immediate-release and extended-release formulations.¹⁴⁸ Simple nebulized saline solution and substances that lessen irritation, such as thyme cough syrup, can also be effective. Other medications, such as acetylcysteine and ambroxol hydrochloride, are also utilized but may not be available in the United States.^{121,149} Caution should be exercised when prescribing expectorants in individuals with neuromuscular diseases, such as amyotrophic lateral sclerosis, due to impaired cough.¹⁴⁹

Opioids

When the cough's etiology has been determined and effectively treated, the goal may be to suppress the cough with antitussives. Cough suppressants are classified as central and peripheral antitussive drugs. Peripheral agents act on receptors in the cough reflex arch, whereas central agents act on the cough center in the medulla oblongata.¹²¹ Therefore, centrally acting medications may produce side effects like sedation.¹⁴⁹ Among centrally acting medications, opioids, such as codeine and morphine, bind to the μ -opioid receptor and suppress the cough center.^{121,150}

Even though codeine has long been promoted as an antitussive, its efficacy has not been demonstrated in clinical trials.¹⁴⁹ Codeine exerts its effect by converting codeine to morphine through cytochrome P450 2D6 activity. Some

Table 44.7 SELECTED PHARMACOLOGIC TREATMENTS OF COUGH IN PALLIATIVE CARE

MEDICATION	SUGGESTED DOSES (IF APPLICABLE)
Guaifenesin (expectorant)	200–400 mg PO q4h 600–1,200 mg ER PO bid
Opioids/Opioid derivatives (cough not responsive to reversal of pathology)	
Morphine	5 mg PO/SL q2–4h PRN
Hydrocodone	5 mg PO q4h PRN
Dextromethorphan (opioid derivative)	15–30 mg PO q4h PRN
Anesthetics (chronic refractory cough)	
Lidocaine (fentanyl and opioid associated cough)	3–5 mL of 4% nebulized bid-tid or 0.5–1.5 mg/kg IV once
Benzonatate	100–200 mg PO tid
Neuromodulatory agents (used in UCC/CHS)	
Gabapentin	300–2,700 mg PO tid
Pregabalin	75–150 mg PO bid
Baclofen	30–60 mg PO tid
Amitriptyline	10–100 mg PO daily
Miscellaneous medications (refer to dosing guidelines)	
Inhaled, nasal or oral corticosteroids (cough secondary to cough variant asthma, eosinophilic bronchitis, lung cancer)	
Glycopyrrolate (anticholinergic utilized at end of life to decrease secretions)	
Ketamine, propofol, dexmedetomidine, pheniramine maleate, lidocaine (opioid-induced cough)	

List is not all-inclusive.

From Morice et al.¹¹⁶; Molassiotis et al.¹¹⁷; Harle et al.¹⁴⁷; Bausewein, Simon¹⁴⁹; Morice, Kardos¹⁵¹; Lim et al.¹⁵²; and Bishop-Freeman et al.¹⁵³

individuals may be rapid metabolizers and others slow metabolizers; therefore it is difficult to predict its action. In those who are rapid metabolizers, there is a risk of oversedation and respiratory depression. Thus, while it had been an antitussive of choice in children, the risks outweigh the benefits and it should be avoided.¹⁵¹ Moreover, in many places it is being eliminated from formularies since there are better medications to use.

In palliative care, morphine is the preferred opioid because it also can treat distressing symptoms, such as dyspnea, which can often co-occur with cough. In an earlier randomized, double-blind, placebo-controlled trial ($n = 27$), daily cough score was reduced by 40% with 5–10 mg of daily morphine.¹⁵⁴ In a recent small double blind, placebo-controlled crossover study ($n = 22$) of those with chronic cough treated with morphine, 78% of individuals had decreased cough frequency with low-dose morphine.¹⁵⁵

The use of nebulized medications to treat symptoms has been an interest in palliative care. However, the evidence for use of nebulized morphine for cough is limited to case reports,¹⁵⁶ thus it should not be considered unless no other options are available to treat the cough. Hydrocodone is another opioid commonly prescribed for cough. Some hydrocodone products also contain the anticholinergic homatropine (1.5 mg/5 mL hydrocodone) to reduce deliberate overdose.¹⁵⁷ In a small ($n = 20$) Phase 2 study of hydrocodone in individuals with lung neoplasms, 19 individuals experienced at least 50% improvement in cough with a median dose of hydrocodone 10 mg daily.¹⁵⁸ Although widely used, there have not been more robust studies about the efficacy of hydrocodone. Because it is an opioid, it may provide benefit for those unable to utilize morphine. Dextromethorphan is an opioid derivative and NMDA receptor antagonist with antitussive efficacy and low toxicity that could be considered for cough suppression.^{120,147}

Corticosteroids

Corticosteroids are utilized in individuals with serious illness to treat multiple distressing symptoms such as pain, nausea, lack of appetite, and fatigue. Generally, their use is limited by the long-term side-effect profile. Although there is not supporting evidence, inhaled corticosteroids are often utilized in acute or subacute cough.¹⁴⁵ Inhaled or nasal corticosteroids may be effective in chronic cough for those individuals who have cough variant asthma and eosinophilic bronchitis.^{116,118,127,159} Even though there is a paucity of studies, in those with cough related to lung cancer, a trial of corticosteroids is warranted, if not contraindicated by other health conditions or chemotherapy regimens.

Anesthetics

The most commonly used peripherally active antitussives are inhaled local anesthetics, such as bupivacaine 0.25% or lidocaine 2%.¹¹⁷ There is evidence for the use of nebulized lidocaine for cough that has not responded to other antitussives.^{117,149,160} Although there have been concerns for safety, reports from case series on the use of inhaled lidocaine for intractable cough did not reveal serious adverse effects.^{159,161} While there is evidence supporting the use of lidocaine for intractable cough, there is a dearth of quality studies.¹⁶⁰ Intravenous lidocaine may be effective in preventing opioid-induced cough,¹⁶² particularly fentanyl-associated cough.¹⁵³ IV lidocaine could be helpful for individuals requiring opioids such as fentanyl in settings such as the intensive care unit. Benzonatate, a peripherally acting oral local anesthetic, may be helpful for cough unresponsive to other antitussives.^{117,147} Individuals with pulmonary disease may utilize this medication on a chronic basis. Caution needs to be exercised due to the possibility of toxicity if taken at higher than prescribed doses because it can cause seizures and cardiac collapse.¹⁶³

Neuromodulatory Agents

CHS is believed to contribute to chronic refractory cough (also known as UCC) that is not relieved by treatment of the underlying pathology or through antitussives. This cough is thought to have a neuropathic component, thus current

treatments have focused on agents that treat neuropathic pain, with the most widely studied being the gabapentinoids.^{164–166} Amitriptyline, a tricyclic antidepressant also utilized for neuropathic pain, has been evaluated for chronic cough.¹⁶⁴

In a study comparing gabapentin and amitriptyline over 6 months, both had short-term efficacy. Individuals in both arms dropped out due to lack of efficacy, but there was a higher discontinuation rate among those in the amitriptyline arm.¹⁶⁴ An RCT compared gabapentin and baclofen for refractory cough secondary to GERD. More than 50% of individuals showed improvement, but gabapentin was better tolerated.¹⁶⁶ As the understanding of chronic refractory cough evolves, treatment modalities may be developed that more effectively treat cough. Studies of medications that exert their effect on the different areas of cough reflex neural pathways are in progress.¹²⁸

Miscellaneous

Other miscellaneous agents utilized for opioid-induced cough include dexmedetomidine,^{161,167} propofol, or ketamine.¹⁶¹ In one study, the antihistamine pheniramine maleate was more effective than lidocaine for the reduction of fentanyl-induced cough.¹⁶⁸ Anticholinergics, such as glycopyrrolate, may be helpful during the dying phase as decreasing secretions may also decrease cough.¹³² Given that these agents are utilized for other purposes, they may provide a secondary benefit in palliating cough.

Nonpharmacologic Interventions

Nonpharmacologic techniques for cough management may help the individual strengthen their cough (cough augmentation) for airway clearance or control their cough (cough suppression).¹⁶⁹ These techniques have not been widely studied in the palliative care population. However, the palliative APRN managing symptoms for individuals with chronic progressive diseases such as amyotrophic lateral sclerosis may find benefit from cough augmentation strategies. Individuals with advancing diseases with chronic cough may also benefit from nonpharmacologic techniques of cough suppression or augmentation (see Box 44.3).

Complementary and Alternative Therapies

Individuals may utilize home remedies and preparations to control cough or improve expectoration. Eucalyptus and myrtol have been used in preparations as expectorants.¹²¹ Traditional Chinese Medicine formulas are included in the Chinese Thoracic Society's guidelines for treatment of cough (2018). These formulas have also been utilized to treat cough, even in the cases of cough unexplained by any pathology.¹²¹ Individuals may utilize honey to reduce cough. Studies evaluating honey for acute cough secondary to cold have been conducted in the pediatric population. Honey was not more effective than dextromethorphan, but may be more effective than diphenhydramine or no treatment. Zinc was found to reduce cold symptoms that include cough if administered within 24 hours of onset of symptoms.¹⁴⁴ These treatments, although marketed as natural, may have unwanted side effects

or interactions with the individual's medical treatment. Thus, the palliative APRN should always inquire about the use of complementary or alternative therapies.

Cough Suppression Nonpharmacologic Therapies

Most studies on cough suppression therapies have been conducted on individuals with chronic cough without life-limiting illnesses. However, in a multicenter randomized controlled study aimed at testing the feasibility of a nonpharmacologic intervention for the management of a respiratory distress symptom cluster (breathlessness, cough, fatigue), individuals participated in a respiratory distress symptom intervention that included controlled breathing techniques, cough easing techniques, acupressure, an information packet, and psychoeducation. This type of study intervention was deemed feasible and acceptable by the participants, but a fully powered trial is necessary for definitive conclusions.¹⁷²

Nonpharmacologic therapies for cough suppression have often been delivered by speech and language therapists or physiotherapists. Cough suppression therapies utilized in key studies can be grouped into four categories: (1) patient education, (2) cough control/suppression techniques, (3) vocal/laryngeal hygiene and hydration, and (4) psychoeducational counseling. These nonpharmacologic interventions have been shown to improve QoL and in some cases decrease cough frequency and severity.^{169,170}

Cough Control/Suppression Techniques

Cough control techniques may be most effective for those individuals with UCC or CHS not adequately controlled through treatment of the underlying pathology or use of pharmacotherapeutic agents. Expert guidelines recommend a trial of cough suppression nonpharmacologic therapy.^{116,123} Simple measures that the individual can utilize include sipping water, chewing gum, and sucking nonmedicated sweets. Speech and language therapists or physiotherapists teach breathing techniques or respiratory training exercises in addition to counseling and education. Therapeutic techniques varies between therapists, thus it has been a challenge to measure efficacy.¹⁷⁰

The efficacy of speech and language therapy for UCC was evaluated in a recent Cochrane Review (2019), where only two studies met the criteria for evaluation. Findings were significant for decreased cough frequency and improved health-related QoL, but these improvements were not sustained over time.¹⁷¹ In a small ($n = 40$) RCT of individuals with chronic cough, the combination of speech pathology treatment with the neuromodulatory agent pregabalin was superior to speech pathology alone in reported improved QoL and reduced cough symptoms.¹⁷³ Although clinicians in another center increased referrals to speech and language therapy for those with chronic cough, they were not able to evaluate the efficacy of the addition of this therapy.¹⁷⁴ High-quality research is needed to determine those aspects of speech and language therapy that provide benefit and how to sustain benefits over time.^{170,171}

Education/Psychoeducational Counseling

An integral component of cough management is education about the anatomy of cough reflex, identification of cough triggers, and the benefits of nonpharmacologic interventions. Psychoeducational counseling can motivate individuals to participate in treatments such as breathing exercises and cough suppression measures and to manage the stress and anxiety that can trigger cough. Through education and counseling, individuals can gain an understanding of cough physiology and acquire skills in ways to avoid cough triggers to control cough.^{169,170}

Vocal/Laryngeal Hygiene and Hydration

Laryngeal irritation due to throat dryness is a cough trigger. Vocal/laryngeal hydration measures include adequate water intake, reduction of caffeine and alcohol, nasal breathing, and nasal douching.^{169,170} These therapies rely on individual motivation and involvement for success, thus the need for continued education and reinforcement.

Cough Augmentation

Techniques for cough augmentation can be utilized to prevent aspiration through enhancing effective airway clearance. Individuals with cerebrovascular accidents, Parkinson's disease, multiple sclerosis, neuromuscular diseases, and spinal cord injury, as well as those who are intubated and mechanically ventilated, may have decreased respiratory strength or endurance and may benefit from therapies to decrease the risk of aspiration.¹⁶⁹

Hyperinflation and Compression

Mechanical or manual hyperinflation (positive pressure mechanical ventilation or non-resuscitation bag) delivered by therapists may increase the inspiratory peak cough flow (PCF) to a level necessary for airway clearance. Hyperinflation may be more effective than unassisted cough for individuals with neuromuscular diseases or spinal cord injury. Thoracic, abdominal, or thoracoabdominal compression are cough augmentation techniques that can help those with expiratory muscle weakness and may be useful in the aforementioned populations.¹⁶⁹

Mechanical Insufflation-Exsufflation Therapy

This therapy involves a series of maneuvers: positive airway pressure (insufflation) followed by a pause, followed by applying negative airway pressure (exsufflation). It has been utilized in those with neuromuscular disease to augment cough and has been evaluated as a means for augmenting cough when weaning individuals from mechanical ventilation.^{175,176} Although widely used and recommended for those with neuromuscular disease, the actual efficacy is unknown due to the paucity of high-quality studies.¹⁷⁵ There is low-quality evidence for cough augmentation through the use of mechanical insufflation-exsufflation as a measure to improve successful extubation from mechanical ventilation. Yet, due to limited studies, actual harms could not be determined.¹⁷⁶ These techniques may be important for further study, especially given the prolonged time on ventilatory support that may be experienced due to the respiratory effects of COVID-19.

Abdominal Electrical Stimulation, Abdominal Binding, Oscillation Techniques

For those with amyotrophic lateral sclerosis and spinal cord injury, abdominal electrical stimulation has been utilized to improve cough in the expulsive phase. Abdominal binding has also been utilized for cough augmentation in those with spinal cord injury, but efficacy is uncertain.¹⁶⁹ In those with bronchiectasis, the use of airway clearance techniques (high-frequency oscillation techniques or airway oscillatory devices) may improve sputum expectoration and QoL.¹⁷⁷

Respiratory Muscle Training

Individuals can participate in respiratory muscle training to improve muscle strength in the inspiratory and expiratory phase and endurance for cough augmentation.¹⁶⁹ Individuals with Parkinson's disease showed significant improvement with the use of expiratory muscle strength training.¹⁷⁸ A Cochrane review of respiratory training evaluated individuals with multiple sclerosis. There was low-quality evidence that the training improves predicted inspiratory muscle strength. However, conclusions about cough efficacy and QoL were not included in the study results, thus it is unclear if this therapy would be of benefit to this population.¹⁷⁹ In those with acute stroke, the use of respiratory muscle training was no more effective than no intervention. In this RCT, cough improved even without training.¹⁸⁰

Most of these therapies have not been supported by high-quality studies and may not be appropriate as disease

progresses and the individual experiences functional decline. Additionally, these therapies may not be available for those who live in rural areas or those without robust multidisciplinary services. The APRN must weigh the potential benefit versus burden and overall goals of care before recommending these therapies.

Interventional Techniques

Cough may be relieved if the underlying pathology is treated (as outlined earlier in the interventional treatment of dyspnea). In those with lung cancer, for example, disease-modifying treatments such as chemotherapy, immunotherapy, or radiation may decrease tumor burden and thus relieve cough. Where available, if the individual has cough secondary to tumor burden not relieved by disease-modifying treatment, endobronchial brachytherapy may be a treatment option.^{117,181} For those with pleural effusions, thoracentesis may relieve the cough. The decision to undergo interventions to address underlying pathology depends on the individual's goals of care and the benefit versus burden of the proposed intervention. The palliative APRN can be instrumental in assisting the individual in decision-making, especially as disease progresses.

PATIENT AND FAMILY EDUCATION

APRNs are in an optimal position to provide essential components of care that include information and education. Individuals and families should understand the potential causes of dyspnea and cough and treatments that may address the underlying pathology and those that will provide symptom relief. Discussions should include information about multimodal treatment, including pharmacologic and non-pharmacologic modalities for dyspnea and cough.^{109,149,169,170} Identification and education about simple, low-cost, and low-risk interventions such as breathing techniques and the use of fans may establish trust and build confidence in individual self-management of dyspnea.^{32,112} Reinforcement of the practice of cough suppression techniques and vocal/laryngeal hydration therapies may help the individual better manage cough.^{169,170} Depending on the disease trajectory and goals of care, education about smoking cessation may be appropriate since smoking cessation may help with both dyspnea and cough. There is a strong evidence base for the use of individual counseling by trained smoking cessation specialists.¹⁸² Thus, if the palliative APRN does not feel skilled in smoking cessation counseling, the individual can be referred to these specialists if available. If specialized counseling is not available, there are online resources available to assist the individual in smoking cessation.¹⁸³

Individual and caregiver involvement is key to providing personalized treatment.^{7,149} Caregivers may experience psychological distress secondary to increased caregiving.¹⁸⁴ They may feel isolated, especially when there are longer trajectories of illness, and they may benefit from social work involvement and referral to community support agencies.⁷ Given

the multidimensional nature of dyspnea and cough, a multimodal plan that is individual and family-centered is essential to ensure appropriate effective management.^{7,170,185}

SUMMARY

The effective treatment of dyspnea and cough, which may co-occur, involves the optimal treatment of the underlying pathology (when appropriate) and the associated affective response and distress related to the symptoms. During the clinical assessment, the palliative APRN should assess the characteristics of dyspnea and cough and their impact on the individual's life. The palliative APRN should recognize that many individuals may experience multiple distressing symptoms unrelated to cough or dyspnea, as well as symptoms associated with dyspnea or cough such as pain, incontinence, depression, anxiety, anorexia, and fatigue. The APRN should evaluate and manage co-occurring symptoms or those that are secondary to dyspnea or cough. Pharmacologic and nonpharmacologic approaches can decrease dyspnea and cough and their impact on the individual's QoL. Further research is necessary to optimize the most effective treatments for dyspnea and cough. Palliative APRNs have a essential role to play in contributing to the further development of this evidence base.

COGNITIVE IMPAIRMENT

Abraham A. Brody and Donna E. McCabe

KEY POINTS

- The palliative advanced practice registered nurse (APRN) must understand the multiple forms of cognitive impairment in order to optimize treatment of each specific form.
- The palliative APRN should perform a thorough assessment of unmet needs and use nonpharmacologic interventions as the first line of therapy for treating behavioral and psychological symptoms of dementia (BPSD) or developmental disability (DD) because pharmacologic interventions have limited efficacy.
- The APRN's prime focus of treatment should be maintaining physical activity and preventing functional decline.
- Advance care planning should occur early in the disease process, when the person living with dementia (PLWD) still has the ability to participate.

CASE STUDY

Diane was a 78-year-old African American woman admitted to the hospital following left-sided hemiparesis. Her history included hypertension, hyperlipidemia, two past minor strokes, bilateral knee osteoarthritis, and cognitive impairment, with a St. Louis University Mental Status Exam (SLUMS) score of 24/30 (1 year ago). Her medications included clopidogrel, atorvastatin, lisinopril, HCTZ, and amlodipine. According to her daughter Lisa, her primary caregiver, prior to this most recent stroke, Diane had been experiencing slow, progressive loss of short-term memory and physical function. She also became more socially isolated and spent much of the day inside with the shades drawn, and she had stopped smiling or eating as much. Lisa spent approximately 20 hours per week caring for her mother, who lived in their home. Lisa had two small children and a husband who was often out of town for work. Regarding care planning, Lisa stated that her mom had previously stated that when it is her time to go, she didn't want "extra measures," but wanted to be left comfortable and wanted to die at home. The advanced practice registered nurse (APRN) queried further and found that Diane would not want medically administered nutrition or hydration if she wasn't able to eat; however, if she had a simple infection, she wanted it treated.

On assessment, Diane was alert and oriented to person and place only and had a new SLUMS score of 14/30, as well as a

positive screen for depression. Diane had 2/5 strength of her left leg and arm, and required a max 1 person assist to transfer. She became physically and verbally aggressive with any attempt to begin physical activity or when passive range-of-motion (ROM) exercises of the lower extremities were performed. Lisa appeared very stressed and scored a 20/26 on the Modified Caregiver Strain Index (MCSI). The computed tomography (CT) scan revealed a new focal hyperattenuation in the primary motor cortex on the right side of the brain (new stroke) and several old deep lesions, 10 mm in diameter, in the lacunar area of the brain consistent with prior CT (old lacunar infarcts). There was also overall moderate brain atrophy (consistent with Alzheimer's disease).

Based on this clinical picture, the APRN diagnosed Diane with mixed dementia and depression. After a discussion with Lisa, the APRN performed an assessment of unmet needs and found that Diane was depressed, had pain, and this had limited her physical exercise and caused aggressive behaviors when moved. The APRN initiated acetaminophen 1,000 mg three times daily for osteoarthritic knee pain. After the first dose of acetaminophen, she reassessed and found Diane was no longer physically or verbally aggressive with ROM exercises or transfer. She also found that Diane loved swing music, so started on a daily regimen of 1 hour of music as a therapy with active engagement (reminiscing and dancing) and started her on citalopram 5 mg daily PO for 1 week, then increased to 10 mg. The APRN ordered physical therapy (PT) and occupational therapy (OT) for post-stroke rehab. The APRN completed a physician order for life-sustaining treatment (POLST) for do-not-attempt-resuscitation (DNAR), limited interventions, and no medically administered nutrition and hydration, but antibiotics for infection. Diane was discharged home with home PT, OT, safety evaluation, and short-term home health aide services to assist the Lisa during the transition period. A follow-up appointment was made for 1 week, at which time there was a discussion of whether to start Diane on an acetylcholinesterase inhibitor and an N-methyl-D-aspartate (NMDA) receptor antagonist (memantine) as well as her long-term plan of care and trajectory. While Diane was not eligible for hospice, further palliative follow-up was recommended for symptomatic care. The APRN discussed the importance of self-care with Lisa. The social worker consulted with Lisa to continue psychoeducation on disease progression and to monitor and treat caregiver strain. Lisa was also referred to the local Alzheimer's Association chapter for caregiver training and support groups.

INTRODUCTION

Cognitive impairment, in its many forms, is a devastating illness that has significant effects on the individual with the impairment and his or her family and caregivers. The most common form of cognitive impairment is dementia, mainly Alzheimer's disease (AD), with an estimated 5.8 million people living with AD in 2019 in the United States.¹ As the population rises over the next 35 years, this number will increase to 13.8 million. Dementia is a heterogeneous illness; there are more than 25 known etiologies, the most common forms being Alzheimer's dementia (approximately 60% of cases), followed by vascular dementia, Lewy body dementia, and frontotemporal dementia (FTD). The remaining etiologies combined represent less than 1% of cases of dementia. Palliative advanced practice registered nurses (APRNs) will be caring for many people living with dementia (PLWD).

Regardless of the etiology, the cognitive symptoms and progression of dementia can alter how the person is perceived by others and endanger their personhood. The language used by clinicians can affect how a person is seen by others. The term "person living with dementia" reinforces personhood and is the preferred term, rather than "dementia patient." Similarly, while we will refer to behavioral and psychological symptoms of dementia (BPSD) herein from a clinical perspective, with the PLWD or family, these issues should be addressed under the rubric of "unmet needs" rather than BPSD or neuropsychiatric symptoms, to reduce stigma.

In addition to dementia, there are many other etiologies of cognitive impairment, the most common of which include Down syndrome, delirium, paraneoplastic syndrome, and neoplastic and benign tumors. While many of the principles provided will relate to forms of cognitive impairment other than dementia, particularly advance care planning and goals-of-care conversations, identification and management of symptoms, and caregiving, this chapter will primarily frame the conversation in terms of care for PLWD. This includes cognitive decline, as in persons with developmental disability (DD), particularly Down syndrome, because these individuals are highly likely to develop dementia in older age. Moreover, it is important to recognize that many individuals with serious illness will have a different primary serious illness, but their care will be complicated due to cognitive impairment. Therefore, this chapter is important even for those who primarily see cancer, heart failure, or renal populations, where the disease is often concomitant.

CLINICAL BACKGROUND AND DIFFERENTIAL DIAGNOSIS IN DEMENTIAS

Dementia is highly underdiagnosed. It is estimated that approximately half of those with dementia and their caregivers are not aware of their diagnosis. Also, people with a known dementia are often diagnosed with just "dementia," not a specific form of the disease. The different types of dementia have different presentations, prognosis, disease progression, and, in

some cases, appropriate therapies. The most common causes of dementia and cognitive impairment to be included in the differential are listed in Table 45.1. While the final diagnosis should be made by a trained geriatrician, neurologist, neuropsychologist, geriatric nurse practitioner, or interprofessional team at an Alzheimer's Disease Center, these resources are not always accessible. Often the primary care provider or inpatient care team may not have made the diagnosis, completed an assessment for the etiology of dementia, or even identified the symptoms of cognitive impairment. It therefore may become part of the palliative care team members' work to make the diagnosis and develop a working diagnosis of the etiology. In certain cases the palliative APRN may also need to ensure that a reversible cause of dementia has not been overlooked.

The assessment should begin by evaluating the person's level of cognitive function using an appropriate screening instrument. There are several valid and appropriate tests available. The Mini-Cog, a brief assessment for cognitive impairment that takes about 2 minutes to complete, can be a starting point² for cognitive assessment. It consists of a three-item registration, a clock drawing test, and a three-item recall. The Montreal Cognitive Assessment (MOCA) and the St. Louis University Mental Status Exam (SLUMS), which have good reliability and validity, are easy and quick to administer and are not biased toward education and socioeconomic status, as is the more traditionally used Mini Mental Status Exam (MMSE) (Table 45.2). As of September 2019, the MOCA requires training and certification for the user, making the SLUMS the most accessible test for evaluation if needed after the Mini-Cog.³ An additional benefit of the MOCA and SLUMS tests are that they are sensitive for mild cognitive impairment.

While screening tools estimate the severity of dementia along a continuum from mild to severe, several rating scales exist to provide more accurate staging. The gold standard tool for staging, the Clinical Dementia Rating (CDR) scale, assesses domains of home life, community life, and personal care in addition to memory, orientation, and problem-solving.⁴ The Quick Dementia Rating Scale (QDRS) is another valid and reliable tool, which, as the name suggests, is brief and takes less time than the CDR, approximately 3–5 minutes.⁵ The cut-off scores for these tools are summarized in Table 45.2.

The palliative APRN should obtain a history. The PLWD or DD should participate to the degree they are able, along with the key informant for the PLWD. The history should include the length and progression of the cognitive impairment as well as the symptoms and their duration and severity. Information on the degree to which function has been impaired related to the cognitive impairment should be ascertained. This information will help determine the type of dementia and can also distinguish if the PLWD has delirium or depression superimposed on dementia. The syndromes of dementia, delirium, and depression, known as the "3Ds," can often coexist.

If the PLWD has sudden onset or clear and sudden worsening of an existing cognitive deficit over a short period, delirium should be strongly considered because dementia has a slower and more progressive course. One common cause of delirium is medication, so the person's medication list should

Table 45.1 DIFFERENTIAL DIAGNOSIS OF DEMENTIA

POTENTIALLY REVERSIBLE CAUSES OF DEMENTIA	COMMON DEMENTIAS	UNCOMMON DEMENTIAS
Depression	Alzheimer's disease	Alcoholic dementia
Infection	Vascular dementia	Huntington's disease
Anemia	Mixed dementia	Progressive supranuclear palsy
Hypothyroidism	Dementia with Lewy bodies	Multiple system atrophy
Syphilis	Parkinson's dementia	Corticobasal degeneration
B ₁₂ deficiency	Frontotemporal dementia	Hydrocephalus
Folate deficiency		AIDS dementia
Drugs (anticholinergic activity)		HSV encephalopathy
Tumors		Traumatic brain injury
Sensory issues (hearing/vision loss)		Prion diseases
Electrolyte disturbances, dehydration		Paraneoplastic syndrome
Increased intracranial pressure		Multiple sclerosis
Other metabolic disorders (hypo-/ hyperglycemia, storage disorders)		Drug-induced
		Progressive multifocal leukoencephalopathy
		Subacute sclerosing panencephalitis
		Whipple's disease

be reviewed to rule out the etiology of cognition-reducing medications (e.g., anticholinergics, antipsychotics, opioids, antiepileptics, sedatives, anxiolytics). Other common causes of delirium in the seriously ill are infection (urinary tract infection and pneumonia in particular), recent surgery with or without anesthesia, dehydration, electrolyte imbalances, and encephalopathies caused by renal or liver failure or viral infections such as herpesvirus, which occur particularly in those who are immunocompromised.

Depression can be a symptom of, a prodrome to, or coexist with dementia. Major depressive disorder can mimic cognitive impairment and can lead to worsened cognitive function. Screening instruments such as the Geriatric Depression Scale 15 or PHQ-9 can be used in persons without cognitive impairment as well as in those with mild to moderate dementia. Persons who screen positive should then receive further evaluation for depressive disorders. Table 45.3 highlights major differences in the presentation of persons with major depression

Table 45.2 DEMENTIA SCREENING INSTRUMENT CUTOFF SCORES

	SLUMS	MOCA	MMSE	CDR	QDRS
Normal	27–30 ^a 25–30 ^b	27–30	28–30	0	0–1
Mild cognitive impairment	21–26 ^a 20–24 ^b		25–27	0.5–4.0 (questionable to very mild)	2–5
Mild dementia	15–19	18–26	19–24	4.5–9	6–12

Table 45.3 PRESENTATION OF DEPRESSION VERSUS DEMENTIA

MAJOR DEPRESSION	DEMENTIA
Acute	Progressive
Oriented	Impaired orientation
Gives up easily	Tries hard even if incorrect
Fewer symptoms at night	Sundowning
Self-referred	Others refer
Diminished concentration ability	Short-term memory deficit
Normal language	Impaired language capabilities
Draws attention to memory problems	Minimized memory problems
Severely depressed	Minor or no depression
Blunted or flat affect	Full range of emotions
Apathy or anhedonia over weeks	Apathy or anhedonia gradual over time
Common suicidal thoughts	Rare suicidal thoughts
Guilt is common	Guilt is uncommon
Sudden sleep pattern/ability changes	Gradual sleep disturbance development
Major weight changes	Gradual weight loss over time

versus dementia. Depression also carries a strong risk for developing Alzheimer's dementia, and up to half of older adults with dementia have concomitant depression and dementia

depending on the setting.⁶ Thus, the two are not mutually exclusive and often need to be treated simultaneously.

Once a longer-standing cognitive impairment has been established based on the scores from screening instruments and informant and patient interviews, lab tests are performed to rule out potentially reversible causes of dementia (if they have not already been performed). Labs should include B₁₂ and folate (deficiency), TSH (hypothyroidism), a complete blood count (severe anemia), and an RPR (syphilis) and HIV test can be considered based on the person's history. Assuming these tests are negative, the next step is to consider imaging based on symptom presentation. A head computed tomography (CT) scan without contrast can rule out tumors and hydrocephalus and examine whether any brain atrophy, white matter changes, or strokes have occurred.

A specialty positron emission tomography (PET) imaging technique using tracers such as florbetapir F-18 (Amyvid) has been approved by the US Food and Drug Administration (FDA); it shows the presence of amyloid plaques, a major cause of AD. However, the test is nondefinitive and does not add to certainty in diagnosis in most cases. Therefore, it should be ordered only by a dementia expert in certain highly specific circumstances where there is atypical presentation.⁷ There are also now biomarkers of Alzheimer's dementia that can be used for preclinical symptom diagnosis through serum analysis. At this point, despite recent advances, these biomarkers, including amyloid- β accumulation levels, should only be used for research purposes.⁸

Once the appropriate tests are performed to rule out non-dementia causes of impairment and combined with the symptomatic presentation, a clinical diagnosis can be made. Table 45.4 summarizes the presenting symptoms of the five most common forms of dementia. Each is discussed in greater detail herein.

Table 45.4 DIFFERENTIATION OF MAJOR CAUSES OF DEMENTIA

ALZHEIMER'S	VASCULAR	MIXED	LEWY BODY	FRONTOTEMPORAL
Short-term memory loss	Impaired executive function	Includes symptoms of both Alzheimer's and vascular	Fluctuating cognition	Disinhibition
Forgetfulness	Motor deficits		Recurrent visual hallucinations	Expressive or receptive aphasia
Difficulty learning new tasks	Difficulty retrieving memories		Parkinsonian movement	Stubbornness
Poor attention	Aphasia		Rapid eye movement (REM) sleep disorder	Selfishness
Difficulty finding words	Inefficiency of thought		Sensitivity to neuroleptics	Facial recognition difficulty
Difficulty with complex tasks	Poor problem solving		Autonomic dysfunction	Emotional distance
Poor recognition			Systematic delusions	Apathy
			Repeated falls	

ALZHEIMER'S DISEASE

AD is characterized by a progressive loss of memory, beginning with short-term memory loss and leading to long-term memory loss, including the loss of decades of life memories. In addition to memory loss, there is at minimum an alteration in one other cognitive domain such as executive function or language that interferes with daily functioning. As AD progresses, the loss of activities of daily living (ADLs) and instrumental ADLs (IADLs) progresses, and eventually loss of speech and coordinated muscle movements, such as swallowing, occurs. The average life span following diagnosis is 8 years, and people usually spend the last 40% of that time in the moderate to severe stage.¹ Between 60% and 80% of all dementias diagnosed are of the Alzheimer's type, though up to 40% of people may have mixed etiology with vascular dementia (see the section on mixed dementia).⁹ The disease is caused by a number of changes in the brain, including formation of amyloid plaques and tau tangles, leading to the damage and destruction of neurons, causing the brain to atrophy. While most individuals diagnosed with AD are older than 65, early-onset AD is thought to progress more quickly.¹⁰

Prior to the onset of AD, the individual can often develop mild cognitive impairment in the form of some memory problems and perhaps some movement difficulties and changes in smell. Not all people will advance from mild cognitive impairment to AD. Mild cognitive impairment is defined as short-term memory deficit and is largely stable over time; it does not affect functional status.

AD is generally divided into mild, moderate, and severe categories, and people will progress over time (<https://www.alz.org/alzheimers-dementia/stages>). In mild AD, the person will start to lose short-term memory, which can lead them to become confused in complex situations, such as with driving. They may become lost, have difficulty managing their financial affairs, ask repetitive questions, forget to turn off the stove after starting to cook a meal, and start to show some alteration in personality, particularly due to the frustration of declining memory. Many PLWD attempt to hide these deficits, and therefore it is often a family member or friend who will make sure that the deficits are brought to the attention of a medical provider. The mild Alzheimer's stage is where these deficits become clear enough for family to recognize and is therefore where the majority of cases are diagnosed. The median time spent in the mild stage is 3.6–5 years, with those older at the shorter end of the spectrum and younger at the longer end.¹⁰

The moderate or middle-stage of AD can last for many years. In this stage, PLWD begin losing the ability to learn new tasks or pieces of information, may no longer recognize family and friends, begin to have difficulty performing complex ADLs such as dressing, and start to have significant impairment in executive function. Assessment of function and interventions to simplify tasks are useful at this stage. PLWD will start to lose more long-term memory, such as where they went to school, what year they are living in, and the fact that they have grandchildren or that their adult children are married. They cannot compare situations and

therefore cannot make decisions about most future care (e.g., advance directives). They can no longer live safely and independently in the community and therefore require help with ADLs and IADLs. Many PLWD may develop significant behavioral problems at this stage, although they are generally manageable with appropriate interventions (see later sections). The behavioral and mood problems include agitation, depression, and aggression. Some individuals may develop delusions or hallucinations, though these are more common in Lewy body dementia. Caregiver strain can also become prominent at this stage.

Severe AD is characterized by complete loss of ability to communicate needs and dependence in all ADLs. PLWD in this stage may be able to string together a few words, but the words are not generally meaningful, and they will eventually lose speech altogether. In this stage, the PLWD can also often develop difficulty with swallowing because they can no longer coordinate movement. Aspiration pneumonias may become frequent and are often a cause of death. People generally enter the severe stage 6 years from diagnosis, depending on the study cited, and the stage generally lasts 1–2 years.¹¹ The median survival time is approximately 8 years from diagnosis, although the older the person was at diagnosis, the shorter the life span. Men are likely to die sooner than women. Race and ethnicity have been also been found to influence survival time due to multiple factors including differences in medical comorbidities as well as social support after diagnosis.¹²

VASCULAR DEMENTIA

Vascular dementia is caused by ischemic or hemorrhagic damage to the brain, primarily through stroke. It is the second most common form of dementia after AD, accounting for approximately 10–15% of all dementias¹³ (excluding mixed dementia). Risk factors for dementia are cerebrovascular in nature (Box 45.1).¹⁴ Unlike in AD, progression is variable and highly dependent upon cardiovascular status and risk for future stroke. Therefore, mortality is also highly variable and difficult to determine, although in general the survival is shorter than in Alzheimer's dementia.

Symptoms of vascular dementia are highly variable and may be sudden or gradual depending on the size and location of the stroke. Early symptoms include impaired executive function, ineffective memory, perseveration, changes in personality, poor verbal fluency, sleep disturbances, and cortical symptoms such as visual disturbances and difficulty doing mathematical calculations. A stepped progression is common as the symptoms worsen with new infarcts that may or may not be recognized.

Some strokes are major and easily perceived, leading to a clear functional loss. Others may be smaller and occur over time, leading to declines in cognitive capacity. One typical form of small stroke is a *lacunar infarct*. Multiple small lacunar infarcts are a common, slow, insidious form of vascular dementia that is often missed until later stages if cognitive screening is not performed frequently.

MIXED DEMENTIA

Mixed dementia occurs when the person develops both AD and vascular dementia. Symptoms from both diseases will be present, as discussed earlier. In addition, individuals with mixed dementia experience depressed mood, motor and sensory changes, and gait abnormalities with higher frequency than those with either AD or vascular dementia separately.¹⁵ The prevalence of mixed dementia is about 22%¹⁶; many cases that are diagnosed as AD turn out to be mixed dementia as determined at autopsy or through symptomatic and radiographic findings. The median survival time of mixed dementia has been estimated at 4.5 years in older populations, with slightly longer survival in younger populations.¹⁷

LEWY BODY DEMENTIA

Lewy body dementia is an overarching term for two separate diseases, dementia with Lewy bodies and Parkinson's dementia. The primary distinction between the two is whether the cognitive symptoms occur at the same time as movement symptoms (dementia with Lewy bodies) or the movement symptoms are followed at least 2 years later by cognitive symptoms (Parkinson's dementia). Lewy body dementia is caused by the formation in the brain of *Lewy bodies*, which

are abnormal clumps of α -synuclein, a protein. It is unclear what causes these bodies to develop, though in most cases it is thought to be genetic–environment interaction. In Parkinson's dementia, Lewy bodies form as well, but the primary pathophysiology is the degeneration of dopaminergic neurons in the substantia nigra.

The movement disorder features of both include resting tremor, shuffling gait, rigidity, and eventually akinesia, which includes both hypokinesia (decreased frequency or absence of movement) and bradykinesia (slowed movement). Behavioral and psychological symptoms include sleep disturbance, including rapid eye movement (REM) sleep disorder, fluctuation in alertness and attention, recurrent visual hallucinations, visual-spatial problems, and depression. People living with Lewy body dementia have sensitivity to antipsychotic medications, so the correct diagnosis must be made before prescribing an antipsychotic for dementia symptoms. Approximately 4.6% of dementia cases are diagnosed as Lewy body dementia,¹⁸ and the average survival time from diagnosis is approximately 4.4 years.¹⁹

FRONTOTEMPORAL DEMENTIA

FTD is an umbrella term used to describe a group of dementias caused by progressive neuronal degeneration in the frontal and/or temporal lobes of the brain. It generally occurs in individuals younger than 65 (median in studies is 52 to 60).²⁰ Survival is highly variable and depends on the subtype of disease, ranging from 3 years in motor neuron disease variants to 12 years in semantic dementia and 9 years in behavioral variant and progressive nonfluent aphasia. People with genetic risk factors make up about 30–50% of cases, although clinicians do not generally test for these markers, and the remainder of cases occur for unknown reasons, although head trauma and thyroid disease are thought to be potential risk factors. Overall, approximately 2.7% and 10.2% of cases of dementia are from FTD in older and younger adults, respectively.²¹

BEHAVIORAL VARIANT

The behavioral variant of FTD, formerly known as *Pick's disease*, is the most common form. Individuals generally present with personality changes and impaired social behaviors. These symptoms vary and can include disinhibition, including inappropriate touching or sexual behavior; impulsiveness; loss of empathy or sympathy; overeating; compulsive behaviors; apathy; and loss of executive function. The nature of these symptoms in the behavioral variant of FTD can be misidentified as a psychiatric disorder, delaying the correct diagnosis. As the disease progresses, symptoms will start to worsen, and people will also begin to have more memory problems and issues with planning and attention in the moderate stage. In the severe stage, people will express severe memory loss and language difficulty, and behavioral symptoms will continue to decline.

SEMANTIC DEMENTIA

People with left-sided semantic dementia commonly present with word-finding difficulties; a “pencil” might be a “writing thing” and an “orange” might be “that fruit.” In right-sided semantic dementia, people tend to present with decreased awareness of other people’s emotions. In both cases, memory remains more or less intact. The disease progresses to the moderate phase, generally about 2–3 years after diagnosis. At this time, people with left- and right-sided disease begin to show a more merged symptom presentation, including trouble with comprehending statements and recognizing faces, and some of the behavioral and psychological symptoms common to the behavioral variant of FTD. As individuals move into the severe stage of the disease, their BPSD worsen and they lose the ability to communicate.

PROGRESSIVE NONFLUENT APHASIA

Unlike those with semantic dementia, people with progressive nonfluent aphasia retain the ability to understand language and know the words they want to say; the first signs of disease relate to their ability to actually produce the speech they wish. This expressive aphasia will continue to worsen over time, and, within 3–4 years, they will enter the moderate stage, where they will only be able to use short phrases to express their needs. They can still, however, read and write well in most cases, so a dry-erase board or paper and notebook can help with communication in this stage. Approximately 5–7 years from diagnosis, people will become completely unable to speak and will start to develop the behavioral and psychological symptoms common to the behavioral variant of FTD.

MOTOR NEURON DISEASE

Motor neuron disease is the most severe form of FTD and causes a precipitous decline. Symptoms are similar to those of the behavioral variant, but people also exhibit muscle weakness, stiffness and atrophy, and loss of coordination and fine motor movement as motor neurons slowly disintegrate, similar to that seen in amyotrophic lateral sclerosis. Eventually the individual will present with dysphagia and dysarthria and are at high risk for developing aspiration pneumonia.

DOWN SYNDROME

Down syndrome, also known as trisomy 21, is generally diagnosed very early in life or during pregnancy through chromosomal or blood testing. The disease is caused by the abnormal development of a third full or partial chromosome 21 during early development. Individuals have a distinct appearance, which includes some but not always all of the following: upward-slanting eyes, flattened facial features, short hands and fingers, protruding tongue, and short stature. Severity is highly variable: some individuals exhibit mild cognitive deficits and others have severe cognitive difficulty, up to the levels seen in advanced dementias.

Life expectancy in Down syndrome is currently 60 years of age; it has increased dramatically over the past 50 years.²² While a certain segment of the population will die in childhood, those individuals who live to adulthood generally develop the same health issues as the general public, though in a more rapid fashion. More than 70% of individuals with Down syndrome over the age of 35 may develop Alzheimer’s dementia superimposed on Down syndrome.²³ Persons living with Down syndrome generally start to develop functional, cognitive, and health declines around the age of 40. The greatest causes of death in this population include congenital heart defect, dementia-related causes (e.g., aspiration pneumonia, falls), and cancers.²⁴ Persons living with Down syndrome toward the end of life often present with issues similar to PLWD; specifically issues related to functional decline such as dysphagia, pressure ulcers, and agitation, particularly around baths and personal care. Persons living with Down syndrome are often shuttled between group care homes and nursing homes as they enter the last several years of their lives, and multiple studies have found that the greater the number of transfers, the higher the risk of deterioration; transfers should therefore be limited as much as possible.²⁵

ADVANCE CARE PLANNING

Advance care planning (ACP) in those with cognitive impairment can be a difficult process. Ideally, individuals will have discussed their wishes with their family/proxy before diagnosis or at least during the early phase of their disease. However, this is often not the case. Studies have shown that those with mild and even early moderate disease may be able to select a healthcare proxy or surrogate decision-maker²⁶ and take part in some healthcare decision-making.²⁷ Depending on the level of cognitive impairment, the level of decision-making permissible may be more or less complex, and a capacity assessment is essential in this process. It is important during this capacity assessment to see if the individual can consistently verbalize their wishes, reasoning, and ability to understand both the short- and long-term risks and benefits of decisions they would be making. Therefore, many decisions are discussed with the healthcare proxy or surrogate decision-maker. However, to the extent possible, the individual should be consulted and input taken in forming a decision.

The most important items to focus on in ACP for those with cognitive impairment include the aggressiveness and amount of care versus quality of life (hospitalization, resuscitation status, intubation, antibiotics, feeding tube placement) and the preferred setting of care based on available caregiving and financial status (home, group home, continuing care community, assisted living, nursing home). In states where orders for out-of-hospital life-sustaining treatments (physician/provider order for life-sustaining treatment [POLST] or medical orders for life-sustaining treatment [MOLST]) are accepted, these documents should be used to help provide clear, across-setting orders for the individual’s wishes (for more information, see Chapter 32, “Advance Care Planning”).

MANAGEMENT OF DECLINE AND SYMPTOMS

There are many challenges in caring for individuals with cognitive impairment related to both cognitive and functional decline and BPSD. These challenges often go hand in hand and require a comprehensive management approach that focuses on the unmet needs of individuals. In this section we first present cognitive and functional decline, and then focus on a philosophy of assessing unmet needs to treat BPSD. BPSD domains can be found in Table 45.5. As a first step toward addressing BPSD, unmet needs should first be assessed and addressed. One useful approach for assessing these unmet needs utilizes the PIECES mnemonic, which stands for Physical, Intellectual, Emotional, Capabilities, Environmental, and Social causes. Information on this approach can be found at <http://pieceslearning.com/>. Should these approaches not address the underlying BPSD, recommended nonpharmacologic (preferred) and pharmacologic (secondary) treatments can be found in Table 45.6 by domain.

COGNITIVE DECLINE

There are currently no pharmacologic or nonpharmacologic agents to reverse cognitive decline in dementia. Two classes of drugs are approved for slowing the progress of Alzheimer's dementia and Lewy body dementia: acetylcholinesterase inhibitors and NMDA receptor agonists. The former include donepezil (Aricept), galantamine (Razadyne), and rivastigmine (Exelon) and are indicated in mild and moderate

dementia. These drugs have been shown to slightly decrease the rate of progression of the disease both cognitively and functionally and are more effective in Lewy body dementia than in AD. While these drugs do have some efficacy, they can also have significant side effects that are worse than the slight benefit of the medication. The most prominent side effect is gastrointestinal disturbance and upset, particularly diarrhea; this can lead to reduced oral intake and fluid/electrolyte imbalances. When starting this class of medication, the benefits and risks should be weighed and discussed with the individual and proxy. These drugs are not miracle cures, so it is important to set expectations appropriately. After initiation, if side effects are significant and do not dissipate, then a discussion needs to occur. Once this class of medication is stopped, the person will lose whatever effect the medication had and will not return to that level if it is restarted.

The second class of drugs, NMDA receptor agonists, consists of only one medication, memantine (Namenda). Memantine is indicated for use in moderate or severe AD; there is limited evidence for use in other forms of dementia. Studies have shown that combining memantine with an acetylcholinesterase inhibitor when the individual reaches the moderate stage of AD has a synergistic effect in slowing the disease greater than one or the other alone; however, the effect size is small at best.²⁸ The drug has limited side effects, so the cost versus small benefit should be discussed and weighed with the PLWD or family.

A third drug, aducanumab (Aduhelm) was recently approved by the Food and Drug Administration for use in individuals with mild cognitive impairment and early stage Alzheimer's disease. However, this was with considerable

Table 45.5 DOMAINS OF BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA (BPSD)

DOMAIN	BEHAVIORS	NEUROPSYCHIATRIC INVENTORY-QUESTIONNAIRE (NPI-Q) CATEGORIES
Psychosis	Delusions and hallucinations	Delusions Hallucinations
Psychomotor agitation	Pacing, wandering, repetitive movements, physical aggression, dressing/undressing	Agitation/Aggression Disinhibition Motor disturbance Anxiety
Aggression	Yelling, calling out, repetitive speech, and verbal aggression	Agitation/Aggression Irritability/Lability
Depression	Depressed mood, other symptoms can vary Depression can also lead to other BPSD	Elation/Euphoria Apathy/Indifference Depression Disinhibition
Apathy	Social isolation, withdrawal	Nighttime behaviors Appetite/Eating
Sleep disturbances	Sundowning, diurnal sleep, rapid eye movement (REM) sleep disorder	Nighttime behaviors

From Corey-Bloom et al.¹⁵, Custodio et al.¹⁶

Table 45.6 TREATMENTS FOR BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA (BPSD)

BPSD DOMAIN	NONPHARMACOLOGICAL INTERVENTIONS	MEDICATION CLASS TO CONSIDER
Psychosis	Reduce environmental stimuli Address sensory impairments Do not dismiss concerns, assure person's safety	Only indication for antipsychotic ^{a,b}
Psychomotor agitation	Redirect and distraction Reduce environmental stimuli	Cholinesterase inhibitors, Memantine
Aggression	Acknowledge person's feelings Don't argue or react defensively Redirection and distraction	Cholinesterase inhibitors Memantine SSRI Trazadone (evening use only) ^a
Depression	Exercise Music as therapy Reminiscence therapy	SSRI (citalopram, sertraline, escitalopram)
Apathy	Socialization Actively involving the person in an activity	Cholinesterase inhibitors Methylphenidate ^{a,c} SSRIs
Sleep disturbances	Exercise Limit napping Good sleep hygiene	Melatonin Trazadone

^a Off label use.

^b Black box warning for increased risk of death, cardiovascular accident, myocardial infarction; requires informed consent prior to prescribing.

^c Contraindicated in those with concurrent cardiovascular disease; do not use in cases where other BPSD domains other than depression are present.

SSRI, selective serotonin reuptake inhibitor.

From Corey-Bloom et al.¹⁵, Custodio et al.¹⁶

controversy due to its lack of efficacy, being approved based on a surrogate endpoint with no proof of clinical improvement and with substantial side effects that can require intensive monitoring.

There is limited evidence about medication use once a person reaches end-stage dementia (e.g., needs help with all ADLs except walking, limited speech capability). Studies have shown that, in severe dementia, there is potentially some improvement in quality of life and reduction in depression symptoms, but these are not at the end stage, and similarly little evidence is available regarding what to do when a person has entered hospice care. Therefore, a conversation should occur with family about the goals of care and potential benefits and burdens of continuing the medication.

An additional method for reducing cognitive decline in PLWD is to ensure that cardiovascular disease, atrial fibrillation, and diabetes management are maintained in place, including both pharmacologic interventions *and* physical activity.^{29,30} There are strong links between these conditions and cognitive decline, likely due to the effects of the illness on brain health, and they may even be one of the causes of the individual's dementia, depending on the type and etiology. While maintaining these in place, it is important for palliative care clinicians to consider how to best support the person and family in self-management.^{31,32}

FUNCTIONAL DECLINE

As people decline over the course of disease, more and more issues will arise related to physical function. This decline can lead to aggression and agitation on the part of the person and to caregiver stress, burden, and burnout, among other issues. The goal is therefore to maintain function or find “work-arounds” for function for as long as possible. Physical and occupational therapists can be highly effective partners in this.^{33,34} They can suggest home modifications and assistive devices, help train caregivers in how to perform transfers or exercises with the PLWD, or help by providing direct therapy to assist with function or strength. Especially with the removal of restrictions on physical and occupation therapy services to persons with no potential for improvement, there are greater opportunities to use these skilled rehabilitation therapists in these areas.

DYSPHAGIA

One of the most common functional problems facing PLWD as they reach the severe stage of dementia is dysphagia. This is a normal part of the disease process. PLWD often lose their ability to coordinate swallowing movements as well as their

ability to feed themselves, leading to a high risk for developing aspiration pneumonias. This often brings up discussions of whether tube feeding would be appropriate. Multiple studies have shown that tube feeding does not prevent aspiration and is no better than spoon feeding, and the potential benefits are far outweighed by the burdens.³⁵ It is therefore important to educate PLWD and family about these benefits and burdens. The earlier in the disease process this can be discussed the better, allowing time for multiple conversations.

An additional issue, particularly in hospices, is voluntarily cessation of eating and drinking by the PLWD or for the family to stop assisting the person to eat and drink. Morally, ethically, and legally, if a person has made a clear statement or advance directive stating the wish to not be hand-fed or hydrated or receive medically administered nutrition and hydration, then we must respect these wishes.³⁶ However, if the person has not voiced the wishes directly and clearly (and ideally in writing), this is more of a legal, moral, and ethical gray area, with cultural and religious elements. Therefore, referrals should be placed for legal and ethical consultation, because laws vary state by state in this regard. Eventually the person who stops eating and drinking voluntarily will die rather comfortably, within an average of 8–10 days, from dehydration.

UNMET NEEDS

Many, though not all, BPSD can be addressed through recognizing the unmet needs of the PLWD or DD such as Down syndrome. One memorable program for assessing for unmet needs is through using the PIECES Learning and Development Model (accessible at <https://pieceslearning.com/>), which is an evidence-based model. The mnemonic stands for Physical, Intellectual, Emotional health, Supportive strategies to maximize Capabilities, social and physical Environment, and Social self, and it serves as a comprehensive assessment for identifying underlying unmet needs. Some of these unmet needs may require pharmacologic or medical intervention, such as physical elements which can include pain, delirium due to an underlying acute illness, or constipation. Others fall more into psychosocial aspects, such as communication issues (intellectual), depression (emotional), loss of function (capabilities), noise or light (environmental), or isolation (social) that more often than not are sensitive to nonpharmacologic interventions.

BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS

PLWD and those with DD may present with a variety of behavioral and psychological symptoms related to their condition. Even though Down syndrome and DDs are separate illnesses from dementia (though often these individuals can develop dementia later in life), for the purposes of simplicity we will refer to behavioral symptoms as BPSD herein, and treatments

(unless otherwise noted) are applicable to both groups. There are six primary clusters of symptoms, and 13 symptoms within that we tend to focus on. When beginning to assess for symptoms, one way to do so in a holistic but straightforward fashion is to use the Neuropsychiatric Inventory–Questionnaire (NPI-Q).³⁷ The NPI-Q is performed with a caregiver and assesses for the presence and severity of the 13 BPSD and how distressing they are to the caregiver. This can be used to prioritize which symptom (or two) to tackle first and can be used to monitor progress in both treating the BPSD and managing caregiver distress. It takes about 10 minutes to complete and can be performed prior to your visit. Completing the NPI-Q, along with utilizing PIECES, are keys to achieving effective BPSD management. Next we discuss the six clusters and effective nonpharmacologic and pharmacologic treatments specific to each.

AGGRESSION

Physical and verbal aggression are highly prevalent in PLWD and DD. This aggression may be caused by any number of issues, usually unmet needs, so assessment using PIECES is necessary to treat the baseline problem. The most prevalent causes include bathing and personal care (see later discussion), unidentified or undertreated pain or depression, and a poor relationship between the care recipient and the caregiver.³⁴ Other potential causes include sensory perception issues (hearing, vision), delirium, medication side effects, and environmental factors (noise, temperature). To reduce aggression, the root cause needs to be identified and treated. Antipsychotics, which are frequently prescribed, are not appropriate and do not work for aggressive behaviors; they only sedate the individual, leading to sleep–wake cycle disturbances which can increase caregiver stress and increase patient morbidity and mortality. Similarly, mood stabilizers such as divalproex sodium have not been found effective. Caregivers need to stay calm because any show of strong emotion (e.g., yelling, threatening movements) will only make the aggression worse. Redirection can be a useful method when aggression is not related to an immediately identifiable and treatable cause. Music therapy, physical activity, and aromatherapy are additional nonpharmacologic modalities. From a pharmacologic perspective the only medication that *has* been found to be effective are the selective serotonin reuptake inhibitors (SSRIs). In older adults, the preferred SSRI include citalopram, escitalopram, and sertraline.

BATHING AND PERSONAL CARE

One of the most difficult areas that PLWD and their caregivers struggle with is bathing and personal care. The loss of dignity that occurs when the PLWD can no longer care for him- or herself after a long life of independence, coupled with cognitive impairment, often leads to verbal or physical aggression. To prevent or reduce aggression, a highly person-centered approach needs to be taken.³¹ Effective, personally tailored interventions may include the following:

- Assessing the person prior to the care for pain and current physical and mental state and altering the routine or stopping the care until these can be better managed
- Addressing the environment such as reducing noise, introducing soothing music
- Adhering to routine, including stopping and interacting with the person prior to initiating personal care, covering private parts to the extent possible, ensuring as much privacy as possible
- Ensuring that the caregiver has developed a relationship with the PLWD and clearly shares step by step what he or she is going to do before doing it. For instance, “Now I’m going to pull your arm through your shirt. Now I am going to lift it over your head. Now I am going to wash you.”
- If performing a bed bath, ensure that the PLWD is only exposed in the area being cleaned, which can both reduce discomfort from being cold or from feeling overexposed.
- Ensuring appropriate water temperature (e.g., warm but not scalding)
- When resistance is encountered, try again a few minutes later (or in the case of a bath a few hours later), provide reasons for the personal care or bath (e.g., “You’ve been working hard, wouldn’t it feel good to freshen up?”), and/or changing the type of bath (e.g., bath, using a shower chair, bed bath with warm wet towels).

PSYCHOMOTOR AGITATION

Psychomotor agitation includes hyperactive behaviors such as repetitive actions, pacing, restlessness, and dressing and undressing. This form of agitation is common in Lewy body dementia and can also result from the overuse of antipsychotics. Removing these medications may stop these behaviors. Other options include physical therapy to help PLWD or those with DD focus on completing specific tasks rather than aimless hyperactivity. Increasing stimulation and companionship may also help reduce this symptom.

PSYCHOSIS

The psychosis cluster includes hallucinations, delusions, and misidentification of people and objects. From a person- and family-centered perspective, the term “psychosis” should not be used, only the individual symptom experienced, as the term “psychosis” can have negative connotations that will cause unease. This cluster of symptoms is the only time when it may be beneficial to use antipsychotics. If the hallucination, delusion, or misidentification is not distressing or causing harm to the PLWD or caregiver, pharmacologic treatment should *not* be prescribed, as the risks outweigh any benefits. If, however, the PLWD is experiencing multiple distressing visual or auditory hallucinations, delusions, or misidentifications, antipsychotic use can be considered. It is important to “start low and

go slow.” Moreover, different antipsychotics have different properties (e.g., quetiapine is sedating whereas olanzapine is activating), so the medication must be given at the appropriate time of day, and an activated PLWD should not be given an activating antipsychotic (or vice versa). For persons with Lewy body dementia or Parkinson’s dementia, the only viable medications are quetiapine and clozapine, though the latter requires frequent blood testing for agranulocytosis. While pimavanserin was approved specifically for this population by the FDA in 2016, it is not currently recommended as a first-line therapy for those with Lewy body or Parkinson’s dementia due to sparse evidence.³⁸

Whenever considering prescribing an antipsychotic, whether typical or atypical, the PLWD, where appropriate, and proxy need to be informed of the black-box warning and the risks for increased heart attack or stroke and must clearly consent to the medication. PLWD or those with DD are also at a higher risk for falls when taking these medications, and certain medications have other significant side effects. For instance, olanzapine causes disturbances in blood sugar in individuals with diabetes. Therefore, the palliative APRN must be knowledgeable about the specific medication prior to prescribing. The conversation, including all side effects, needs to be documented in the chart.

APATHY

Apathy, including social isolation, withdrawal, and lack of interest, is common in PLWD. Nonpharmacologic measures to engage the PLWD or those with DD are important: music therapy, multisensory behavioral interventions, physical activity, dancing, singing, and talking have been found to be effective.³⁹ Pharmacologically, acetylcholinesterase inhibitors have shown to be mildly beneficial in some studies but not others, but the side effects likely outweigh the benefits, and other classes, such as stimulants and neuroleptics, have not shown any efficacy.⁴⁰

DEPRESSION

Depression can be identified using the Geriatric Depression Scale in mild to moderate dementia⁴¹ and the Cornell Scale for Depression in Dementia,⁴² an informant-based interview, can be used for individuals living with moderate to severe dementia. Treating depression in PLWD can often lead to significant decreases in other BPSDs, so the person should be assessed for depression early on. Treatment for depression should focus on nonpharmacologic measures (e.g., music, reminiscence, and physical activity).³⁹ Pharmacologic interventions have not shown efficacy in improving depression using depression scales in this population⁴³; however, as discussed earlier, they lead to significant improvement in agitative behaviors and thus may not be the best measure to use. If the APRN chooses to use a pharmacologic treatment to augment nonpharmacologic treatments, then citalopram, sertraline, or escitalopram, which present fewer issues in the geriatric population, are preferred.

SLEEP DISTURBANCE

Sleep disturbances occur in approximately 38% of the dementia population and can have significant consequences, including significantly increasing caregiver stress.⁴⁴ One of the most common disturbances is alteration of the diurnal sleep pattern. PLWD are often sleepy and take long naps during the day, becoming restless in the early evening. This early evening agitation is often called *sundowning*. The most important way to avoid or decrease these sleep-pattern changes is to prevent the PLWD from taking long naps throughout the day. This requires the person to be engaged and not socially isolated. The physical environment should be kept bright, if possible with natural light or specialized lights that mimic daylight. Only one nap of no more than 1.5 hours should be permitted. Sleep medications in this population can cause significant side effects and can lead to falls. Stimulants during the day (pharmacologic or nonpharmacologic, such as caffeine) can cause agitation and should therefore be avoided as much as possible. Melatonin has shown limited efficacy in this population, although no substantial side effects occurred in doses of 1–3 mg. Alcohol should also be avoided. Finally, regular physical activity can help to maintain the proper sleep–wake cycle.

A second type of sleep disturbance is *REM sleep disorder*, which is more prevalent in Lewy body dementia than in other forms. In REM sleep disorder, individuals act out their dreams in ways such as walking, talking, screaming, or displaying physical aggression. Clonazepam is the suggested treatment in individuals who have REM sleep disorder, but it is not recommended in PLWD due to the risk for rebound agitation. Melatonin has shown some efficacy in treating this disorder, and acetylcholinesterase inhibitors such as donepezil have shown some efficacy, though the evidence is limited.⁴⁵

PAIN

While pain in and of itself is not associated with cognitive impairment, identifying and managing pain in this population can be difficult. PLWD and those with DD still experience pain, though they often cannot communicate that they do. In general, older adults may not identify pain by using the word “pain,” instead describing it in terms of soreness, achiness, “the arthritis,” or having difficulty with “that” (e.g., using their hands, walking).^{46,47} While the rating scale of choice (faces, numeric, or verbal descriptor) can all be used in individuals with mild and early moderate dementia, PLWD should be assessed at times other than when they are resting because they may forget that they had pain with movement. The assessment should be done immediately after the PLWD completes a movement, or even during the movement. The palliative APRN should observe for pain behaviors such as bracing, verbalizations, and facial expressions indicating pain and should examine the person’s problem list for potential painful conditions (e.g., osteoarthritis, compression fractures, neuropathies). In individuals with moderate and severe dementia, a pain assessment instrument specifically for use in this population should be used (e.g., the PAINAD) in

addition to the person’s subjective report and reporting from the primary caregiver.⁴⁵

Once identified, treatment of pain in this population generally follows the same recommendations as for other populations—with some differences. Mild pain should be treated using nonpharmacologic interventions. Medications should be given on a scheduled basis rather than as needed because the PLWD may not request or will forget to request pain medicine. For mild to moderate pain, acetaminophen is the first-line treatment, not exceeding 3 g per day. If pain is not controlled with acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) are generally the next step for short-term treatment, potentially a COX-2 inhibitor for longer term treatment. Most pain in older adults comes from osteoarthritis and lower back pain, and opioids have not been shown to be effective in this group and thus should not be prescribed.⁴⁸ For other forms of pain, such as from fractures, pressure injuries, or cancer, opioids may be a more evidence-based approach.

SPIRITUAL SUPPORT

Spiritual support can improve the quality of life for both the PLWD or those with DD and their caregivers. Higher religiosity has been found to slow cognitive and behavioral decline in dementia. Spiritual support can give meaning to the caregiver’s experiences, reducing stress⁴⁹ and improving his or her overall mental health.⁵⁰ Therefore PLWD or those with DD and their caregivers should be encouraged to use spiritual support, whether in the community, an assisted living facility, nursing home, or hospital setting. The palliative APRN should facilitate such services as appropriate and possible.

WORKING WITH CAREGIVERS

Caregivers for PLWD and those with DD have a high risk of burden, stress, and burnout. Caregivers, especially spouses, may become ill themselves, even necessitating hospital admission. If the caregiver’s needs are not met, the PLWD is significantly more likely to be placed in a nursing home or other long-term care facility rather than remaining at home. Paid caregivers, if they become burned-out and leave, cause further trauma to the PLWD and family because they have to develop a new therapeutic relationship, which can cause further decline. PLWD are also at higher risk to be victims of elder abuse, possibly perpetrated by caregivers. Assessing caregiver stress can reduce the possibility for abuse or maltreatment. The palliative APRN should also routinely screen for abuse among PLWD or those with DD.⁵¹

Providing support for the caregiver is just as important as support for the PLWD or those DD. This can take many forms, such as training sessions from the local Alzheimer’s Association (applicable regardless of type of dementia), adult day health programs for the care recipient to give the caregiver some personal time, or respite care in a facility. The most

important part of helping the caregiver is to manage BPSD, as outlined earlier, and to manage the caregiver's expectations. When working with the caregiver to manage BPSD it is important to understand what are the most concerning BPSD and what potential evidence-based nonpharmacologic and pharmacologic treatments they would be willing to implement, and then to implement changes in a way that does not overwhelm them. Generally, start with one symptom and 1–2 changes to make and monitor from there.

Caregivers should be monitored for burden, stress, and burnout. The NPI-Q, mentioned earlier, measures both severity of BPSD and distress to caregivers and can be used as a proxy. The Modified Caregiver Strain Index is also a quick and easy tool to use with the caregiver to measure their strain. Some additional instruments include the Pines Burnout Inventory⁵² and the Zarit Burden Inventory.⁵³ When the caregiver's stress starts to rise, it is important to identify the source, correct it, and, if necessary, provide some form of respite.

HOSPICE CARE

While PLWD should begin to receive palliative care early in the disease trajectory, they are not eligible for hospice care until they have very severe dementia. Depending on the region, PLWD must meet the FAST 7C level of debility, which means they cannot speak more than six distinct intelligible words and they have functional dependence with the exception of ambulation, or FAST 7A plus debility in 50% of ADLs. Of note, the FAST scale should only be used in AD and not in other forms of dementia or DD. Instead, the Palliative Performance Scale is another way to determine eligibility, for those individuals who score at or below a 40. PLWD frequently also must have a secondary condition, which could include a recent history of multiple Stage 3 or 4 pressure ulcers, aspiration pneumonia, septicemia, pyelonephritis, recurrent fever, or inability to maintain sufficient intake of food and fluids (as defined by loss of 10% weight in a 6-month period or an albumin level of <2.5 g/dL). It is important to understand the hospice's understanding of what their Medicare Administrative Contractor requires as eligibility.

Once a PLWD is deemed eligible and admitted to hospice, the palliative care team must closely scrutinize standing orders prior to signing the order set. For instance, the emergency kit often provided to PLWD in homes usually includes lorazepam or another short-acting benzodiazepine. Because benzodiazepines can cause rebound confusion and delirium in older adults, particularly those with cognitive impairment, including this in the kit should be discouraged. Haloperidol, prochlorperazine, and promethazine are often included in these kits; these medications should not be permitted in cases where the person has Lewy body dementia or Parkinson's dementia because they have dopaminergic blocking activity and may worsen symptoms.

Once admitted to hospice, it is important to continue following the PLWD because many (though not all) hospice clinicians have limited knowledge of dementia care. They may

need help with recognizing and developing a plan of care for treating pain, BPSD, or other symptoms. Given that PLWD tend to have longer stays in hospice than persons with cancer and experience significant functional disability associated with end-stage dementia, special attention needs to be paid to skin integrity. When working with hospices, it is often important to request occupational and physical therapy consultation to help train the caregiver to prevent contractures and prolong function (specifically ambulation) as long as possible and to evaluate for home safety. These therapists can also train the caregiver in how to perform transfers when the PLWD cannot ambulate even with assistance, thus preventing caregiver injury. OTs are experts at providing "workarounds" for functional and cognitive limitations, and PTs can be of great help in teaching caregivers about exercises they can use to help the PLWD maintain strength as long as possible and prevent contractures once the PLWD has lost too much strength to bear weight. These services are included within the hospice benefit but are often not provided unless directly requested. Finally, some PLWD are live-discharged from hospice due to a "stabilization" of their condition. It is important to closely follow the transition away from hospice as it can be an incredibly stressful time for the caregiver due to loss of the substantial services provided by hospice.

ROLE OF THE APRN

The palliative APRN has a wide role in managing cognitively impaired individuals. While a specific diagnosis should probably not be made without consulting a neurologist, geriatrician, AD center, or geriatric APRN, most treatment falls well within the scope of practice and range of knowledge of the palliative APRN. This includes managing nonpharmacologic and pharmacologic interventions for BPSD; advance care planning; referral to physical or occupational therapy for exercise regimens and physical function; assessing and managing caregiver stress, burden, and burnout; and directing care or attending on hospice care.

SUMMARY

Most forms of dementia are irreversible and progressive. While those with DD are not necessarily progressive, they are at higher risk for dementia and early death. The most significant problems related to this group of diseases are the presentation and worsening of BPSD over time, progressive decline in functional status, and progressive increase in caregiver burden, stress, and burnout, leading to placement in a nursing home or other institutional setting. Therefore, the palliative APRN must (1) create a clear plan of care early in the disease, if possible with the PLWD and proxy present; (2) provide clear expectations to the caregiver about the PLWD's course; (3) implement nonpharmacologic and pharmacologic interventions to manage functional decline and BPSD; and (4) train caregivers to provide appropriate care. These steps can help the PLWD or those with DD and their caregivers

deal with this devastating group of diseases to the greatest extent possible.

SERIOUS MENTAL ILLNESS

Kristyn Pellecchia and Ryan Murphy

KEY POINTS

- The palliative advanced practice registered nurse (APRN) should have baseline knowledge of psychiatry in the palliative care context and of how serious mental illness (SMI) can intersect with other life-limiting illnesses.
- The palliative APRN can identify barriers and use a trauma-informed care approach to work alongside a patient population that is often stigmatized.
- The palliative APRN benefits from understanding primary pharmacologic management of SMI diagnoses and how to utilize interdisciplinary resources to facilitate best outcomes.

allowed the palliative APRN to assist with an inpatient medical admission when her cancer had progressed. Workup revealed that she had multiple-level bowel obstructions secondary to tumor burden, and no surgical intervention was offered. AM was transitioned to inpatient hospice due to symptom burden, and she died comfortably in a safe space.

INTRODUCTION

There are many challenges to treating individuals with concurrent mental illness and life-threatening illness. This patient population presents with a unique set of needs that often go unmet.¹ As seen in Case Study 1, patients with serious mental illnesses (SMI) often have a difficult time navigating the healthcare system. These individuals are labeled as “difficult patients” because symptoms of their illness may lead to frequently missed appointments, declined therapies and interventions, and poor or irregular adherence to treatment regimens.²

Patients with SMI may have difficulty understanding their illness trajectory, the risks and benefits of treatment, and the necessary goals of care pertaining to the treatment plan, reflecting changes in capacity for medical decision-making. These situations can further be complicated when individuals are actively using illicit substances or have a history of illicit substance use to treat pain or symptom burdens. Substance use disorder (SUD), discussed in a separate chapter, is common in populations with SMI,³ with about half of patients with SMI having a comorbid SUD.⁴ The symptom burden of SMI is high and is the source of multiple areas of suffering; these patients will present with poor relationships and lack of social structure, poverty, homelessness, history of incarceration, and inability to care for themselves.

The palliative APRN is in a unique position to support this patient population; SMI is a chronic, often life-limiting illness that is inherently accompanied by significant psychosocial and spiritual distress. Care of this population necessitates meticulous assessment, collaboration, and communication. It also requires a holistic approach to recognize the complexity of patient needs, something that can be best met through interdisciplinary work and truly patient-centered care to optimize health outcomes.

To start, it is important to understand what constitutes SMI. Mental illness is highly prevalent, with nearly one in five individuals in the United States living with some sort of qualifying condition.⁴ In 2017, it was estimated that 4.5% of all US

CASE STUDY 1: THE PATIENT WITH SERIOUS MENTAL ILLNESS

AM was a 44-year-old woman with medical history that included hypertension, Stage IV chronic kidney disease, Stage IV anal carcinoma with metastases to liver and lung, and an unclear, undertreated serious mental illness (SMI). She was referred to palliative care for pain management during an acute admission. Nursing reported that AM was actively using heroin immediately prior to admission and often had difficulty engaging with the nurses or following treatment plans. The palliative APRN agreed to follow AM in the outpatient clinic and slowly built rapport. While trying to create a comprehensive treatment plan for AM, the palliative advanced practice registered nurse (APRN) made referrals to oncology, psychiatry, primary care, and physical therapy. At the next visit, AM reported not following-up with any of the referrals, noting she would not be able to follow a schedule with all of those providers, so she wanted to focus on just oncology and palliative care.

The palliative APRN recognized that even though physical symptoms were controlled quickly, AM benefited from weekly or biweekly visits for psychosocial support. After trust was established, AM shared her history of long-standing physical and emotional abuse, illicit drug use, and multiple admissions to psychiatric facilities for paranoia and hallucinations that started in her teenage years. Antipsychotic medications were offered and AM adamantly refused, citing a history of adverse effects from the medications. The palliative APRN attempted to adapt practice to meet the needs of AM, not necessarily to focus on perfect health outcomes, in line with the harm reduction model. Though AM had a mistrust of the medical field, after about a year she

adults carried an SMI diagnosis: approximately 11.2 million people. Mental illnesses can have a varying effect on all aspects of daily life, with SMI resulting in “serious functional impairment, which substantially interferes with or limits one or more major life activities.”⁴ Classically, SMIs include schizophrenia, schizoaffective disorder, severe bipolar disorder, and severe major depression. However, other mental disorders such as severe personality disorders and eating disorders may also be included if the functional impairment is serious enough.

This patient population warrants a more compassionate approach to care due not only to high symptom burden, but also to expected decrease in life span. While the average life span in the United States is nearly 79 years, in contrast, a person with SMI has a shortened life expectancy less by a range of 15–25 years.¹ This mortality gap is theorized to be 25% due to suicide, homicide, and accidental deaths and 75% due to poor physical health.⁵ The *standardized mortality ratio* describes the observed number of deaths within a study population compared to the standard population⁶; a ratio greater than 1.0 means there are excess deaths in the study population. That said, people with SMI have an increased mortality ratios for cancer (2.4), cardiovascular disease (3.6), and chronic obstructive pulmonary disease (9.9).¹ Poor physical health may be due to medication side effects, reduced access to medical care, and/or higher rates of substance abuse (including tobacco).³

Palliative APRNs can draw from cornerstone philosophies within the specialty to impact the care of these individuals. Historically, palliative care has aimed to alleviate suffering in a more comprehensive way than other areas of medicine. A pioneer in the field of end of life care, Dame Cicely Saunders made a point to educate on the concept of “total pain”: the idea that suffering is the summation of someone’s physical, psychological, social, spiritual, and emotional struggles,⁷ with the emphasis that, “mental distress may be perhaps the most intractable pain of all.”⁸ The idea of total pain becomes particularly important when working with palliative care patients with SMI who regularly present with complex trauma and burden profiles. Case Study 1 depicts a woman who experienced significant, life-long, multidimensional suffering. Like other SMI patients, AM often had high burden from both her mental and physical diseases due to fear of seeking medical assistance, lack of social network, poor emotional coping skills, and inability to self-advocate for assistance that could result in relief of suffering. Only addressing one aspect of pain would leave that patient at risk for experiencing retraumatization, lack of opportunity for closure in her personal relationships, and/or death with uncontrolled symptom burden.

Palliative care principles, consisting of effective communication, holistic assessment of symptom burden, evaluation of decision-making capacity, advance care planning alongside decision-makers, and interdisciplinary care (including psychiatric care when possible) should be applied to these patients.³ The Palliative APRN in Case 1 used the therapeutic approach of careful and compassionate rapport-building to establish a trusting relationship that likely allowed AM to accept palliation of her symptoms and a peaceful end of life. This chapter also aims to introduce trauma-informed care and harm reduction, principles that are helpful when trying to create a

trusting relationship like the one in the case study. Palliative APRNs can be the leaders in reframing care to focus on all aspects of suffering for patients with SMI by using the inherent philosophy of care that nurses employ in relationship-building and holistic care along with the framework of total pain as advocated by Saunders.

In fact, psychiatry and palliative care have long shared similar ideals in treatment planning that is focused on detailed assessment based on the biopsychosocial model, successful communication, rapport-building, symptom management, family-centered care, and interdisciplinary management.⁹ SMIs, such as schizophrenia and bipolar disorder, for example, are not curable disorders and thus the approach is focused on relief of symptoms and improved quality of life, clearly in line with palliative care.⁹ Psychiatry and palliative care both focus on relationships with the patient and family and understand the therapeutic benefit of being with suffering that cannot be cured. Hence, palliative psychiatry is an “emerging subspecialty discipline at the intersection of palliative medicine and psychiatry”¹⁰ that clearly adds value to the core palliative team. Since many psychiatric disorders are chronic and have high rates of relapse, palliative psychiatry aims to address symptom burden and optimize quality of life in these patients. The palliative psychiatrist and the palliative psychiatric APRN work collaboratively with palliative care teams and provide expertise in the following areas:

- Complex treatment planning (i.e., psychopharmacological and nonpharmacological interventions as well as psychotherapies)
- Diagnostic challenges in the assessment of psychiatric symptoms in a terminally ill patient
- Clarification of ethical issues (e.g., decisional capacity assessment)
- Advice and support to the palliative care team
- Assistance in identifying risk for complex grief and in bereavement care

Just as in primary palliative care, palliative psychiatry recognizes that best health outcomes may be met by focusing on the debility of the symptoms rather than the disease itself. While this chapter is focused on assisting palliative APRNs, it is important to recognize the growing need to incorporate palliative psychiatric providers into the team.

GENERAL APPROACH TO WORKING WITH SMI PATIENTS

To successfully engage with this patient population, the palliative APRN can understand the barriers to care, pull from both trauma-informed care and harm reduction practices, become self-aware of personal biases, and utilize interdisciplinary teams when available. In Case Study 1, AM did not disclose a history of psychiatric hospitalizations to the palliative APRN for months. She reported that she felt a significant

shift in how healthcare providers interacted with her after learning about a psychiatric diagnosis. Healthcare providers may be less comfortable with the management of these patients due to lack of knowledge of SMI disease trajectories or treatment plans. Moreover, in palliative care settings, clinicians may be confused about *when and if* patients are able to engage in their own advance care planning based on their current capacity, as discussed later in this chapter. These patients are clinically complex on many levels, with a wide variety of barriers in the way of successful outcomes.

In the face of these barriers, a different approach may be useful to create therapeutic relationships with this patient population. *Trauma-informed care* is an approach that assumes that most, if not all, individuals have experienced some level of trauma in their pasts.¹¹ As such, an individual's view of self, others, and systems are influenced by that trauma. Proponents of this care assert that the trauma-informed lens should be uniformly integrated in all patient assessments. When implemented systemically, this concept has the ability to shift the mindset of the clinician from "what is wrong with this person?" to "what has happened to this person?"¹² Trauma-informed care consists of five key principles: safety, choice, collaboration, trustworthiness, and empowerment, further explored in Table 46.1.

While trauma-informed care can be used to benefit all patients, there is a clear application within those of the SMI patient population who have life-limiting illness. Whether trauma is formally a part of their SMI diagnosis, such as post-traumatic stress disorder (PTSD), or other health conditions have created more implicit traumas over time, this lens helps the provider recognize that behavior may be a symptom of trauma. Due to the fact that the patient accessing palliative care has a

life-limiting (thus implicitly traumatic) illness, the incidence of posttraumatic stress symptoms is high in the terminally ill population. The palliative APRN can use the trauma-informed principles to create a meaningful, therapeutic relationship with these at-risk individuals.

Another useful clinical lesson can be derived from the world of addiction medicine. Harm reduction is similar to trauma-informed care in its aim to make care patient-centered, formally allowing for the patient to partner in the creation of expectations and desired health outcomes.¹³ Harm reduction also does not penalize the patient if health outcomes are not met or even if the patient engages in behaviors that negatively affect well-being.¹⁴ For example, partnering with a patient to reduce the amount and frequency of methamphetamine use, if not altogether stopping use, is considered harm reduction. Again, this type of care comes with core principles, seen in Table 46.2, which can be applied to patients within this population.¹⁵

This framework can be useful for the palliative APRN when initiating care of individuals with SMI. This philosophy supports the idea that all patients are the true experts of their experience. While the healthcare provider provides guidance based on evidence based practice, to date, the patient has survived and navigated their illnesses without the help of the healthcare provider. When approaching the care of patients with SMI and life-threatening illness, harm reduction principles create an environment of honesty, realistic expectations, and true partnership.

When working alongside these patients, it is also important for the clinician to be aware of implicit and personal biases. It is clear that mental illness is stigmatized in our society,¹⁶ and, even with the best intentions, those stigmas can lead to implicit or explicit biases.¹⁷ The palliative APRN can reflect on their experiences of working with patients who have concurrent SMI to try to identify which patients or encounters have made them uncomfortable. Is the APRN able to recognize moments of transference or countertransference when in a difficult situation? Being self-aware of biases and even one's own personal traumas is an important factor in creating a collaborative, successful partnership with SMI patients.

Assessment of patients with SMI is the same as with all other palliative care patients and should be holistic, systematic, and compassionate. A psychiatric history, including past treatments, hospitalizations, symptoms of mania and psychosis, and suicide attempts should be obtained at the start of treatment. Assessing the support system of the patient and finding collateral information from past psychiatric providers, past psychiatric hospitalizations, outpatient mental health centers, and case managers will also contribute to the assessment. Patients with SMI often receive care within silos,¹⁸ contributing to care disparities at end of life. These patients find themselves with medical illnesses that psychiatric providers are uncomfortable managing as well as with psychiatric illnesses that palliative providers have less experience in treating. Good palliative care means breaking down these silos and working together with psychiatric providers who may have been the biggest source of support for these patients. The patient's psychiatric provider can assist the palliative APRN in better understanding their SMI diagnosis, treatment plan,

Table 46.1 TRAUMA-INFORMED CARE PRINCIPLES

PRINCIPLE	DEFINITION	IN PRACTICE
Safety	Ensuring physical and emotional safety	Clinical areas are welcoming and privacy is respected
Choice	Establishing individual patient choice and control	Individuals are given clear messages about their rights and responsibilities to help design their care plans
Collaboration	Making decisions with the individual, sharing power	Individuals are provided a significant role in planning and evaluating healthcare services
Trustworthiness	Providing clarity, consistency, and interpersonal boundaries	Respectful and professional boundaries are maintained during clinical encounters
Empowerment	Prioritizing empowerment and skill building	Affirmation and validation are provided at every clinical encounter

From University at Buffalo.¹²

Table 46.2 HARM REDUCTION PRINCIPLES

PRINCIPLE	DEFINITION	APPROACHES
1. Humanism	Providers value, care for, respect, and dignify patients as individuals. Recognize that individuals with serious mental illness (SMI) may choose a different path. It is important to recognize that people do things for a reason; harmful health behaviors provide some benefit to the individual, and those benefits must be assessed and acknowledged to understand the balance between harms and benefits. Understanding why individuals make decisions is empowering for providers.	Moral judgments made against individuals do not produce positive health outcomes. Compassion at end of life is imperative. Grudges based on past behavior are not held against individuals. A respectful death is a right for everyone. Palliative care services are user-friendly and responsive to patients' needs. The palliative APRN accepts patients' choices.
2. Pragmatism	No individual will ever achieve perfect health behaviors. The palliative APRN must be accepting of the individual with SMI. Health behaviors and the ability to change them are influenced by social and community norms; behaviors do not occur within a vacuum. The palliative APRN must understand the social determinants of health (SDOH) of the individual with SMI.	A range of palliative, supportive approaches is provided. The palliative APRN provides care messages about actual harms to individuals as opposed to moral or societal standards.
3. Individualism	Every person presents with his or her own needs and strengths. The palliative APRN seeks to find those in the individual with SMI. People present with spectrums of harm and receptivity and therefore require a spectrum of intervention options. The palliative APRN facilitates collaborative care for the individual with SMI.	The palliative APRN assesses strengths and needs for each individual, and no assumptions are made based on harmful health behaviors. The palliative APRN does not have one universal application of protocol or messaging for individuals with SMI. Instead, the APRN tailors messages and interventions for each individual and maximizes treatment options.
4. Autonomy	Although the palliative APRN offers suggestions and education regarding individuals' medications and treatment options, individuals ultimately make their own choices about medications, treatment, and health behaviors to the best of their abilities, beliefs, and priorities.	The palliative APRN–patient partnerships is important, and is exemplified by patient-driven care, shared decision-making, and reciprocal learning. Care negotiations are based on the current state of the individual.
5. Incrementalism	The palliative APRN understands that any positive change is a step toward improved health, and positive change can take years. The palliative APRN understands and plan for backward movements or return of unhealthy behaviors.	The palliative APRN can help individuals celebrate any positive movement. It is important to recognize that, at times, all people experience plateaus or negative trajectories. The palliative APRN provides valuable positive reinforcement.
6. Accountability without termination	Individuals are responsible for their choices and health behaviors. Individuals are not “fired” for not achieving goals. Individuals have the right to make harmful health decisions, and palliative APRNs can still help them to understand that the consequences are their own.	While helping individuals to understand the impact of their choices and behaviors is valuable, backward movement is not penalized. The palliative APRN works in collaboration with and the support of a team to discuss an individual's care.

From Hawk et al.¹⁵

and disease trajectory and provide assistance in assessing decisional capacity in patients with psychotic disorders.

In addition to working with the psychiatric provider, the palliative APRN works with the other members of the interdisciplinary team to provide good care. Social workers can assist with completing an in-depth biopsychosocial and spiritual evaluation that may highlight areas of distress, particularly if that patient now has a terminal diagnosis and is approaching end of life. A pharmacist may be needed to confirm the safety of medication regimens for both SMI and palliative needs (e.g., in identifying medication interactions that may be significant with psychotropics). The palliative APRN can promote the patient's wellness by being the leader in communication between all of the involved caregivers.

The next section reviews major psychotic disorders and bipolar disorders to assist the palliative APRN in being be

more attuned to the symptoms and burdens of these patient populations. In addition, PTSD will be discussed because it has particular relevance and high prevalence in the palliative care population. The authors encourage readers to consult with psychiatry resources for more in-depth information and to consult with psychiatric colleagues if available and whenever possible.

PSYCHOTIC DISORDERS, MOOD DISORDERS, POSTTRAUMATIC STRESS DISORDER

PSYCHOSIS

First, it is important to understand the phenomenon of psychosis. This symptom, characterized by hallucinations and/or

delusions, can be seen in patients with varying psychiatric disorders, which are categorized as primary and secondary psychotic disorders. Schizophrenia, schizoaffective disorder, and delusional disorder are the main primary psychotic disorders of which psychosis is the cardinal symptom. Affective disorders, such as bipolar and major depression, as well as anxiety disorders, such as obsessive compulsive disorder (OCD) and PTSD, may also present with psychosis when severe.

Secondary psychotic disorders are those in which psychosis is prominent and there is evidence that it is the direct pathophysiological consequence of a medical condition or a substance or medication. Secondary psychotic disorders may be seen in Alzheimer's dementia, Parkinson's disease, diffuse Lewy body disease, frontotemporal lobar degeneration, cerebrovascular disease (including cerebrovascular accident [CVA] and brain tumor), Huntington's disease, prion disease, traumatic brain injury, and HIV, among others (Box 46.1).

¹⁹ *It is important to remember that patients with severe and persistent mental illness may also develop secondary psychotic*

disorders, when new or different psychotic symptoms arise. Proper assessment diagnosis, and treatment are essential.

SCHIZOPHRENIA SPECTRUM AND OTHER PSYCHOTIC DISORDERS

Schizophrenia, schizoaffective disorder, and delusional disorder fall under the umbrella of the schizophrenia spectrum and other psychotic disorders (as described in the *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5]).²¹ These disorders are diagnosed after all other potential reasons for the psychosis are ruled out (e.g., neurocognitive disorders, substance use, delirium). Schizophrenia is a heterogeneous syndrome with a cluster of symptoms that are significant enough to cause an impairment in occupational or social functioning. The primary symptoms of schizophrenia are two or more of the following: delusions, hallucinations, disorganized speech/thought, grossly disorganized or catatonic behavior, and/or negative symptoms. Cognitive impairment is often seen

Box 46.1 PSYCHIATRIC SYMPTOMS DEFINITIONS

Hallucinations are defined as sensory perceptions without the presence of an external stimulus and may be visual, tactile, auditory, gustatory, or olfactory. Hallucinations may or may not cause distress to the patient, and the patient may or may not have insight into the fact that the hallucination is not based in reality. In schizophrenia and other primary psychotic disorders, hallucinations are primarily auditory, followed by visual, and are often negative in nature, speaking in a derogatory manner to or about the patient. Visual hallucinations in schizophrenia are usually surrealistic, featuring “denatured people, parts of bodies, unidentifiable things and superimposed things.”²⁰ Hallucinations occurring in delirium are usually distressing to the patient and are most often visual hallucinations of different animals or shapes. In PTSD, patients may experience visual and auditory hallucinations consistent with the theme of the trauma or of a depressive nature, and paranoid delusions as well. Hallucinations experienced in Alzheimer's dementia, Lewy body disease, and other organic brain syndromes are predominantly visual and may or may not be distressing. In Parkinson's disease, visual hallucinations predominate and are often not disturbing to the patient. In affective disorders, hallucinations are often auditory and congruent with their mood, whether elevated (i.e., in mania) or depressed. Not all hallucinations are considered pathological; for example, hearing one's voice called or a comforting voice in times of distress, seeing a deceased loved one, or the lights and visions seen or voices heard during profound religious experiences are considered within the range of normal.²⁰ Often, when a person is close to death, comforting visions will appear and reassure them.

Delusions are fixed, false beliefs, and their content may reflect a variety of themes (e.g., persecutory, referential, grandiose, erotomanic, somatic, religious, or nihilistic).²¹ The most common delusions are persecutory and are often referred to as *paranoia*; these are seen frequently in schizophrenia spectrum disorders as well as neurocognitive disorders. Delusions seen in schizophrenia spectrum disorders are often bizarre while those in neurocognitive disorders are less so and reflect more ordinary life experiences. A common delusion in Alzheimer's disease, for example, is that people are stealing from the patient, reflecting the fact that they do not remember what happened to an item. Another non-bizarre and common delusion is that one is being spied on or that someone is poisoning the patient's food. A bizarre delusion example would be that aliens have implanted devices into one's brain and record everything one does to report back to the mother ship. Other bizarre delusions include thought withdrawal or insertion, where the patient believes that their thoughts are being controlled by an outside force. Delusions, like hallucinations, may also be more or less disturbing to the patient, a fact that should be understood when considering potential treatments.

Thought disorders (i.e., disorganized thinking) are prevalent in schizophrenia and schizoaffective disorders and are often identified through the patient's speech.²¹ When one is talking with a person with a thought disorder, the observer will feel as if the patient is not making any sense or that they are very difficult to follow. The patient may switch from one topic to another quickly, with little association between thoughts (*derailment* or *loose associations*) or thoughts may be *tangential*, with vaguely related ideas connecting them. Thoughts (and hence speech) may also be completely incoherent, which is described as “word salad.” Disorganized or abnormal motor behavior exists along a spectrum “from childlike ‘silliness’ to unpredictable agitation” as well as catatonia (i.e., marked decrease in reactivity to the environment).²¹ Negative symptoms include diminished emotional expression and *avolition*. Patients with these symptoms will not express emotion; their voice sounds flat and monotone, and their facial expression is blunted. Avolition includes diminished desire to participate in work, social activities or hobbies, or even self-care. Other negative symptoms include diminished speech, lack of ability to experience pleasure, and lack of interest in social activities.

From American Psychiatric Association.²¹

in schizophrenia and leads to functional impairment, but does not de facto imply lack of capacity for medical decision-making. It is distinguished from schizoaffective disorder or major depressive disorder with psychosis by the lack of significant mood disturbances.

Lifetime prevalence of schizophrenia is about 0.3–0.7%, and most patients are chronically ill, require daily living supports, and they experience exacerbations and remissions of active symptoms. Schizophrenia generally develops in the late teenage to early adulthood years, but onset, particularly in women, may occur during middle age as well. Over the life course of a patient with schizophrenia, generally the psychotic symptoms diminish while the cognitive symptoms remain stable.

Schizophrenia is one of the top 10 most common disorders in the world, and the long-term disability burden is by far the highest among all mental illnesses. Drug and alcohol use are more prevalent in patients with schizophrenia than in the general population, and the prevalence of comorbid substance use disorder is approximately 42%.²² Methamphetamine and cannabis in particular can initiate psychosis in patients who are susceptible to schizophrenia, which has a strong hereditary component, and these substances can contribute to worsened disease trajectory and quality of life.

Due to their symptomatology and resulting functional impairments as well as the stigma against them, patients with SMI, and in particular schizophrenia, avoid healthcare and experience many healthcare disparities leading to lower quality and quantity of life.²³ These vulnerable patients have a higher rate of hospital mortality, fewer advance care plans, higher use of long-term institutional care, and are less likely to receive opioids and significantly less likely to access palliative care.^{1,3} They have lower rates of specialist use, worse survival after a cancer diagnosis, and more unnecessary aggressive and invasive interventions.^{1,3} In addition, these patients at end of life present with complex ethical situations related to decisional capacity and autonomy (in the form of refusing care and involuntary treatment) as well as stigma, necessitating strong interdisciplinary teamwork with psychiatry, outpatient care, social work, and clinical ethicists. Of note and discussed later, most patients with SMI, when not in the throes of an acute exacerbation and who are stabilized on medication, have decisional capacity.

Schizoaffective disorder is a psychotic disorder similar to schizophrenia in that the patient has primary symptoms of schizophrenia as well as major mood episodes (manic or depressive). The psychosis occurs outside of the mood disorders, as opposed to a patient with bipolar or major depression who may become psychotic only during the mood episodes. Negative symptoms may be less severe than seen in schizophrenia. Schizoaffective disorder is less common than schizophrenia, with a prevalence rate of 0.3%.

Delusional disorder is a psychotic disorder in which a patient presents with delusions but not usually with hallucinations. Functioning is not usually as impaired as in schizophrenia and schizoaffective disorder outside of the impact of the delusion. This type of psychotic illness can be difficult to identify as their behavior appears normal when their delusional ideas are being discussed or acted on. However, these

patients can become hostile, litigious, and aggressive if their delusions are challenged. This can be particularly difficult when addressing delusions that are persecutory, erotomanic, or rooted in jealousy.

In Case Study 1, the palliative APRN surmised that AM had previously been diagnosed with a schizophrenia spectrum disorder. AM presented to the office disheveled, physically agitated, and reported her needs in a way that was very difficult to follow. AM was not forthcoming about psychiatric history and unwilling to engage with psychiatry referral, making multidisciplinary care challenging. The palliative APRN had to take time to interpret her speech and try to elicit more direct responses with motivational interviewing, despite AM's clear thought disorder. This became easier over time as rapport was built. Even though communication was challenging due to AM's untreated psychosis, it was determined that she had decisional capacity related to her medical decision-making as she clearly articulated the risks and benefits of both adhering and not adhering to proposed treatments. Through careful exploration of her wishes, the APRN learned that the patient's goals included being pain free and living as long as possible, even though the patient did not always agree with oncology or primary medical treatment plans. Despite her fear of medical facilities, through use of trauma-informed care, a trusting relationship was eventually created. AM felt comfortable coming into the hospital when she felt she was acutely decompensating, eventually dying on inpatient hospice service.

CASE STUDY 2: THE PATIENT WITH BIPOLAR DISORDER

EM was a 32-year-old woman with medical history including hypertension, asthma, lupus, rheumatoid arthritis, fibromyalgia, seizure disorder, anxiety, and depression. She was referred to palliative care for pain/symptom management and psychosocial support. EM had frequent acute medical events leading to admission, including asthma exacerbations requiring intubation and lupus flares with pain crisis. She shared with the palliative service that she had little social support in the community and often felt she did not have the necessary resources to care for her three young daughters.

During an assessment with the palliative licensed social worker (LCSW), EM confided that she had been previously hospitalized for a suicide attempt. She was starting to feel that she would be "better off if I never woke up again," but never had any regular relationship with a psychiatrist. She described a history of shift in mood to feeling very irritable and anxious, accompanied with a very high energy level, only sleeping 3 hours per night and spending money on unnecessary items, leaving her without enough funds for rent and food. During these episodes EM experienced asthma crises and pain crises which would often correspond with more despondent and suicidal moods.

The palliative APRN successfully linked EM to a psychiatric provider who diagnosed these as manic episodes from bipolar disorder; he suggested the mood stabilizer and antiepileptic agent valproic acid (Depakote), which significantly reduced her manic episodes, regulated her sleep, and reduced her anxiety. EM

experienced significantly less frequent asthma exacerbations and eventually was able to start on duloxetine for her pain associated with fibromyalgia and depression. Once her mental illness was under more control, the palliative care team was able to address her deeper relational wounds with her family caused by many years of untreated mania.

BIPOLAR DISORDER

Bipolar disorders are considered the “bridge” between psychotic disorders and depressive disorders.²¹ Distinctions are made between bipolar I and bipolar II disorders (with bipolar II displaying less severe functional impairments during hypomania and lack of psychosis); however, both cause serious functional impairment over the course of a lifetime. The defining feature of bipolar disorders is the presence of at least one manic/hypomanic episode as well as at least one depressive episode in their lifetime. Some patients have more manic and hypomanic episodes than depressive, while others have more depressive, and still others have mixed episodes or rapidly cycle between mania and depression. *Mania* is an altered mood state that is distinct from the patient’s normal or depressed moods and is abnormal and persistently elevated, expansive (i.e., very enthusiastic, grandiose, extremely friendly), or irritable accompanied by high energy. Patients who are manic will engage in multiple projects (i.e., increase in goal-directed activity), particularly in areas that they are not knowledgeable about, and they may engage in these projects at all hours. During this time the patient will also experience symptoms of inflated self-esteem or grandiosity, decreased need for sleep (i.e., only needing 3 hours of sleep as opposed to their normal 8 hours), increased or pressured speech, mood lability, flight of ideas or thoughts, distractibility (i.e., inattention), psychomotor agitation, and/or excessive involvement in activities that have a high potential for painful consequences.²¹ A person who is manic may be loud, difficult to interrupt, highly distractible, unable to focus, forceful or pressured in their speech, and may become psychotic as well. The high impulsivity and extremely poor judgment during manic episodes may increase the risk of danger to self and others.

Rapid cycling is a high-risk situation, defined as four or more mood episodes in a year. Patients with rapid cycling have a poorer long-term prognosis, more suicide attempts, and poorer response to pharmacotherapy.²⁴ Rapid cycling is seen more often in patients with a history of childhood trauma.²⁵ Antidepressant therapy in the absence of a mood stabilizer may also induce rapid cycling, which underlies the importance of proper assessment and history-taking in any patient with a history of depression. When a patient with bipolar disorder has episodes with mixed features, this indicates that the mood state has both manic and depressive features, and it is a sign of more severe illness and poorer treatment response.^{26,27} Mixed states are extremely uncomfortable and distressing for patients and are associated with higher rates of comorbidity, psychosis, suicide, and substance abuse.²⁷ Recognizing that

a patient has bipolar disorder (i.e., has a history of mania or hypomania) is a key task in the assessment of the patient with SMI for both safety and well-being and should trigger referral or consult with a psychiatric provider.

In Case Study 2, EM’s manic episodes were clearly defined by irritable mood and a reduced need for sleep, accompanied by increased energy and impulsive buying which caused her to not be able to provide for the basic needs of her family. This elevated activity level with little rest often led to exacerbations in her asthma, sometimes requiring acute admission. Once admitted, EM rarely could follow nursing care or directions from medical providers. This discord led to her being loud and sometimes agitated. In addition, her pain crises often corresponded with depressed mood. The palliative APRN successfully identified the need for psychiatric evaluation, which led to proper diagnosis and stabilization through appropriate pharmacology interventions. After the SMI was addressed, continued support allowed for decreased psychosocial distress with ongoing counseling to promote successful personal relationships.

CASE STUDY 3: THE PATIENT WITH POSTTRAUMATIC STRESS DISORDER

JH was a 37-year-old man with medical history of posttraumatic stress disorder (PTSD) and active IV drug use leading to endocarditis following bioprosthetic valve replacements, septic pulmonary embolism, splenic abscess, and osteomyelitis. He was referred to palliative care for pain management, support, and goals of care during an acute admission for severe sepsis with multifocal infection. In conjunction with the pain and addiction medicine service, JH was placed on methadone for both opioid use disorder and pain management.

The palliative APRN and LCSW utilized motivational interviewing to get to know JH on a deeper level. He revealed that he was previously in the Navy and had been involved in the 9/11 terrorism attack response. JH shared that these experiences resulted in physical, emotional, and psychological traumas that manifested in severe physical pain. This pain is what led JH to seek analgesia through illicit drug use, specifically heroin. JH had multiple admissions for sepsis, with frequent signing out against medical advice (AMA), although after methadone induction JH was able to remain admitted until discharge.

JH remained homeless and experienced difficulty in initiating follow-up with the methadone clinic due to severe mistrust of medical providers, hypervigilance related to his PTSD, and deep spiritual pain in the context of drug use. However, the palliative APRN and team continued to work diligently with JH, even though he experienced multiple relapses. The team celebrated his successes when he was able to stay off heroin, referred him to a clean needle program, and provided a nonjudgmental and caring safe place for the patient to receive care for his many wounds. Treatment consisted of adjuvant pain medications, methadone treatment for pain and opioid use disorder, sertraline for his PTSD symptoms, and social work assistance in finding safe shelter, food, clothing, and a shower. Over time JH was able to sustain longer

and longer periods of time off heroin, experienced fewer hospitalizations, and was able to reestablish contact with a long-lost daughter. He retained capacity for decision-making and refused the recommendation of amputation. He eventually died comfortably in the hospital after admission related to his osteomyelitis.

POSTTRAUMATIC STRESS DISORDER

While PTSD may not always be considered a SMI, the incidence increases from 8% in the general population to 35% in cancer patients, making it a significant mental illness in the palliative care context. Furthermore, significantly ill or terminal individuals are at risk of experiencing significant PTSD symptoms at high rates, though they may not meet all DSM-5 criteria for formal diagnosis (68% in a study of breast cancer patients, 64% in ICU patients with various life-threatening conditions, and up to 88% in a study of terminal cancer patients).²⁸ Patients with a history of trauma, particularly in childhood, have worse health outcomes, including chronic health conditions, depression, and substance abuse.²⁹

PTSD develops as a reaction to actual or threatened death, serious injury, or sexual violence that is experienced directly to self, is witnessed, or that has occurred to a loved one. It may also be experienced as secondary trauma by medical professionals and first responders who bear witness to their patients' traumas. Symptoms include intrusive reexperiencing of the trauma (e.g., nightmares, flashbacks), hyperarousal and increased reactivity (e.g., hyperstartle, hypervigilance), and avoidance of reminders of the event(s), as well as negative alterations in cognition and mood. These patients often have dysfunctional coping mechanisms, irritable and depressed mood, difficulty trusting authority, and withdrawal from social support, all leading to challenges with relationships, adherence to treatment, and maintaining work, and spiritual distress. Substance use and mood disorders are frequently comorbid, pain sensation is altered, somatization may occur, and sleep is frequently problematic as well.³⁰

In Case Study 3, JH reported to the team that after being a 9/11 first responder, his untreated emotional pain led to physical pain. Eventually the pain was so intense JH sought out analgesia through illicit drug use. He noted that after injecting heroin and fentanyl, his body and mind both "felt quiet for the first time" since being in the service. He also deeply distrusted medical providers (a symptom of PTSD) which caused him to leave the hospital before treatment was complete and experience recurring infection.

Patients who have a history of PTSD are at increased risk for a return of symptoms at end of life, even if their disorder has been previously under control, because they now are facing impending death. In addition, in a study by Bickel et al., Veterans Administration patients who suffer from PTSD have increased symptom burden at end of life, and PTSD may be a risk factor for terminal delirium and increased antipsychotic usage in the last week of life.³⁰ (see Chapter 23 "Care of the Veteran With Palliative Care Needs," for information on PTSD in the Veteran.)

Whether the trauma that has caused PTSD is more recent or in the distant past, patients with active PTSD symptoms are at risk for a less than desirable dying experience due to several factors. Communication may be worsened due to the coping factor of avoidance of reminders of death. Anger, irritability, and mistrust are common symptoms of PTSD that may lead to breakdown of important discussions with providers regarding end-of-life decision-making, and they also may cause poorer family and social relationships and support. Life review has been shown to increase quality of life and depression and anxiety scores, and it leads to a greater sense of meaning at end of life; however, due to avoidance symptoms seen in PTSD, patients may not engage in life review and, if they do, may experience retraumatization and increased symptoms.²⁸

NONPHARMACOLOGICAL AND PHARMACOLOGICAL APPROACHES TO SERIOUS MENTAL ILLNESS

Treatment of psychosis in palliative care includes pharmacological and nonpharmacological approaches and is based on the etiology, assessment of the risks and benefits of treatment and nontreatment, reversibility of the condition, and concomitant symptoms, along with the consideration and discussion of goals of care for the patient. Improved level of functioning, including the ability to resolve relationship issues and perform other end-of-life tasks, should be considered.

NONPHARMACOLOGICAL APPROACHES

Patients with serious mental illness and psychotic disorders in particular have many factors that contribute to a poor quality of life. A palliative approach to this patient population aims at enhancing their quality of life not only through medication but also through many nonpharmacological approaches. A qualitative study by Sweers et al. (2013) showed that patients with schizophrenia—no different from most individuals—desire warm, trusting, and skilled companionship at end of life; absence of pain and physical deterioration; respect for and promotion of their autonomy; social support and to not die alone³¹; and attendance to spiritual concerns (i.e., finding meaning in suffering, illness, and death). As a provider, cultivating a compassionate presence for patients with SMI will go a long way in developing the trust and rapport necessary to providing beneficial palliative care.

Meeting basic needs such as housing, relationship/social, food, hygiene, and recreation and entertainment are tantamount to living a higher quality of life but are often unmet in the SMI population. Needless to say, these basic needs should be thoroughly addressed by the palliative care team. Research in patients with SMI has shown that cognitive-behavioral therapy (CBT) can also be potentially beneficial in addressing needs, if appropriate to the patient's medical condition.³² Mobilizing social support for help in decision-making may also contribute to improved quality of life and avoidance of aggressive interventions at end of life.

For patients with PTSD, traditional pharmacotherapy and psychotherapy approaches may not be helpful and may worsen symptoms in patients with a life-limiting illness, particularly if the primary trauma is disease-related. Standard psychotherapeutic approaches often cause worsened symptoms before improvement, and this process may be too time-intensive and will also not be effective as long as the primary trauma continues. Standard pharmacological treatment (i.e., selective serotonin reuptake inhibitors [SSRIs] sertraline and paroxetine) also may take too long to reach their therapeutic potential, similar to treatment for depression at end of life. Benzodiazepines are contraindicated in PTSD and are too often used inappropriately for treatment of PTSD-related anxiety, frequently causing worsened symptoms, presumably due to disinhibition. General approaches to patients with PTSD include cultivating compassionate presence, allowing the patient to feel in control of decisions and situation, validation of their experience, avoidance of triggers such as loud noises and restraints, and a focus on strengths and resilience.³³ In addition, psychoeducation about PTSD and when symptoms are likely to be exacerbated should occur with families and patients, which will help the patient mentally prepare and improve trust between provider and patient.

Other approaches to treatment of PTSD at end of life have been developed including modified CBT, modified eye movement desensitization reprocessing (EMDR), a stepwise psychosocial model guided by palliative care social workers, and life review techniques (including meaning-centered psychotherapy and *dignity therapy*, a short course of psychotherapy that focuses on highlighting meaning and purpose when someone is at end of life³⁴), as well as spiritually oriented psychotherapeutic techniques to address areas of spiritual pain frequently seen in patients with PTSD.³³ Complementary and alternative medicine (CAM) techniques may be helpful for patients with PTSD but caution is necessary to avoid triggering traumatic memories (e.g., massage in patients with sexual trauma).³³

The palliative APRN should adhere to principles of trauma-informed care in the approach to patients with a history of trauma. It is not recommended to probe into the trauma history as this may cause a resurgence of symptoms. However, if a patient discloses trauma, the APRN should respond with gentle and compassionate acknowledgment of the suffering and difficulty the patient has experienced. Recognize symptoms of trauma and refer the patient accordingly to social work, psychology, and/or psychiatry. If the patient has a 3-month or longer life expectancy, consider an SSRI such as sertraline or paroxetine. Trauma-informed care is congruent with a palliative approach in its focus on partnering with the patient to empower them to make informed choices and participate in their own care, as well as in its focus on interdisciplinary collaboration. Taking steps to ensure the patient's physical and emotional safety is key, as well as developing good rapport as a trustworthy provider who informs the patient of the details of what proposed treatments entail, what are expected outcomes, and potential risks, as well as identifying who will be involved in providing care (Box 46.2).

Box 46.2 APPROACH TO PATIENT WITH TRAUMA HISTORY

1. Respond gently and acknowledge suffering.
2. Recognize symptoms of trauma.
3. Make appropriate referrals.
4. If life expectancy >3 months, consider starting an SSRI.
5. Focus on partnering with patient and give control to patient as much as possible.
6. Ensure emotional as well as physical safety.

Racine, Killam, Madigan¹¹, University at Buffalo. Buffalo Center for Social Research.¹²

PHARMACOLOGICAL TREATMENT

For patients with psychotic disorders, first- and second-generation antipsychotics are utilized in addition to treatment of any underlying organic disorder that may be causing psychosis. Antipsychotics, reviewed in Table 46.3, are also used in treatment-refractory depressive disorders or depression with psychosis, as well as in patients with severe OCD. Antipsychotics are also appropriate for patients with bipolar illness because they have mood stabilizing properties and particularly in patients who are psychotic while manic. As the stress of medical illness may worsen psychotic symptoms in patients, it is important to be cautious about de-prescribing antipsychotics in patients who are not imminently dying.³ Care should be taken regarding antipsychotic dosages in psychotic disorders because these are usually much higher than when used for treatment of delirium and nausea. Likewise, it is recommended to utilize psychiatric provider consultation if needing to stop antipsychotic therapy for any medical contingency. Antipsychotic therapy may also improve the psychotic patient's ability to participate in decision-making, which is not an insignificant consideration.

Patients with bipolar illness require a mood stabilizer such as lithium or valproic acid to control symptoms of decreased need for sleep, severe irritability and/or grandiosity, mood lability, and impulsivity seen in mania and hypomania in particular. Lithium is also protective against suicide. In addition to lithium and valproic acid, other first-line mood stabilizers include carbamazepine and lamotrigine. The palliative APRN is reminded to consult prescribing guides for mood stabilizers and seek psychiatric consultation for more detailed pharmacologic information. Antipsychotics are second-line, but are often prescribed as well for psychosis associated with bipolar and/or mood stabilization. Avoid antidepressant use that is unopposed by a mood stabilizer as it may trigger manic episodes and rapid cycling.

ANTIPSYCHOTIC CAUTIONS

Use of antipsychotics in elderly patients with dementia increases risk of stroke and all-cause mortality by about two

Table 46.3 FIRST- AND SECOND-GENERATION ANTIPSYCHOTICS

NEUROTRANSMITTER	FIRST-GENERATION “TYPICAL” ANTIPSYCHOTICS (FGAS)	SECOND-GENERATION “ATYPICAL” ANTIPSYCHOTICS (SGAS)
	D ₂ ANTAGONISTS	D ₂ /5-HT _{2A} ANTAGONISTS (*WITH 4 NOTABLE EXCEPTIONS)
Side effects	Higher risk of EPS (dyskinesia, parkinsonism, akathisia, dystonia), tardive dyskinesia QTc prolongation Hyperprolactinemia Falls Sedation Anticholinergic effects Lowered seizure threshold Cholestatic jaundice Sexual dysfunction <i>Rare but potentially fatal:</i> Agranulocytosis, neuroleptic malignant syndrome (NMS), sudden death	More variation in neurotransmitter action than in FGAs, thus more variation in side effect profiles, Lower risk of EPS QTc prolongation Hyperprolactinemia Falls Sedation Lowered seizure threshold Higher risk of metabolic syndrome, hyperlipidemia, diabetes mellitus, weight gain Sexual dysfunction <i>Rare but potentially fatal:</i> NMS, sudden death, agranulocytosis, DRESS, myocarditis, cardiomyopathy
	<i>Black box risk in patients with dementia:</i> 1.6 to 1.7-fold increased risk of mortality when used to treat behavioral symptoms of dementia	
Examples	<i>High potency:</i> Fluphenazine, haloperidol, loxapine, perphenazine, pimozide, thiothixene, and trifluoperazine <i>Low potency:</i> Chlorpromazine, thioridazine	Olanzapine, risperidone, quetiapine, clozapine, ziprasidone, brexpiprazole <i>*exceptions:</i> Pimavanserin (no D ₂ affinity) Aripiprazole and brexpiprazole (D ₂ receptor partial agonists) Cariprazine (D ₃ -preferring D ₃ /D ₂ receptor partial agonist)
Dosages	<i>High potency:</i> 1–10 mg of a high potency antipsychotic medication (higher risk of EPS) <i>Low potency:</i> 100–800 mg of a low potency antipsychotic medication (higher risk of sedation, orthostatic hypotension, dry mouth, constipation)	Variable
Efficacy	No notable differences in efficacy between FGAs and SGAs Chosen for individual efficacy (history of good effect) and side-effect profile	

Drug reaction with eosinophilia and systemic symptoms (DRESS), extrapyramidal symptoms (EPS).

times, and this is considered to be a black-box risk of all antipsychotics. Antipsychotics should be used with great caution in patients with dementia after clear and documented risk-benefit discussions with the surrogate decision-maker.

Antipsychotics increase the risk of seizures by lowering the seizure threshold: typically, the more sedating the antipsychotic and the higher the dose, the higher the risk. Additionally, antipsychotics cause and worsen parkinsonism of any etiology. Pimavanserin is the only antipsychotic approved by the US Food and Drug Administration (FDA) for treating psychosis in Parkinson's disease, and it does not carry the same risk as most other antipsychotics in worsening parkinsonism because it does not have any affinity for dopamine receptors.³⁵ In addition, clozapine and low-dose quetiapine have a lower risk of worsening movement symptoms and may be considered in treating problematic psychosis in

Parkinson's disease and atypical parkinsonian disorders along with dopamine agonist tapering.

Antipsychotics are metabolized through P450 pathways and thus serious interactions may occur from induction or inhibition of hepatic metabolism (e.g., antiemetics, methadone, or certain antibiotics and antivirals). Hence, it is important to consult pharmacists and also perform drug–drug interaction checks before prescribing these agents. In addition, antipsychotics pose a risk of dose-dependent QT prolongation and resulting torsade de pointes. Additive effects of antipsychotics with other medications may also occur, such as increased sedation, hypotension, and QT prolongation. Antipsychotics may also reduce the effect of antiparkinsonian medications.³⁶ As with all treatments, a proper risk-benefit analysis and discussion should occur before using these medications.

OTHER ISSUES WITH SMI PATIENTS

DECISIONAL CAPACITY AND ADVANCE CARE PLANNING

Assessment of capacity to make medical decisions in patients with schizophrenia spectrum disorders can be challenging due to questions regarding capacity, refusal of care, and presence or history of suicidal behavior. Thus, issues related to determining capacity may present a barrier to advance care planning and complex decision-making in these patients. Research shows that many patients with schizophrenia spectrum disorders that are in remission *can* participate in end-of-life decision-making and have the same concerns as nonpsychiatric patients in regards to fear of physical pain, fear of dying alone, and hope for self-determination.³⁷ It is important to note that legal guardians may not always be able to make decisions related to healthcare, and these patients may not have the social support or skills to engage and enlist healthcare proxies in advance care planning. While barriers exist to determining decision-making capacity, advance care planning is vital to the provision of good palliative care and should include psychiatric as well as medical contingencies. Consultation and collaboration with psychiatry will help in determining the level of decision-making capacity the patient has, treatment of psychiatric symptoms to improve capacity, identification of potential healthcare surrogates, and engagement of the patient in complex medical and psychiatric decision-making.³⁷ In addition, training caregivers and surrogate decision-makers in end-of-life communication and legal issues may improve palliative care for these patients.

PAIN PERCEPTION

Patients with schizophrenia have difficulty with identifying and reporting pain,³ which may contribute to reports that these patients have lower utilization of opioids. Utilizing caregivers who have a good relationship and are familiar with the patient, building trust and rapport, and using the Pain Assessment in Advanced Dementia Scale (PAINAD) may be helpful, even though the PAINAD scale has not yet been validated in this patient population.³

RISK OF VIOLENCE

While some patients with schizophrenia may exhibit hostility, most schizophrenic patients are not aggressive and are more likely to be victimized than to commit a violent act. Nonetheless, aggressive behavior has been diagnostically linked to schizophrenia, mania, alcohol abuse, organic brain syndrome (i.e., delirium and dementia), seizure disorder, and personality disorders,³⁸ with an increased risk of aggression in an acute psychiatric setting seen in younger males, and with nonadherence to treatment, substance abuse, impulsivity, and a history of violence.³⁸ The higher the degree of impulsivity combined with observed dysphoric and irritable affective state, the higher the risk of aggression, which is seen in patients with schizophrenia and bipolar disorder, as well as

dementia, implying that aggression is related to a complex serotonergic dysfunction.³⁹ The palliative APRN should identify and screen for factors that increase risk of violence and enlist psychiatric provider assistance in further assessment and proper management. Signs of increasing impulsivity, dysphoric and/or irritable mood, substance use, history of violence, and untreated paranoia and command hallucinations, no matter the etiology, should be given serious attention and warrant further assessment and mitigation of risk.

SUICIDE

Increased risk for suicide is associated with previous attempts and recent psychiatric hospitalization along with history of multiple hospitalizations; comorbid psychiatric, somatic, and substance use disorders; rapid cycling or predominantly depressive states; current mixed or depressed state; and longer duration of untreated illness.⁴⁰ Sociodemographic risk factors include being divorced, living in social isolation, being an unmarried parent, having occupational problems, age (<35 or >75 years), and having acute stressors. Impulsive and depressive personality traits and family history of suicide also indicate higher risk.

Suicide risk is high in patients with schizophrenia and schizoaffective disorder, with about 5–6% of patients with these disorders dying of suicide; 10–50% will at some point attempt suicide.⁴¹ Command hallucinations increase suicide risk, as do comorbid substance use, depressive symptoms, feelings of hopelessness, being unemployed, and after a psychotic episode or hospital discharge.²¹ Risk of suicide is higher in newly diagnosed patients with schizophrenia.⁴¹

Important in the care of the patient with bipolar illness is that the combination of impulsivity, poor judgment, psychosis, and/or irritability increases the danger for violence, which is particularly high in this patient population. In fact, the lifetime risk of suicide is 20–30 times higher than that of the general population, and 15–20% of bipolar patients die of suicide.⁴² One-third to one-half of all bipolar patients attempt suicide at least once in their lifetime.⁴² Referral to a psychiatric provider is preferred in patients with untreated bipolar disorder, and, if not possible, curbside consult may be fruitful.

EM, the patient in Case Study 2, alternated between depression with passive suicidal thoughts and mania, with her poor treatment adherence and associated asthma exacerbations leading to hospitalization. When working with SMI patients in a palliative care setting, a thorough suicide risk assessment along with assessment of their current mental state at every visit, along with timely referrals to psychiatric care, is very important in caring for this population.

SUMMARY

Working with the SMI patient population in a palliative care setting presents unique challenges. SMI causes substantial interference with everyday life, thereby increasing the potential domains of suffering.⁴ The SMI patient population is at risk for increased symptom burden, worse health outcomes,

and early mortality,⁵ not only due to higher incidence of suicide and accidents, but also to lifestyle risk factors such as cigarette smoking; physical illnesses such as cardiovascular, respiratory, and metabolic disease; and worse access to care when compared to patients without SMI. This becomes particularly important and challenging when these individuals experience a life-limiting or terminal condition in addition to their mental health disorder. The care of these patients can be greatly positively impacted by the involvement of a palliative APRN.

Palliative care and psychiatry hold similar values, noting that treatment should include detailed biopsychosocial and spiritual assessment, successful communication, symptom management, family-centered care, and interdisciplinary management.⁴³ Regardless of the SMI diagnosis, or if the patient has experience psychosis or mania, the palliative APRN can use the notion of “total pain” to recognize that suffering is multidimensional and may need special care in the context of a life-threatening or terminal diagnosis. Concepts such as trauma-informed care and harm reduction can be used to create successful, therapeutic, and lasting relationships with this patient population. This patient-centered care can also help to recognize the individual’s health-related goals rather than the goals of the healthcare system. It is important for the palliative APRN to have a baseline knowledge of each of the SMI diagnoses in order to best collaborate with the patient’s mental health provider. The palliative APRN should initiate communication when talking to psychiatry and other medical specialties to ensure the best possible health outcomes for this patient population, and the palliative APRN may be positioned to advocate for palliative psychiatry to be integrated into the primary palliative care team for improved patient and team care.

PATIENTS WITH SUBSTANCE USE DISORDERS AND DUAL DIAGNOSES

Jeannine M. Brant and Tonya Edwards

KEY POINTS

- Substance use disorders (SUDs) are a growing concern across the United States and pose significant challenges in assessment and management.
- Co-occurring substance use and mental health disorders commonly exist.
- A variety of risk assessment tools exist to help identify and manage patients with SUDs.
- Criteria from the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) are used to diagnose SUDs.
- Palliative advanced practice registered nurses (APRNs) who manage patients with SUDs monitor the 5 A's at each visit: analgesic response, activities of daily living, adverse events, affect, and aberrant behaviors.

results of his positive urine drug screen test were discussed with him. Discharge included extensive opioid education, a 1-week supply of short-acting morphine, stool softeners/bowel stimulants, and details on naloxone nasal spray use in case of overdose. A referral was placed for social work to reconnect the patient with drug rehabilitation and to schedule a follow-up outpatient clinic appointment in 1 week.

The palliative APRN saw William for follow-up in the outpatient clinic 1 week later. A pill count was conducted. William reported he ran out of his morphine tablets early, although he appeared comfortable. The palliative APRN suspected a diagnosis of opioid diversion or opioid misuse. The palliative APRN set boundaries and arranged for an intervention that same day with a specialized opioid interdisciplinary team. The purpose of the intervention was to reduce opioid misuse, abuse, diversion, and the frequency of drug-related aberrant behaviors. The patient was placed in the high-risk category, and a care agreement was signed. After evaluation, he was given a 1-week supply of morphine and an appointment to return for a 1-week follow-up.

CASE STUDY: A PATIENT WITH SUBSTANCE USE DISORDER

William was a 43-year-old man who recently reported to the emergency room with abdominal pain. He has a newly diagnosis of metastatic colon cancer and was treatment-naïve. A computed tomography (CT) scan revealed concern for a small bowel obstruction. He admitted to current polysubstance abuse. His CAGE questionnaire was 4/4. He previously completed drug rehabilitation and was no longer in touch with a drug rehabilitation sponsor. He rated his abdominal pain 8/10 and stated he had taken hydrocodone, 2 tabs, twice today with no pain relief. During examination, he was very drowsy, with slurred speech. William was placed on a 24-hour observation for further assessment and monitoring.

The palliative advanced practice registered nurse (APRN) was requested to see the patient for symptom control; the APRN ordered a stat urine drug screen with additional confirmatory screening. Results were positive for cocaine, amphetamines, THC, benzodiazepines, and hydrocodone. After completing a medical history, opioid risk assessment, and psychological assessment, the APRN ordered short-acting morphine for acute pain control. Naloxone was also added to the medication list. William's pain decreased to 3/10 within the hour, and he was discharged the next day with a pain level of 2/10. At discharge, the

INTRODUCTION

Substance use disorder (SUD) is defined as substance abuse and/or dependence, ranging from mild to severe, as characterized by 11 diagnostic criteria: hazardous use, interpersonal problems, neglected responsibilities, withdrawal, tolerance, increased use over time, failed attempts to quit, time spent focused using the substance, mental and health problems, abandoned interests, and cravings.¹ *Dual diagnosis* is defined as a co-occurring SUD and diagnosed mental health condition.²

Palliative advanced practice registered nurses (APRNs) are on the frontline of managing symptoms in patients with serious illnesses, and inevitably some of these patients will have a SUD, and, often, a diagnosis of a mental disorder coexists. Managing these patients is challenging for palliative APRNs: prescribing opioids can contribute to the problem, yet underprescribing can lead to suboptimal pain management. Fears about loss of licensure can also surface, reinforcing the need for palliative APRNs to have adequate knowledge about caring for this population. This chapter provides an overview of SUD and dual diagnoses and describes implications for the palliative APRN in assessing and providing care for patients with SUD and dual diagnoses.

SUDs are a growing concern in the United States. According to the Substance Abuse and Mental Health Services Administration 2019 survey, 13% of the US population used an illicit drug in the past month, an increase from 9.2% in 2012. Yet the prevalence of those with a diagnosed SUD remained stable between 2015 and 2019. Of those with a SUDs, 71.1% reported an alcohol use disorders in the past year, 40.7% an illicit drug use disorders, and 11.8% a combined alcohol disorder and SUD. Prescription drug use disorders are also a concern; encouragingly, the rate decreased from 0.9% in 2015 to 0.6% in 2019.³

Patients with SUDs often have co-occurring mental health issues (i.e., dual diagnosis) which further complicate their care.² Approximately 24.5% of adults aged 18 or older had either a mental illness or SUD in 2019. Of those individuals, 16.8% had only a mental illness, 3.9% had only a SUD, and 3.8% had both.³ Patients with chronic pain are also at a greater risk for SUDs. Two meta-analyses found that non-medical use of prescription opioids has been found to be as high as 48–60%, whereas five systematic reviews estimated prevalence to range from 0.05% to 81%. The wide variability is due to varying definitions within studies.⁴

While the exact incidence of SUD in palliative care patients is unknown, it is likely close to that of the general population. Some data are available on patients with cancer. One systematic review of 28 studies found opioid use disorders ranging from 2% to 35% and alcohol disorders from 18% to 25.5%.⁵ Of 482,688 veterans with a cancer diagnosis, 6.64% were found to have a SUD.⁶ Another study found opioid use disorders among patients with gastrointestinal cancers rose substantially between 2005 and 2014, with a compound annual growth rate of approximately 22%.⁷ Given this current crisis, palliative APRNs need to better understand SUDs, how to identify them, and how to manage pain and symptoms safely, according to the risk stratification of the specific patient. A tailored approach to care will ensure the best possible outcomes while minimizing abuse, misuse, and diversion.

DEFINITIONS

Many definitions apply to the concepts of addiction and substance abuse. Some definitions, such as *tolerance* and *physical dependence*, can be confusing and are often used erroneously when referring to patients with SUDs. For example, *addiction* involves genetic and biobehavioral influences, whereas *tolerance* and *physical dependence* are strictly physiologic phenomena.^{8–10} Table 47.1 defines terms related to this topic.

BARRIERS

Multiple barriers exist in the assessment and management of patients with SUD and/or dual diagnoses. One of the challenges of working with patients with SUDs is the lack of knowledge as well as the lack of standardized practices and guidelines in place for palliative care programs. One qualitative study of healthcare professionals who provided care

for patients during a palliative trajectory perceived that care for patients with SUD is often fragmented, with providers lacking knowledge about how to manage their multiplicity of care needs. Moreover, the study suggested that care was experience-based, rather than practiced with a foundation of evidence.¹¹ Increased education for both hospice and palliative care providers and better infrastructure for care are essential for quality and patient safety.¹²

Stigma is another barrier associated with SUDs, which is often rooted in shame and guilt. The more stigmatized patients feel, the less likely they are to disclose a SUD. Using judgment-free language, avoiding terms like *drug-seeking* or *junkie*, and categorizing substance abuse as a disorder can encourage a more open therapeutic relationship. One educational training program, Improving Addiction Care Team (IMPACT), focused on improving providers' attitudes, beliefs, and experiences about SUD treatment. The IMPACT team, comprised of a physician, social worker, and two addiction counseling peer partners, provided patient consultation in patients with SUDs and helped to guide hospital-based care. Their role-modeling and SUD therapy-directed interventions resulted in improved perceptions about SUD and better patient engagement and communication.¹³ These types of programs are recommended to provide a more humanized approach to the care of patients with SUDs.

PATHOPHYSIOLOGY

SUDs and addiction are complex phenomena that involve an interplay of neurobiological, genetic, and behavioral components. A wide array of neuroadaptive theories apply to the development of these disorders and the permanent brain changes that occur, but, overall, the pathology involves three stages: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation. Impulsivity is common with use disorders because these are often relied on to relieve tension and anxiety. Impulsivity then leads to compulsivity, which drives the ongoing behavior.^{14,15} Dopamine plays a major role in all stages and specifically drives negative reinforcement; that is, drugs are taken to avoid negative emotions rather than to feel good.¹⁶ The individual then becomes preoccupied on obtaining the substance for escape.

Physiologically, neural systems, including dopamine neurons and the mesolimbic system, are sensitized when introduced to a potentially addictive substance. Changes in the glutamatergic connections within various parts of the brain (ventral tegmental area, nucleus accumbens, prefrontal cortex, and amygdala) are thought to contribute to this sensitization. Neurocognitive imbalance between the impulsive amygdala, which signals pleasure, and the prefrontal cortex, which signals future decision-making, is also thought to occur. These brain changes endure even after the individual stops taking the substance, which explains why relapse rates for addiction remain high. Up to 92% of patients relapse within 8 weeks of tapering buprenorphine.¹⁷ Sex-related differences have been recently recognized and indicate that women experience a more rapid escalation to addiction, have

Table 47.1 DEFINITION OF TERMS RELATED TO SUBSTANCE USE DISORDER

TERM	DEFINITION
Aberrant behaviors	Any medication-related behaviors that depart from strict adherence to the prescribed therapeutic plan of care
Addiction	A neurobiological disorder with genetic and environmental influences that results in psychological dependence on the use of substances for their psychic effects; characterized by craving and compulsive use despite harm
Compulsive	An irresistible urge, especially against conscious wishes
Craving	A strong desire to obtain and use a psychoactive substance for its intoxicating effects
Drug misuse	Use of prescription or over-the-counter drugs that does not follow medical indications or prescribed dosing
Drug abuse	Use of a drug for nontherapeutic purposes to obtain psychotropic effects
Diversion	Unlawful channelling of pharmaceuticals from legal sources to the illegal marketplace
Euphoria	A sense of intense happiness and well-being
Illicit drug	A drug that is not legally permitted or authorized
Nonmedical use	Use of a prescription drug without a prescription or in a manner that is not prescribed
Physical dependence	A physiological neuroadaptation characterized by a withdrawal syndrome if the drug is stopped or decreased abruptly or if an antagonist is administered
Pseudotolerance	A need to increase dosage that is due not to tolerance but to other factors, such as disease progression, new disease, increased physical activity, lack of compliance, change in medication, drug interaction, addiction, and deviant behavior
Pseudoaddiction	A pattern of drug-seeking behavior in patients with pain who are receiving inadequate pain management; can be mistaken for addiction
Substance abuse	The use of any substance for nontherapeutic purposes to obtain psychotropic effects
Tampering	Manipulation of a pharmaceutical to change its drug delivery performance
Tolerance	A physiologic response resulting from the regular use of a drug in which an increased dosage is needed to produce the same effect

From Federation of State Medical Boards of the United States⁸; and Smith et al.¹⁰

a more profound withdrawal response, and are more vulnerable to treatment outcomes.¹⁸ Genetic influences are also involved, and more than 1,500 human addiction genes have been identified. The highest heritability has been found to be opioid addiction.¹⁹ Further research is needed to determine which genes play the greatest role and to understand the exact influence the genes have on the development of addiction.

Environmental factors, stress, reward-based learning, and conditioning effects with potential epigenetic effects also contribute to the development of addiction. Stress and traumatic experience early in life that result in externalizing psychopathology has been linked to SUDs and addiction.²⁰ This also decreases an individual's ability to self-regulate, further complicating the problem.²¹ This pattern underlies the stimulus–response habits, aberrant memories, and maladaptive behaviors that characterize addiction (Figure 47.1).²⁰ Interestingly, the neurobiological and genetic aspects of substance addiction parallel changes observed in behavioral addictions, such as gambling, internet/video game use, and shopping. Figure 47.1 provides the pathophysiologic aspects of addiction.

Substance abuse and addiction result from the imbalance between the cortex and the amygdala. Underlying influences can contribute to the phenomena.

Figure 47.1 The pathophysiologic aspects of addiction.

ASSESSMENT

A detailed patient history, opioid assessment tools, urine drug screens, and the prescription drug monitoring program (PDMP) are effective tools for discovering SUDs.²² First, the palliative APRN must obtain a baseline history and physical examination, which includes screening all patients for opioid risk prior to starting opioid therapy. Universal precautions should be practiced consistently when assessing, diagnosing, and managing all pain in the palliative care setting (Box 47.1).²³ This methodology, which overall involves preliminary monitoring of all patients to determine

their level of risk of substance misuse, any history of non-adherence with opioids, and past substance abuse or family history of abuse.^{22,24} If detected, the APRN should implement an effective ongoing opioid monitoring strategic plan that is reassessed at each patient encounter. However, accurate assessment of opioid history and substance abuse is fraught with potential stigma linked to substance abuse and lack of trust, thus necessitating skilled, open interviewing techniques.²⁵

Identifying patients at greatest risk for substance abuse is a key component of the assessment. Sociodemographic,

**Box 47.1 UNIVERSAL PRECAUTIONS AND
ASSESSMENT GUIDE**

1. Use therapeutic interview skills:
 - Withhold judgment until ample evidence is available.
 - Spend adequate time with the patient to assess verbal and nonverbal behaviors.
 - Focus on the patient, not specifically on the pain or other symptom.
 - Explore patient fears, expectations of treatment, goals.
 - Use reflective listening—reflect back using a slight modification of what the patient said.
 - Clarify understanding.
 - Encourage the patient to keep talking.
 - Communicate a therapeutic alliance.
2. Perform a thorough physical examination to make a pain diagnosis, including:
 - Pain and symptom assessment
 - Effect of pain on sleep, mood, function, relationships, sex, recreation
 - Medical history
 - Functional assessment: how the pain and symptoms affect function
3. Conduct a psychosocial history and psychological exam, informing the patient that this is a routine part of the assessment which includes:
 - Adverse childhood events and family upbringing
 - History of sexual or physical abuse
 - Family and social support
 - History of depression, anxiety, psychiatric disorders
 - Substance use history
 - Screening for addiction risk in all potential candidates for chronic opioid therapy
 - Access the prescriptive drug monitoring program prior to the visit to determine the patient's use of prior medications, pharmacy use, and areas of concerns
 - Urine drug screening at baseline
4. Determine potential treatment options, discuss benefits and burdens of proposed intervention, and provide informed consent.
5. Complete a treatment agreement.
6. Conduct an opioid trial or controlled substance.
7. Assess the impact of the opioid intervention on pain and function, with regular assessment of the 5 A's of opioid therapy: Analgesic response, Activities of daily living, Adverse events, Affect, and Aberrant behaviors.
8. Regularly review the diagnosis, comorbidities, substance use disorders, and treatment plan.
9. Summarize each visit with the patient, reviewing treatment plan, goals of treatment, and follow-up.
10. Document each visit and ongoing treatment planning.

Data from Kim et al.³⁵; Arthur⁴⁰; and Christo et al.⁴²

psychological factors, drug-related factors, family history, and genetics have all been linked to addiction risk.²⁵ The strongest link appears to be the presence of psychosocial, drug-related, and genetic factors combined. Therefore, a social history must include a history of drug abuse and a family history of alcoholism and sexual abuse.²⁶

Psychological assessment deserves special recognition as there is a high prevalence of mood disorders accompanying both chronic pain and SUD.²⁷ Mental health conditions like depression, anxiety, and personality disorders can contribute to and also complicate the presentation of the SUD.^{26,27} For example, patients with a SUD are more likely to have increased mental health concerns, including use of higher doses of opioids, higher levels of alcohol use, higher rates of tobacco use, and higher rates in the use of benzodiazepines, and have a higher rate of depression.^{26,27} Multiple tools are available to monitor for depression, anxiety, and other mental conditions. Being aware of an underlying mental health disorder can lead to earlier detection of problems. If aberrant behaviors are detected, the palliative APRN should carefully interpret the meaning of the behaviors and their influence on the treatment plan.²⁸

RISK ASSESSMENT TOOLS

Opioid risk assessment is an important part of initial and ongoing assessment and surveillance.²⁹ Several screening tools exist to identify potential problems (Table 47.2). Some of the more common tools include the CAGE, which is widely used to assess for alcoholism, and the Screener and Opioid Assessment for Patients with Pain-Revised (SOAPP-R) and the Opioid Risk Tool (ORT), which screen for opioid abuse.²⁹ The SOAPP-R has been shown to be a valid tool to screen patients with cancer for substance abuse.³⁰ The Current Opioid Misuse Measure (COMM), can be used during the monitoring phase. A score of 9 or higher is associated with a higher degree of aberrant behaviors. A systematic review of tools used to monitor ongoing opioid therapy indicated that further testing of these tools is needed because there is limited evidence to support their ability to detect misuse and SUDs in patients taking opioids.²⁹ While these tools have good internal consistency, they are not “lie detector tests,” and the accuracy of the assessment depends on how honestly the individual completes the responses.²⁹

Using objective measures to assess the risk for substance use can help to eliminate implicit biases around individuals with SUDs. For example, the palliative APRN may overestimate the risk in an individual who is a heavily tattooed construction worker and underestimate the risk in a well-dressed, high-profile bank manager. Racial biases lead to overestimation of SUD. One study reported that Black patients were more likely to undergo urine drug testing, required to attend more office visits, and received more restrictive opioid prescriptions than White patients.³¹ Patients with poorly managed pain can also exhibit addictive behaviors (i.e., pseudoaddiction).

Table 47.2 SUBSTANCE USE DISORDERS RISK SCREENING TOOLS

TOOL	DESCRIPTION	COMMENTS
CAGE (Cut, annoyed, guilty, eye)	4 items	Interview to screen for alcohol use One positive response warrants caution. Two affirmative responses are considered a positive result.
CAGE-AID (Adapted to include drugs)	4 items	Interview to screen for drug and alcohol use Consider modifying yes/no questions to open-ended questions.
COMM (Current Opioid Misuse Measure)	17 items	Self-administered Use during chronic opioid monitoring. Score of 9 or higher suggests aberrancy.
DAST (Drug Abuse Screening Test)	20 items	Self-administered Questions refer to past 12 months.
DSM-V Structured Clinical Interview	Interview	Assessment of the 11 characteristics in the DSM-V criteria Takes 30–60 minutes to complete
ORT (Opioid Risk Tool)	5 items	Self-administered For initial visit for pain treatment Predictive of substance abuse
PDUQ (Prescription Drug Use Questionnaire)	42 items	Interview Score >15 indicates a substance use disorders. Predictive of substance abuse
RAFFT (Relax, alone, friends, family, trouble)	5 items	Self-administered Three affirmative responses are considered a positive result.
SOAPP-R (Screener and Opioid Assessment for Patients with Pain-Revised)	24 items	Self-administered or interview to screen for drug and alcohol use Intended for patients with chronic pain on long-term opioid therapy Score of 7 or higher indicates the person is likely to abuse. Validated in patients with cancer

Data from Yasin et al.³⁰; Webster, Dove³²; and Fishman.³³

Aberrant behaviors and risk factors for substance abuse are included in Table 47.3. Risk should be evaluated so that strategies can be employed to regain control over the plan.

that using the PDMP for patient assessment resulted in an 8.9% reduction in opioids dispensed.³⁹ Efforts are under way to link state PDMPs to detect misuse, abuse, or diversion of opioids across state lines.

PRESCRIPTION DRUG MONITORING PROGRAMS

PDMPs, state-based electronic databases that track controlled substances to prevent misuse, abuse, and diversion, provide additional assessment data. Databases contain prescriber- and patient-level data on drugs with high misuse and abuse potential, including opioids and benzodiazepines.³⁸ They are used to evaluate patient risk by ensuring appropriate prescribing and dispensing of controlled substances. The PDMP should be used in conjunction with other screening tools and ongoing assessment for aberrant behaviors. While not diagnostic, PDMPs are another tool that should be used at baseline and during follow-up to evaluate aberrant behaviors and drug use patterns.

Using individual Drug Enforcement Agency (DEA) numbers, palliative APRNs can register for their state's PDMP and access the database to examine patterns of prescription drug use in patients. Databases will reveal if a patient is using multiple prescribers or multiple pharmacies, which suggests abuse or illegal activities. One study found

URINE DRUG TESTING

Urine drug testing is another assessment tool available to monitor for controlled substance misuse, abuse, and diversion.⁴⁰ This results in immediate action to increase or modify opioid safety practices. Urine drug testing can be an operative tool for adherence to opioid pain medication treatment. However, urine drug testing is infrequently used, and there is a lack of knowledge and standardized practices that limit its use.⁴⁰

Urine drug testing has two types: screening assays and confirmatory testing.²² *Screening test assays* detect antibodies or drug metabolites and report only a positive or negative result. Urine *confirmatory tests* specify separated molecules by a chromatograph and are analyzed using a mass spectrometer. Although the confirmatory testing is more expensive, the results reveal specific drug identification.⁴¹ Abnormal urine drug testing can show illicit drug or alcohol abuse or an abstinence of prescribed opioids.⁴² However, interpretation can be challenging; therefore, the palliative APRN

Table 47.3 ABERRANT BEHAVIORS AND RISK FACTORS FOR SUBSTANCE ABUSE/ADDICTION

BEHAVIORS LESS SUGGESTIVE OF ADDICTION	BEHAVIORS MORE SUGGESTIVE OF ADDICTION	RISK FACTORS FOR ADDICTION
Drug hoarding when symptoms are improved	High opioid dose	White male
Acquiring drugs from multiple medical sources	Selling prescription drugs	Younger age
Aggressive complaining about the need for a higher dose	Forgery of prescriptions	Higher pain intensity and lower pain tolerance
Unapproved use of a medication to treat a symptom (e.g., use of an opioid to treat anxiety)	Concurrent illicit drug use	More pain complaints
Unsanctioned dose escalation (once or twice)	Multiple prescription/medication losses	More pain-related limitations
Reporting psychic effects	Ongoing unsanctioned dose escalations	Depression and psychotropic medications in younger populations
Requesting specific drugs	Stealing or borrowing drugs	Psychological comorbidity: panic, anxiety, depression, agoraphobia, low self-reported health status
Second opinion for pain requested	Obtaining prescription drugs from nonmedical sources	Substance abuse history; positive CAGE-AID results
Smoking cigarettes to relieve pain	Repeated resistance to change—inflexibility	Genetic predisposition
Drinking alcohol to relieve pain	Prostitution for drugs or for money to obtain drugs	Financial distress
Urine toxicology screens positive	Unanticipated positive results in urine toxicology	
Nonadherence to appointments	Frequent pain clinic or emergency department visits	
	Financial distress	

Data from Yennurajalingam et al.²⁸; Pinkerton, Hardy³⁴; Kim et al.³⁵; Childers et al.³⁶; and Sehgal et al.³⁷

should have essential knowledge of test interpretation grounded in an understanding of drug metabolic pathways. An understanding of the metabolism of opioids to explain the presence pro-drugs and of apparent un-prescribed drugs is essential.

The APRN should routinely request a urine drug testing for low-risk patients, minimally once per year; moderate-risk patients should be tested two times yearly; and high-risk patients should be tested three or more times per year.⁴⁰ Often, a urine drug test is collected at baseline, or random testing can be employed within the first 3 months upon initiation of opioid therapy. The purpose for undergoing urine drug testing is based on current guidelines (see Table 47.4).⁴³

When ordering urine drug testing, the APRN should communicate the key intention of obtaining the test, which is to safeguard the patient on opioid therapy.⁴¹ If the urine drug test yields abnormal results, the APRN should initiate a nonconfrontational open dialog with the patient. Understanding pro-drugs and metabolites will enable the palliative APRNs to interpret results correctly⁴⁰

(see Chapter 43, “Pain,” for information on interpreting results of the urine drug test).

DIAGNOSIS

Diagnosing SUDs can be a long and arduous process. It often cannot occur during the first appointment unless the diagnosis is preestablished and overt. Otherwise, patients can be observed over time, and a diagnosis or dual diagnosis often emerges over time.

SUBSTANCE USE DISORDER

The palliative APRN can use the *Diagnosis Statistical Manual of Mental Disorders* (DSM-5) criteria to diagnose a SUD.¹ The DSM-5 classification includes an amendment for prescription opioid use disorders.²⁶ Key changes recently occurred with elimination of the words “tolerance”

Table 47.4 PALLIATIVE CARE URINE DRUG TESTING RECOMMENDATIONS

CATEGORY	RECOMMENDATION AND COMMENTS	RATIONALE
1. Who to test	Test all palliative care patients receiving chronic opioid therapy (>3 months).	Removes palliative APRN subjectivity and makes testing consistent with chronic disease management paradigm
2. How to test	Explain the urine drug testing and its purpose to ensure patient understanding.	Removes fear; informs patients that urine drug testing is not punitive but rather part of standard procedures
	Review the urine drug testing parameters may be included in a Controlled Substance Agreement for pain management from palliative care.	Clearly delineates urine drug testing role in therapy
	Conduct comprehensive medication testing, which includes illicit drugs, opioids, and other substances, such as benzodiazepines.	Tests for suspected therapeutic metabolites and other substances
	Develop collaborative relationship with the Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory with knowledge about urine drug testing performing urine drug testing on palliative patients, with results available on same day.	Results can be falsely positive or negative; laboratory proficiency will minimize this variability.
	Use Point-of-care (POC) testing on the initial palliative care consultation visit, but inconsistent results should be verified with urine drug testing.	POC testing is for screening only.
	Ensure accurate sampling and monitoring . . . etc.	Indicates if the sample has been tampered with
3. When to test	Initiate urine drug testing when starting palliative care patient on chronic opioid therapy.	Aids in risk stratification
	Test according to assessment of risk stratification via SOAPP-R/ORT and other factors.	Allows for more frequent screening for high-risk patients
	Develop palliative care program procedure to determine frequency of urine drug testing while maintaining minimum requirements (e.g., having patient flip a coin or roll dice at each visit).	Removes burden from palliative care staff tracking while providing fairness for random testing
4. How to interpret results	Confirm appropriate interpretation from laboratory that performs testing.	Identifies the type of aberrant medication use so that behavior can be specifically addressed
	Classify findings as (1) prescribed drug not detected, (2) illicit drug detected, (3) nonprescribed drug of concern detected.	
	Construct pathways for palliative care patients in constructing a differential diagnosis if (1) drug not detected (e.g., diversion, hoarding, lab error); may need additional testing to determine absence; (2) illicit drug detected (e.g., addiction, seeking additional pain relief, lab error); (3) nonprescribed drug detected (e.g., multiple providers).	Allows the palliative APRN to understand the finding; absence of prescribed drug with presence of illicit drug requires immediate action
5. How to handle test result discrepancies	Verify discrepancies with laboratory.	Lab results should always be verified.
	Schedule an immediate follow-up visit to discuss findings with patient in non-judgmental manner.	The patient may disclose the reason for the discrepancy; promotes therapeutic communication.
	Develop a plan based on the findings.	The plan will vary and depends on the problem detected.

Data from Peppin et al.⁴⁴; and Arthur et al.⁴⁵

and “withdrawal symptoms” for patients who are prescribed opioids by a medical professional.²⁶ The DSM-5’s 11 criteria combine substance abuse and dependence into a single disorder and a stratified graded structure.¹ Criteria include the following:

- Perceptions about use, such as taking more of a substance than intended, desire to cut down or stop using the substance, craving the substance, and being consumed with obtaining the substance
- Functional elements, including inability to manage current roles and responsibilities and forgoing opportunities (e.g., family outings, social relationships)²⁵
- Continued use despite harm and endangerment physically, psychologically, and socially²⁵
- Development of tolerance and physical withdrawal²⁶

Mild SUDs require the presence of two or three symptoms from the list, a moderate SUD includes four or five symptoms, and six or more symptoms indicate a severe SUD. A longstanding criticism of the DSM criteria is that patients with cancer often exhibit some of these symptoms and yet they may not have a SUD. The diagnosis of a SUD is not valid if the opioid is taken as prescribed.

DUAL DIAGNOSIS

A dual diagnosis of a SUD and a psychiatric disorder is well-recognized in the literature, and both genetic and environmental risks are proposed. Of those individuals with a SUD in the United States, approximately 45% have a coexisting psychiatric disorders.³ One recent study found co-occurring SUDs ranged from 26.4% with alcohol and 10.6% for methamphetamine.⁴⁶ Within the palliative care and cancer population, one study found that 12.4% of patients with advanced cervical cancer had a dual diagnosis.⁴⁷

Diagnostic pitfalls exist, and identifying the actual problem may be challenging. For example, the onset of each disorder can be variable. According to one study, two-thirds of patients were diagnosed with late-onset SUD and mood disorders (after age 18). Psychotic disorders, on the other hand, were more prevalent with an early-onset (before age 18) diagnosis. When compared to the late-onset group, the early-onset group had a higher number of psychiatric admissions.⁴⁸ The palliative APRN may therefore be the first to detect the dual diagnosis, depending on the patient’s situation.

Another complicating factor is that the relationship between mental illness and SUD is bidirectional, indicating that they affect one another and can cloud the assessment. For example, substances can lead to manic activity, but this can also be exhibited in anxiety and attention-deficit hyperactivity disorders (ADHD).⁴⁹ Obtaining a detailed history is important to understand how each problem contributes to the current situation. Assessment tools for anxiety, depression,

and addiction are warranted, as are reports from family members and other mental health professionals. If not previously evaluated, the palliative APRN may need to consult psychiatry or clinical psychology to conduct a full evaluation of the patient.⁴⁹

Overall, the interplay between substance use and mental illness is complex, and caution should be taken in making a formal diagnosis of SUD and/or a dual diagnosis. Building a relationship with the patient and assessing and managing the patient over time will ensure a more accurate conclusion.

MANAGEMENT

Managing pain and symptoms and providing overall care in patients with SUDs can be challenging. Many palliative care patients will require chronic opioid therapy or other treatments, such as benzodiazepines, that may pose risks for those with SUDs. Risk of relapse for those in remission is a valid fear, and yet undertreatment of pain and symptoms is also common due to a lack of understanding of the appropriate care of these patients. Balancing comfort with opioids along with the risk of opioid misuse, abuse, and diversion is imperative in this population.²⁴ For patients with a co-occurring SUD and mental illness (see Chapter 46, “Serious Mental Illness”), pain and symptom management may be even more challenging. Management of the existing depression, anxiety, or mood disorder is foundational to managing the patient’s pain.^{50,51} Having a well-defined plan in place that focuses on the goals of care and stratifies patients according to addiction risk allows for individualized pain and symptom care while monitoring patients for aberrant behaviors and signs of addiction.⁴⁵ This will provide the best care for the patient while at the same time preventing misuse, abuse, and diversion.

RISK STRATIFICATION

Risk stratification is one of the first steps of the management plan. The palliative APRN should make a clinical assessment if aberrant opioid behaviors are discovered based on obtained clinical, history, risk assessment tools, the PDMP, and urine drug testing.²⁸ The palliative APRN can make an opioid safety plan for prevention of known aberrant opioid behaviors. A strategic opioid therapy plan provides a basis for managing patients with SUDs; it includes ongoing risk assessment and monitoring and deploys a corrective personalized action plan.⁴³ Stratifying patients according to their risk for a SUD is the first step in the management plan. Prominent risk factors have been recognized and associated with high risk for substance abuse, such as family history of SUD or mental health issues, young male gender, and tobacco or alcohol use.⁵² The APRN can observe the patient’s behaviors and adherence over time (Table 47.5).

Table 47.5 MANAGEMENT ACCORDING TO RISK

RISK STRATIFICATION	RISK ASSESSMENT TOOLS	OTHER RISK CONSIDERATIONS	MANAGEMENT STRATEGIES
Low	SOAPP-R score <10 ORT score <4	No family history No past/current history of substance use disorders No psychological comorbidity	Annual adherence monitoring Review prescription drug monitoring program (PDM) twice per year Urine drug testing every 1–2 years
Medium	SOAPP-R score 10–21 ORT score 4–7	Family history positive Past history of treated substance use disorders; can be on pharmacotherapy for addiction Psychological comorbidity, past or current <25 years of age	Adherence monitoring every 6 months Review PDM 3 times per year Urine drug testing every 6 months to 1 year
High	SOAPP-R score >21 ORT score <7	Current substance use disorders or addiction Current aberrant behaviors (those more suggestive of addiction) Major psychiatric disorders that is untreated	Weekly to monthly adherence monitoring Management by pain and addiction specialists recommended Review PDM 4 times per year Urine drug testing every 3–6 months Prescribe opioids cautiously; chronic opioid therapy may be prohibitive in terms of risk to the patient.

Data from Dalal, Bruera²²; Yennurajalingam et al.²⁸; Yasin et al.³⁰; and Gourlay, Heit.⁵³

GOALS OF CARE

Pain and symptom management goals provide a foundation for measuring the success of the plan of care. The 5 A's can be used to measure the success of a management plan: analgesia, activities of daily living, adverse events, aberrant behaviors, and affect⁸ (Table 47.6). The palliative APRN should document the 5 A's at each visit to assess the patient's response to the treatment plan. Goals should be clear to the patient when treatment is started. Physiologic and psychosocial functioning should be included in the plan because they reflect an improvement in overall quality of life. Affect is especially important to patients with dual diagnoses.

Both pain and SUDs lead to dysfunction, so management should lead to optimal functioning. This focus on function allows the palliative APRN to individualize care and prescribing options.

MANAGEMENT OF PAIN

The pain management plan should be based on a systematic approach that includes the following:

- Diagnosis of the problem with consideration of potential dual diagnoses

Table 47.6 5 A'S OF OPIOID THERAPY MANAGEMENT

5 A'S	DEFINITION	ASSESSMENT
Analgesia	Level of comfort	Decrease in pain intensity Effectiveness of the intervention on the pain
Activities of daily living	Functional status	Increased physical capabilities Psychologically intact Family/social relationships intact Appropriate medication and healthcare utilization
Adverse events	Side effects related to treatment	Sedation Euphoria Other physical and psychological effects
Aberrant activities	Behaviors that warn of potential substance misuse, abuse, or addiction	Behaviors that suggest concern; see Table 47.3
Affect	Psychological functioning	Improved psychological affect Ability to cope with illness

Data from Hwang et al.⁷ and Volkow et al.²¹

- Conservative approaches (e.g., physical therapy, non-opioids, co-analgesics to assist in opioid-sparing)
- Nonpharmacologic modalities
- Therapeutic interventions such as anesthetic blocks
- Chronic opioid therapy and other controlled co-analgesics (e.g., benzodiazepines) only when conservative approaches are not effective.

(See Chapter 43, “Pain,” for more information about pain management.)

Often practitioners feel that opioids should be avoided in patients with SUDs; however, current literature suggests that many of these patients can be safely managed using a detailed and vigilant monitoring program.^{24,54} Dosing can be challenging in this population, especially in terms of drug tolerance. Patients with active opioid use will be tolerant of opioids and may require higher doses, but aberrant behaviors may preclude the palliative APRN from prescribing opioids for these patients. Contributing to addiction and diversion can result in loss of licensure, so caution is warranted. The most important component is careful surveillance for all patients: some high-risk patients may show substantially improved function using opioids, while some low-risk patients may experience deterioration in function.

Prescribing medications may be complicated. Palliative APRNs may prescribe certain medications for pain management but not for substance abuse, unless they have completed addiction graduate education or specific coursework. APRNs should consider training to prescribe medications as appropriate for SUDs. For example, naltrexone and nalmefene are approved for patients with alcohol use disorders; methadone and buprenorphine can be prescribed for opioid use disorders.⁵⁵ Specific barriers exist for palliative APRNs in managing patients with SUDs. State-by-state variation in APRNs’ prescribing privileges for opioids reveals restrictions for medication management and buprenorphine prescribing. Palliative APRNs may prescribe buprenorphine after they complete 24 hours of training; are licensed in a state where they can prescribe Schedule III, IV, or V medications; and can demonstrate the ability to treat and manage opioid use disorders.⁵⁶ APRNs should refer to state laws regarding license requirements.

Determining the right opioid can be difficult because all opioids can be potentially abused. Oxycodone has been shown to have a higher abuse potential compared to morphine and hydrocodone,⁵⁷ and tapentadol has a low abuse potential although risk still exists.^{58,59} One exception is buprenorphine, which has been found to have a lower abuse potential. In terms of formulation, long-acting dosing should be optimized while the need for breakthrough doses is minimized. This allows for a therapeutic blood level to control pain while avoiding peaks and troughs and “clock-watching” to take the next dose.⁶⁰ Abuse-deterrent opioid formulations are another option. These opioids resist manipulation, such as crushing, dissolving, or extracting; any attempts to do so will inactivate the opioid.^{61,62} While this property can be of benefit in

high-risk patients, these drug formulations can be expensive, and more evidence is needed to determine their role in managing high-risk patients taking chronic opioid therapy. Some reports indicate that those on abuse-deterrent opioid formulations may inadvertently be encouraged to use heroin, resulting in more safety concerns.⁶³

While methadone cannot be crushed and abused due to its high protein-binding affinity, safety concerns relate to the potential for accumulation, oversedation, and potential death.^{64,65} Palliative APRNs can prescribe methadone for pain, but only licensed methadone maintenance clinics can prescribe it for addiction. Buprenorphine, a partial opioid agonist that is used in opioid addiction, may be useful for pain management and has been shown to have the lowest abuse potential.⁶⁶ While APRNs can prescribe buprenorphine for pain, restrictions also exist on prescribing this agent for addiction. Buprenorphine has a ceiling dose and therefore should be used only in patients with anticipated lower doses of opioids.⁶⁷

Naloxone co-prescription is an important consideration for APRNs ordering any opioid therapy. This short-acting opioid antagonist has been shown to be especially beneficial in patients with nonmedical opioid use. One study found a 47% reduction in opioid-related emergency department visits per month at 6 months and 63% fewer visits at 1 year for patients who received a naloxone prescription.⁶⁸ Naloxone recommendations are included in Box 47.2.

SUBSTANCE USE AGREEMENTS

Substance use agreements, also known as contracts, are an additional optional component of the management plan. Substance use agreements have been shown to improve provider satisfaction, decrease emergency department visits, and improve patient adherence. Substance use agreements are highly controversial, and yet some experts recommend that

Box 47.2 NALOXONE CO-PRESCRIPTION RECOMMENDATIONS

These are the Centers for Disease Control and Prevention (CDC)⁶⁹ recommendations:

- History of drug overdose
- History of a SUD
- Requiring large opioid doses ≥ 50 mg morphine equivalents/day
- Concurrent use of benzodiazepines

Other appropriate indications:

- Morphine equivalent doses >100 mg/day⁷⁰
- Patients on methadone⁷¹
- Pulmonary, renal, or hepatic disease comorbidities⁷⁰
- Recent history of incarceration⁶⁸

they be employed for all patients taking controlled medications or chronic opioid therapy for greater than 3 months, regardless of risk.^{24,72} Agreements should spell out the risks and benefits of treatment, provide education about the plan of care, outline the responsibilities of the patient and the palliative APRN, and allow a transparent conversation to occur between the patient and the APRN. Agreements should include the following:

- Designated prescriber
- Designated pharmacy
- Frequency of refills
- Times when refills are prohibited (e.g., after hours, weekends)
- Dosage changes
- Screening and consequences for positive screens (e.g., urine, blood, pill counts)
- Need to secure medications and dispose of them safely if needed
- Supportive therapy requirements (e.g., psychiatry)
- Safe use of medications

CHAT MODEL OF CARE

Applying all assessment components and care concepts to the management plan deserves a calculated and planned approach. To determine the best plan of care, the palliative APRN should be reminded that risk stratification guides the management plan. The higher the risk, the more frequent the monitoring and the more cautious the dosing of opioids should be. The Compassionate High Alert Team (CHAT) model (Figure 47.2) provides a solid framework for a tiered opioid risk stratification and for the appropriate care needed for palliative care patients.⁷³

The palliative APRN should engage other team members and encourage them to use the CHAT model for high-risk patients. When diversion is suspected, the palliative APRN and team should follow the 5 S's plan: limiting the opioid supply, selecting a drug with a lower street value, scheduling more frequent visits, scheduling more frequent urine drug testing, and involving a substance abuse specialist. Actual proof of diversion calls for the discontinuation of opioids. APRNs should follow the rules listed in the substance use agreement, which may include discharge from the practice, discontinuance of opioids, transition to non-opioids, and the need to include substance abuse providers. All efforts should be made to maintain the patient within the practice, even though opioids may not be continued. When the palliative APRN decides to discontinue opioids, a plan of tapering medications should be initiated.

If a patient is placed in the high-risk category, the palliative APRN can involve the CHAT specialized interdisciplinary team. The CHAT approach involves an APRN

or a physician, a registered nurse, a psychologist or counselor, a pharmacist, a patient advocate, a social worker, and/or security personnel.^{22,43} A pre-huddle takes place prior to the patient visit, and the CHAT team meets together with the patient to discuss a strategy and an opioid safety plan.⁴³ During the collective meeting with the patient, the palliative APRN will address concerning matters related to current opioid use, including expectations, the need to establish trust, goals of safe opioid therapy, and risks and dangers with opioid misuse, abuse, or addiction.^{22,43} The APRN will continue to engage in a compassionate, nonjudgmental fashion. A post visit huddle with the team only is the final step of the visit. All disciplines document their roles and the outcomes specific to their specialty to ensure a successful subsequent opioid treatment plan.⁴³

SUMMARY

The assessment and management of patients with SUDs and dual diagnoses is complex and calls for advanced skills and a calculated interdisciplinary approach to care. The palliative APRN should understand the challenges inherent in managing patients with SUDs and those with co-occurring mental illness but should still approach patients with compassion and in a nonjudgmental manner. As with William in the chapter's case study, the palliative APRN can often successfully manage SUD and dual diagnoses using appropriate guidelines and an interdisciplinary collaborative approach. While occasionally opioids will need to be discontinued because of diversion or other reasons, palliative APRNs should understand that by using a systematic approach and a chronic disease model, the majority of patients can be well-managed and can achieve both comfort and an improved quality of life.

ANXIETY

Kira Stalhandske

KEY POINTS

- Anxiety and existential distress occur across the continuum of chronic and serious illness and impact the patient and family.
- The National Consensus Project for Quality Palliative *Clinical Practice Guidelines* outlines the need for the palliative interdisciplinary team to address psychological and psychiatric aspects of care in the context of serious illness.
- Assessment and treatment of anxiety by the palliative advanced practice registered nurse (APRN) is essential and should be individualized to address all aspects of suffering: emotional, social, physical, and spiritual.

CASE STUDY: A PATIENT WITH ANXIETY AND DISTRESS

Mr. C was a 48-year-old married man who worked in academia. His past medical history was significant for asthma, obstructive sleep apnea necessitating continuous positive airway pressure (CPAP) at night, NYHA Class II heart failure, and anxiety. He was referred to palliative care for metastatic pancreatic cancer.

Mr. C had been in his usual state of health until 2 months prior to presentation, which including occasional anxiety due to shortness of breath on exertion due to his asthma and heart failure. When he began developing a sense of unease and increased anxiety, coinciding with being at home during the COVID-19 pandemic. Approximately 6 weeks prior to diagnosis he began experiencing intermittent abdominal pain described as a sharp ache that was in a “V shape extending down to the pelvis” and that radiated to his back. He found leaving his home and being outdoors relieved his anxiety and pain.

Mr. C’s symptoms were initially attributed to progressive anxiety in the setting of a global pandemic and being at home in quarantine. His primary care provider prescribed buspirone 15 mg twice daily, clonazepam 0.5–0.75 mg at night as needed for anxiety, and cyclobenzaprine 10 mg at night as needed for pain and anxiety. He took extra-strength acetaminophen with no relief. He had a known intolerance to nonsteroidal anti-inflammatory drugs (NSAIDs).

Mr. C presented to the emergency department with a 1-week history of progressive abdominal pain and 25–30 pounds of unintentional weight loss. Workup revealed a pancreatic mass concerning for malignancy, with multiple hepatic masses and pulmonary nodules consistent with metastatic disease. He was

admitted for biopsy of the liver mass, which confirmed metastatic pancreaticobiliary adenocarcinoma. Upon admission to the hospital, the clonazepam and cyclobenzaprine were discontinued. He was continued on buspirone 15 mg twice daily and lorazepam 0.5 mg every 6 hours as needed. He was started on hydromorphone 4 mg orally every 4 hours as needed for pain.

At the palliative care consultation, Mr. C’s most burdensome symptoms were anxiety, adjustment and coping with new diagnosis of metastatic pancreatic cancer, cancer-related pain, constipation, and intermittent nausea. His regimen was continued. He shared that he felt a sense of “calm” and decreased anxiety with the confirmation of a diagnosis and was motivated to figure out a treatment plan. He explored fears of loss of function and prolonged debility with progressive advanced illness. Mr. C shared that he was most concerned about his spouse and reflected on their relationship and partnership. His spouse was a consistent presence at his bedside during restricted visiting hours because of the pandemic.

The palliative advanced practice registered nurse (APRN) communicated with the various teams about Mr. C’s preference for information. Mr. C wanted direct information about his disease and to participate in conversations about his care and any future decisions. The palliative APRN provided anticipatory guidance about his transition home after hospitalization and provided an overview of the role of outpatient palliative care.

Mr. C was discharged after a week-long hospitalization with plans for outpatient follow-up with oncology and palliative care. He had a chest port placed for anticipated chemotherapy. At the follow-up visit, the palliative APRN adjusted his pain medications and he was continued on buspirone.

The following week Mr. C had increased anxiety and saw his primary care provider, at which time he was initiated on citalopram 40 mg daily. The oncologist started him on olanzapine 5 mg at night for reports of worsening nausea. He had improvement with his nausea, insomnia, and anxiety with initiation of olanzapine. After a few days, he reported increased daytime jitteriness, which was attributed to high-dose citalopram. He was in contact with the palliative APRN, and there was discussion about clarifying the prescribing roles for the various providers.

One week later, Mr. C presented to his outpatient oncologist for further management. He was visibly jaundiced and hypotensive and was readmitted for evaluation for possible biliary obstruction or liver failure due to rapid progression of his cancer. After further imaging and evaluation, he was found to have multifocal biliary obstruction due to intrahepatic metastases which were too small for endoscopic intervention. Given rapid progression of his cancer and liver failure, Mr. C and his spouse decided

to go home with hospice. Mr. C died at home with his spouse by his side a few days after discharge.

This case study highlights assessment by the palliative APRN to address physical and psychological symptoms associated with Mr. C's advanced cancer. The palliative APRN engaged in rapport-building, reflective listening and feedback, normalization of emotional and psychological reactions of the patient and family to coping with serious illness, anticipatory guidance, and communication and collaboration with healthcare providers across healthcare settings (inpatient providers, outpatient/ambulatory care providers, and community-based hospice). The palliative APRN supported patient and family decision-making over the trajectory of his illness from diagnosis to exploration of cancer-directed treatment to pursuit of hospice care.

INTRODUCTION

Anxiety is present in the everyday lives of humans. Anxiety is unique and specifically identified within the National Consensus Project for Quality Palliative Care's (NCP) *Clinical Practice Guidelines* (NCP) Domain 3: Psychological and Psychiatric Aspects of Care: "The interdisciplinary team assesses and addresses psychological and psychiatric aspects of care based on the best available evidence to maximize patient and family coping and quality of life."¹ Due to the physical, affective, behavioral, and cognitive responses that anxiety may escalate, it can be clinically implicated in several of the domains of the NCP *Clinical Practice Guidelines*, such as Domain 1: Physical Aspects of Care; Domain 2: Physical Aspects of Care; Domain 4: Social Aspects of Care; and Domain 7: Care of the Patient at the End of Life.

Anxiety is a multidimensional subjective and objective experience with manifestations of physical, affective, behavioral, and cognitive responses.² As such, it can be considered both positive and negative. The experience is the physiological reaction that occurs in response to a perceived harmful attack or threat to survival. These include feelings of worry, apprehension, tension, and nervousness that are unpleasant and distressful, but they are a common response for patients and family members when faced with a serious diagnosis.

Anxiety is a natural and expected part of the coping process that helps us adapt to everyday concerns. However, extreme distressful anxiety can impair daily function, causing disability and disruptions in quality of life for patients, family, and caregivers. Specific differentiation between anxiety as a normal response and a specific diagnostic criterion that requires professional intervention and treatment is outlined according to the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5-TR).³ The experience of apparent uncontrollable physical, affective, behavioral, and cognitive symptoms having no specific stimulus warrants consideration of a pathological disorder. Anxiety disorders are categorized according to criteria and range in complexity and severity from panic attacks, acute stress disorder, generalized anxiety disorder, social anxiety disorders, phobias,

Table 48.1 ASSOCIATED CAUSES AND MIMICS OF ANXIETY

Acute emotional disruption	Interpersonal stresses
Anger	Legitimate worries and concerns
Anxiety disorders	Loss of control
Coping style (poor pattern)	Pain
Delirium	Physical symptoms
Fear	Side effects of medications
Financial concerns	Spiritual and existential crisis
Grief and bereavement	Withdrawal states

obsessive-compulsive disorder, PTSD, anxiety secondary to a medical condition, and substance-induced anxiety disorders.⁴

Common situations, medical conditions, medications, and substances are associated with and can cause nonspecific anxiety symptoms. Existential and psychosocial concerns increase anxiety when a person is faced with mortality; long-term or permanent disability; loss of control; family and financial crisis; loss of meaning, hope, and purpose; and religious or spiritual crisis.^{5,6} There is also considerable overlap and confusion among the anxiety, depression, and delirium that commonly arise as part of an illness trajectory and that can either lead, progress to, or continue in a vicious downward cycle when not recognized and treated appropriately (Table 48.1).

Despite the importance of mental health and the increasing prevalence of mental health disorders, US healthcare delivery systems are complex and fragmented, and patients and families are offered little guidance in navigating these systems to manage medical conditions effectively. The result is that anxiety is underestimated, untreated or undertreated, and unrecognized by healthcare professionals. Furthermore, intensified financial stress and social economic burden contribute to anxiety. Given this, anxiety is a contributory factor for caregiver burden, chronic distress, mortality, and comorbidity of the family and caregivers.^{7,8} Barriers to appropriate professional intervention are also created by the lack of an integrated palliative care curriculum, inadequate professional resources, personal experiences, limited assessment skills and clinical knowledge, and personal biases associated with the stigma and stereotypes related to diagnosis. This often leads to acceptance of not treating anxiety or its physical, emotional, and psychosocial manifestations.

This chapter presents palliative care from the palliative advanced practice registered nurse (APRN) perspective, focusing on APRN competencies as an effective team member or leader for patient- and family-centered care. Assessment and management of anxiety are based on national quality clinical practice guidelines, evidence-based research, and recommendations by national professional organizations.

DEFINITIONS AND THE DISTRESS CONTINUUM

Any serious illness, such as cancer, is a life-altering experience. In the 1970s, Weissman and Worden identified the first 100 days after the diagnosis of cancer as an “existential plight” in which patients suddenly confront their mortality. This is an extremely fragile period filled with fear and anxiety. Information, communication, and overall psychosocial support are priority needs for the patient’s mental well-being.

How anxiety is defined when an individual is diagnosed with a serious illness ranges from normal adjustment issues to syndromes that meet the diagnostic criteria for mental disorders. It occurs on a continuum of increasing levels and severity of psychosocial distress ranging from normal adjustment to adjustment disorders and subthreshold mental disorders to diagnosable mental disorders (Figure 48.1).^{9–11} Anxiety can manifest as physical and emotional symptoms, and it impacts individuals’ ability to cope with serious illness.¹² As healthcare professionals, palliative APRNs must appreciate a variety of related concepts and the distinctions between normal adjustment issues and mental disorders along the distress continuum to anticipate potential or actual needs, treatments, and interventions (Table 48.2).

Normal adjustment or psychosocial adaptation is not defined as a single event or as occurring in a specific moment in time. Adjustment and adaptation are constant and represent an ongoing process. Coping behaviors are continually integrated as the individual learns to manage life and relationships that incorporate and integrate a serious illness into daily activities. As personal, professional, and family relationships change, the individual is confronted with solving and mastering cancer-related and other illness-related emotion issues, and situations.^{13–15}

Psychosocial distress has been defined as an unpleasant experience of an emotional, psychological, social, or spiritual nature that interferes with the ability to cope with treatment. It extends along a continuum, from common normal feelings of vulnerability, sadness, and fears, to problems that are disabling, such as depression, anxiety, panic, and feeling isolated or in a spiritual crisis.^{9–15}

Adjustment disorders are a diagnostic category in DSM-5-TR. For some, the psychosocial stressors associated with a cancer diagnosis are identifiable, having a reactive

psychopathology less severe than the diagnosable mental disorders that impair social or occupational behavior significantly. The DSM-5-TR anxiety disorders are a group of mental disorders whose common symptoms include excessive, unwarranted, often illogical anxiety, worry, fear, apprehension, and/or dread.⁴

PREVALENCE AND INCIDENCE: ANXIETY, DEPRESSION, MENTAL DISTRESS, AND CHRONIC DISEASE CONNECTION

There is a close relationship between the prevalence of anxiety and depression and the incidence of chronic illness. In 2018, more than half (51.8%) of US adults had at least 1 of 10 the following chronic conditions (arthritis, cancer, chronic obstructive pulmonary disease, coronary heart disease, current asthma, diabetes, hepatitis, hypertension, stroke, and weak or failing kidneys), and 27.2% of US adults had multiple chronic conditions.¹⁶ Anxiety and depression are common in patients with serious or life-limiting illness. Receiving a diagnosis of a serious illness can be traumatic and debilitating. There is an increased incidence of PTSD symptoms for patients with a cancer diagnosis.¹⁷ Progression of disease, increased medical interventions, hospitalizations, and intensive or critical care have been associated with psychological trauma.¹⁸ There is a higher association of severe anxiety and depression symptoms for those with multiple medical conditions and for those with higher physical symptom burden.^{16,19–21}

The US Centers for Disease Control and Prevention (CDC) and the National Center for Chronic Disease Prevention and Health Promotion (NCCDPHP), Division of Population Health recognized that chronic diseases can exacerbate symptoms of depression, and depressive disorders can lead to chronic diseases.²² Anxiety, when unrecognized, unassessed, and undertreated, with other comorbid conditions, potentiates adjustment disorders. The CDC report *Mental Illness Surveillance Among Adults in the United States*, which supplements the CDC’s *Morbidity and Mortality Weekly Report* (MMWR), compiled the first national data to measure the prevalence and effect of anxiety and other mental health conditions for adults in the United States. It underscored the correlation between

Figure 48.1 The distress continuum.

Table 48.2 SUMMARY OF PSYCHOSOCIAL DISTRESS DEFINITIONS

Normal adjustment	Ongoing life processes and coping responses associated with living with cancer to: • Manage emotional distress • Solve specific cancer-related problems • Gain mastery or control over cancer-related life events
Psychosocial distress	Extends along a continuum ranging from: • Common normal feelings of vulnerability, sadness, and fears to problems that are disabling (i.e., depression, anxiety, panic) • Feeling isolated • Spiritual crisis Unpleasant experience of: • Emotional, psychological, social, or spiritual nature that interferes with the ability to cope with cancer treatment
Adjustment disorders	A diagnostic category of the fifth revised edition of the American Psychiatric Association's <i>Diagnostic and Statistical Manual of Mental Disorders</i> (DSM-5-TR): • Reactions to an identifiable psychosocial stressor with a degree of psychopathology • Less severe than diagnosable mental disorders yet in excess of what would be expected • Result in significant impairment in social or occupational functioning (i.e., major depressive disorder, generalized anxiety disorder)
Anxiety disorders	Group of mental disorders whose common symptoms include excessive, unwarranted, often illogical anxiety, worry, fear, apprehension, and/or dread. The DSM-5-TR examples include generalized anxiety disorder, panic disorder, agoraphobia, social anxiety disorder, specific phobia, obsessive-compulsive disorder, and posttraumatic stress disorder.

From PDQ Supportive and Palliative Care Editorial Board.¹¹

mental illness and chronic illness.²³ Executive highlights pertaining to chronic disease and anxiety/mental illness are as follows:

- 25% of all US adults have a mental illness, and nearly 50% of US adults will develop at least one mental illness during their lifetime.
- Mental illness is associated with increased occurrence of chronic diseases such as cardiovascular disease, diabetes, obesity, asthma, epilepsy, and cancer.
- Treatment of mental illnesses associated with chronic illness reduces the effects of both and supports better outcomes.
- Chronic diseases can coexist in people who have suffered from depression^{23,24} (Table 48.3).

Table 48.3 ANXIETY AND CHRONIC DISEASE PREVALENCE

MEDICAL CONDITIONS	EXAMPLES
Cardiovascular	Angina, congestive heart failure, hypovolemia, mitral valve prolapse, myocardial infarction, paroxysmal atrial tachycardia
Endocrine	Carcinoid syndrome, Cushing's disease, hyperglycemia, hypoglycemia, hyperthyroidism, hypothyroidism, pheochromocytoma
Immune	HIV/AIDS, systemic lupus erythematosus
Metabolic	Anemia, hypercalcemia, hyperkalemia, hypoglycemia, hyponatremia, hyperthermia
Respiratory	Asthma, chronic obstructive pulmonary disease, hypoxia, pneumonia, pulmonary disease, pulmonary edema, pulmonary embolus
Neurological	Akathisia, encephalopathy, brain lesion, seizure disorders, post-concussion syndrome, vertigo, cerebral vascular accident, dementia
Neoplasms	Islet cell adenomas, pheochromocytoma
Cancer	Hormone-producing tumors, pheochromocytoma

From Loving, Dahlin²; Noufi et al.³; and Borneman, Brown-Saltzman.⁷

ANXIETY AND THE OTHER SIDE OF THE DISTRESS CONTINUUM: ADJUSTMENT, INTEGRATION, AND LIFE TRANSFORMATION

Anxiety, whether positive or negative, occurs throughout life. It is a continual process with many revolving cycles, not a linear progression. When a patient is diagnosed with a serious illness, anxiety is often identified and separated into categories based on different life experiences. Palliative care practice differs because it embraces and incorporates the integrative nature and multidimensional holistic human needs approach to care, which challenges the assumption that anxiety and disease are separate processes. Anxiety needs to be viewed as a multidimensional experience within an integrated whole. Life and serious illness need to be understood as a whole, not as separate entities. The role of the palliative APRN is to understand and address anxiety from an interdisciplinary team perspective and to support adjustment from a medical and holistic perspective.

Cancer and serious illness are experienced within a continuum ranging from positive to negative in terms of adjustment. Positive adjustment is the patient's psychosocial adaptation process or increased ability to cope. Negative adjustment is the patient's inability to cope or the presence of anxiety and mental disorders that may require professional treatment.²⁴

Palliative care professionals encourage patients and families to focus on life rather than on the illness. The patient's life and illness are not separate but coexist in a way that can be balanced, meaningful, and purposeful, integrating the illness into a whole that also includes the patient's many roles, responsibilities, personal identity, and life experiences.²⁵ Integration is not just a matter of incorporating disease management into one's daily activities but rather integrating the disease experience physically, mentally, emotionally, and spiritually.²⁴

The clinical courses of cancer are prediagnosis, diagnosis, treatment, post-treatment, remission, reoccurrence/palliative care, and survivorship.²⁴ Within each clinical course there is an anxiety experience, normal adjustment and support, and an adjustment period.²⁶ Other diagnoses such as heart conditions, respiratory illnesses, and neurological conditions include diagnoses, treatment, adjustment, progression, with a continuing cycle of treatment, adjustment and progression leading to palliative care. Anxiety and adjustment are natural parts of the illness experience. The clinical courses should not be considered as separate entities but rather as an ongoing experience of anxiety, challenges, and adjustment (Tables 48.4, 48.5, and 48.6). Anxiety adjustment goes beyond the natural state of adaptation, coping, and integration. Adjustment outcomes have been identified in different categories, such as healing, psychosocial and spiritual pain in palliative care, posttraumatic growth, stress-related growth, benefit-finding resilience, subjective well-being, and self-actualization.²⁷⁻²⁹

Life-transforming change can result from the illness experience. Some patients experience a total paradigm shift, where unanticipated discovery of personal abilities and untapped resources helps the patient overcome the challenges of a serious illness diagnosis and life challenges outside of illness. With this shift, the patient's life is taken to a previously unknown level where he or she experiences a more fulfilling, purposeful, and meaningful life, one with greater depth psychosocially and spiritually (Figure 48.2).

Some patients describe a reduction in negative experiences; others identify an increase in positive experiences. These changes can occur in the areas of self-care, relationships, spirituality, being true to oneself, personal strength, and priorities or purpose. The "domains" of this change are pre-diagnosis, diagnosis of a serious illness, adaptive beliefs and attributes, pragmatic actualization, and transformation, extrapolated from research in the cancer experience. Each domain has its own categories and process themes.²⁵

A pre-illness, such as pre-cancer, is trauma and healing. The process theme focuses on the pre-illness state and diagnosis as a challenging event. The domain of the illness or cancer has three subcategories: debilitation, challenges to normal life, and coping. The debilitation subcategory focuses on the process themes of symptoms and treatment side effects. The challenges to normal life subcategory focuses on the process themes of uncertainty, heightened awareness, and loss. The major view expressed by patients

Table 48.4 SUMMARY OF ADJUSTMENT STAGES WHEN DIAGNOSED WITH CANCER OR ANOTHER SERIOUS ILLNESS: PRE-DIAGNOSIS AND DIAGNOSIS

PHASE	ANXIETY EXPERIENCE	NORMAL ADJUSTMENT AND SUPPORT	ADJUSTMENT PERIOD
Prediagnosis	Normal levels of anxiety and concern Crisis: Psychological and existential	Support systems, personal, religious, spiritual	1 week
<i>Diagnosis</i>			
Phase 1	Disbelief Denial Shock High level of distress, emotions Inability to remember or understand	Compassionate communication skills to deliver "bad news,"	Variable, 1–2 weeks
Phase 2 Dysphoria	Distress ranges: Illness-death depression, anxiety, insomnia, anorexia Poor concentration: Inability to function in daily roles Hope: Increased with understanding and awareness of treatment	Education and information	Variable, 1–2 weeks
Phase 3 Adaptation	Coping strategies: Problem-focused Emotion-focused Meaning-focused	Personalized coping styles and strategies	Variable, 1–2 weeks

From PDQ Supportive and Palliative Care Editorial Board.¹¹

Table 48.5 SUMMARY OF ADJUSTMENT STAGES WHEN DIAGNOSED WITH CANCER OR OTHER SERIOUS ILLNESSES: TREATMENT, POST-TREATMENT, REMISSION

TREATMENT	POST-TREATMENT	REMISSION
Anxiety experience: Treatment fears and focuses: Side effects Disruptions in daily life Effectiveness Survival	Anxiety experience: Positive anticipation, ambivalence, vulnerability Fear: Lack of physician connection and medical care	Anxiety experience: Normal anxiety regarding recurrence
Normal adjustment and support: Understanding Short-term discomforts outweigh long-term gains	Normal adjustment and support: Balance of positive expectations, reality of fears, apprehensions	Normal adjustment & support: Coping strategies Expression of emotions (i.e., honesty, nonjudgmental acceptance)
Adjustment period: Variable	Adjustment period: Variable	Adjustment period: Variable

From PDQ Supportive and Palliative Care Editorial Board.¹¹

in this subcategory is “it’s not just about the diagnosis (e.g. heart disease, cancer).” Support comes in the form of education and lowering distress.

The adaptive beliefs and attributes domain has two subcategories: personal life and hope. Personal life focuses on the process themes of maintaining a personal life, tolerance and the expectation that life could be improved, mastery of life skills, and improved situational challenges. The hope category’s process themes focus on motivation, protection, and surrounding oneself with people who provide support and offer grounding in personal truth and what is found as meaningful.

The domain of pragmatic actualization entails turning hope into reality. It has two subcategories: exploring and resources. Exploring focuses on the process themes of proactive learning, research, personal decisions and choices, and active experimentation. The resources subcategory focuses on

gathering and giving in a wide range of meaningful relationships, unexpected resources, expanded spirituality, and conservation of resources in times of greater need.

The domain of transformation focuses on a recurrent process theme, “it’s not just about the diagnosis,” in terms of applying newly discovered personal resources and heightened skills to non-diagnosis issues. Applying these new-found personal resources and abilities ultimately leads to a greater sense of gratitude, life appreciation, and empathy and a higher interest in life-fulfilling pursuits.²⁵

SCREENING AND ASSESSMENT

The sequential screening, evaluation, and referral process is undertaken when anxiety or psychosocial issues arise. Formal validated screening assessment tools should be utilized to evaluate the patient’s and family’s coping.^{30–34} For cancer related anxiety, guidelines from the American Society of Clinical Oncology (ASCO) and the National Comprehensive Cancer Network (NCCN) recommend screening for anxiety at time of initial cancer diagnosis and periodically when clinically indicated or at changes in cancer status, treatment plan, or transitions in care.^{9,31,35}

Screening tools for other diagnoses that use a brief, self-report questionnaire method can be used in a variety of practice settings for evaluation of anxiety and depression symptoms. The Anxiety Screening Index (ASI) is a 16-item self-report index, with scores rated on a scale of 0 to 4. Higher scores are associated with increasing levels anxiety.^{2,34} Initial screening for anxiety and depression may use the Patient Health Questionnaire for Depression and Anxiety (PHQ-4). If the patient screens positive for depression, the PHQ-9 can be used to monitor depression and treatment over time.^{2,35} The seven-item GAD-7 questionnaire can be used for screening and monitoring over time.³⁵ The patient’s score establishes the level and severity of distress to guide next steps. If distress is high, a referral for an in-depth psychosocial assessment by an appropriate mental health professional is made.²⁶

Table 48.6 SUMMARY OF ADJUSTMENT STAGES WHEN DIAGNOSED WITH CANCER OR ANOTHER SERIOUS ILLNESS: PALLIATIVE CARE AND SURVIVORSHIP

PALLIATIVE CARE	SURVIVORSHIP
Anxiety experience Disbelief, denial, shock, crying, withdrawal, isolation, spiritual/religious anger Shift: palliative curing to healing	Anxiety experience Greater appreciation, reprioritizing of life values, strengthening of spiritual or religious beliefs
Normal adjustment and support: Palliative care: Hope through what is meaningful	Normal adjustment and support: National organizations (i.e., programs, tools, resources) Physical, emotional well-being support
Adjustment period: Weeks	Adjustment period: Gradual over many years

The expression of, assessment for, and interventions for anxiety are placed in the cultural and spiritual domains of the NCP *Clinical Practice Guidelines*. Domain 5 addresses spiritual, religious, and existential aspects of palliative care. Domain 6 addresses cultural aspects of care.¹ Inappropriate or incomplete awareness of cultural, religious, and spiritual beliefs or needs can lead to inappropriate and unacceptable plans of care, resulting in unnecessary and undue anxiety and distress.

Comprehensive anxiety assessment includes performing a detailed history, review of systems, physical exam, and diagnostic and laboratory evaluation. A detailed history to identify contributing or predisposing factors to anxiety includes reviewing an individual's medications that mimic anxiety symptoms, substance use history, anxiety-associated medical conditions, and lifestyle contributions. Common cognitive and physical manifestations of anxiety can be detected by a review of systems. Physical examination is appropriate and may reveal symptoms of tachycardia, tachypnea, diaphoresis, skin changes, tongue changes, palpitations, rapid speech, restlessness, and tremors.^{2,34} Physiological derangements may be contributing to anxiety symptoms and can be identified by laboratory testing, including complete blood cell counts, metabolic panels, cardiac studies, hormonal studies (e.g., thyroid), infectious workup, and toxicologies. Comprehensive assessment of psychosocial and spiritual assessments of the patient and family, support systems and coping are critical to creating a treatment plan. Assessment of patient and family understanding of medical condition, expectations and treatment preferences.

CAREGIVER AND FAMILY-FOCUSED ASSESSMENT

Screening and assessment are not just patient-focused but are also family-focused, based on the standards of the NCP *Clinical Practice Guidelines*.¹ Family members are the most common caregivers, and their needs often go unaddressed. Many are easily overwhelmed physically, mentally, socially, and financially. Caregiver stress and burden can lead to

increased health risks in terms of heart disease, hypertension, immune impairment, and cognitive functioning that may meet DSM-V criteria for a psychiatric condition.³⁶ Caregiver stress can also contribute to decline in the care recipient.³⁷ When assessing caregivers, the palliative APRN should identify the specific problems, needs, strengths, and resources they have for themselves and those that affect the patient's care.³⁸ Use of the CARES framework is recommended in oncologic settings for a systematic assessment and approach to support family caregivers and is appropriate to other settings: Considering caregivers as part of the unit of care, Assessing the caregiver's situation and needs, Referring to appropriate services and resources, Educating about practical aspects of caregiving, and Supporting caregivers through bereavement.³⁹

Communication with patients and family members and their participation as partners in care are key. By partnering with them, the palliative APRN can identify their needs and set out the next steps. The patient and family are part of the process since assessment is a combination of self-report and evaluation by members of the professional team. This approach to assessing caregivers' needs and strengths can improve the overall health and quality of life for both the patient and caregivers.⁴⁰ The five major components of the caregiver experience that provide insight into caregiver stress are caregiver context, primary stressors, secondary stressors, resources, and outcomes.⁴¹

Caregiver context addresses sociodemographic information, history of illness, and caregiving and living arrangements. *Primary stressors* from the patient experience are symptoms, impairments, activities of daily living, behavioral and cognitive issues, and the caregiver's subjective burden. *Secondary stressors* are tension and conflicts of employment, relationships, and maintaining roles and responsibility. *Resources* are social, financial, emotional, and gains from experience. *Outcomes* are either positive or negative health outcomes related to the caregiver.⁸ Assessment of family caregiver distress and identification of bereavement resources, support groups, and counseling should be provided to family caregivers who have high levels of distress and anxiety because they have higher risk for complicated grief, distress, and anxiety following the patient's death.⁴²

The National Center on Caregiving (<https://www.caregiving.org>) offers support and guidance in the development of policy, resources, and programs. It serves as a central resource on caregiving and long-term care issues.⁴³

TREATMENT

The palliative care approach to treatment occurs across a continuum, with many different and simultaneous dependent, independent, and collaborative team approaches and interventions. Referral to psychiatric or mental health specialist is appropriate when the patient has preexisting psychiatric pathologies, suicidal ideation, or when anxiety symptoms interfere with the patient’s ability to function or are persistent and progressive despite intervention.³⁵

PHARMACOLOGIC MANAGEMENT

Common medications and substances that can cause nonspecific anxiety symptoms are listed in Table 48.7. Pharmacologic agents used to manage anxiety are listed in Table 48.8.

When considering treatment, the APRN should evaluate the extent or severity of the patient’s anxiety symptoms and their impact on function, quality of life, and prognosis to determine if there is time to benefit from treatment.^{12,48–51} For patients with limited prognosis of days or weeks, the use of rapid-acting agents such as benzodiazepines and antipsychotics is preferred.

Table 48.7 ANXIETY-CAUSING MEDICATIONS AND SUBSTANCES

ALCOHOL AND NICOTINE WITHDRAWAL	BRONCHODILATORS AND SYMPATHOMIMETICS
Analgesics	Caffeine (stimulants)
Anticholinergic	Cannabis
Anticonvulsants	Cocaine
Antidepressants	Corticosteroids and anabolic steroids
Antiemetics	Digitalis toxicity
Antihistamines and decongestants	Epinephrine
Antihypertensives	Hallucinogens
Antiparkinsonian drugs	Sedatives (hypnotic withdrawal and paradoxical reaction)
Antipsychotics	
Anesthetics and analgesics	
Benzodiazepines (and their withdrawal)	

From references Loving, Dahlin²; Noufi et al.⁵; and Borneman, Brown-Salzman.⁷

Benzodiazepines are commonly used for the relief of acute anxiety and may be used alone or as combination therapy with an antidepressant. They have a rapid onset and can reduce nausea. Common side effects include sedation, memory loss, delirium, confusion, and gait instability. Acute toxicity and overdose can cause respiratory suppression, especially in patients with lung disease, and can cause cognitive impairment.⁵⁰ With long-term use of benzodiazepines, there are risks for physical dependency, abuse, and addiction.^{12,49} Use of long-acting agents can prevent the loss of efficacy that can occur with shorter-acting agents.^{12,49}

Most antidepressants are effective for treating anxiety, although therapeutic effect may take several weeks to months to be reached, and lower doses are tolerated best. Antidepressant selection may depend on prior antidepressant use and potential drug–drug interactions. Many clinicians treating anxiety disorders use serotonergic agents, selective serotonin reuptake inhibitors (SSRIs), or serotonin-norepinephrine reuptake inhibitors (SNRIs) as their first choice due to these agents’ reliability and effectiveness for panic, generalized anxiety disorders, PTSD, and obsessive-compulsive disorder. Common side effects are managed with low-dose titration. SSRIs have no adjuvant therapeutic effect on neuropathic pain, unlike SNRIs.⁵ Tricyclic antidepressants are effective and inexpensive, and they serve as an adjuvant for neuropathic pain. Tricyclics can promote sleep and appetite but have a high side-effect burden.

Antipsychotics are reliable, but long-term use can produce the side effect of movement disorders. This risk makes them a second-line treatment. They are valuable when a rapid anxiolytic effect is needed and if the patient cannot tolerate benzodiazepines or has respiratory compromise.⁵²

Ketamine (S-ketamine), an analgesic used for refractory pain (operative/postsurgical and cancer-related pain), has positive effects on severe psychological distress and has a rapid effect on stress, anxiety, and depression.⁵³ A single dose of oral ketamine has been demonstrated to provide rapid and sustained relief of anxiety and depression.⁴⁴ When used for analgesia, ketamine is commonly administered in a continuous intravenous infusion and now in an approved intranasal preparation for depression. Ketamine can be compounded to be used in various routes of administration, including oral and buccal.

The geriatric population has special considerations, and medication adjustments are required. Treatment of anxiety often reflects the balance between goals and the length of life remaining. This is especially true in geriatric palliative care evaluation and treatment. For patients with less than a few months to live who are minimally ambulatory, the palliative APRN can prescribe benzodiazepines for rapid relief of symptoms or brief treatment. They are considered a second-line drug based on their longer half-life, which causes adverse drug effects. Benzodiazepines overall have a paradoxical effect that may actually cause more anxiety, especially in the elderly, and they are not recommended because they can increase confusion. Typically, tricyclic antidepressants and β -adrenergic agents are not well-tolerated. The most common side effects in the elderly are ataxia, cognitive impairment, and excessive

Table 48.8 COMMON PHARMACOLOGIC TREATMENT OPTIONS FOR ANXIETY

GENERIC NAME	APPROXIMATE ORAL DAILY DOSE AND RANGES (MG)	COMMENT
Benzodiazepines		
Alprazolam	0.25–2 tid–qid	Short-acting
Clonazepam	0.5–2 bid–qid	Long-acting
Diazepam	5–10 bid–qid	Long-acting; rapid onset with single PO dosage
Lorazepam	0.5–2 tid–qid	Short-acting; multiple routes, PO, SL, IV, IM. Preferred for patients with impaired hepatic function, no metabolites.
Midazolam	Infusion dosing sedation: 0.5–1 mg/h, effective dose range 1–20 mg/h.	Use for terminal agitation. Most commonly used medication for palliative sedation. Routes IV or SC.
Azapirones		
Buspirone	5–20 tid	Extended time to peak effect similar to antidepressants Low potential for abuse and toxicity
Antidepressants		
<i>Serotonin reuptake inhibitors</i>		
Citalopram	20–40 daily	Risk for QT interval prolongation. Not recommended for use greater than 40 mg daily.
Fluoxetine	10–80 daily	Longest half-life among serotonin reuptake inhibitors
Paroxetine	10–60 daily	Short half-life, side effects-sedation
Sertraline	50–200 daily	Few drug–drug interactions
<i>Tricyclics</i>		
Nortriptyline	10–150 at bedtime	Less anticholinergic side effects
Amitriptyline	10–75 at bedtime	Anticholinergic side effects
Desipramine	12.5–150 daily	Least sedating tricyclic antidepressant
Imipramine	12.5–150 daily	High risk for orthostatic hypotension
<i>Serotonin-norepinephrine reuptake inhibitors</i>		
Duloxetine	30–60 daily	Role for treatment of neuropathic and central pain. Activating effects can help with energy. Consider dosage in the morning to avoid insomnia.
Venlafaxine	75–375 daily	Avoid use in hepatic and renal impairment (CrCL <30 mL/min) Can be utilized in immediate release formulation the setting of renal impairment.
Other Antidepressants		
Mirtazapine	7.5–60 daily	Promotes sleep and appetite at low doses Oral disintegrating tablets available
Bupropion	100 mg immediate release bid, 150 mg extended release bid	Risk of seizures at doses >450 mg/daily
Antipsychotics/Neuroleptics		
Olanzapine	5–15 daily ^a	PO, SL, and IM routes. Oral disintegrating tablets available. Has less extrapyramidal side effects and less demonstrated QTc effects compared to Haloperidol.
Quetiapine	25–200 daily ^a	Preferred for patients with Parkinson's disease
Risperidone	1–3 daily ^a	

Table 48.8 CONTINUED

GENERIC NAME	APPROXIMATE ORAL DAILY DOSE AND RANGES (MG)	COMMENT
Haloperidol	0.5–2 q2–12h	Inexpensive and multiple routes of administration (IV, PO, and IM)
Chlorpromazine	12.5–50 q4–12h	IV, PO and PR. Side effects sedation, extrapyramidal side effects and hypotension. Most common use for palliative sedation with terminal delirium/agitation.
Antihistamines		
Hydroxyzine	25–50 q4–6h	Risk of anticholinergic side effects and delirium
GABAergic		
Gabapentin	600–2,400 mg/day	Use for social and generalized anxiety and panic disorders.
Ketamine		Multiple routes IV, oral, buccal and intranasal. May require compounding. Dosing is variable to use and route. A single oral dose of 0.5 mg/kg has been demonstrated to provide anxiety relief. (Irwin)

^a In divided doses

From Noufi et al.⁵; Irwin, Hirst³⁵; Irwin, Iglewicz⁴⁴; Felton et al.⁴⁵; Prommer⁴⁶; and Garakani et al.⁴⁷

sleepiness. Opioids are indicated for treatment of anxiety secondary to dyspnea in terminally ill patients.⁵⁴

NONPHARMACOLOGIC TREATMENT

Dignity therapy (DT) is a brief, individualized psychotherapy to relieve psychological and existential distress in patients with a serious and life-limiting illness, allowing them to reflect on memories and issues important to them and to recall or share with others.⁵⁵ The interdisciplinary team should explore opportunities for patients to engage in life review, legacy-making activities, and honoring future moments.

Palliative care includes holistic integrative therapies as well as conventional therapies. Holism and palliative care philosophy are inseparable since they both focus on the total

person, with the belief that the mind, body, and spirit are inseparable and interdependent and that health, illness, and dying are manifestations of the life processes of the whole person.^{54–59,62} In both holistic and palliative care, the partnership among the patient, family, and provider generates a sense of empowerment and enables healing (if not necessarily a cure) and transcendence. Nonpharmacologic therapies used for anxiety are outlined in Table 48.9.

There are many integrative holistic therapies that can be used to decrease anxiety. They can improve the overall quality of life for patients and families. Maximum benefits with minimal risk can be achieved when complementary/alternative medicine and therapies are integrated with conventional treatments. This can be accomplished through collaborative interdisciplinary team processes as a component of the overall plan of care (Table 48.10).

SUMMARY

Anxiety contributes to increased suffering and impacts coping and provision of care for the patient and family. Palliative care is a comprehensive, evidence-based specialty provided by a supportive interdisciplinary team that addresses patient- and family-centered needs. Whether the illness is life-threatening, chronic, progressive, advanced, or terminal, the identification and management of anxiety are central to effective treatment. Anxiety is a common response in patients and family members and is manifested in various physical, affective, behavioral, and cognitive responses. Palliative care incorporates anxiety into professional practice standards with the goal of anticipating, identifying, assessing, and addressing it via core and interdisciplinary team approaches.

The interdisciplinary team, through supportive listening and exploration of the patient's history and an understanding of their medical condition, expectations, fears, hopes, and adjustment to illness, can align delivery of care to meet the needs of the patient and family. Social workers assess and address adjustment to illness, coping, support systems, and needs and provide therapeutic grief and bereavement counseling and support of emotional and logistical aspects of care. Chaplains or spiritual care providers explore aspects of faith, existential distress, and coping and may provide prayer, support of faith-based traditions or practices, and connection with community-based spiritual care providers. Child life specialists facilitate developmentally based interventions for coping and communication for children and adolescents.

Palliative APRNs assess diagnose, treat, and evaluate the effectiveness of anxiety management. They provide anticipatory guidance and support to the patient and family and collaborate with other health providers and specialists to ensure the patient and family receive clear, direct, and compassionate information about their medical condition, treatments, and prognosis.

DELIRIUM

Bonnie D. Evans and Erica J. Hickey

KEY POINTS

- Delirium is commonly encountered across palliative care settings and at the end of life and is associated with distressing symptoms and negative outcomes for both patients and family caregivers.
- Awareness of risk factors that can precipitate a delirium by the palliative advanced practice registered nurse (APRN) can help to prevent delirium, as well as target interventions to limit the duration and severity once it has developed.
- Evaluating the potential burden of interventions for delirium versus benefit in palliative care patients, especially at end of life, can be challenging and requires an individualized, family-centered approach and ethical healthcare decision-making.
- Multicomponent, nonpharmacological interventions should be the first approach for the prevention and management of delirium, and the role of pharmacological treatment continues to be evaluated.
- More research is needed to better understand the underlying pathophysiology of delirium and to develop evidence-based interventions for modifiable risk factors, pharmacological management, and effective family caregiver support.

CASE STUDY: POLYPHARMACY

Anna was an 89-year-old woman living with her daughter and scheduled to start 6 weeks of radiation therapy (XRT) with weekly chemotherapy for Grade II squamous cell esophageal cancer. Anna had declined to have a stent or feeding tube placed, and her primary care physician (PCP) requested a palliative care consultation prior to beginning treatment. On the initial home visit, the palliative advanced practice registered nurse (APRN) found a frail-appearing woman who was a fair historian and aware of her cancer diagnosis. Anna had completed an advance directive which signified her daughter as the designated surrogate decision-maker or healthcare proxy. However, there had been little discussion around any limitations of treatment, except for feeding tubes. Anna stated that she hoped to live to be 90 and to be kept comfortable. An out-of-hospital order for life-sustaining treatments had not been completed.

Review of systems was positive for fatigue, weight loss, dysphagia, dyspnea on exertion, poor appetite, radicular low back pain, history of falls, and mild memory problems; she reported that she felt “down” but denied suicidality. Her past medical

history (PMH) included coronary artery disease (CAD), atrial fibrillation (AF), anticoagulation therapy, systolic heart failure, hyperlipidemia, chronic obstructive pulmonary disease (COPD), chronic kidney disease (CKD) Stage 3, depression, anxiety, insomnia, mild cognitive impairment, spinal stenosis, and hearing impairment.

Anna had a complex medication regimen including digoxin 0.125 mg PO daily, metoprolol 50 mg PO twice daily, furosemide 60 mg PO daily, warfarin 2.5 mg PO daily, gabapentin 300 mg PO twice daily, sertraline 50 mg PO daily, ipratropium bromide/salbutamol inhaler 1 puff 4 times daily, and simvastatin 20 mg PO daily. She had three as-needed medications: ondansetron 8 mg PO every 8 hours as needed for nausea, tramadol 50 mg PO every 6 hours as needed for pain, and diphenhydramine 25 mg PO at bedtime as needed for insomnia.

Anna appeared thin and fatigued with some short-term memory deficits. Her vital signs included a blood pressure 98/66, apical rate 90/min. She had 3+ pitting edema to mid-calf bilaterally; her albumin level was 2.7 g/dL, body mass index was 21, and Eastern Cooperative Oncology Group (ECOG) Performance Status Score was 2.

The palliative APRN was concerned about Anna’s high risk for complications during her cancer treatment. She had several predisposing risk factors for developing a delirium: her advanced age and multiple comorbidities, especially esophageal cancer, depression, and mild cognitive impairment. Malnutrition, frailty with a recent fall, and hearing loss also added to her risk. Anna’s precipitating risk factors for delirium included polypharmacy, pain, dysphagia, and the potential side effects of her planned radiation and chemotherapy. The care plan developed by the palliative APRN focused on trying to limit complications from treatment, including delirium.

1. *Polypharmacy*: A stepwise approach to tapering and simplifying Anna’s medications was discussed with her PCP. Due to hypotension and poor oral intake, her furosemide dose was decreased. The simvastatin was discontinued, and the warfarin would be stopped if she had another fall. The use of diphenhydramine was discontinued since it appeared on the list of medication unsafe for older adults due to its anticholinergic properties. Tramadol was also discontinued since it was contraindicated with sertraline and gabapentin. It was replaced with low-dose oxycodone 2.5 mg PO every 6 hours as needed for pain.
2. *Optimal nutrition*: Speech and language pathology was consulted for swallowing evaluation and safe intake. Nutrition was consulted for optimal foods for calories, protein, and nutritional value.

3. *Family caregiver education:* The palliative APRN reviewed the medication list for safe administration. She also discussed safety precautions in the home, given Anna's increasing weakness and falls; sleep hygiene techniques; pain management strategies; and changes to report in Anna's condition, including mental status.

After 2 weeks of daily XRT and two chemotherapy infusions, Anna was started on a scopolamine patch for copious oral secretions and on a fentanyl patch 12.5 µg/h every 3 days for increasing pain at the radiation site. After another fall, she was evaluated at the emergency department (ED) and treated for dehydration. Her furosemide and warfarin were discontinued. Two days after the ED visit, Anna's daughter called the palliative APRN to report that her mother was sleeping more and seemed confused. Upon arrival, the palliative APRN noted that Anna did not recognize her and was lethargic and dozing unless stimulated. She could not maintain eye contact or follow commands and was oriented to self only. Anna had been not eating, and the palliative APRN noted the new prescriptions for fentanyl and scopolamine.

Based on delirium diagnostic criteria, Anna was exhibiting an acute change from her baseline cognitive status. She was unable to maintain attention, had an altered level of alertness with lethargy, and disturbances in memory and orientation. The daughter had not noticed any hallucinations or agitation. The palliative APRN reviewed her findings with the daughter that were consistent with a hypoactive delirium. As Anna's healthcare proxy, her daughter wanted her transferred to the hospital. The palliative APRN facilitated the hand-off to the ED. Anna's delirium was treated with hydration, antibiotics for a urinary tract infection, and pain management, but it was slow to resolve. Anna again declined the placement of any feeding tubes and did not want to resume her cancer treatment. Hospice was requested, and she returned to her daughter's home where she died a month later.

This case prompted the palliative APRN to research educational materials for family caregivers on delirium and to investigate assessment tools for delirium screening for family caregivers to use in the home care setting, such as the FAM CAM¹ or the Single Question in Delirium (SQiD).²

INTRODUCTION

Delirium may develop at any age. The etiology may be due to myriad factors including an acute illness, the adverse effect of a medication, hospitalization, or surgery. Underlying patient vulnerabilities, such as advanced illness and multiple comorbidities, add to this risk.³ Palliative care is specialized care for patients and families coping with a progressive illness. Therefore, by definition, palliative care patients are at increased risk for the development of a delirium, and this risk increases toward the end of life.⁴ The palliative APRN needs education in the assessment, diagnosis, prevention, and management of delirium and its associated symptoms. Family caregivers of patients with delirium also need support and education to better understand it and to participate in nonpharmacological interventions.

DEFINITIONS

Delirium is an acute and complex neurocognitive disorder.⁵ There are no definitive laboratory or diagnostic tests for delirium because it is based on clinical presentation.⁵ The syndrome of delirium in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) is defined by five features⁶ (see Box 49.1). The disturbances in attention and awareness described are based on an abrupt change from the individual patient's baseline cognitive status. This can be challenging to identify when the patient is not known to the provider, when the symptoms fluctuate, or if symptoms overlap with the features of depression or dementia, all of which can contribute to the underdiagnosis or misdiagnosis of delirium.^{4,7} Delirium may be first identified by the family or a consistent family caregiver who recognizes the altered mental status. In evaluating the patient, especially in the acute care setting or during care transitions, the palliative APRN should locate someone familiar with the patient in order to elicit their baseline and establish a timeline for any changes.

The patient with delirium, in addition to being easily distractible, may also exhibit varying levels of awareness of the environment, from hypervigilance to lethargy. Sleep–wake cycle disturbances are common and have been used as a diagnostic criterion.⁴ The patient may sleep during the day and become active or agitated at night. The DSM-5 further delineates delirium by the duration of symptoms from acute (lasting hours to days) to persistent (lasting weeks or months).⁶ Delirium can also be described as subsyndromal and terminal (see Box 49.2).

**Box 49.1 THE FIVE FEATURES OF DELIRIUM IN
THE DIAGNOSTIC AND STATISTICAL MANUAL
OF MENTAL DISORDERS (DSM-5)**

1. Disturbance in attention and awareness: Reduced ability to direct, focus, sustain, and shift attention along with reduced orientation to the environment.
2. Develops over a short period of time: Usually hours to days, and symptoms tend to fluctuate in severity over the course of the day
3. At least one additional disturbance in cognition: Memory deficit, disorientation, alteration in language, visuospatial or perceptual distortion
4. Changes from baseline of points 1 and 3 that cannot be explained by a preexisting, established, or evolving neurocognitive disorder
5. History and physical and/or diagnostics should provide evidence that the disturbances are the consequence of another medical condition, substance intoxication or withdrawal, exposure to a toxin, or due to multiple etiologies

From American Psychiatric Association.⁶

Box 49.2 ADDITIONAL DEFINITIONS FOR DELIRIUM

Subsyndromal or attenuated delirium is defined as the presence of some of the core symptoms of delirium, without meeting the diagnostic threshold, and falls along the continuum between no symptoms and delirium.⁶

Terminal delirium is a phrase often used for delirium that occurs in the final days or weeks of life and can be refractory to treatment.⁷

Patients with delirium can present with four different subtypes of psychomotor activity: hyperactive, hypoactive, mixed, and non-motor subtype^{4,6,8,9} (Table 49.1). There is concern that patients with a hypoactive delirium may be less likely to be recognized (e.g., symptoms may be interpreted as a mood disorder or fatigue) and that the poor prognosis noted in some studies may be iatrogenic.^{8,10,11} Across all motor subtypes, newly diagnosed delirium in the setting of advanced illness is indicative of a potentially life-threatening clinical situation that needs prompt evaluation and discussions regarding treatment options.^{10,12} In the palliative care setting, the underlying etiology of delirium is usually viewed as multifactorial, requiring a comprehensive approach.⁴ The role of the family caregiver in the context of delirium can be significant because they offer familiarity and can assist in nonpharmacological management techniques. A family caregiver is defined as the spouse, family member, partner, or friend who is the primary person assisting with care.¹³

PATHOPHYSIOLOGY

Delirium occurs across multiple medical conditions and can be associated with a wide range of signs and symptoms. Moreover, as stated earlier, it is often multifactorial. This contributes to the challenge of clarifying the dysregulation of neuronal activity that occurs, and a variety of theories have been postulated. Based on changes noted in electroencephalography and

Table 49.1 FOUR PSYCHOMOTOR BEHAVIOR SUBTYPES OF DELIRIUM

Hyperactive	A extremely high level of psychomotor activity, often combined with mood lability, agitation, refusal to cooperate with medical care, perceptual disturbances.
Hypoactive	A abnormally low level of psychomotor activity, often may be accompanied by reduced motor activity, sluggishness, lethargy that can approach stupor, and perceptual disturbances.
Mixed	Includes individuals whose activity level fluctuates between extremely high and abnormally low.
Non-motor	Normal or no motor features.

From Bush et al.⁴; American Psychiatric Association⁶; Evensen et al.⁸; and Meagher et al.⁹

resting-state functional magnetic resonance imaging in delirium, Shafi et al.¹⁴ propose that delirium is the result of a breakdown in brain connectivity and brain plasticity that can occur when individuals are exposed to a stressor. Potential stressors could include surgery, anesthesia, systemic inflammation, infections, and psychotropic drugs, as well as neurodegenerative disorders such as dementia and comorbid conditions.¹⁴

A review of the literature by Maldonado¹⁵ identified seven significant theories or mechanisms to explain the underlying pathophysiology of delirium: neuroinflammation, neuronal aging, oxidative stress, neurotransmitter deficiency, neuroendocrine aberrations, diurnal dysregulation, and neuronal network disconnectivity. More than likely, these mechanisms overlap or complement each other. The most common changes in neurotransmitters in delirium include reduced cholinergic activity and/or melatonin availability; an excess of dopamine, norepinephrine, and/or glutamate; and variable changes in serotonin, histamine, and γ -aminobutyric acid.¹⁵ In one study, patients who developed postoperative delirium were positive for a central nervous system biomarker (phosphorylated neurofilament heavy subunit [pNF-H]) that is consistent with dysfunction of the blood–brain barrier.¹⁶ These results lend support to the role of neuroinflammation in the development of delirium in this population.

To date, the dopaminergic–cholinergic imbalance has largely been the focus of the pharmacological approach to the treatment of delirium symptoms.⁴ However, the role of antipsychotic medications for delirium symptoms remains unclear.¹⁷ An integrative literature review of neuroimaging evidence of delirium across 11 studies was done by Kalvas and Monroe.¹⁸ Commonly noted structural abnormalities included impaired white matter integrity, brain atrophy, ischemic lesions, edema, and inflammation. These findings were frequently found in the frontal lobe and limbic system, which are areas involved in attention, the stress response, and emotional regulation, thus offering some possible explanation for the symptoms of delirium.

To further the understanding of the neurobiology of the four delirium clinical motor subtypes, FitzGerald¹⁹ conducted a review of the literature that included 61 studies and found evidence of four key characteristics of motor disturbances in delirium. Delirium motor subtypes appear to be connected with levels of arousal/cognitive function, reactions to delirium phenomenology (e.g., delusions or psychosis), disturbances in circadian rhythm, and clinical context (e.g., medications and underlying medical conditions).¹⁹ Longitudinal studies are recommended to further investigate the factors that influence delirium motor subtypes. As additional disturbances in neurotransmission are investigated, new therapeutic options for the prevention and treatment of delirium may evolve, and the palliative APRN needs to stay current on the literature to adapt clinical practice guidelines accordingly.

INCIDENCE AND PREVALENCE

Delirium is commonly found across all palliative care settings and is most prevalent prior to death. A systematic literature

review indicated, for patients 65 years of age or older on a general medical unit, a prevalence rate (present on admission) for delirium of 18–35% and an incidence rate (new onset) for delirium of 11–14%.⁷ In the intensive care unit, the higher prevalence rate for delirium was 7–50% and the incidence rate was 19–82%. In this same study, up to 40% of nursing home residents presented to the ED with a delirium.⁷ Following hip surgery, one study revealed that patients aged 80 years or older were two times more likely to develop a postoperative delirium; if patients had a diagnosis of dementia, they were six times more likely to develop a postoperative delirium.²⁰ These numbers demonstrate the increased vulnerability to delirium with advanced age and cognitive impairment.

A meta-analysis of 42 studies across palliative care settings revealed prevalence estimates of delirium to be 4–12% in the community on initial assessment, 9–57% in the acute care setting at the time of the first palliative care consultation, and 6.6–73% on admission to an inpatient palliative care unit.²¹ Pooling these data revealed that up to one-third of patients had a diagnosis of delirium at the time of admission to an inpatient palliative care unit, and the cumulative incidence rate over the entire admission was 7–45%. Prior to death, the prevalence of delirium was higher at 58–88% in the inpatient palliative care setting and 42–44% in the community.²¹ The lower rates of terminal delirium in the community could indicate that the familiar environment of home may be protective against the development of delirium and/or that the caregiver burden of managing associated symptoms and behaviors may prompt admission to an inpatient palliative care or hospice facility.

RISK FACTORS

The development of delirium is complex and multifactorial; key to the prevention and treatment of delirium is an understanding of factors that put individuals at risk.^{4,7} Risk factors for delirium have been categorized as either *predisposing*, which implies a nonmodifiable, host-related vulnerability (e.g., age or preexisting medical conditions), or *precipitating*, which implies a potentially modifiable risk and can contribute to the development of delirium (e.g., medications or surgery)⁷ (Table 49.2). A conceptual model for delirium by Inouye and Charpentier²² describes the baseline vulnerability of a patient and precipitating risk factors as highly interrelated and cumulative. Fewer precipitating risk factors may be sufficient to trigger a delirium in patients with a higher number of predisposing risk factors.²²

There are common predisposing factors for delirium: older age, dementia, functional disability, and a high burden of comorbid conditions, as well as male sex, visual or hearing impairment, history of alcohol abuse, and depression.^{7,10} Delirium is more common in combination with dementia, and dementia is more likely to develop after delirium.^{7,23} It can be challenging to recognize delirium in older adults with cognitive impairment. In these cases, a distinction must be made between the baseline cognitive disturbance and an acute decline in mental status. Age, as an independent factor, may

Table 49.2 RISK FACTORS FOR THE DEVELOPMENT OF DELIRIUM

PREDISPOSING FACTORS: NONMODIFIABLE	PRECIPITATING FACTORS: POTENTIALLY MODIFIABLE
Age >70 years	Polypharmacy
Male gender	Use of psychoactive (e.g., benzodiazepines and opiates) and anticholinergic medications
Multiple comorbidities	Infection
Dementia/Cognitive impairment	Electrolyte disturbances
Depression	Dehydration
History of transient ischemic attack or stroke	Hypoxia
Brain metastases	Surgical or general anesthesia
Frailty	Organ failure (especially renal)
Functional impairment	Pain
Poor nutritional status	Sleep alterations
Visual or hearing impairment	Restraints
History of alcohol abuse	Change in environment

From Seiler et al.³; Bush et al.⁴; Inouye et al.⁷; and Shenvi et al.²⁴

relate to functional age and frailty rather than actual chronological age.

Precipitating factors frequently reported for delirium include medications, acute illness, infection, electrolyte imbalances, hypoxia, dehydration, surgery, anesthesia, and high pain levels.^{4,10} Medications that can cause or worsen delirium include anticholinergic medications (including tricyclic antidepressants, antihistamines, muscle relaxants, promethazine, typical antipsychotics), sedative hypnotics (benzodiazepines, zolpidem), corticosteroids, high-dose opioids, and polypharmacy of four or more drugs.^{24,25}

A nursing assessment tool was developed to improve screening for potentially reversible risk factors for delirium in patients at the end of life, with the acronym CHIMBOP^{26,27} (Box 49.3). The risk factors in this assessment tool for delirium are common, although not specific, to patients at the end of life. Pain is included, and inadequate pain management has been associated with an increased risk of delirium.²⁸ Assessing pain in patients with delirium who are unable to report their pain requires additional expertise and the use of pain assessment tools for the nonverbal and/or cognitively impaired patient.

Environmental risk factors for delirium in hospitalized patients that have been identified are physical restraints, frequent environmental/room changes, absence of clock or watch, lack of reading glasses, disruption of day/night cycles, noise and light disturbances, no visible daylight, isolation room, and no visitors.^{29,30} The potential for lack of visitors

P: Pain

From Harrison et al.²⁶; and White, Hammond.²⁷

in health facilities has increased due to policies protecting patients and staff from COVID-19, which, if they continue, could negatively impact patients who are at risk for or are experiencing a delirium.

Over the past decade there has been an increase in delirium research in hospitalized patients, particularly in the critically ill.³¹ Delirium risk factors, for example, have been the focus of study in critically ill trauma patients³² and postoperative head and neck cancer patients.³³ There has, however, been limited data collected regarding delirium risk factors in community-dwelling older adults. One prospective study of older adults living in the community (86.5% in their homes) who presented to the hospital with a delirium found that 80% had either a cognitive (mainly dementia) or other neurological disorder (cerebrovascular disease or Parkinson's disease) and 23% had depression, revealing that neurological deficits were a strong predisposing risk factor for delirium in this community setting.³⁴ In addition, infections of primarily the lung and urinary tract (49%), adverse effects of drugs (30.8%), dehydration (26%), and electrolyte disturbances (18.7%) were the most frequent precipitating risk factors for delirium in this same study population. The researchers underscore that a significant finding was the relatively higher incidence of infections as a precipitating risk factor for delirium when compared to most inpatient studies. For the palliative APRN working in the community, this study emphasizes careful monitoring of patients with underlying neurological disorders for any change in mental status. Moreover, the correct diagnosis and rapid treatment of community-acquired infections could help to limit further neurological decline, as always based on the goals of care.

A prospective, observational study of delirium risk factors was conducted in 410 hospitalized palliative care patients with a high prevalence of delirium (55.9%). On multivariate regression, the most relevant predisposing risk factors for the development of delirium in these palliative care patients were frailty, impaired hearing and vision, brain neoplasms, and male gender. Frailty was measured across the component of mobility/function and it was associated with a 15-fold increased risk of developing delirium. The most relevant precipitating risk factors for delirium in this population were acute renal failure and pressure ulcers.³ Given the vulnerability

and medical complexity of palliative care patients and the multifactorial etiology of delirium, it can be challenging to distinguish between predisposing and precipitating risk factors in this population. Accordingly, the palliative APRN's approach to prevention and management should be broad and multifaceted.

Potentially modifiable or precipitating risk factors for delirium can vary by clinical setting, whereas predisposing risk factors are host-related and nonmodifiable.³⁴ However, the age, gender, or medical conditions most commonly treated in a particular specialty unit or clinic, may be somewhat specific. Accordingly, awareness of the predisposing and precipitating delirium risk factors most relevant to the APRN's clinical setting and patient population is needed to provide optimal care.

OUTCOMES

Although delirium is considered an acute syndrome, evidence suggests that cognitive and functional impairments can persist. Hospitalized patients are most at risk for long-term cognitive and functional decline.³⁵ Following elective surgery, patients who developed delirium had persistent (for up to 18 months) and clinically meaningful impairment of functional recovery compared to those who did not develop delirium.³⁶ In another study, critically ill ICU patients diagnosed with a delirium were followed and their cognitive and executive function evaluated at 3 months and 12 months post-discharge. At 3 months, 40% had cognitive scores consistent with moderate traumatic brain injury and 26% had cognitive scores consistent with mild dementia; there was minimal improvement at 12 months (34% and 24%, respectively). The duration of delirium in this study was found to be associated with worse cognitive scores.³⁷ These study results point to the need for functional and cognitive assessments prior to discharge in patients treated for delirium, given the possibility that they may not have returned to their pre-admission baseline status. It is important to recognize that the cognitive disturbances associated with delirium can affect language, memory, orientation, and the ability to communicate. Patients experiencing delirium are less likely to be able to participate in discussions around symptom management or treatment preferences.⁴

Persons with dementia who develop delirium have even worse outcomes than those with delirium alone. This includes higher rates of rehospitalization, institutionalization, mortality, and subsequent cognitive decline.³⁸ The interrelationship of dementia and delirium is not fully understood. Delirium may reveal an underlying vulnerability of the brain or unrecognized dementia and/or it may lead to neuronal damage and chronic cognitive impairment/dementia. These are ongoing hypotheses that need further study.³⁸

Delirium has also been associated with an increased risk of institutionalization post-discharge. In one meta-analysis, older adults who developed a delirium had higher rates of institutionalization (33.4%) versus controls (10.7%).³⁹ Similarly, patients who had surgery to repair a hip fracture and developed postoperative delirium (POD), were more likely to be discharged to a nursing home than patients who

did not experience POD.⁴⁰ Interestingly, in a study of critically ill patients, 80% were found to have subsyndromal delirium (SSD) or cognitive dysfunction that did not meet diagnostic criteria for delirium. The duration of SSD was found to have an independent association with increased odds for being discharged to an institution. Those with SSD for 5 days were 4.2 times more likely to be discharged to an institution than those with SSD for 1.5 days.⁴¹ The prognostic implications of subsyndromal delirium support the need to assess and report all delirium symptoms (even when they do not validate a diagnosis of delirium) with the goals of reducing complications and preventing progression to delirium.

Critically ill patients who developed delirium were compared to those without delirium in one systematic review and delirium was found to be associated with a longer length of stay, longer duration of mechanical ventilation, and a greater than twofold increase in hospital death.⁴² In an exploratory analysis of hospitalized older adults followed for 3 years, delirium was strongly associated with mortality, finding that 81% of those who had developed a delirium died within 3 years versus 49% of those without delirium.⁴³ Similarly, in a retrospective analysis of mortality rates in Medicare beneficiaries who had an emergency room visit and were diagnosed with delirium, there was a fivefold increase in mortality within 30 days of discharge when compared to those without a delirium diagnosis. This increased risk in mortality persisted over the 12 months of the study.⁴⁴ These studies illustrate that delirium is a poor prognostic indicator associated with an increased risk of hospital death and that the increased mortality risk can continue post-discharge.

Study results on mortality and delirium vary when factoring in delirium subtypes. One systematic review of ICU patients found a consistent association between mortality and hypoactive delirium.⁴⁵ Another study of older adults admitted to a subacute unit with delirium indicated that although hyperactive delirium was the most prevalent motor subtype, only hypoactive delirium was associated with higher mortality.⁴⁶ However, Evensen et al. studied geriatric patients for 12 months following a hospitalization for delirium and found significant mortality (43%) but no statistical difference in mortality across the 4 delirium motor subtypes.⁸ The exact relationship between delirium and mortality is unclear. Delirium may be a marker for disease severity and not causatively linked to mortality. The significant negative short- and long-term outcomes and complications associated with delirium demand preventive interventions for patients at high risk and timely recognition and treatment for those who develop it.

ASSESSMENT SCALES

There is a wide variety of delirium assessment tools available that vary in the number of items, level of training required, and ease of administration, as well as the optimal setting and patient population for the use of each one. In practice, the palliative APRN should choose the most appropriate tool for the clinical situation and use it consistently and regularly because

standardized screening can increase the chance of detection.⁴⁷ It is best practice that the team uses one assessment tool for consistency.

Delirium scales have been developed for different purposes, such as identification of delirium, diagnosis, determining the level of severity, and delineating delirium motor subtypes.⁴ Table 49.3 lists details of the delirium assessment scales reviewed in this chapter. Two delirium assessment instruments that are considered the gold standard for delirium screening, alongside the clinical diagnosis using DSM-IV criteria, are the Confusion Assessment Method (CAM)⁴⁸ and the Delirium Rating Scale–Revised-98 (DRS-R-98).⁴⁹ They both require additional training and expertise.⁵⁰ The CAM is a clinical algorithm developed by expert panel consensus in 1990 to allow non-psychiatric clinicians to assess for delirium; it is based on four of the nine features of delirium originally described in the DSM-III–Revised (see Figure 49.1). The CAM assessment, which has been translated into at least 12 languages, shows high sensitivity (94%) and specificity (89%) and is widely used in practice.⁷

THE DRS-R-98 includes inattention and motor subtypes and rates symptom severity over a 24-hour time frame. The DRS-R-98 and the Memorial Delirium Assessment Scale (MDAS)⁵¹ were found by a panel of experts reviewing delirium assessment tools to be the best options for monitoring delirium severity in the context of palliative care.⁵² Another study of newly consulted palliative care patients in both inpatient and outpatient settings also found the MDAS to be a valid and reliable tool for delirium screening and severity monitoring in palliative care settings; however, there is still a lack of consensus regarding the optimum cutoff scores for a positive screen.^{53,54} Jones et al. also evaluated delirium severity instruments and did a methodological review of 11 tools.⁵⁵ Based on the results, six instruments of high quality were selected that best captured delirium symptoms and severity on a continuous and quantitative scale: the CAM–Severity Score (CAM-S),⁵⁶ DRS-R-98,⁴⁹ MDAS,⁵¹ Confusional State Examination (CSE),⁵⁷ Delirium-O-Meter (DOM),⁵⁸ and the Delirium Observation Screening Scale (DOS).⁵⁹ Accurately identifying and monitoring the severity of delirium can help to target treatment, monitor response to clinical care, and provide meaningful prognostic information.⁵⁵

The Neelon-Champagne Confusion Scale (NEECHAM)⁶⁰ and the Nursing Delirium Screening Scale (Nu-DESC)^{61,62} are both shorter versions of delirium screening tools designed to be used by nurses during routine clinical practice. The Delirium Motor Subtype Scale (DMSS)⁹ was developed to improve the identification and subsequent understanding of the four motor subtypes of delirium: hyperactive, hypoactive, mixed, and non-motor. Using the DMSS, a study of older adults who developed delirium following hip fracture surgery showed that the majority demonstrated variable motor subtypes over the course of their delirium, supporting the need for frequent assessment.⁶³

In a review by delirium research experts on the assessment of delirium in palliative care, the authors concluded that there is no one tool that can capture the complexity of delirium in palliative care patients and that more validation studies are needed for the use of current instruments in palliative care

Table 49.3 SUMMARY OF DELIRIUM ASSESSMENT SCALES

ASSESSMENT TOOL	DESCRIPTION	NUMBER OF ITEMS AND TIME TO COMPLETE	PRIMARY USE COMMENTS
Confusion Assessment Method (CAM) ⁴⁸ Short Version Long Version	Requires training. Includes brief formal cognitive testing.	4, 3 minutes 10, 5 minutes	Screening scale; widely used in hospitalized older patients ⁶⁴ Validated for use in palliative care ^{53,65}
CAM-ICU ⁶⁶	Requires training.	8, 2–3 minutes	Screening scale For use with nonverbal or intubated ICU patients
CAM-Severity Score ⁵⁶ CAM-S Long Version CAM-S Short Version	Requires training. Scores symptoms noted in the CAM, combined with formal cognitive testing.	10, 10–15 mins 4, <5 minutes	Severity scale
FAM-CAM ¹	Requires training. Uses input from family caregivers, in person, by telephone or electronically	11, 5–10 minutes	Screening scale
Delirium Rating Scale Revised-98 (DRS-R-98) ⁴⁹	Requires training. Differentiates delirium from dementia, depression and schizophrenia. ⁵³	16, 20–30 minutes	Diagnosis and severity scale Initial assessment and repeated measurement Use validated in palliative care ⁵²
Memorial Delirium Assessment Scale (MDAS) ⁵¹	Requires clinician training.	10, >10 minutes	Diagnosis and severity scale Validated for use in palliative care ^{52–54}
Confusional State Examination (CSE) ⁵⁷	Requires training.	22, 30 minutes	Screening and severity scale
Delirium-O-Meter (DOM) ⁵⁸	No training, observation scale for nurses at the bedside.	12, 3–5 minutes	Severity scale
Delirium Observation Screening Scale (DOS) ⁵⁹	Requires training. Based on observations over an 8-hour nursing shift.	13, 5 minutes	Severity scale; early recognition
Neelon-Champagne Confusion Scale (NEECHAM) ⁶⁰	Requires training. Observation scale for nurses at the bedside.	9, 10 minutes	Screening and monitoring scale
Nursing Delirium Screening Scale (Nu-DESC) ^{61,62}	Requires training. Observation scale for nurses at the bedside.	5, 1–2 minutes	Screening scale
Single Question in Delirium (SQiD) ²	Requires training. One question for family caregiver on confusion.	1, < 1 minute	Screening scale Use has been supported in oncology patients ⁵³
Delirium Motor Subtype Scale (DMSS) ⁹	Can be used by a variety of clinical staff.	11	Identifies four motor subtypes
DMSS-4 ^{67,68}	Shortened version.	4	Valid and reliable in the ICU setting

across a variety of medical conditions and palliative care settings.⁵² The palliative APRN should have a basic understanding of the range of delirium assessment tools available and how to choose the most appropriate tool for the clinical setting and population being targeted. Table 49.4 offers guidance. This is by no means an exhaustive review of available assessment tools for delirium. For more information, the website for the Network for Investigation of Delirium Unifying Scientists

(NIDUS) has a list of Delirium Measurement Resources available at <https://deliriumnetwork.org/measurement/>.⁶⁹

ASSESSMENT

Delirium is a clinical diagnosis, one that requires the ability to determine the baseline cognitive status of the individual

Figure 49.1 Delirium diagnostic criteria.
From Inouye, van Dyck, Alessi et al.⁴⁸

along with a time frame for any acute mental status changes. Input from family caregivers or other informants may be needed for an accurate assessment. Not knowing the baseline cognitive status is reported to be a common reason for most missed diagnoses of delirium.²⁵ If delirium is suspected, brief cognitive screening tools and bedside observation for key

clinical features aid in diagnosis.²⁵ Examples of brief cognitive screening tools are the Mini-Cog and the Short Portable Mental Status Questionnaire.^{70,71} Validated delirium screening tools are numerous and based on standard diagnostic DSM-V criteria.⁶ Given the relative subjectivity of delirium observational tools, evidence-based guidelines recommend

Table 49.4 KEY FEATURES AND QUESTIONS TO AID IN THE SELECTION OF A DELIRIUM ASSESSMENT TOOL IN PALLIATIVE CARE

FEATURES	QUESTIONS
Intended use	What is the purpose of use? - Clinical, research, quality assurance What types of tools are available? What is the intended focus of the tool? - Screening, diagnostic, severity, neuropsychological assessment In what types of palliative care settings will the tool be used? - Acute/tertiary palliative care, hospice, outpatients How will the assessments be documented, reported, and used?
Ease of use	Who will administer the tool –ideally and/or practically? Nurses, physicians, advanced practice providers, other staff What types of additional resources may be needed? What type of additional training is required? Is there a formal training program and/or availability of a training manual? How much time is required to administer the tool? How often will the tool be administered? What is the level of patient, family, and staff burden?
Psychometric properties	<i>Comprehensiveness</i> Which domains of delirium should be represented in an ideal tool? Which domains of delirium are represented in the tool? Which domains are not represented? <i>Reliability and validity</i> What types of reliability and validity evidence have been gathered in palliative care settings? What is the sensitivity and specificity of the tool in palliative care?

From Leonard et al.⁵² (pp. 176–190)

that clinicians use observational instruments in conjunction with tools that directly assess cognition.⁷² Delirium symptoms can fluctuate and therefore patients may need frequent assessments throughout the day to screen for delirium and monitor severity.

History-taking should focus on known predisposing risk factors, especially older age and a previous diagnosis of mild cognitive impairment or dementia. Precipitating risk factors may be noted on initial presentation and may also accrue during an acute illness or hospitalization (e.g., polypharmacy, immobilization, urinary catheter). A careful review of current medications looking for categories of drugs associated with incident delirium and any new medications or recent changes in dosages may reveal additional instigating factors.

A hallmark for the diagnosis of delirium is that it is due to the presence of an underlying medical condition. Common causes of delirium that present to the ED have been identified as infections (estimated at 30–40%), followed by acute neurological disorders (hemorrhage, stroke, intracranial mass), and adverse effects of medications.²⁴ A detailed physical and neurological exam should incorporate an assessment for dehydration, urinary retention, constipation, infection, or pain. The differential diagnosis for delirium includes distinguishing it from depression, dementia, delirium superimposed on dementia, or psychosis (Table 49.5 summarizes key characteristics of each). Cognitive status at baseline may not be known or symptoms may be atypical or overlapping, and this adds to the challenge of an accurate diagnosis.⁷³ Of note, acute onset and an altered level of consciousness is most suggestive

of a delirium. Dementia has a more gradual and insidious progression of cognitive decline. Neurovegetative symptoms associated with depression could also present similarly to a hypoactive delirium with apathy and lethargy. Standardized depression screening tools are available that are designed to measure depression based on the age of the patient, such as the Geriatric Depression Scale (GDS).⁷⁴

Lab work and diagnostics should be tailored to the patient, but a basic evaluation should include an electrocardiogram, complete blood count, metabolic panel, glucose level, and urinalysis with culture.²⁴ Additional diagnostics or neuroimaging may be needed if the etiology is unclear or there is a history of falls, worsening neurological findings or focal deficits, or the patient is on anticoagulants.^{24,25,75} The extent of any diagnostic testing should be guided by the goals of care and any advance directives, along with the overall assessment of prognosis. The focus of treatment can vary from a full investigation into the underlying etiology with high-risk interventions, to looking for more easily reversible risk factors and/or minimizing the distress of associated symptoms.

Terminal delirium in dying patients denotes a particularly poor prognosis, and the extent of evaluation and treatment can be challenging to determine. The potential for additional time or enhanced ability to communicate with the patient may be extremely valuable to the family, and a timed trial of hydration or antibiotics can sometimes help to determine if the delirium is potentially or even partially reversible. One study of patients with advanced cancer in an inpatient palliative care unit estimated that approximately 50% of delirium

Table 49.5 DISTINGUISHING THE CLINICAL FEATURES OF DELIRIUM, DEMENTIA, DEPRESSION AND PSYCHOSIS

CHARACTERISTIC	DELIRIUM	DEMENTIA	DEPRESSION	PSYCHOSIS
Onset	Abrupt (hours to days)	Insidious	Variable: can be associated with major life changes	Variable
Course	Fluctuates	Progressive	Variable	Chronic with exacerbations
Reversibility	Potentially	Irreversible	Potentially	Potentially
Duration	Hours to months	Months to years	Variable (at least 2 weeks)	Months to years
Level of alertness	Fluctuates	Generally normal	Normal	Normal
Orientation	Fluctuates	Impaired	Selective impairment	Normal
Memory	Impaired	Impaired recent memory worse	Selective impairment	Intact
Attention	Impaired	Normal until end stage	Generally normal	May be impaired
Psychomotor behavior	Variable	Generally normal	Variable (vegetative or agitation)	Variable
Perception/illusions hallucinations, or delusions	Common	Usually absent	Absent except in severe cases	Common
Sleep–wake cycle	Disrupted, cycle may be reversed	Fragmented	Early morning awakening common	Variable

From Shenvi et al.²⁴; Weng et al.⁷⁶; Loving and Dahlin⁷⁷; and Milisen et al.⁷⁸

episodes could not be reversed.⁷⁹ Impending death and the increased likelihood of irreversible terminal delirium distinguishes the experience of delirium in hospice and palliative care from other settings or contexts.⁸⁰

PREVENTION AND MANAGEMENT

There is limited evidence for both pharmacological and non-pharmacological approaches to the management of delirium symptoms, especially in the palliative care patient population. Clinical guidelines for delirium vary widely in quality and often do not include tools for implementation.⁸¹ Yet, as discussed previously in this chapter, delirium places significant burdens on patients, caregivers, and staff.⁸² While the evidence for symptomatic management of delirium is scarce, fortunately the literature on nonpharmacological prevention of delirium is more robust. Primary prevention is almost always preferable to treating a problem once it has occurred, and delirium prevention is paramount. A review of current research also suggests that it is possible to successfully treat reversible causes of delirium in 20–50% of palliative care patients who are not actively dying,⁸³ making identification and treatment of root causes a priority. Many of the nonpharmacological interventions for prevention also continue to be applicable in delirium management.

Before addressing specific interventions, it is important to note that palliative care patients often have different needs from the general population, especially when approaching end of life, and the specific needs of palliative care patients must shape an APRN's approach to both delirium prevention and management. Above all, the individual patient's values and goals of care as well as prognosis should help to guide any delirium prevention or management interventions.

NONPHARMACOLOGICAL PREVENTION

The standard for delirium prevention is to use a multi-component, nonpharmacological intervention that targets known delirium risk factors, as exemplified by Inouye et al.'s Hospitalized Elder Life Program (HELP).⁸⁴ The HELP program employed an interdisciplinary team and used eight interventions to address delirium risk factors (sleep deprivation, dehydration, immobility, cognitive impairment, and vision or hearing impairment) in hospitalized, older adults. The outcome was a significant reduction in both the total number of risk factors for individual patients, total number of delirium episodes, total number of days with delirium, and new delirium cases.⁸⁵ Multicomponent, nonpharmacological prevention interventions have been shown to be highly effective in reducing the incidence of delirium and falls in hospitalized (non-ICU) adults,⁸⁶ and there is moderate-quality evidence that multicomponent, nonpharmacological prevention approaches decrease the incidence of delirium by approximately 30% in this same population (although the effect of these interventions on patients with a history of dementia is uncertain).⁸⁷ Box 49.4 summarizes current recommendations for multicomponent, nonpharmacological

Box 49.4 ENVIRONMENTAL NONPHARMACOLOGICAL INTERVENTIONS FOR PREVENTION OF DELIRIUM

Levels of light in the patient's room should correspond to the time of day (light during the day, dark at night).
Decrease environmental noise and stimulation during sleep hours and reduce staff/family interruption when possible.
Discourage daytime napping and caffeinated beverages late in the day.
Assist with safe feeding and hydration, if necessary.
Consider implementing a toileting schedule, if necessary.
Whenever possible, provide a healthcare team that knows the patient well and with whom the patient is familiar.
Encourage family and friends to visit and involve them as much as possible in care.
Avoid switching patients between different rooms.
Use a clock, posted schedule, or orientation white board to help remind patients of the date and time.
Make sure patients have access to their glasses, hearing aids, and dentures. Use an interpreter when needed.
Assess for and treat impacted cerumen.
Communicate clearly and consistently and reorient frequently.
Avoid restraints as much as possible to avoid immobility, injury, and discomfort.
Encourage and assist with mobility, up out of bed when possible, and range of motion.
Avoid urinary catheterization if possible.

From Marcantonio¹⁰; Bush et al.⁸³; Inouye et al.⁸⁴; National Institute for Health and Care Excellence⁸⁸; and Hosker, Bennett.⁸⁹

delirium prevention interventions to guide palliative APRN practice.

The relatively straightforward interventions in the HELP protocol (e.g., promote sleep, mobility, and adequate nutrition)⁸⁵ are applicable to the practice of palliative APRNs across all healthcare settings and in the hospice and home settings. Palliative APRNs may be in a position to work on quality improvement projects in hospital or long-term care settings and to educate nursing and medical staff to incorporate these interventions into their practice and unit-based procedures. Inpatient or community palliative APRNs should take the opportunity to educate high-risk patients and their family caregivers about how they can maintain relevant preventive measures at home, when applicable. In the inpatient setting, this should also be incorporated into discharge planning and education. The American Geriatrics Society (AGS) has combined the HELP interventions with Geriatrics principles to form the AGS CoCare: HELP program, designed as a comprehensive care model for hospitalized older adults.⁹⁰ This can be a helpful tool for palliative APRNs looking to actualize the HELP protocols in their institution. Further information and resources for implementation are available on the website: <https://americangeriatrics.org/programs/ags-cocare-helptm>

While the majority of research on multicomponent non-pharmacological interventions has not focused on palliative

care patients but rather on populations of hospitalized adults and older adults,^{85–87} the risks of nonpharmacological interventions for delirium prevention are low, the potential benefits are significant, and the interventions are in line with basic nursing care. They are currently the best tools that palliative APRNs have to prevent delirium, as long as they are tailored to the individual patient.

TREATING REVERSIBLE ETIOLOGIES

In the general population the first step in managing delirium symptoms is to address any modifiable precipitating causes, such as infections, medication adverse effects, or electrolyte imbalances.⁸⁸ This can be challenging in palliative care patients with advanced illnesses who often have multiple possible risk factors and potential precipitating factors.⁴ In the palliative care setting, addressing reversible etiologies of delirium can still be a critically important step, though as mentioned earlier, clinicians must be sure to take an individualized approach. The palliative APRN is positioned to counsel patients and families about their treatment options and to formulate a plan that is in line with the patient's goals of care. In an article on clinical assessment and management of delirium in palliative care patients, Bush, Tierney, and Lawlor⁴ outline an approach to decision-making when considering whether to address reversible causes of delirium for patients at end of life. They suggest a thorough discussion of several topics with patients and/or proxy decision-makers, including “clarification of the known clinical status; the trajectory of the illness and the suspected or known delirium precipitants; the functional status prior to the episode of delirium; the desire for further investigation, based on the patient's prior expressed goals of care; and the risk and burden of further investigation or treatment.”⁹⁴ (p. 1630) If there is considerable ambivalence as to whether an intervention should be pursued, especially in patients with advanced disease, it is often helpful to consider a time-limited trial of the intervention and then re-evaluate the plan of care with the patient and family. Box 49.5, adapted from the European Society for Medical Oncology (ESMO) *Clinical Practice Guidelines* for delirium in adult cancer patients,⁸³ lists examples of interventions that may be helpful in treating the root causes of delirium.

NONPHARMACOLOGICAL MANAGEMENT

The efficacy of nonpharmacological strategies in managing delirium symptoms after their onset has limited evidence-based support. A systematic review by Siddiqi et al.⁸⁷ examined 39 delirium prevention studies that focused on hospitalized adults (age 16 and older, non-palliative care-specific; ICU patients were excluded) and found that it is uncertain whether multicomponent, nonpharmacological preventive interventions have any effect on delirium severity or duration. Yet several clinical recommendations and guidelines for delirium management still encourage continuing the use of the interventions in Box 49.4 as part of good nursing care to promote patient safety, sleep, and cognition/orientation.^{10,88,89} These recommendations are based on clinical experience, in the

Box 49.5 COMMON INTERVENTIONS FOR TREATING REVERSIBLE DELIRIUM ETIOLOGIES

Consider stopping or tapering psychoactive or anticholinergic medications.
For patients on opioid therapy, consider opioid rotation or dose reduction.
Consider steps to improve oral hydration or consider intravenous hydration, if necessary, for dehydration.
Consider electrolyte supplementation for electrolyte imbalance.
Consider antibiotics, antifungals, or antivirals as appropriate for infection.
If known brain metastases or tumors, consider dexamethasone in consultation with oncology and neurology.
If antineoplastic treatments may be contributing to delirium, consider discussion with oncology about alternatives or discontinuation.
Initiate or escalate bowel regimen for constipation.

From Bush et al.⁸³

context of limited support for other approaches.¹⁰ Additional nonpharmacological interventions for patients with a hyperactive delirium can help to maintain safety (see Box 49.6).

PHARMACOLOGICAL PREVENTION

Current literature does not support the role of pharmacological interventions in delirium prevention. A systematic review by Siddiqi et al.⁸⁷ found that the efficacy of using pharmacological approaches to prevent delirium remains uncertain. Of the studies reviewed in this paper, there was no clear evidence for the use of donepezil (a cholinesterase inhibitor), antipsychotics as a general drug class, or melatonin in delirium prevention. This was due to very low-quality evidence, study imprecision/inconsistency, and study heterogeneity, respectively.⁸⁷ The ESMO *Clinical Practice Guidelines* for adult patients with cancer also do not recommend pharmacological prevention of delirium in cancer patients due to a lack of available evidence, though they do conclude that de-prescribing medications may be helpful in older patients.⁸³ At this time

Box 49.6 NONPHARMACOLOGIC SAFETY INTERVENTIONS FOR PATIENTS WITH HYPERACTIVE DELIRIUM

Educate nursing staff or caregivers to use de-escalation techniques
Use bed alarms or floor mat alarms to prevent wandering or getting up unassisted
Clear the floor of unnecessary objects (e.g., wastepaper bins, shoes, trash, IV poles)
Remove potentially dangerous objects (e.g., cutlery, sharp objects, scissors, phone cords) from the room
Consider a one-on-one sitter or family member to be with patient at all times

nonpharmacological interventions remain the standard of care for delirium prevention.

PHARMACOLOGICAL MANAGEMENT

The evidence is equivocal regarding the efficacy and safety of using medications such as antipsychotics or benzodiazepines for delirium symptoms in both adult palliative care patients and hospitalized adult patients in general. One significant exception is the routine use of benzodiazepines in the treatment of alcohol and benzodiazepine withdrawal and the delirium associated with these conditions.^{91,92} Current delirium management guidelines recommend avoiding pharmacological intervention for non-withdrawal-related delirium in mild-moderate cases, and palliative APRNs should avoid using medications to treat delirium unless symptoms become severe and distressing to the patient or the patient is at risk of harming themselves or others.^{83,88} Table 49.6 summarizes the recent literature related to pharmacological delirium management. It is important to note that recent systematic reviews differ in their study inclusion and exclusion criteria and hence on the evidence they examine,⁹³ which may account for their disparate findings.

While clinical guidelines are in agreement that using pharmacological agents to treat severe/distressing delirium may be appropriate, there is no current consensus on which agents to use. Table 49.7 summarizes the National Institute for Health and Care Excellence (NICE) and ESMO guidelines for using medications in severe delirium.^{83,88} It is important to note that distressing symptoms do not manifest only in hyperactive delirium. Patients with hypoactive delirium may also experience distress from psychotic symptoms, which may benefit from treatment with antipsychotics.⁸⁸ When considering using antipsychotics or benzodiazepines to treat severe delirium, palliative APRNs should evaluate the risks and benefits of the particular medication in light of the individual patient's clinical condition, goals of care, and the potential adverse effects of the drug and take into consideration the policies of the APRN's specific institution. Consultation with a pharmacist may also be helpful. In the palliative care population, the benefits of treating distressing symptoms may outweigh the risks of certain adverse effects, such as prolonged QTC or sedation, especially in patients at the end of life. It is also important to note that the use of antipsychotics or benzodiazepines for delirium is off-label in the United States and not FDA approved.¹⁰ If prescribing antipsychotics or benzodiazepines for severe delirium, consider the following points:

1. Always start with the lowest clinically effective dose and titrate up slowly.^{10,83,88}
2. Start with as-needed (prn) administration. If scheduled dosing is required, limit use to the shortest period of time possible.⁸³
3. If doses need to be continued after hospital discharge, discharge teaching should include a clear plan as to when and under what conditions the medication will be discontinued.¹⁰

4. Monitor carefully for adverse effects.

Table 49.8 summarizes common medications used in delirium management, including doses, routes, adverse effects, cost, and other pertinent considerations.

MANAGEMENT OF REFRACTORY TERMINAL DELIRIUM

Symptoms of terminal delirium that are distressing and refractory to nonpharmacological measures, as well as a trial of as-needed or scheduled pharmacological measures as a last resort, are a unique challenge in caring for patients at the end of life. For patients who are actively dying with severe, refractory delirium, historically the next step has been to consider palliative sedation, usually with IV benzodiazepines or other sedative medications. Chapter 57, "Palliative Sedation" provides comprehensive information on the process. However, it is important to note that, as with most aspects of delirium management, the literature on palliative sedation for management of terminal delirium is weak, and the evidence base is evolving. A systematic review by Beller et al.,⁹⁴ which looked at 14 different studies, found that delirium was still challenging to manage despite palliative sedation. Beller et al.⁹⁴ found "no evidence from randomised controlled trials (RCTs) and limited evidence from observational studies about the efficacy of palliative sedation in terms of a person's quality of life or symptom control, compared with non-sedated people,"^{94 (p. 15)} though they cautioned that the studies they had evaluated were of low quality. Nonetheless, for severe, refractory terminal delirium, a trial of palliative sedation may be the only available option and can be considered as a possible approach for these cases.^{83,89,93}

THE FAMILY CAREGIVER EXPERIENCE

Delirium is not experienced in isolation: it is an unpredictable and distressing syndrome shared by patients, their family caregivers, and the healthcare professionals involved.⁸⁰ Symptoms of delirium can result in different burdens for the patient who is experiencing them versus the family who is witnessing them. A literature review by Partridge et al.⁹⁵ (2013) indicated that the distress may be even greater in relatives witnessing the delirium and can have long-term psychological impact. In retrospective, qualitative interviews of elderly patients who had experienced a delirium during a hospitalization, their family caregivers, and nursing staff were analyzed and three common themes of delirium-related burden were revealed.⁸² There were shared burdens, albeit from different perspectives, related to the symptoms of delirium (e.g., disorientation, hallucinations), the emotional response to the delirium (e.g., fear, helplessness), and the situational factors (e.g., loss of control, lack of knowledge).

Some specific concerns described by caregivers included not knowing if the symptoms would resolve, the inability to communicate, and changes in the patient's personality.⁸² Anxiety

Table 49.6 PHARMACOLOGICAL MANAGEMENT OF DELIRIUM: SUMMARY OF RECENT REVIEW ARTICLES AND LITERATURE

AUTHOR (YEAR)	DESIGN	POPULATION	STUDY DESCRIPTION	FINDINGS AND CONCLUSIONS
Grassi et al. ⁹⁶ (2015)	Review article	Palliative care patients	Examines the management of delirium in palliative care.	Typical and atypical antipsychotics are equally effective in treating delirium in palliative care. The authors find no basis on which to make recommendations about other classes of drugs.
Kishi et al. ⁹⁷ (2016)	Meta-analysis	Adults	Examined the use of antipsychotics to treat adults with delirium. The primary outcome measure was the response rate. Secondary outcome measures were time to response, Clinical Global Impression-Severity Scale (CGI-S), severity of delirium, adverse effects, and discontinuation rate.	Antipsychotics showed a greater efficacy than placebo or usual care in terms of response rate, CGI-S scores, time to response, and delirium severity scale scores. There was a higher incidence of sedation and dry mouth with antipsychotics vs. placebo or usual care. There was a lower incidence of extrapyramidal symptoms (EPS) and time to response was shorter with second-generation antipsychotics vs. haloperidol. The authors conclude that second generation antipsychotics are safer and more efficacious at treating delirium than haloperidol, though they suggest the need for further research using larger sample sizes.
Neufeld et al. ⁹⁸ (2016)	Systematic review and meta-analysis	Adult medical or surgical inpatients	Evaluated the use of antipsychotics for delirium prevention and treatment, examining 19 randomized controlled trials and cohort studies.	The authors found no association between antipsychotic use and change in delirium severity, duration, ICU length of stay (LOS), or hospital LOS. They found no association between antipsychotics and mortality. They reported a high level of study heterogeneity and concluded that there is not sufficient evidence to support the use of antipsychotics for treatment of delirium.
Cerveira et al. ⁹⁹ (2017)	Systematic review	Elderly patients (>60)	Examines the efficacy of pharmacological and nonpharmacological modalities for treating delirium.	The authors found that olanzapine and haloperidol decreased delirium severity; droperidol decreased hospital LOS and improved the delirium remission rate; and rivastigmine improved cognitive function, decreased caregiver burden, and decreased the duration of delirium. The authors suggest that pharmacological treatments are effective at improving delirium duration and severity in the elderly, though they recognize that overall the studies on this subject are few and the sample sizes are small.
Lawley, Hewison ¹⁰⁰ (2017)	Integrative literature review	Adult patients with advanced cancer	Examined the clinical management of delirium in advanced cancer patients.	The author finds limited evidence for the efficacy of the reviewed interventions (opioid rotation, atypical antipsychotics, methylphenidate hydrochloride, celiac plexus block, and exercise therapy), concluding that there is currently no clear evidence to guide practice in delirium management and there is a need for further research.
Burry et al. ¹⁰¹ (2018)	Systematic review	Hospitalized adults	Evaluated the efficacy of antipsychotics vs. non-antipsychotics or placebo on delirium duration, severity and resolution, hospital length of stay, mortality, health-related quality of life, adverse effects, and discharge disposition. Evaluated the efficacy of typical vs. atypical antipsychotics to improve the above outcomes.	The authors did not find evidence for the efficacy of antipsychotics in decreasing delirium severity, altering mortality, or resolving symptoms, though the data were of poor quality. There were no data to assess the efficacy of antipsychotics to change delirium duration, health-related quality of life, hospital LOS, or discharge disposition. There was no difference in the frequency of EPS between antipsychotic and non-antipsychotic drug regimens or typical and atypical antipsychotics.

Table 49.6 CONTINUED

AUTHOR (YEAR)	DESIGN	POPULATION	STUDY DESCRIPTION	FINDINGS AND CONCLUSIONS
Bush, et al. ⁸³ (2018)	Literature review for Guidelines	Adult cancer patients	Review of the literature on pharmacological management of delirium to inform clinical guidelines.	Haloperidol and risperidone are not recommended for use in treating symptoms of mild-moderate delirium. Olanzapine, quetiapine, and aripiprazole may be beneficial for managing delirium symptoms. "Methylphenidate may improve cognition in hypoactive delirium in which neither delusions nor perceptual disturbance are present and for which no cause has been identified." ⁷⁵ (p. iv ¹⁵⁶) Benzodiazepines may be helpful to use for sedation and anxiolysis in the treatment of severe, distressing, delirium symptoms. Pharmacological agents should be used only when symptoms have become distressing to the patient or when those symptoms are causing safety concerns. Medications should be used only for short periods of time and at the lowest effective dose.
Wu et al. ¹⁰² (2019)	Network meta-analysis	Adults in any setting	Examined the evidence for pharmacological delirium treatment and prevention methods, including only randomized controlled trials.	The authors conclude that haloperidol plus lorazepam may be the best pharmacological treatment for delirium symptoms and that ramelteon may be the best drug to use for delirium prevention. They did not find any increase in all-cause mortality for any of the pharmacological interventions studied.
Finucane et al. ⁹³ (2020)	Systematic review	Terminally ill adult patients	Examined the safety and efficacy of pharmacologic management of delirium symptoms.	The authors found no high-quality evidence that either supports or refutes pharmacological management of delirium symptoms in terminally ill adults. They found possible slight worsening of delirium symptoms with haloperidol or risperidone vs. placebo (low-quality evidence). And they found possible slight increases in EPS with haloperidol and risperidone (moderate- to low-quality evidence).
Hui et al. ¹⁰³ (2020)	Single center, double-blind, randomized trial	Adult advanced cancer patients with terminal delirium and refractory agitation on a palliative care/supportive care unit	Examined IV haloperidol dose escalation vs. neuroleptic rotation to chlorpromazine vs. haloperidol + chlorpromazine and the effects of these regimens on Richmond Agitation Sedation Scale (RASS) scores.	RASS score decreased significantly within 30 mins and remained decreased at 24 hours in all three groups. There was no significant difference in RASS scores between the groups. Hypotension was the most common serious side effect, and there were no treatment-related deaths. The authors conclude that while the study was small and limited by design (no placebo group), these three different antipsychotic regimens may decrease agitation in patients with terminal agitated delirium.
Li et al. ¹⁰⁴ (2020)	Systematic review	Adult patients in non-ICU healthcare settings	Evaluated the efficacy and safety of benzodiazepines in treating non-withdrawal related delirium.	Two studies (RCTs) were identified that fit selection criteria. The authors found insufficient evidence of benzodiazepine efficacy in treating delirium in non-ICU patients. The current evidence does not support the routine use of benzodiazepines to treat delirium in this patient population.
van der Vorst et al. ¹⁰⁵ (2020)	Multicenter, randomized controlled, phase III trial	Adult, hospitalized advanced cancer patients	Examined the efficacy and tolerability of olanzapine vs. haloperidol in treating delirium.	The authors did not find a statistically significant difference in efficacy between haloperidol and olanzapine. While they found less adverse effects with olanzapine vs. haloperidol overall, this difference was not statistically significant.

Table 49.7 MEDICATIONS FOR SEVERE DELIRIUM: SUMMARY OF NICE AND ESMO GUIDELINES

ORGANIZATION	AUTHOR (YEAR)	GUIDELINE TITLE	FINDINGS/RECOMMENDATIONS
European Society for Medical Oncology (ESMO)	Bush et al. (2018) ⁸³	Delirium in adult cancer patients: ESMO Clinical Practice Guidelines	Question the use of antipsychotic medications in general for severe delirium - Concerns for potential lack of efficacy - Concern for adverse effects Recommend against using haloperidol or risperidone - Lack of evidence to support the efficacy of these agents in even mild-moderate delirium - Possibility of causing harm Recognize a potential role for olanzapine, quetiapine, and aripiprazole in managing delirium symptoms - Less risk of extrapyramidal symptoms (EPS) - Evidence for efficacy is still insufficient Recognize a possible role for benzodiazepines in acute cases - Anxiolytic and sedating effects may be helpful - Concern for significant adverse effects, including sedation, risk of falls, and risk of contributing to delirium symptoms
National Institute for Health and Care Excellence (NICE)	NICE ⁸⁸ (last updated March 14, 2019)	Delirium: Prevention diagnosis and management	Recommend consideration of short-term (less than 1 week) haloperidol for patients who have not responded to de-escalation and who: - Have become distressed - Pose a danger to themselves or others Use antipsychotic medications with caution or avoid completely in Parkinson's disease or Lewy body dementia.

Table 49.8 COMMONLY USED MEDICATIONS FOR SYMPTOMATIC TREATMENT OF SEVERE DELIRIUM

MEDICATION CLASS	GENERAL CONSIDERATIONS		
Antipsychotics	Consider lowering the initial dose in elderly and frail patients or if administering with a benzodiazepine.⁸³ Caution if seizure hx. May lower seizure threshold.^{106–111} May cause agranulocytosis. If not at end of life and if in line with goals of care, monitor CBC if history of leukopenia or neutropenia, and d/c if ANC <1,000 or if unexplained drop in WBC count.^{106–111} Antipsychotics carry a black box warning for increased risk of mortality in elderly dementia patients (cardiovascular and infectious events).^{106–111} If possible, avoid antipsychotics in older adults and in older adults with dementia.^{112,113} Avoid first-generation antipsychotics, such as haloperidol, in patients with Parkinson's disease and Lewy body dementia due to risk of significant adverse effects, including worsening extrapyramidal symptoms (EPS) and worsening parkinsonian symptoms.^{114,115} For a detailed review of the management of delirium in patients with Parkinson's disease, see the article <i>Management of Delirium in Parkinson's Disease</i> by Ebersbach et al, 2019.¹¹⁴ When possible, avoid IM administration in palliative care and especially comfort care patients		
DRUG NAME	DOSE/ROUTE*	DRUG-SPECIFIC CONSIDERATIONS	RETAIL COST
Haloperidol (first-generation antipsychotic)	Initial Dose: 0.5–1 mg PO or SubQ STAT or q 1 hr. PRN (0.25–0.5 mg if elderly or frail) For scheduled dosing, give q8–12h Routes: PO, SubQ, IM, IV	Adverse effects include: prolonged QTc and extrapyramidal side effects (EPS)^{83,110} Avoid in patients with Parkinson's or Lewy body dementia due to increased risk of EPS^{83,114,115} If long-term use, taper gradually to prevent withdrawal. Do not discontinue abruptly.¹¹⁰ If administering via IV, requires electrocardiogram (ECG) monitoring,⁸³ if not at end of life.	Low: This is a generic medication and relatively affordable. 0.5 mg tablets are approximately \$0.83 /pill.¹¹⁶
Chlorpromazine (first-generation antipsychotic)	Initial Dose: 12.5–25 mg PO or rectal STAT For scheduled dosing, give q6–12h. Routes: PO, rectal, deep IM, IV (diluted, slow push or infusion)	Adverse effects include: sedation, prolonged QTc, EPS, orthostatic hypotension, anticholinergic effects, local irritation from IV infusion.^{83,107} Avoid in patients with Parkinson's or Lewy body dementia due to increased risk of EPS.^{114,115} Use cautiously in hepatic or renal insufficiency.⁸³	Moderate: \$6.23 per pill (10 mg)¹¹⁷

(continued)

Table 49.8 CONTINUED

DRUG NAME	DOSE/ROUTE*	DRUG-SPECIFIC CONSIDERATIONS	RETAIL COST
Risperidone (second-generation antipsychotic)	Initial Dose: 0.5 mg PO (0.25–0.5 mg if elderly or frail) STAT For scheduled dosing, give up to q12h Routes: PO, ODT	Adverse effects include: EPS, hypotension, sedation, insomnia, anxiety. ^{83,109} May worsen parkinsonian symptoms in patients with Parkinson's disease. ¹¹⁴ Caution if severe hepatic or renal insufficiency (reduce dose). ⁸³	Low: \$0.6/tab (0.5 mg), though prices vary widely according to tablet strength. ¹¹⁸
Olanzapine (second-generation antipsychotic)	Initial Dose: 2.5–5 mg PO or SubQ STAT (reduce dose if elderly or frail) For scheduled dosing, start with nightly dosing Routes: PO, ODT, or IM	Adverse effects include EPS, sedation, orthostatic hypotension as well as weight gain, hyperglycemia, and hyperlipidemia with long-term use. ^{83,108} May worsen parkinsonian symptoms in patients with Parkinson's disease. ¹¹⁴ Use caution if concomitant benzodiazepine use due to increased risk of respiratory depression and sedation. ⁸³ Caution if hepatic insufficiency (reduce dose). ⁸³ In patients with Lewy body dementia may still cause high levels of adverse effects. ¹¹⁹	Moderate: \$6.87/pill ¹²⁰
Quetiapine (second-generation antipsychotic)	Initial Dose: 25 mg (immediate release) PO STAT (12.5–25 mg if elderly or frail) For scheduled dosing, give q12h. Routes: PO	Adverse effects include: sedation, prolonged QTc, EPS, orthostatic hypotension, anticholinergic effects. ¹¹¹ Caution if hepatic insufficiency (reduce dose). ⁸³ The most practical choice for delirium in Parkinson's disease (lower risk of worsening symptoms), but efficacy has not been proven. ¹¹⁴ Use with caution, as it may still exacerbate EPS. ¹¹¹ In patients with Lewy body dementia may still cause high levels of adverse effects. ¹¹⁹	Moderate: \$3.43/pill ¹²¹
Aripiprazole (third-generation antipsychotic)	Initial Dose: 5 mg PO or IM STAT (reduce dose if elderly or frail) For scheduled dosing, give daily. Routes: PO, IM, ODT	Adverse effects include EPS, orthostatic hypotension. Insomnia, dizziness, drowsiness, agitation, headache. ^{83,106} May worsen parkinsonian symptoms in patients with Parkinson's disease. ¹¹⁴ Use caution in patients with impaired cytochrome P450 2D6 metabolism (reduce dose). ⁸³ May have cytochrome P450 2D6 and 3A4 drug–drug interactions. ⁸³	High: \$9.13–32.23 per pill ¹²²
MEDICATION CLASS	GENERAL CONSIDERATIONS		

Benzodiazepines

First-line treatment for delirium related to alcohol or benzodiazepine withdrawal.^{91,92}
 Consider lower initial dose in elderly and frail patients or if administering with an antipsychotic.⁸³
 Use cautiously in patients with severe liver disease, renal disease, myasthenia gravis, or severe pulmonary insufficiency, unless using for end of life care.^{83,123–124}
 Use caution if concurrent high-dose olanzapine treatment. There are reports of fatalities with concurrent use of these medications.⁸³
 May be considered for patients with Parkinson's disease and Lewy body dementia,⁴ taking into account possible adverse effects listed below, though note that no studies have examined their use for managing delirium in this population.¹¹⁴
 When possible, avoid IM administration in palliative care and especially in comfort care patients

Table 49.8 CONTINUED

DRUG NAME	DOSAGE/ROUTE*	DRUG-SPECIFIC CONSIDERATIONS	COST
Lorazepam	Initial Dose: 0.5–1 mg PO, SubQ or IV STAT and q1h PRN (0.25–0.5 mg if elderly or frail) Max Dose: 2 mg Routes: PO, SubQ, IM, IV, sublingual	Adverse effects include: sedation, worsening of delirium symptoms, increased fall risk, paradoxical agitation, and local irritation with SubQ injection. ^{83,123} Avoid IM/IV use in renal failure and use IM/IV route cautiously in renal impairment (avoid frequent dosing or high doses) due to risk of propylene/polyethylene glycol toxicity. ¹²³ Avoid using in hepatic failure. ¹²³	Low: \$0.80 /pill ¹²⁵
Midazolam	Initial Dose: 2.5 mg IV or SubQ STAT and q1h. PRN (0.5–1 mg if elderly or frail) Max Dose: 5 mg maximum cumulative dose Routes: IV, SubQ, IM	Adverse effects include: sedation, worsening of delirium symptoms, increased fall risk, anxiety, insomnia, dizziness, and paradoxical agitation. ^{83,124} Caution if administering subcutaneously (may cause site irritation). ⁸³	Low: \$10.48/2 vials (1 mL) of 5 mg/mL ¹²⁶

*Dosages and routes are adapted from Bush et al. 2017, 2018^{4,83}, and Marcanonio, 2017¹⁰

Antipsychotics and benzodiazepines are not approved by the US Food and Drug Administration (FDA) for treatment of delirium symptoms. While the authors have endeavored to include accurate dosing and side effect information, please always consult with a pharmacist, pharmaceutical reference book, or the drug manufacturer data sheet when prescribing. Lists of adverse effects in this table are those of most concern in the palliative care population, but they are not comprehensive.

related to the sense of losing their loved one even before they died has been noted in families of patients with delirium in the palliative care setting.⁸⁰ The inability to communicate may lead to frustration and fear in the patient and also heighten distress in the family who worries that they may not be able to resolve issues or say their final good-byes. Terminal delirium with agitation was a significant determinant of family distress identified by bereaved family members of palliative care patients.¹²⁷ In addition, family caregivers can have ambivalent feelings regarding the balance of relieving delirium-related suffering with sedation and the desire to maintain consciousness and communicate.^{80,127}

A literature review of 15 studies on the role of family caregivers of palliative care patients with delirium identified three themes regarding caregiver participation in the management of delirium: detection/prevention, symptom monitoring, and advocating for the patient⁸⁰ (Box 49.7). In general, the family caregivers studied were positive about participating in caring and advocating for patients with delirium at the end of life. Facilitating this participation could be highly valued and meaningful for many caregivers; however, the authors point out that the optimal level of family caregiver participation may vary and requires an individualized approach and more investigation.

Interventions for the family caregivers of patients with delirium fall into two general categories: education and support.⁸⁰ Education found to be helpful by caregivers includes information regarding the risk factors, causes, symptoms, expected progression, implications, and treatments for delirium, as well as advice on how to respond to the patient with delirium.^{80,128,129} Delirium may linger beyond a hospitalization or develop in the home, therefore, family caregivers in the community could also benefit from education regarding delirium. A review of seven studies on delirium education for family caregivers, revealed four teaching methods: verbal

instruction, informational leaflets, both verbal instruction and leaflets, and training in the use of a delirium assessment tool for caregivers to report delirium symptoms electronically. There were no conclusions regarding an optimal method, and the authors emphasize the need for more evidence-based educational interventions for caregivers.¹³

Caregiver support is described as either support for the caregivers themselves to improve the caregiver experience and well-being or support that enhances the ability of the caregiver to improve patient outcomes (e.g., reduce delirium incidence, severity, or duration).⁸⁰ A patient outcome in the context of terminal delirium could also include a peaceful death. Given the high levels of caregiver distress associated with delirium, techniques to improve the caregiver experience can include providing therapeutic presence, discussing coping skills, and investigating ways to maintain the patient–caregiver relationship.¹²⁷

Caregiving from a physical distance is a new phenomenon as the result of the COVID-19 pandemic and may continue into the future. An editorial in the *Journal of the American Geriatrics Society* voiced the concern that restricted visitation, isolation from staff, personal protective equipment, and workload demands all place older hospitalized and nursing home patients at increased risk of delirium and necessitate a redoubling of preventive and management strategies. The editorial recommends that family caregivers be seen as essential healthcare workers and that visitor passes be given to caregivers of COVID-19-negative patients with cognitive impairment or delirium. And it suggested recommendations to allow them to have hospital health screening and education about personal protective equipment to allow their participation, clearly underlying their importance.¹³⁰ Assisting family caregivers to connect virtually to receive education about delirium and collaborate on goals of care and treatment may

Box 49.7 THE ROLE OF CAREGIVERS IN THE MANAGEMENT OF DELIRIUM

Assist in prevention and detection: Those individuals most familiar with the patient may be able to detect even prodromal or sub-syndromal symptoms earlier and assist in preventive strategies.

Monitor symptoms: Caregivers can offer invaluable insight into changes in behavior, severity of symptoms, and/or response to treatment(s).

Advocate for the patient: Caregiver knowledge of the needs and wishes of the patient can be incorporated into decision-making, goals of care, and the treatment plan.

From Finucane et al.⁸⁰

increasingly need to be offered through a variety of methods, especially when direct patient contact is restricted.

RESEARCH

The multifactorial etiology of delirium, combined with the range of comorbidities (vulnerabilities) in patients with advanced disease, presents a particular challenge to the study of delirium in palliative care. Despite the relatively high incidence and prevalence of delirium in this population, the breakdown in neuronal networks that leads to a disruption in cognition and attention is not completely understood and may vary with the different psychomotor subtypes. Hypotheses regarding the pathophysiology of delirium require further testing, and more biomarkers need to be identified to advance the science and improve on the current evidence-based guidelines.

Many of the strategies for the prevention of delirium are nursing-driven, and palliative APRNs play a significant role in the development and testing of clinical guidelines, policies, and prevention programs relevant to palliative care and hospice settings. In the palliative care population, particularly at the end of life, symptom management may be the focus, and currently there is no one drug approved for the treatment of delirium. Research is needed on the best pharmacological options based on patient symptoms, along with pharmacological approaches for severe, refractory terminal delirium. Multicomponent nonpharmacological approaches for delirium are recommended; however, identifying the best combinations for improving patient outcomes needs further study. Continued research into the optimal interventions for the support and education of family caregivers is another important area where palliative APRNs offer significant contributions, especially with the emerging dilemma of physical distancing and restrictions on visitation.

SUMMARY

Delirium is associated with poor outcomes, is a poor prognostic indicator, and preventing it from developing is the ideal.

However, once it has been diagnosed, each episode is unique and careful assessment of predisposing and precipitating risk factors can help to determine the most appropriate interventions. Working collaboratively with the interdisciplinary team, patients, and family caregivers, is the palliative APRN's best approach to the treatment of delirium, given its multifactorial nature. The consistent use of validated screening tools to identify delirium early and monitor treatment is a key component to reducing severity and duration. In the palliative care population, balancing the burden of even minimally invasive interventions with the potential for benefit, in the context of the goals of care, should be incorporated into treatment decisions. Terminal delirium demands additional considerations when communication can be impaired and opportunities for closure and good-byes limited, all of which can have a long-lasting impact on the family.

DEPRESSION AND SUICIDE

John Chovan

KEY POINTS

- National guidelines require the interdisciplinary team to address the psychological and psychiatric aspects of care for patients and families in palliative care.
- Adjusting to the news of a life-limiting disease requires drawing on past experiences and developed coping mechanisms that may be maladaptive. Every individual is different in their adjustment.
- Not all instances of a depressed mood constitute a diagnosable depressive disorder.
- The palliative advanced practice registered nurse (APRN) uses evidence-based practices and patient-centered care to support their patients and families across the trajectory of their disease, including complementary and alternative therapies as well as referrals to psychiatric and mental health specialists as needed.
- Assessing for patient safety includes evaluating for self-harm in depressed palliative care patients and their families at every encounter.

across the spectrum of a diagnosis of a life-limiting illness. This includes screenings, the psychological and psychiatric aspects of setting goals of care as part of the treatment plan, supporting the patient and family, and delivering and assessing interventions (Domain 3: Psychological and Psychiatric Aspects of Care).¹

The initial response by patients and families to learning such a diagnosis varies. Disbelief, needing time to let the news sink in, shock, sadness, anger, and denial are all potential psychological responses. Yet not all the psychological responses are pathological. This chapter focuses on feelings associated with depression that accompany patients and their family members (as defined by the patient) throughout the trajectory of a chronic, life-threatening illness. Because symptoms associated with depression can emerge at any time throughout the course of the illness, the framework used to examine the symptoms associated with depression involves the four stages of the illness trajectory: (1) at the time of diagnosis; (2) during treatment, including initial treatments and subsequent planned or unplanned treatments; (3) after treatment, including when the planned course of treatment is completed or when the goals shift away from treatment; and (4) during active dying.^{2,3}

CASE STUDY: THE PATIENT WITH DEPRESSION

Theresa is a 41-year-old African American transgender female who lives with her wife of 10 years Regina, in a mid-sized Midwestern city. Regina is a stay-at-home mother and cares for their 9-year-old twin boys, Asa and Jeremy. Theresa has been living with sickle-cell disease since her diagnosis when she was 4 years old. She describes her infrequent pain crises as “worse than knives being stuck into me.” During Theresa’s last admission, Regina asked her if she had noticed that her pain episodes were starting to get closer together. Theresa told Regina to stop worrying about it and that she was imagining things. But Theresa suspected that was indeed the case and that she might be getting worse.

INTRODUCTION

Per the National Consensus Project for Quality Palliative Care *Clinical Practice Guidelines for Quality Palliative Care*, the interdisciplinary palliative care team must address the psychological and psychiatric aspects of care that can occur

DEFINITION OF DEPRESSION

The term “depression” has a technical definition but is often used colloquially in healthcare. When a person says, “I’m depressed,” in all likelihood the person has not assessed and diagnosed themselves according to evidence-based standards. It often means that they are feeling blue, have low spirits, or are unhappy. It may also mean that they are lonely, having physical or psychic pain, or are angry and need to talk.⁴ Motivating a person to the point of being able to report “I’m depressed” may be a very complex challenge. For clarity, the terms used in this chapter are

- *Mood*: One’s perceived emotional state.
- *Sadness*: The feeling of being unhappy or in low spirits, also called a depressed mood.⁵
- *Depressive symptoms*: The behavioral indicators associated with a depressed mood include sleep changes, anhedonia, guilt, helplessness, hopelessness, changes in energy level, reduced ability to concentrate, appetite changes, psychomotor slowing, and suicidal ideation or attempts.

Depressive symptoms can worsen over time in frequency, severity, duration, and impact on functioning to the point of causing disability, thus meeting criteria for a depressive disorder.

- *Dysthymia*: A condition of persistent depressive symptoms of insufficient severity and frequency to meet criteria for a depressive episode.⁶
- *Depressive episode*: A pathological state that meets pre-defined criteria based on the existence of a depressed mood or anhedonia as well as five of nine defined depressive symptoms for at least 2 weeks.⁶ Most encounters in palliative care and hospice in which the patient says “I’m depressed” will present a constellation of symptoms that very likely do not meet the criteria for a depressive episode.⁷
- *Depressive disorder*: One of the constellations of pathological mood syndromes in which the hallmark feature is severe and persistent depressed mood and associated pathology that limits one’s ability to function in social, occupational, or other important settings. These include major depressive disorder, pervasive depressive disorder, premenstrual dysphoric disorder, substance-induced depression, and depression due to another medical condition.⁶ Some palliative care and hospice patients will have a depressive disorder in addition to a chronic, life-threatening somatic illness.^{8–10}

To provide optimal care, the palliative advanced practice registered nurse (APRN) must understand the symptomatology of both somatic and psychiatric illness and the interplay between them.^{11–13}

DEPRESSED MOOD AND LIFE-THREATENING ILLNESS

CASE STUDY: THE PATIENT WITH DEPRESSION (CONTINUED)

Three months after her last admission, Theresa was sleeping in later during the day and calling off work because she did not feel like going in. One Saturday, while Regina was out shopping with Jeremy, Theresa was walking up the stairs to go back to bed and found it more difficult to breathe, so she stopped midflight. Asa came down the stairs and stopped to ask her if she was all right. Trying not to frighten her son, she calmly asked him to call 911 and request an ambulance. She was so proud of Asa’s poise while talking on the phone with the operator but was so tired of being in pain and so tired of dealing with these crises. At the hospital, Theresa was evaluated and found to have a pulmonary embolism, likely from a deep vein thrombosis.

Throughout the course of a chronic, life-threatening illness, a patient’s response to the illness is often a waxing and waning mood. Patients and their families are often faced with

impactful news and difficult decisions that can trigger depressive symptoms and thoughts of suicide. As a member of the multidisciplinary team, the APRN assesses for symptoms, plans interventions, and implements them to alleviate these symptoms.

Prior to diagnosis, patients and their families may be anxious in anticipation of the unknown to come but may not show evidence of depressive symptoms. Patients may find that changes they have observed prior to seeking medical attention or the process of going through diagnostic procedures is stressful, triggering depressive symptoms. Persons with pre-existing depressive disorder may find that these stressors will make their depression worse or cause a relapse of depression that had been in remission.¹⁴

At diagnosis, no matter how prepared the person may be, hearing the news for the first time can be a stressor that triggers feelings of sadness, hopelessness, guilt, pain, regret, and helplessness in patients and families. At any point along the illness trajectory, depressive symptoms can become pathological or preexisting depression can be made worse.^{15–18}

As treatment begins and continues, difficulties with side effects from the treatments or intermittent and recurring exacerbations can trigger disappointments and depressive symptoms in patients and their families. Patient’s feelings of guilt about the impact the diagnosis and treatment have had on the family can cause a depressed mood. Discussions about code status, naming a healthcare proxy, and decisions about a living will can cause the patient’s or family members’ moods to sag. Physical symptoms can trigger depressive symptoms as the patient and their family try to cope with a new sense of normal, particularly pain. Spiritual angst can also cause depressive symptoms to emerge.^{19–21}

Remissions or return to baseline from exacerbations can offer hope that dangles by a thread. The specter of relapsing or another worse exacerbation is a stressor that can cause depressed mood or make a depressive disorder worse. It can also increase anxiety levels to pathological magnitudes.^{22,23}

During end-stage disease and the dying phase, resolution of depressive symptoms prior to the onset of active dying process is ideal. However, patients with depressive symptoms may still have trigger stressors, leaving them at risk for a difficult death. The focus of the palliative APRN is on comfort, which allows for the mood of the family to concomitantly be managed. For the family, the dying process of a loved one can be complex and layered, particularly if there is unfinished business when the patient dies.^{24–27}

At the end of a patient’s life, family members may be asked about the patient’s previously expressed wishes. This is a major stressor to those who have not had difficult conversations about the patient’s desires, and it can trigger depressive symptomatology and anxiety in the healthcare proxy and family. Grief is a normal response but can become pathological if it persists and has a negative impact on ability to function.²⁸

Emerging research on the neuroendocrine response to grief has shed light on the involvement of the hypothalamic-pituitary-adrenal (HPA) axis in depressive symptoms of loss. Psychological reactions temper the

dysfunction of the HPA axis, but increases in mean cortisol levels and flattened diurnal cortisol slopes are seen immediately and long after a loss. Both of these changes are associated with negative health outcomes.²⁹ The palliative APRN anticipates these potential responses to a life-limiting illness and living with a life-limiting illness and takes into account facets of culture, gender identity, sexual orientation, and other unmodifiable social determinants of mental health and illness.³⁰

After comprehensive assessment, the palliative APRN collaborates with the multidisciplinary team to develop a care plan, marshal community resources, and organize supportive information in anticipation of patient and family questions and concerns. Although the scope of practice for a palliative APRN clearly includes psychiatric symptom management, the extent to which APRNs may manage psychiatric and mental health issues varies according to state laws and institutional policies.¹² Psychiatric and mental health specialist colleagues may be necessary to assist in severe and persistent mental illnesses, such as recurrent, refractory major depressive disorder; schizophrenia; and bipolar disorder. As part of primary care, all APRNs screen for depressive symptoms. Many APRNs can provide therapy and prescribe antidepressants as delineated by scope of practice. As appropriate, referral of a patient or family member to a psychiatric or mental health professional may be necessary. Such multidisciplinary team members include a psychiatric and mental health nurse practitioner or a clinical nurse specialist, a social worker, a psychologist, a psychiatrist, an inpatient consultation team, or an outpatient mental healthcare provider.^{31,32}

EPIDEMIOLOGY OF DEPRESSION IN CHRONIC ILLNESS

Depression is associated with severe, chronic illness. Table 50.1 lists some types of chronic illnesses and their associated rates of depression.³³ The rate of depression is quite high for cardiac and neurological chronic illnesses. The palliative APRN should be familiar with this epidemiology to anticipate and monitor for depressive symptoms in persons with these chronic illnesses.^{33–37}

Table 50.1 DEPRESSION IN CHRONIC ILLNESS

CHRONIC ILLNESS	% EXPERIENCING DEPRESSION
Heart Disease	45–65
Parkinson’s disease	40
Multiple sclerosis	40
Cancer	25
Diabetes	25

From WebMD.³³

HISTORY AND PATHOLOGY

When a person reports depressive symptoms, the APRN should consider reversible physical causes of the symptoms (Box 50.1).^{38–42} For example, hypothyroidism causes symptoms that mimic depression and can be corrected medically, often with levothyroxine (Synthroid). It can be detected with a blood test that measures circulating levels of thyroid-stimulating hormone (TSH) and thyroxine (T4).³⁹ Metastatic disease to the brain can cause mood swings, including depression, as the lesions alter function in mood-related foci of the cerebrum.⁴⁰ Normal-pressure hydrocephalus can cause gait and mood changes that mimic depressive symptoms; a consult to neurology or neuropsychiatry is appropriate.⁴¹ Unmanaged pain is a common cause of stress, and subsequent somatic symptoms and depressive symptoms, yet it is correctible. Pain can include distress from insomnia, anorexia, dysphagia, and existential rumination, which can lead the patient to ask, “Why me?”⁴² Appropriate total pain management can alleviate these stressors and their comorbid depressive symptoms. If potential physiological causes are ruled out, or detected and treated, but the symptoms remain, the APRN can conclude that the symptoms are psychiatric and not due to a correctible physical cause. A referral to a specialist should be considered.

Acute stress does not always result in maladaptive responses. The diathesis–stress model of mental illness posits that persons may be genetically predisposed to development of a mental illness.⁴³ Incipient mental illness is expressed only after stressors trigger the symptoms. A family history of depression can point to a genetic predisposition to depression. Genetic markers have been identified for predisposition to depression and subtypes of depression.⁴⁴ The palliative APRN’s comprehensive history can uncover threads of a genetic predisposition.

The process of taking a history allows the palliative APRN to build rapport with the patient and family when evaluating a new patient for depressive symptoms. Evidence of prior depressive symptoms is the best predictor of future depressive symptoms. Onset, duration, measures that exacerbate it or alleviate it, and amount of debility that the symptoms induce

Box 50.1 PHYSICAL CAUSES OF DEPRESSION

- Cardiac surgeries
- Dementia

- Seizures
- Strokes
- Traumatic brain injury

From APA Working Group³⁸; Puchalapalli, Mahmood³⁹; Pidani et al.⁴⁰; and Israelsson et al.⁴¹

are all features that give insight into how to approach treatment. The therapeutic use of self allows the APRN to defuse any anxiety or reticence about discussing depression, particularly if the distress is in any way related to fear of rejection and the stigma of mental illness.⁴⁵

Understanding the pathology attributed to depression continues to evolve. For the past 50 years, the *monoamine theory* of depression has been the paradigm to explain symptoms. The theory states that the lack of monoamine neurotransmitters in sufficient quantities to trigger postsynaptic neurons to fire appropriately in the prefrontal cortex and in the limbic system causes depression. The monoamines, primarily norepinephrine, serotonin, and dopamine, are the major neurotransmitters implicated in this theory. The theory holds up in that monoamine therapy, such as the monoamine oxidase inhibitors (MAOIs; e.g., phenelzine [Nardil]), tricyclic antidepressants (TCAs; e.g., amitriptyline [Elavil]), selective serotonin reuptake inhibitors (SSRIs; e.g., citalopram [Celexa]), and serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine [Effexor]) do offer symptomatic relief. With these therapies there is often a protracted delay between therapy initiation and onset of symptom relief, and their effect on depressive symptoms is inconsistent. When symptoms are detected before permanent neurological changes take effect, the symptoms can be reversed, and treatment eventually can be discontinued. More severe symptoms, however, will require life-long treatment.^{46,47}

The *neurotrophic theory* of depression complements the monoamine theory.⁴⁸ Stress-induced atrophy and loss of neurons and glia in the structure and function of the cortex, particularly the prefrontal cortex and the limbic system's hippocampal pyramidal neurons, are mechanisms that contribute to depression.⁴⁹ Stress causes dendrites to retract in these areas and decreases spine density through inflammatory mechanisms, such as pro-inflammatory cytokines, interleukins, tumor necrosis factor, and peripheral growth factors.^{48,50,51} Furthermore, the inflammatory response results in an increase of neurotoxic amyloid- β peptides that can cause cell death, particularly in refractory depression.⁵² Changes in glutamergic signaling have been seen in animal models of depression.⁵³ These findings serve as emerging evidence linking a history of major depressive disorder with Alzheimer's disease.⁵⁴

An amalgam of these theories results in the *neurodevelopmental theory* of depression.^{55,56} This theory underscores the importance of where along the developmental trajectory an insult to normal development might occur to impact on mood regulation.⁵⁷ For example, if a mother has an infection during pregnancy, the fetus could experience an insult from the mother's immune system; altering its brain at that point in development that could result in mood dysregulation. Early childhood trauma could impact on the development of the hippocampus and prefrontal cortex, which have been shown to be reduced in size for people with depression. A high fever during late childhood could result in inflammation that has a negative impact on cortical structures that play a role in mood regulation. These theories together continue to expand our knowledge of the

mechanisms of depression and its etiology to inform the development of new treatments and explain how current treatments have an effect.

ASSESSMENT

All persons with chronic illness are at risk for depression.^{58,59} The palliative APRN uses evidence-based guidelines to inform their nursing practice.^{60–64} Risk factors for depression are listed in Table 50.2.⁶⁵ A targeted assessment for depression, performed as part of the complete patient and family assessment, provides evidence on which to plan symptom management. In doing the targeted assessment, the APRN looks for evidence that will support or rule out depressive symptoms and depression.^{38,60–64} A focused history and physical examination will determine the need for appropriate diagnostic tests and their interpretation.

The palliative APRN should first review the patient's record for prior history of depression. If the patient has a history of depression, the APRN should discover what treatments were initiated and their effectiveness. The APRN should also inquire about other mental health issues, including bipolar disorder, personality disorders, disorders that emerge in childhood, and schizophrenia. The APRN must inquire about physiological conditions that can contribute to or mimic depression. The family history should examine the patient's and family's history of suicide. Exposure to a suicide or suicide attempt is a major risk factor for suicide.

A medication history should help determine interventions for depression. It should include specific medications that were helpful in the past and those that were not and any allergies to medications or products in pharmaceuticals. The medication review should include all current prescription medication, over-the-counter preparations, supplements, and allergies to avoid known sensitivities and reduce the risk of drug–drug interactions. Finally, there should be discussion about the patient's and the family's knowledge and beliefs about psychiatric illness, pharmacotherapy, and complementary and alternative therapies. The reader is referred to *Oxford Textbook of Palliative Nursing 5th ed*, Chapter 4, “Principles of Patient and Family Assessment” for detailed information.²

The physical impact of the illness and the treatment can cause depressive symptoms, as can the patient and family response to it. For depression, the examination should be focused on mood and psychomotor changes. A mnemonic for the features of depression is SIG E CAPS, a play on the prescription to “Take (Sig) energy (E) capsules (Caps),” which stands for Sleep changes, Interest changes, Guilt or hopelessness, Energy decreases, Concentration difficulties, Appetite changes, Psychomotor changes, Suicidal ideation.⁶⁶ The assessment and history should include the following:

- **Depressed mood:** A depressed mood is characterized by negative emotions as reported by the patient. Simply asking “How is your mood?” can elicit a response from the

Table 50.2 RISK FACTORS FOR DEPRESSION AND SUICIDE IN ADULTS

DOMAIN	RISK FACTOR	AT RISK FOR DEPRESSION	AT RISK FOR SUICIDE
Mood	Depressed mood	Depression as a child or teen	Feel hopeless, socially isolated, or lonely
Stressors	Stressful life event or experienced trauma	Yes	Yes
Substance abuse	More than socially acceptable use of legal substances. Use of illegal substances	Yes	Yes; May worsen thoughts of suicide and can instill recklessness or impulsivity enough to act on thoughts
Family	Genetic link or environmental exposure to mental illness, substance abuse, or suicide	Family history; also trauma, including verbal physical or sexual abuse	Family history; also trauma, including verbal physical or sexual abuse
Psychiatric	Any psychiatric disorder but especially anxiety, posttraumatic stress disorder, personality disorders	Yes. Plus: • Borderline personality disorder • Certain personality traits, such as having low self-esteem and being overly dependent, self-critical, or pessimistic	Yes. Plus: • Psychosis • Paranoia
Somatic illness	Chronic, life-threatening illness; chronic pain	Yes	Yes
Medications	Taking a substance that can participate in inducing depressive symptoms.	Certain medications, such as some high blood pressure medications or sleeping pills	Beginning initiating an antidepressant for symptoms of depression; child, adolescent, elderly taking SSRI,
Development	Difficulties of developmental stage or insult to brain during developmental periods that impact on future development	Insult to brain from prenatal to mid-twenties.	Identify as LGBTQ+ with an unsupportive family or in a hostile environment. In adolescents and children, being unsure of sexual orientation.
Means	Access to and lethality of means to harm self.	No	Lethality of means increases the risk for harm to self (e.g., firearms, explosives)
History of suicide	Exposure to suicide or experienced a previous attempt	Yes, especially if close to the person who has died.	Previous suicide attempt or exposure to a successful suicide increases the likelihood of a suicide attempt.

From Schaakxs et al.⁶⁵

patient that indicates an unaltered mood (euthymia) or a mood that is not normal for him or her (dysthymia). “Is this a change from your usual mood?” will help distinguish the patient’s current state from his or her baseline and will give insight into the duration of a possible depressive episode.

- *Sleep changes:* Decreased need for sleep, early morning wakening, or an increased need for sleep can all indicate depression. Questions can include: “How are you sleeping? Any difficulty falling asleep? Once you fall asleep, do you stay asleep? Once you wake up in the middle of the night, do you have trouble falling asleep? Do you sleep until your planned waking time? Has this changed from your usual sleep schedule?” Changes in sleep patterns are associated with depression, particularly sleep difficulties in the early to the middle part of the sleep cycle.⁶⁷
- *Lack of interests or anhedonia:* The depressed patient may report lack of interest in activities he or she used to

enjoy or a general lack of interest in anything. The APRN might ask, “What sorts of activities are you interested in doing? Has this interest changed recently?”

- *Feelings of guilt, hopelessness, or helplessness (Beck’s cognitive triad)*⁶⁸: Excessive guilt and feelings of worthlessness indicate thoughts about the self and can be elicited by asking the patient, “Tell me about your feelings of self-worth. Are there things you feel guilty about?” Thinking about the world is captured by asking the patient to describe how others view him or her from their perspective. “Are you feeling helpless and that others do not want to help you?” And finally, the patient may see the future as dim when depressed and may believe that there is no way out of his or her current situation: “Do you feel hopeless?”
- *Energy:* Changes in level of energy, typically decreases, are associated with depression: “How is your energy level? Has this changed recently? For how long have you felt your energy was this way?”

- *Concentration*: Changes in ability to concentrate, typically more difficulty concentrating, are associated with depression: “How is your ability to concentrate? Has this changed recently?”
- *Appetite*: Changes in appetite, either up or down, and significant weight loss without intentional dieting are features associated with depression. The APRN can ask, “How is your appetite? Is that a change from your usual appetite? Have you lost weight? How much? Over what period of time?”
- *Psychomotor slowing*: Moving more slowly than usual, difficulty initiating activity, such as getting out of bed or off the couch, slower gait, and slower speech are symptoms of depression. Self-report is not as reliable as observation by a friend or family member. The nurse can ask the patient whether the friend or family member has mentioned anything unusual about the patient’s ability to move or walk.
- *Suicidal thoughts or attempts* are associated with depression.^{69,70}

SUICIDE

Risk factors for suicide include exposure to a completed suicide or suicide attempt, thoughts about committing suicide, planning to commit suicide, possessing the means to commit suicide, having access to the means to commit suicide, the potential lethality of the means (e.g., the amount of physical

damage that the means could cause), and an unsuccessful attempt at suicide in the past. Other risk factors for suicide are also listed in Table 50.3.⁷¹

The palliative APRN screens for suicide by asking these questions⁷²:

1. Has anyone close to you attempted or completed suicide?
2. Have you ever tried to hurt yourself?
3. Are you currently thinking about hurting yourself?
4. Do you have a plan?
5. How are you planning on doing it?
6. Do you have means to implement such a plan?

Access to means that are of higher lethality (e.g., firearms) contribute to a greater risk of suicide. If the patient or family member reports that the patient has thoughts about committing suicide, along with a plan and access to the means, the palliative APRN should arrange for the patient not to be left alone and then seek advanced psychiatric help.⁷²

Suicide can trigger physical or psychiatric illness in the surviving members of the family and friends.^{73,74} When someone takes his or her own life, the first question typically asked is, “Why?” Even when a suicide note is left behind, questions remain unanswered. The palliative APRN will be better able to support the survivors if they have previously thought about their own beliefs and attitudes about suicide, and how it fits into their own philosophy of life. Exploring

Table 50.3 DIFFERENTIAL DIAGNOSIS FOR DEPRESSION

DIFFERENTIAL*	DESCRIPTION	COMMENTS
Grief	Normal emotional reaction to a loss	The prominent symptom is emptiness, not anhedonia and depressed mood. Self-esteem is preserved, although feelings of sadness come and go. Persons experiencing grief may express a desire to be with the lost loved one, but they do not think of suicide as a way to make the bad feelings go away. Over time, can evolve into a depressive disorder.
Depressed mood	Sadness or feeling blue; also called intermittent dysthymia	A depressed mood by itself is not a depressive disorder but a stand-alone symptom. It can be debilitating and can progress to a depressive disorder.
Adjustment disorder	Clinical disorder as defined in DSM-5; difficulty adapting to a new sense of normal	The parameters for depressive symptoms (number, severity, duration, and impact) are of a lesser degree and do not meet the criteria for major depressive disorder.
Major depressive disorder	A depressive disorder characterized in DSM-5 by multiple symptoms over a defined period.	In adults, five or more symptoms (<i>SIG E CAPS</i>), including depressed mood, for at least 2 weeks with an impact on at least one functional domain (e.g., home, work, school, interacting with others). May be recurrent. For children, symptoms are fewer and can include irritability.
Bipolar disorder	A mood disorder characterized by alternating depression and manic mood states.	Must meet criteria for major depression during depressive episodes and either mania or hypomania as defined in DSM-5 (<i>DIG FAST</i> : distractibility, irresponsibility, grandiosity, flight of ideas, activity increases, sleep is decreased, talkative)

DSM-5 depressive disorders include disruptive mood dysregulation disorder, major depressive disorder, persistent depressive disorder, premenstrual dysphoric disorder, substance/medication-induced depressive disorder, and depressive disorder due to another medical condition.

From Franklin et al.⁷¹

other people’s views, including other members of the multidisciplinary team, is beneficial. It allows the APRN to anticipate their own personal reactions and perspectives so they can best help members of the patient’s family and other team members.

Medically assisted death may be perceived differently. In this case patients legally obtain and use prescription medications to commit suicide. This typically is not done due to depression; rather, they are exercising their own autonomy in determining when and how their life will end. In many states, medically assisted death is legal.⁷⁵ The palliative APRN should support persons who request information about medically assisted death according to the laws of the state in which he or she practices.⁷⁶ See Chapter 53, “Navigating Ethical Dilemmas” and Chapter 57, “Palliative Sedation.”

ONGOING ASSESSMENT

At the initial encounter, the palliative APRN collects baseline data. At subsequent encounters, the APRN assesses the patient and family for any changes from this baseline, using them to measure progress, emerging issues, and the effectiveness of treatments: “Compared to [before or last time] we met, is it the same, better, or worse?”⁷⁷ During each encounter, the palliative APRN builds a trusting relationship with the patient and family to facilitate the sharing of information. This is particularly important when discussing mental health issues because of the sensitive nature of mental illness and the stigma associated with it.

The palliative APRN continues to build the database from which an appropriate plan of care will be derived, including evidence of risk for and symptoms of depression, as well as related substance abuse and risk for suicide. The acuity of each symptom is also determined, as is frequency (e.g., nearly every day, most days, 2 or 3 days per week, weekly, once per month or less), duration (e.g., nonstop, months, days, just that day, a few hours), and impact on daily function (e.g., can or cannot work, can or cannot take care of one’s own needs, can or cannot cook for oneself, bedbound).

Several standardized tools are available to screen for depression. There are two items on the Palliative Care Observation Scale (PCOS) that can be used to screen for depression.⁷⁸ Other tools may be categorized by the age of the persons they were designed to measure. For example, the Children’s Depression Rating Scale (CDRS) is useful for children under the age of 18. With persons over the age of 14, useful tools include the Patient Health Questionnaire-9 (PHQ-9), Beck Depression Inventory (BDI), the Center for Epidemiological Studies Depression Scale (CES-D), and the Hamilton Depression Scale (Ham-D).^{79–84} Elderly patients can be evaluated using the Zung Self-Rating Depression Scale, the General Well-Being Schedule Depression (GWB-D) Subscale, the Geriatric Depression Scale (GDS), and others.^{85–88}

Newly diagnosed patients without a history of depressive disorder will likely not meet the criteria for a diagnosis of major depressive disorder. They may have fewer

symptoms, or their symptoms may not have persisted long enough to meet the criteria. In these cases, adjustment disorder with depressed mood may be an appropriate diagnosis.⁸⁹ The palliative APRN must remember that depressive symptoms that persist can evolve into a pathologically significant major depressive disorder diagnosis. Although the labels of the diagnoses themselves may not completely inform treatment, the evaluation of the existence of symptoms and their severity, duration, and impact will provide a baseline to direct evaluation of agreed-upon therapeutic interventions. The *Diagnostic and Statistical Manual of Psychiatric Disorders* (DSM-5) lists the specific criteria for these disorders.⁶⁴

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for depressive symptoms is shown in Table 50.4.⁶ When these symptoms are observed, the palliative APRN collects appropriate data to differentiate sub-pathological conditions, such as normal grief, from higher-acuity conditions based on the constellation of signs and symptoms, their characteristics, and the impact on the individual and family. Only then can appropriate interventions be planned and implemented to address the specific needs of the individual or family.

Table 50.4 COMMON PHARMACOTHERAPIES FOR DEPRESSION

CLASS	GENERIC NAME	BRAND NAME
Selective serotonin reuptake inhibitors (SSRIs)	citalopram	Celexa
	escitalopram	Lexapro
	fluoxetine	Prozac
	paroxetine	Paxil
	sertraline	Zoloft
	vilazodone	Viibryd
Serotonin-norepinephrine reuptake inhibitors (SNRIs)	desvenlafaxine	Pristiq
	duloxetine	Cymbalta
	venlafaxine	Effexor
Serotonin and dopamine reuptake inhibitor	bupropion	Wellbutrin
Serotonin and catecholamine reuptake inhibitor	mirtazapine	Remeron
Serotonin modulator	vortioxetine	Trintillex
N-methyl-D-aspartate (NMDA) receptor agonist	esketamine	Spravato

Note: APRNs will also discover that some patients are prescribed older classes of antidepressants, such as tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). For specific approved drug information including safe prescribing for persons taking these medications, the reader is advised to review information available at FDA.gov.

From US Food and Drug Administration.¹⁰⁰

MANAGEMENT/INTERVENTIONAL TECHNIQUES

CASE STUDY: THE PATIENT WITH DEPRESSION (CONTINUED)

As a child, Theresa lived as a boy. Her father and uncles had taught her how to hunt and fish along with her male cousins. She enjoyed those time bonding with her family, but she always knew that she was transgender and decided to transition to living as a girl in high school. She was always treated differently before her transition because of her sickle-cell disease. But when she came out as a girl, the bullying worsened. As an adult, she worried about her sons and what was in store for them in their lives, particularly if she were to die young. Her pain crises were getting closer together, and she felt guilty for being hospitalized and debilitated all the time. The thought of committing suicide was happening more frequently, and she found a sort of solace that her father's shotgun and a box of shells were in the bedroom closet.

Evidence-based interventions and approaches for helping patients with depressive symptoms are based on the principles that (a) the patient–clinician relationship is important to the development of a successful plan of care, (b) the patient and the family are at the center of the therapeutic relationship, and (c) an interdisciplinary approach will result in optimal care. Ongoing monitoring of effectiveness is key to managing depression.^{12,13}

Within the context of palliative care, the goal is to maximize quality of life by minimizing symptoms and minimizing the impact of symptoms and therapy on the patient.⁹⁰ Techniques for treating depression and depressive symptoms include talk therapies, pharmaceutical interventions, and complementary therapies to achieve this goal. The link between the anatomy and physiology of the brain and these processes explains in part the success of various treatment modalities.⁹¹

PSYCHOTHERAPY

Current evidence for depression shows that management is best when it includes psychotherapy.^{92–94} Psychotherapy has been shown to cause changes in the brain and thus result in mood changes. For patients and families with depressive symptoms, processing their feelings aloud can help them find peace, make meaning out of their situation, and develop hope. The challenge for patients with serious illness is finding a supportive and affordable group therapy or therapists at a convenient location. The emergence of telehealth and its rapid expansion during the COVID-19 pandemic has increased familiarization with videoconferencing tools in all areas of our lives. Access to high-quality, professional psychotherapy is now ubiquitous, albeit limited by costs. Early evidence shows that, although a reduction of symptoms and increased coping occurs with teletherapy, patients are more likely to cancel meetings or not be present for their appointments than in a

traditional format.^{95,96} The palliative APRN with training in therapy provides opportunities for the person to process his or her feelings. Otherwise, a referral to a professional trained in brief therapy, cognitive-behavioral therapy, or other therapeutic techniques can be made to manage depressive symptoms in palliative settings.⁹⁷

PHARMACOLOGIC MANAGEMENT

Pharmaceutical therapy is the most common technique used for managing depressive symptoms. This choice, however, may depend on the patient's prognosis.⁹⁸ For patients who have a prognosis of longer than 2–3 months, there are more options. SSRIs and SNRIs are first-line medications for treating depressive symptoms in adults, children, and adolescents.⁹⁹ Table 50.4 lists the generic and brand names of commonly prescribed antidepressants.¹⁰⁰ Table 50.5 lists the side effects of SSRIs and SNRIs.⁴⁷

A common patient concern regarding antidepressants is the sexual side effects of the SSRIs, specifically orgasmic delay in men and women and erectile dysfunction in men. These side effects can be treated with psychotherapy or with the addition of bupropion (Wellbutrin). A referral to an expert in women's or men's health may be in order.¹⁰¹

Like any other medication in palliative care, antidepressants are initiated at the lowest therapeutic dose and the dosage is adjusted as needed. Subtherapeutic effects are often observed in the first few weeks, but full therapeutic effect is achieved in 6–8 weeks after pharmacotherapy has started. Citalopram (Celexa) and its levo-isomer escitalopram (Lexapro) have been used to control depressive symptoms while minimizing side effects. Duloxetine (Cymbalta) is used to alleviate depressive symptoms and some somatic symptoms of depression. Mirtazapine (Remeron) has demonstrated a

Table 50.5 COMMON SIDE EFFECTS OF SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIS) AND SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIS)

SSRIS	SNRIS
Agitation	Agitation
Anorexia	Discontinuation syndrome
Anxiety	Headache
Constipation	Hypertension (dose-related)
Diarrhea	Nausea
Discontinuation syndrome	Sleep disturbances
Dizziness	Sweating
Dry mouth	Tremor
Headache	
Insomnia	
Nausea	
Sexual dysfunction	
Somnolence	
Sweating	
Tremor	

From Taylor et al.⁴⁷

more rapid onset than SSRIs when used to treat major depression, but the side-effect profile is often debilitating. Off-label uses of mirtazapine include treating anxiety symptoms, nausea, pruritus, insomnia, and anorexia. When either discontinuing an antidepressant or switching to a new antidepressant, a taper or cross-taper over 2 weeks is required to avoid discontinuation effects.⁴⁷

The rise of the neurotrophic theory of depression creates an opportunity for the emergence of new treatments. Esketamine, like its racemic mixture ketamine, shows a rapid antidepressant action by increasing prefrontal cortex spine synapses.^{102–104} An N-methyl-D-aspartate (NMDA) receptor antagonist, as is memantine [Namenda], it increases glutamate transmission and relieves some symptoms of depression when combined with an SSRI.¹⁰⁵ Similarly, scopolamine, an anticholinergic agent has an impact on neuroplasticity by modulating NMDA receptor gene expression.¹⁰⁶ Psychostimulants (e.g., methylphenidate [Ritalin]) have rapid onset and treatment effectiveness in the treatment of depression, including short-term effectiveness in palliative care.^{107–109} Effectiveness of psychedelic drugs in the treatment of depression is emerging in combination with psychotherapy and as standalone therapy.^{110,111}

Long-standing thought has been that the combination of pharmacologic treatment and psychotherapy produced effects that were greater than the use of either modality alone. Recent evidence supports the effectiveness of psychotherapy alone for short-term depressive symptoms and the combination of both modalities if the trajectory of illness is longer term.¹¹² The European Palliative Care Research Collaborative (EPCRC) derived recommendations for the prevention, detection, and treatment of depression in palliative care patients that include pharmacotherapy and talk therapy. They also recommend open communication, patient involvement in care planning, and regular assessment of symptoms as situations change along the course of illness. For patients with severe depression, the EPCRC recommends a referral to a mental health specialist.¹¹³

Complex Medication Use

Palliative care patients with long-standing depressive disorders may be taking medications unfamiliar to the palliative APRN. The SSRIs and SNRIs that are used today are third- and fourth-generation medications that manipulate the monoamine neurotransmitters. Earlier medications with similar effects are the MAOIs and TCAs.

If a patient is taking a drug from one of these earlier classes, the palliative APRN needs to be aware of the patient's risk for a life-threatening condition-serotonin syndrome (SS; Box 50.2).^{101,114} Of note, one substance commonly taken by patients is St. John's wort, an over-the-counter herbal medication that is used to augment mood and to treat other ailments by increasing serotonin levels. Although not approved by the U.S. Food and Drug Administration as a pharmaceutical, St. John's wort, in combination with other serotonergic drugs, can cause SS.¹¹⁵

Box 50.2 SEROTONIN SYNDROME: A LIFE-THREATENING CONDITION

Sustained levels of serotonin in the synaptic cleft alleviate depressive symptoms. Combinations of medications that increase the level of serotonin in the synaptic cleft, however, can be additive and cause concentrations of serotonin to rise to dangerously high levels. When this happens, evidence of serotonin syndrome (SS) emerges.

SS presents as three or more of the following symptoms: agitation; diarrhea; heavy sweating not due to activity; fever; mental status changes, such as confusion or hypomania; muscle spasms (myoclonus); overactive reflexes (hyperreflexia); shivering; tremor; and uncoordinated movements (ataxia).

This is a crisis that is typically treated by stopping the medication and administering benzodiazepines, intravenous fluids, and cyproheptadine, a serotonin antagonist antihistamine.

From Jing, Straw-Wilson¹⁰¹; and Tormoehlen, Rusyniak.¹¹⁴

MAOIs and TCAs must not be taken with SSRIs and SNRIs. If the patient's depressive symptoms become refractory to his or her older medications, then a washout period of 2 weeks is required before starting the more current medications.⁴⁷

If the patient is taking an MAOI, diet must be restricted to avoid foods high in tyramine, a precursor to serotonin. These foods include some cheeses; beer; dried meats, such as salami and pepperoni; chicken livers; meat bouillons and gravies; and fermented foods, such as kimchi, sauerkraut, tofu, soy sauce, and fish sauce.¹¹⁶ When liberalizing a diet to affect a goal of improving quality of life, the benefits and burdens of continuing or discontinuing the MAOI in light of the wishes of the patient to eat foods high in tyramine must be weighed. The palliative APRN educates the patient and the family on this tradeoff to inform their decision-making.

Management of Concomitant Diagnoses

The palliative APRN must note the presence of other mental health diagnoses and the effect of medications on other conditions. Some bipolar disorders are characterized by the existence of a depressed mood and are treated with mood stabilizers. The use of an SSRI or SNRI in a patient with bipolar disorder may trigger a manic episode, a pathological state that may have been revealed in the history.¹¹⁷ If mania is discovered, SSRI and SNRI antidepressants should be avoided. In these cases, mood elevators (e.g., lithium) are the first-line therapy.⁴⁷

Depression can also be accompanied by psychosis, or not being in touch with reality. If psychotic features are also present, the patient requires antipsychotics in addition to, and sometimes instead of antidepressants.⁴⁷ These medications can cause metabolic changes (such as hyperlipidemia, hyperglycemia, and prolonged QTc interval) that can precipitate other comorbid conditions. For example, some antipsychotics

(e.g., quetiapine [Seroquel]) cause hyperlipidemia, which can lead to coronary artery disease and distributed atherosclerosis. Olanzapine (Zyprexa) causes hyperglycemia that can lead to diabetes mellitus. Cardiac conduction may be affected, such as a prolonged QTc interval (nominally, longer than 400 ms) caused by haloperidol (Haldol), leaving the patient at risk for lethal dysrhythmias. Any side effects should be treated according to evidence-based guidelines.¹¹⁸

Of note, the palliative APRN should use caution when attempting to manage agitation or delirium in a patient who is already taking antipsychotics as the patient's illness progresses toward end of life. High levels of antipsychotics can lead to neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by muscle cramps and tremors, fever, symptoms of autonomic nervous system instability like unstable blood pressure, and alterations in mental status (agitation, delirium, or coma). NMS is treated symptomatically, with ice packs for fever, supportive respiratory and circulatory care, and dantrolene for muscle rigidity.¹¹⁴

SS and NMS are life-threatening emergencies. NMS is distinguished from SS by the presence of bradykinesia, muscle rigidity, elevated white blood cell count and plasma creatine kinase level. Prevention of these conditions should include a referral to a mental health professional for alternative approaches to optimal patient care.¹¹⁴

Safe Prescribing

Safe prescribing begins with a thorough history that includes diet, allergies, and medications, both historical and current, and herbal supplements.¹¹⁹ Avoiding concomitant substances (such as St. John's wort) and foods that induce serotonin will decrease the likelihood of SS. Understanding the patient's use of antipsychotics and safe prescribing will help avoid NMS.

Safe prescribing also includes minimizing the availability of lethal doses of any medication that could be used as a means of suicide.¹¹⁹ For example, consider a patient who has depressive symptoms and is being treated for anxiety with benzodiazepines. The patient has a 30-day supply of lorazepam (Ativan) in 1 mg tablets and the APRN understands that the maximum safe dosage of lorazepam in 24 hours is 10 mg.¹²⁰ In a moment of despair due to new-onset depression, this patient could attempt to kill themselves by taking all 30 pills at once and, if not found soon enough, would succeed.

A patient who is planning suicide could hoard pills over time to build a lethal stash. Even acetaminophen in large enough quantities can damage an otherwise healthy liver and cause death.¹²¹ The palliative APRN should consider dosages, amounts, and refills of medication to prevent their lethal use. Interventions and therapy for depression can relieve some symptoms, so the patient may start to feel less fatigued and more energetic as the therapeutic effects emerge. But these effects can occur for a time before effecting the patient's suicidal intentions, thus increasing the risk for suicide.¹²² The palliative APRN must remain vigilant for depression and assess for and document suicidal ideation, plan, means, and access at every interaction. The challenge is tailoring such practices to

promote a supportive encounter that meets the needs of the patient without enabling a dysfunctional response.¹²³

NONPHARMACOLOGIC INTERVENTIONS

Depressive symptoms can be improved with physical activity, such as walking, swimming, and yoga, and with proper nutrition and sleep hygiene.¹²⁴ Talk therapies can assist patients and families to find a new sense of normal and create meaning in the patient's situation, which can mitigate depressive symptoms.^{10,124}

Evidence for the effectiveness of complementary therapies continues to grow, although accessibility to these therapies is mixed.¹²⁵ Various approaches have shown efficacy in reducing psychological symptoms including depression. Table 50.6 summarizes identified evidence.^{126–136} Reiki therapy has been shown useful for relieving pain, decreasing anxiety and depression, and improving quality of life.¹²⁶ Patients and families reported decreased depressive symptoms when patients participated in an art therapy session. They reported their depression decreased later than did their anxiety.¹²⁷ Clinical hypnosis in palliative care has been shown to decrease pain and to lessen stress for the patients and families. It also shows some evidence of controlling somatic, psychiatric, and spiritual symptoms.¹²⁸ For patients with metastatic lung cancer, higher levels of mindfulness in patients and in spousal caregivers were associated with less depressive symptoms in both groups, and higher levels of mindfulness of patients was associated with decreased depressive symptoms in the spousal caregivers.¹²⁹ Reflexology and relaxation techniques both improved anxiety and depression in patients with cancer. Reflexology also improved pain and physical symptoms.¹³⁰ Live music interventions decreased pain, anxiety, and depression and increased feelings of well-being.¹³¹ Animal-involved therapy decreased psychological symptoms in patients who previously owned pets but increased symptoms in patients who had not previously owned pets.¹³² Mindfulness approaches were shown to reduce patients' psychological symptoms and to improve quality of life.¹³³ Treating co-occurring anxiety and depression with chamomile has been effective.¹³⁴ Acupuncture has decreased depression and other psychological symptoms as well as shown benefits with cancer-related pain, stress, and nausea.^{135,136}

PATIENT AND FAMILY EDUCATION

Palliative APRNs provide quality care by offering patient and family education that includes information about the following:

1. *Stressors trigger depressive symptoms.* Reducing exposure to stressors that can be manipulated will reduce the likelihood of the development of longstanding depressive symptoms. Stress management is healthy.
2. *Sadness is a normal response to loss.* When sadness worsens and impairs functioning over a period of time, seeking help through individual or group therapy or a healthcare provider can assist patients to cope with the sadness.

Table 50.6 COMPLEMENTARY AND ALTERNATIVE MODALITIES FOR DEPRESSION IN PALLIATIVE CARE

STUDY	YEAR	MODALITY	DEPRESSIVE SYMPTOMS	OTHER
Billot et al. ¹²⁶	2019	Reiki	Decreased	Decreased anxiety Improved quality of life Pain relief
Collette et al. ¹²⁷	2020	Art therapy	Decreased in patients and families	Decreased anxiety
Brugnoli ¹²⁸	2016	Hypnosis	Decreased	Decreased pain Controlled physical symptoms Controlled other psychological symptoms Controlled spiritual stress Lessening stress for patients and family

Breitbart et al. ¹³³	2015	Mindfulness	Decreased	Decreased anxiety Improved overall quality of life.
Amsterdam et al. ¹³⁴	2020	Chamomile	Decreased if coexist with anxiety	Decreased anxiety if coexist with depression
Birch et al. ¹³⁵	2020	Acupuncture	Decreased	Initial anxiety
Fink et al. ¹³⁶	2020	Acupuncture And massage	Decreased	Improved cancer related pain Improved cancer related nausea Improved cancer related stress

3. *Depression and depressive symptoms are evidence of psychiatric illness*, not lack of moral character, and they can be treated with pharmaceutical and nonpharmaceutical interventions.
4. *Taking all medications as prescribed is important.* Symptoms take time to go away. Partial effects of a medication may be felt in 2–4 weeks after initiation, but the full effects might not be felt for 6–8 weeks.
5. *Medications should not be stopped abruptly and only under the direction of the prescriber.* Patients and family members should know the signs and symptoms of dangerous conditions like NMS and SS.
6. *Patients need to be monitored for thoughts of self-harm or harm to others.* This may include identifying a trusted person to whom to disclose such thoughts. Families need to know to trust their instincts and call for help as needed.¹³⁷

7. *The overall strategy for safe treatment is a combination of medications as prescribed; appropriate diet, exercise, and sleep, and management of alcohol intake to reduce the possibility of side effects and dangerous interactions.*

CASE STUDY: THE PATIENT WITH DEPRESSION (CONCLUSION)

Theresa resigned from her job because of her health getting worse, causing her to feel unproductive and useless. She never wanted to rely on welfare, and being on Social Security Disability made her feel worse. Regina took a part-time job at the local bakery to help make ends meet. One day, Regina came home from work to find Theresa unable to talk or move her limbs. At the hospital, Regina learned that Theresa had experienced a severe stroke. Theresa continued to decline and was put on a ventilator. She never breathed on her own again.

SUMMARY

Pain and symptom management for persons with chronic, life-threatening illness is profoundly important. It is the most sacred honor to work with patients and families while they are facing enormous physical, emotional, social, and spiritual challenges. Symptoms of depression are very common in patients and their families in these circumstances. The palliative APRN cares for people with symptoms of depression by being fully present, having done their own psychic and spiritual work; by understanding what to look for during an assessment; by offering treatment options based on sound scientific and nursing evidence; and educating patients and families. Disentangling the causes for the constellation of depression symptoms requires keen insights and a strong base of scientific knowledge. The palliative APRN uses the nursing process to assess patients, diagnose needs, plan interventions, implement care, and evaluate the effectiveness of that care according to professional, legal, and institutional scopes and standards of practice. Helping patients to cope emotionally maximizes their quality of life, the goal of palliative care. As we alleviate the suffering from depressive symptoms and disorders, we improve the quality of life for them, their families, their caregivers, and ourselves as APRNs and fellow human beings.

PALLIATIVE EMERGENCIES

Ann Quinn Syrett, Marcia J. Buckley, and Beth Carlson

KEY POINTS

- Hemorrhage is a frightening experience for both patient and family. The palliative advanced practice registered nurse (APRN) should screen for and discuss potential for hemorrhage in high-risk patients, reassuring them and their families that if a significant bleed occurs, a plan of action exists and needs to be promptly initiated.
- Spinal cord compression remains a presenting symptom for 20% of cancer patients. The palliative APRN should maintain vigilance for its probability and symptoms of potential onset. With the exception of steroids, the palliative APRN must consider the patient's overall prognosis before initiating therapy.
- Seizures are a medical emergency. Brain metastases are the most common etiology of seizures in palliative care and increases risk of sudden death. Education and planning is needed to urgently treat seizures when they occur and use antiepileptic medications to prevent recurrence.
- Superior vena cava syndrome is a true medical emergency if the airway becomes obstructed. Lung cancer accounts for more than 70% of all cases annually. Early diagnosis and management can lead to a longer time between recurrences.

at home surrounded by his family before having a catastrophic gastrointestinal hemorrhage. He was given opioid and anxiolytic medications to ensure he was comfortable when he died.

INTRODUCTION

This chapter discusses four palliative emergencies: hemorrhage, spinal cord compression, seizures, and superior vena cava syndrome. Each emergency has different ramifications for the patient because all of these conditions can result in terminal event. It should be noted that each symptom may be terrifying for family to witness, both as a symptom and as a dying event. Therefore, though rare, the palliative advanced practice registered nurse (APRN) must assess for their potential occurrence and then plan accordingly. With proactive planning, patients may still be managed in both the acute and community setting. However, there must always be a plan for planned sedation for a crisis situation or palliative sedation if the conditions become a terminal event. Palliative sedation is a special therapy that requires a particular expertise; discussion is beyond the scope of this chapter but it is covered in Chapter 57.

HEMORRHAGE

Hemorrhage as a cause of death is relatively rare. Akinola et al.¹ defined major hemorrhage as “that [which] is likely to rapidly result in a patients’ death due to a massive loss of circulating volume.” There is a consensus in the literature on the importance of identifying at-risk patients. The pathophysiology of a bleed is related to the underlying cause or type of cancer a patient has, thereby creating insight into who may be susceptible. Often patients may have a slight bleed before a major bleed, allowing time for planning. Table 51.1 depicts etiology and risk according to tumor type.^{1–4}

Treatment will depend on the underlying cause of the bleed, extent of the bleed, patient risk factors, and prognosis, as well as goals of care and where the patient is located. The focus here will be on patients who experience catastrophic bleeding as a result of malignancy. Consider two patients. The first is an older patient with dementia and a neck mass with occasional bleeding. This patient lives at a skilled facility with a do-not-transfer order in place. The plan for the potential bleed from the neck mass is for management with a small

CASE STUDY: HEMORRHAGE

Karl was a 63-year-old man with anaplastic thyroid cancer status post total thyroidectomy, total neck dissection, and extensive radiotherapy and chemotherapy. He continued to show progression of disease. Karl had a laryngeal ulceration and was followed by the palliative care team for symptom management. He had episodes of bleeding thought to be secondary to weakening of the arterial wall due to radiation. The palliative advanced practice registered nurse (APRN) met with Karl and his wife to discuss his significant risk for life-threatening bleeding. Karl expressed his wishes regarding no resuscitation and adamantly stated he wanted to die at home, not in the hospital. Karl was admitted to home hospice. Karl's opioid medications were liberalized for as-needed usage to be given both sublingually as well as subcutaneously in the case of a major bleed. The family was instructed on measures to take in the event of a terminal hemorrhage incorporating non-pharmacologic measures (such as using dark towels, bedding, a basin at the bedside, moist towelettes). Karl enjoyed 2 months

Table 51.1 RISK AND ETIOLOGY OF HEMORRHAGE IN ADVANCED MALIGNANCIES

TUMOR TYPE	AT RISK FOR	ETIOLOGY
Head and neck cancer	Carotid artery rupture	Direct invasion of arterial wall, damage to the wall due to radiation
Lung tumors	Catastrophic hemoptysis	Tumor erosion into a vessel wall. Irritation, tumor necrosis
Gastrointestinal (GI)	Hematemesis, melena	Erosion or ulceration through the bowel wall; esophageal varices; Coagulopathies due to liver involvement
Genitourinary (GU)	Hematuria, clots	Sloughing of the tumor mass
Gynecologic (GYN)	Vaginal bleeding	Direct invasion, tumor erosion
Hematologic	Petechiae, ecchymosis, sentinel bleed	Disruption in platelet function; disseminated intravascular coagulopathy (DIC); Idiopathic thrombocytopenia purpura (ITP)

From Akinola et al.¹; Gershman et al.²; Smith, Jackson³; and Abt et al.⁴

sandbag, liquid morphine, dark towels, and psychosocial support to the nursing assistant staff to key her at the facility. The second patient is an older adult in the hospital with a bleeding esophageal mass. The plan for the potential bleed from the neck mass is for management with packing and IV opioids. In both situations, preparation and support is given to staff, and medications are used to ensure comfort with imminent death related to hemorrhage.

INCIDENCE

In people with cancer, approximately 10% will experience at least one episode of bleeding, and 6–14% will experience a significant bleed during their cancer course. If hemorrhaging occurs suddenly, there is a short window of time in which to support the patient and try to control the bleed.^{1–4}

MANAGEMENT

Early discussion with patients at risk for hemorrhage can help guide overall treatment decisions as do an individual's prognosis, comorbidities, and quality of life.⁵ The palliative APRN has a role in clarifying goals of care and developing a realistic management plan, which are essential.^{5,6} Prevention of hemorrhage is the first goal. The APRN should review the patients' medications and herbal supplements to identify any that may potentiate bleeding (Table 51.2).⁷ A pharmacist can

be invaluable in identifying culpable medications, drug interactions, and the effects of complementary substances (such as herbs) in patients on multiple medications and noncontrolled substances. An assessment and discussion of the benefit-to-burden ratio of anticoagulants is critical.

If bleeding occurs via the nose, rectum, or vagina, careful packing of the orifice may help. Acetone, a hemostatic agent, may be used for vaginal packing; gauze soaked in tranexamic acid can be used with nasal packing. Nonadherent saline-soaked dressings provide a compression dressing and may slow or stop even arterial bleeding. Bleeding surface wounds can be treated with hemostatic dressings such as alginates and hemostatic agents such as epinephrine or tranexamic acid syrup.⁸ The palliative APRN should consult a wound ostomy certified nurse (WOCN) whenever possible. The WOCN can assess the patient in their setting of care to determine the best dressing regimen and necessary supplies. There may be a need for multiple dressing and supplies that are often expensive.⁹

Hematuria is initially often treated with a three-way Foley catheter to decompress the bladder and allow for saline irrigation. Intravesically administered agents have been tried but lack supportive studies for use.¹⁰ However, administering anti-fibrinolytic agents can be effective for refractory bleeding. Endovascular techniques are quite effective but not without risks. Cystoscopy with laser coagulation is a favored strategy, as is radiation therapy.^{9–11}

Severity of hemoptysis in the patient with lung cancer will determine initial management. The integrity of the airway, the patient's ability to manage secretions, and a review of realistic outcomes and goals of care will guide these steps. More aggressive therapies would include bronchial airway embolization, ablation, and tumor debulking. Surgical intervention is rarely an option for palliation.²

Acute onset of an upper gastrointestinal (GI) bleed carries a high mortality rate in people with advanced disease. Endoscopic interventions, saline gastric irrigation using a nasogastric tube (NGT), or initiation of argon plasma and laser therapies can be employed, but the success rate is variable. Transcutaneous arterial embolization may be effective in select situations, as is external beam radiotherapy with or without chemotherapy.^{10,12} The overall performance status of the patient, as well as prognosis,

Table 51.2 MEDICATIONS AND HERBAL SUPPLEMENTS THAT MAY POTENTIATE BLEEDING

Medications	Anticoagulants (warfarin, heparin), anti-inflammatory medication (steroids); Cox-2 inhibitors (celecoxib), non-steroidals (ibuprofen, naproxen, aspirin)
Herbal supplements	Arnica, turmeric celery, chamomile, clove, garlic, ginger, ginkgo biloba, ginseng, horse chestnut, licorice root, onion, and willow bark

From Pori.⁷

play key roles in determining if they are surgical candidate and what treatment will be employed.

There are systemic therapies available to treat hemorrhage. Phytonadione (vitamin K) is important in aiding the liver to produce multiple clotting factors (II, VII, XI, X). It can be given orally, subcutaneously, or intravenously (IV). In one study, oral phytonadione was shown to be as effective as IV administration in returning a patient's International Normalized Ratio (INR) to an acceptable level.¹³ Vasopressin has been shown to slow upper GI bleeds. Octreotide, a somatostatin analog, is also effective in the management of upper GI bleeding, usually given either subcutaneously twice to three times or as a continuous IV infusion.

The continued use of platelet and blood transfusions becomes an ethical discussion. On one hand, transfusions may help for a while, but their effect becomes shorter and shorter. On the other hand, without these transfusions, death will come sooner. Moreover, even with a change of focus to comfort, the majority of hospice programs will not admit patients still pursuing transfusions because they see them as curative therapies. Quality of life appraisal is highly personal and should be part of the ongoing goals of care discussions.^{14,15}

A terminal hemorrhage may cause death within minutes, often before any sedating medicine administered takes full effect. Depending on where a patient receives care (i.e., the hospital, residential settings, or long-term care settings) frontline caregivers and families need education and support. The palliative APRN should provide a description of what the potential bleeding will look like and how it will occur, with an emphasis on the low probability of survival from bleeding out. Nonetheless, the APRN should make a plan for patient comfort. In addition, the plan should include measures to support family and caregivers. Box 51.1 describes tips to prepare for hemorrhage.

MALIGNANT SPINAL CORD COMPRESSION

CASE STUDY: MALIGNANT SPINAL CORD COMPRESSION

Jean was a 68-year-old female with history of tobacco smoking, osteoarthritis, and gastric reflux. She was admitted to the hospital from her chiropractor's office presenting with progressive back pain and new onset of left leg weakness and bladder/bowel incontinence. Imaging revealed a large left lung mass and bony metastatic lesions to her ribs, thoracic and lumbar spine, and pelvis. Jane was started on high-dose steroids with improved neurological symptoms. Pathology results from an ileum bone biopsy revealed metastatic high-grade neuroendocrine tumor. Jean underwent palliative radiation to her lumbar-sacral spine and pelvis to improve motor function and reduce pain. Due to her poor functional status, she was not a candidate for chemo- or immunotherapy. She was admitted to inpatient hospice, receiving long-acting oxycodone and scheduled lorazepam to control her pain and anxiety. Jean enjoyed some quality time with family and friends before dying peacefully a few weeks later.

Box 51.1 PREPARATIONS FOR A TERMINAL HEMORRHAGE

1. Identify patients at risk for significant bleed.
2. Mitigate risk factors.
 - a. Eliminate nonsteroidal and anticoagulant medications.
 - b. Consider therapies if in accordance with patient wishes.
3. Develop a plan of action depending on whether the patient is home, in a skilled nursing facility, in a hospital.
4. Prepare family and caregivers for the possibility.
 - a. Take into consideration that herald (or initial) bleeding episodes often indicate a major bleed within 24–48 hours.
5. Have appropriate medications available. If patient is at home, consider prefilled syringes near the bedside. Instruct and coach family regarding use of
 - a. Opioids
 - b. Anxiolytics
6. Prepare the bedside.
 - a. Encourage use of darker bed linens.
 - b. Place dark towels particularly under potential site of bleed and have extras nearby.
 - c. Have a small sandbag to apply pressure, as appropriate.
 - d. Have supplies such as a basin, gloves, wash clothes.
 - e. Have suction available if appropriate for patient situation.

INCIDENCE

Malignant spinal cord compression (MSCC) is a fairly common sequelae of malignancy and is considered a medical emergency. Approximately 20% of all patients diagnosed with a malignancy present with a MSCC as their presenting symptom.^{16–19} As many as 85–90% are due to metastatic disease to vertebral bones. Often, as the tumor grows, it surrounds the thecal sac, obstructing the venous plexus. Vasogenic edema ensues, and, if left unchecked, the patient will sustain a spinal infarction.¹⁷ Prompt diagnosis of MSCC can have profound effects on outcomes for the patient. Outcomes for people who develop a spinal cord compression for reasons other than cancer (infections, rheumatoid arthritis, neurological diseases/insults including primary astrocytomas/ependymomas) will often have better outcomes.^{17,20}

The majority of MSCCs are due to metastases to the vertebral bone, with the spine being the third most common site. The neurological deficits that occur can be permanent due to direct compression of the cord or cauda equina, interruption of the vascular supply to the cord, or actual fracture of the vertebra. Less common etiologies of MSCC would be direct extension of the tumor through the intervertebral foramina or via leptomeningeal spread.^{17,21,22}

SIGNS AND SYMPTOMS

Recognition of the signs and symptoms of MSCC is crucial to avoid complete and irreversible paralysis. A patient's overall

Table 51.3 SIGNS AND SYMPTOMS OF MALIGNANT SPINAL CORD COMPRESSION

Back pain (localized, mechanical, radicular)	80–95% of patients present with back pain Often worse at night Often felt when coughing or sneezing Described as aching and constant
Motor deficits	35–75% of patients present with motor deficits Weakness of lower extremities Cauda equina syndrome: Lower extremity weakness in a patchy distribution
Sensory deficits	Multiple dermatomes can be involved Urinary retention Overflow incontinence Bowel incontinence Gait abnormalities

From Laufer et al.¹⁷; and Wänman et al.¹⁸

functional status, which correlates to survival, can be diminished greatly by MSCC. Twenty-three percent of people with a MSCC do not have any history of cancer. Back pain is common and can precede other symptoms by several weeks, causing an important delay in the diagnosis and treatment of MSCC.^{17,20}

These symptoms may be missed in older adults, particularly those individuals who live in skilled facilities and already have musculoskeletal pain and bowel and bladder conditions.

If worsening back pain is present and varies with position changes, MSCC should be presumed until ruled out. MSCC should be considered in the differential diagnosis in patients presenting with thoracic pain, since this portion of the spine rarely produces pain from other conditions. Pain that only occurs with movement can be an important indicator of spinal instability, which may need rapid surgical intervention. Weakness with ambulation, the inability to walk, and increased deep tendon reflexes are the most significant predictors of MSCC.¹⁶ Bladder and bowel dysfunction are later signs of cord compression, and history should include questions of sexual function. Table 51.3 lists presenting signs and symptoms.^{17,18}

DIAGNOSTICS

Magnetic resonance imaging (MRI) of the entire spine, with and without contrast, remains the gold standard of diagnosis. The palliative APRN should first order this imaging immediately when MSCC is suspected. MRI of entire spine has replaced all radiologic modalities as the diagnostic of choice and needs to be done as soon as a MSCC is suspected.^{16,17,19,23} It produces the most accurate anatomical image of intraforaminal and leptomeningeal disease and shows clear definition of the adjacent bone and soft tissue structures. Plain spinal films are not useful in patients with suspected MSCC.

MANAGEMENT

When a MSCC is identified, prompt treatment is essential for preservation or restoration of a person's function. It also promotes quality of life, most notably relief of pain. The APRN

must consider a patient's predicted prognosis along with their values and goals prior to any treatment decision. Standard treatments for managing MSCC include corticosteroids, radiotherapy, and/or decompressive surgery. Even prior to MSCC being diagnosed, many providers initiate therapy with the use of a glucocorticosteroid. Dexamethasone decreases vasogenic edema by inhibiting prostaglandin E_2 , along with inhibiting vascular endothelial growth factor.^{24,25} This decrease in edema and inflammation reduces pain. There must be consideration of the benefits of steroids versus the burden of possible distressing GI and mental side effects from moderate to high-dose steroids including propensity to infection.²⁶

Radiation therapy (XRT), used as a single-modality treatment, has been shown to improve ambulation, improve neurologic status, and decrease or even eliminate pain, thereby improving quality of life and sometimes lengthening survival. In a study of 688 patients were randomly assigned to receive either a single dose of 8 Gy or a 5-day course totaling 20 Gy with evaluation of post radiation ambulatory status. There were no statistically significant differences between the two groups either in function or survival.²⁷ A study looking at pain management as well as neurological improvement found short-course (1, 5, or 10 days) XRT had significant improvement in pain scores and supported the fact that the patient benefits from the shortest course possible based on extent of tumor.²⁸

While XRT remains the mainstay of treatment, Le et al.²² recognized that, for some individuals, surgical approaches can actually be more effective. It is the treatment of choice for patients with either high-grade MSCC or those with an unstable spine. It is often combined with either XRT or stereotactic radiation therapy (SRS) based on whether the tumor is radiosensitive, the degree of cord compression, and overall stability of the spine. Pain control is not achieved with an unstable spine or with bracing. The 2017 update of Bone Metastases Guidelines concluded that surgery, radionuclides, bisphosphonates, and kyphoplasty/vertebroplasty do not replace the need for external beam radiation therapy and these therapies can be done in tandem.²⁹

SUPPORTIVE THERAPIES

In a select group of patients who have MSCC, there appears to be a role for physical medicine and rehabilitation.^{30,31} Physical therapy consultation may be warranted to optimize function and safety for both the patient and their care providers. If a patient with a short prognosis develops an MSCC, the palliative APRN can order a trial of steroids with a course XRT to alleviate pain, optimize quality of life, and try to preserve some modest function and dignity.

SEIZURES

CASE STUDY: SEIZURES

Ms. K was a 74-year-old woman brought to the emergency department (ED) by ambulance after family witnessed a sustained tonic-clonic seizure at home, relieved by 10 mg intramuscular

midazolam. Past medical history was significant for metastatic breast cancer; her status was post mastectomy, chemo, and radiation. Labs revealed liver dysfunction and a repeat positron emission tomography (PET) scan revealed disease widely metastatic to liver, spine, and brain. A head MRI revealed a parieto-occipital lesion. Ms. K experienced another seizure while transferring to the ICU and received 4 mg of IV lorazepam for seizure cessation. Oral levetiracetam 750 mg twice a day and oral dexamethasone 6 mg twice a day were initiated to decrease cerebral edema and risk of seizure. Ms. K improved mentally and physically. An electroencephalogram (EEG) revealed no seizure activity. The palliative APRN met with Ms. K and her family to review her understanding of options, determine her goals for care, and provide support. Ms. K chose to prioritize her comfort with the goal of home hospice. The patient and family were educated about the risk of seizure recurrence. Ms. K was prescribed an antiepileptic medication, a steroid, and an as-needed benzodiazepines in the event of another seizure. She was surrounded by her loved ones when she peacefully died at home.

Epilepsy is a disorder characterized by recurrent unprovoked seizures and categorized by its related etiology of onset as focal, generalized, or unknown.³² Experiencing a seizure is considered a medical emergency.³³ Basic knowledge of seizure presentation, predisposing factors, and anticipatory management is crucial to expediting resolution or relief of the symptoms and preventing recurrences.

INCIDENCE

Approximately 1.2% of the US population or 3.4 million have been affected by epileptic episodes.³⁴ Seizure prevalence is highest in those younger than 1 year and older than 65 years. Nearly 50% of seizures occur in persons without a prior history of epilepsy.³⁵ After two initial unprovoked seizures, approximately 30–50% of patients will experience a seizure recurrence and become epileptic.³⁶

The most common cause of seizures in the older adult (>65 years) is stroke. The risk of epilepsy due to unprovoked seizure is at its highest more than 7 days after the initial stroke.³⁷ It is estimated that 60% of patients with brain metastases will experience seizure depending on the primary tumor.³⁸ The actual incidence of seizures in dying patients is unknown.³⁹ Many studies establish that patients with brain tumors are at risk for seizure, and this is associated with a higher risk of sudden death, thus highlighting the goal of proactively working to minimize seizures and their negative impact on quality of life.^{40–44}

PATHOPHYSIOLOGY

The International League Against Epilepsy updated the operational classification of seizure types in 2017. Seizures are divided into focal, generalized, or unknown onset, with subcategories of motor, nonmotor, with retained or impaired awareness for focal seizures (Table 51.4).³² The expanded terminology for focal or generalized onset allows greater

Table 51.4 INTERNATIONAL LEAGUE AGAINST EPILEPSY (ILAE) CLASSIFICATION OF SEIZURE TYPES, EXPANDED VERSION

Focal onset <i>Aware vs. impaired awareness</i>	Motor onset: Nonmotor onset:	Automatisms, atonic, clonic, epileptic spasms, hyperkinetic, myoclonic, tonic Autonomic, behavior arrest, cognitive, emotional, sensory
Generalized onset	Motor: Nonmotor (absence)	Tonic-clonic, clonic, tonic, myoclonic, myoclonic-tonic-clonic, myoclonic-atonic, atonic, epileptic spasms Typical, atypical, myoclonic, eyelid myoclonia
Unknown onset	Motor Nonmotor Unclassified	Tonic-clonic, epileptic spasms Behavior arrest

From Fisher et al.³²

transparency in naming seizure types.³² Status epilepticus focal seizures occur with or without loss of consciousness. Generalized status epilepticus (tonic-clonic, absence, myoclonic) are always associated with loss of consciousness, and these have a greater incidence of associated mortality. When a seizure involves loss of consciousness, there will be a postictal state that may include somnolence, confusion, and/or headache; it may last several hours.³³

CLINICAL FEATURES

Factors influencing the risk of seizure recurrence include a history of long seizure duration and failure to respond to other medications.⁴⁵ Table 51.5 outlines predisposing factors for seizures. Mortality from these underlying predisposing factors resulting in acute symptomatic status epilepticus is six times greater compared to chronic epilepsy. Death may occur from metabolic stress related to muscular convulsions, rhabdomyolysis, lactic acidosis, aspiration pneumonitis, neurogenic pulmonary edema, and respiratory failure.⁴⁶

DIAGNOSIS

Status epilepticus of any type is determined by a neurological examination and involves repeated seizures lasting at least 5 minutes without a recovery period of greater than 30 minutes.³⁵ Therefore, witnesses' accounts of activity prior to a seizure and description of seizure activity, including any incontinence or loss of consciousness, are crucial in determining the seizure type. Suspect a structural cause if aura or heightened sensory experience occurs before the seizure. Versive eye movements (deviation to one side) are associated with focal seizures. An electroencephalogram (EEG) is helpful in determining status epilepticus in an unresponsive patient. Adults present with an abnormal EEG finding with first unprovoked seizure about 51% of the time.³⁶ A

Table 51.5 PREDISPOSING FACTORS FOR SEIZURES

FACTOR	EXAMPLES
Structural	Brain tumor, metastasis, stroke, head trauma, subarachnoid hemorrhage
Degenerative	Cerebral palsy in young patients, Alzheimer's disease in older patients
Systemic	Cerebral anoxia/hypoxia or infections (such as encephalitis, meningitis, abscess), fever, sleep deprivation
Metabolic	Hepatic encephalopathy, uremia, electrolyte abnormalities, such as sodium, calcium, magnesium, phosphorus, or glucose metabolism
Drug treatments	Use of seizure threshold-lowering drugs, such as antibiotics, antiarrhythmics, chemotherapy, opioids, or psychotropics
Withdrawal	Rapid withdrawal from alcohol intoxication or antiseizure medication

From Lee et al.³⁴; Khan et al.⁴⁷; and Buckley MJ, Syrett A, Palliative emergencies. In: Dahlin C, Coyne P, Ferrell B, eds. *Advance Practice Palliative Nursing*. Oxford: Oxford Unity Press, 2016: 362.

computed tomography (CT) head scan without IV contrast is appropriate in emergent situations to evaluate new-onset seizures in the setting of trauma. MRI is the study of choice for determining structural lesions that are triggering seizures and is indicated for patients considering palliative surgery and/or radiation.³⁴

MANAGEMENT

Primary management when a seizure occurs includes the ABCs: patent airway, effective breathing, and adequate circulation. The workup involves a thorough history from the patient and witnesses to the seizure, a full neurological exam and individualized neuroimaging, and lab studies as appropriate to the patient's goals of care.³⁵ Table 51.6 summarizes suggested post-seizure laboratory testing and the rationale.

The American Academy of Neurology guidelines suggest prudent consideration of testing on an individual basis because there has not been strong evidence to support or refute the recommendations.³⁶ When seizure etiology is unknown, glucose and thiamine should be given together immediately to rule out treatable causes.³³ Knowledge of seizure type is helpful in determining if neuroimaging is warranted.³⁴

Treatment of seizures should be initiated after 5 minutes of sustained seizure activity because it is unlikely to stop spontaneously.³⁵ In a hospice situation, 5 minutes can seem like 5 hours to a loved one, and every effort should be made to treat the seizure, with the goal of comfort. If the patient has an IV in place, this route is preferable, although this is not always possible in palliative/hospice settings. Antiseizure medications may be administered subcutaneously, sublingually, or rectally. Table 51.7 reviews commonly used antiseizure medications used to stop status epilepticus.^{33,35,48}

Table 51.6 SUGGESTED POST-SEIZURE LAB TESTING

TEST	EVALUATION
CBC	Leukocytosis, thrombocytopenia, plethora
Blood chemistries	Ammonia, urea, sodium, calcium, magnesium, phosphorus, or glucose abnormalities
TSH	Low TSH indicates hyperthyroidism-associated seizures
Urinalysis	Increased glucose, infection
C-reactive protein	Inflammatory marker, increased after tonic-clonic seizures
Coagulation studies	Increased risk of intracranial bleeding
Vitamin B ₁₂ , folate	Vitamin B ₁₂ deficiency, folate deficiency
Prolactin	Elevated levels seen after seizure
Blood cultures	Infectious cause
Blood gas	Hypoxia and metabolic imbalances
Toxicology	Overdose of tricyclic antidepressants, cocaine
Pregnancy test	Possible eclampsia

From Buckley MJ, Syrett A, Palliative emergencies. In: Dahlin C, Coyne P, Ferrell B, eds. *Advance Practice Palliative Nursing*. Oxford: Oxford Unity Press, 2016: 363.

In the palliative setting, it may be desirable to use lower doses of benzodiazepines with frequent repeat doses available as needed when the goal is to avoid long periods of unconsciousness.³⁹ If in the acute setting, regardless of the response to these first-line benzodiazepines, initiate a conventional antiepileptic drug (AED). The preferred non-sedating, fast-acting antiepileptic with minimal drug interactions is levetiracetam.^{39,49} Third-line treatment for status epilepticus includes valproate and general anesthesia (phenobarbital, propofol, ketamine) inducing chemical coma, with the goal to alleviate suffering while accepting the risk of respiratory failure.^{33,45,46} Clinical pharmacists may be helpful to evaluate medication regimens to optimize seizure control and improve quality of life.⁵⁰

The decision to initiate long-term empiric treatment with antiseizure medication is individualized based on the risk of seizure recurrence, the consequences of seizure recurrence, and potential interactions.^{36,37} The European Stroke Organisation has issued guidelines based on an assessment and evaluation approach due to lack of reliable evidence. There is weak support to recommend routine prophylaxis with antiseizure medications after one post-stroke unprovoked seizure.³⁷ A study of 225 people found evidence that oral cannabidiol can decrease seizure incidence in Lennox-Gastaut syndrome.⁵¹

After two or more unprovoked seizures on separate days, empiric monotherapy with a long-term antiseizure agent should be initiated to prevent recurrences. In cases of seizures

Table 51.7 COMMONLY USED ANTIEPILEPTIC MEDICATIONS (AEDS) FOR STATUS EPILEPTICUS (SE) CESSATION

First line, early SE:	Common dosing	
Lorazepam	0.1 mg/kg bolus IV (at least 4 mg)	Benzodiazepines are first-line treatment for seizure cessation
Midazolam	10 mg IM or buccal	Repeat bolus every 5 minutes
Diazepam	10 mg bolus, rectal	Sedation; SE is considered refractory if starting midazolam continuous infusion
Second line, established SE:		
Levetiracetam	250–4,000 mg/d; 30 mg/kg IV bolus over 10 min	Nonsedating, low side-effect profile
Phenytoin/fosphenytoin	18–20 mg/kg bolus/4–6 mg/kg/d	Administer fosphenytoin at rate of 50 mg/min
Valproic acid	500–2,500 mg/d; 15–45 mg/kg bolus 6–10 mg/kg/min	Nonsedating, mild hypotension
Phenobarbital	30–180 mg/d; bolus 10 mg/kg, infuse max 100 mg/min	Alcohol withdrawal; sedating, respiratory depression, hypotension
Third line, refractory SE:		
Propofol	Goal <48 hours and not >5 mg/kg/h	Associated with higher mortality and morbidity.
Ketamine	1–3 mg/kg IV bolus; 6–10 mg/kg/h	Ketamine has less respiratory depression;
Pentobarbital/thiopental	5–15 mg/kg IV bolus then continuous infusion to maintain burst suppression on electroencephalogram (EEG)	pentobarbital has the most and is reserved for severe cases of refractory SE

From Douglas, Aminoff³³; Grönheit et al.³⁹; Alkhachroum et al.⁴⁶; Daly, Lugassy⁴⁸; and Trinka et al.⁵²

caused by a brain lesion, consider increasing or initiating steroids in addition to starting an anticonvulsant. Patients undergoing cerebral radiation should receive steroids (dexamethasone 4 mg to maximum 16 mg daily) to prevent seizures associated with cerebral edema.⁵³ If undergoing surgical resection of the brain tumor, consider weaning off antiseizure medications after surgery. If palliative chemotherapy is an option, preference should be given to antiseizure medications that do not induce cytochrome P450 activity; these include levetiracetam, gabapentin, lamotrigine, and pregabalin.^{36,51} The benefits of prophylaxis in primary brain tumor patients should be considered on an individual basis, taking into consideration the known risk of psychomotor slowing and general cognitive decline.^{43,54} Compared to older generation AEDs (phenytoin, carbamazepine, and valproic acid), the newer generation AEDs (levetiracetam) have fewer adverse cognitive side effects.^{36,53,55}

The palliative APRN has a large role in planning for seizure management in the hospice setting. First, the APRN needs to assess the cause of seizures and the use of medications. If the cause of the seizure is reversible, then long-term anticonvulsant treatment is not warranted. Although anticonvulsants are often initiated on diagnosis of a brain tumor, they have not been shown to prevent seizures in patients with no seizure history.⁵³ In addition, current guidelines do not recommend the use of anticonvulsants prophylactically in stroke patients. Therefore, it is recommended to consider stopping prophylactic dosing of antiseizure medications in patients with no seizure history.⁵³ If medications are continued, the APRN should consider the appropriate medication, with the preference being to avoid enzyme-inducing medications or those that require frequent blood draws to monitor medication levels.³⁹

Experiencing and witnessing a seizure can be terrifying for both patient and family, necessitating proactive planning to avoid recurrence. In the hospice and home setting, benzodiazepines should be available for suppression of seizures if

they occur. These should be administered sublingually, subcutaneously, or via a gastronomy tube. The rectal route may cause more distress for patients and families in the event of terminal seizures. Family instruction should include avoiding putting anything in the mouth and protecting the seizing person from falls or injury. Families need reassurance that if seizures become refractory, palliative sedation is warranted for patients to allow for a peaceful death.

SUPERIOR VENA CAVA SYNDROME

CASE STUDY: SUPERIOR VENA CAVA SYNDROME

Mr. P was a 62-year-old male tobacco smoker with history of diabetes and hypertension. He presented with progressive difficulty swallowing for weeks and acute shortness of breath with stridor. On exam, Mr. P had a short neck and edematous upper extremities. He was tachycardic and hypoxic. Chest CT revealed a right-sided mediastinal mass encroaching on his laryngopharynx. Thoracic surgery emergently placed a stent to open his airway and obtained a tissue biopsy of the mass. Mr. P's respiratory status stabilized immediately, and his swallowing improved. Pathology results revealed non-small cell cancer. He underwent surgical resection followed by radiation to the mass. Mr. P required hospitalization a few months later with aspiration pneumonia requiring ICU-level care. Imaging revealed progression of his cancer and recurrent superior vena cava syndrome (SVCS). The palliative APRN met with Mr. P and his family to discuss his wishes regarding restenting, intubation, and resuscitation. Mr. P opted to forgo further procedures and transitioned to a comfort-measures-only plan of care. As his breathing became more labored, Mr. P received opioid and anxiolytic medications to ensure his comfort until his peaceful death.

INCIDENCE

Superior vena cava syndrome (SVCS) is a group of symptoms resulting from an obstruction of blood flow from the upper body to the right atrium. It is considered an emergency in the presence of neurological symptoms or respiratory distress.⁵⁶ This relatively rare syndrome was first described in 1757, by Scottish surgeon William Hunter, in a patient suffering from syphilis aortitis. In most cases, it is caused by a carcinoma of the bronchus or metastases to paratracheal or paracardinal lymph nodes compressing on the SVC.⁵⁶ The common use of implantable intravenous devices such as central line catheters and pacemakers has increased the prevalence of thrombosis-related SVCS. In rare cases, SVCS develops from infections, such as tuberculosis or histoplasmosis, which increase pleural thickening and cause significant systemic-to-pleural venous shunting.⁵⁷

In the United States, approximately 15,000 cases of SVCS occur annually. Lung cancer is responsible for approximately 72% of SVCS cases, with an estimated 50% related to non-small cell lung cancer (NSCLC) and 22% caused by small cell lung cancer (SCLC). Median survival after cancer-related SVCS symptom presentation is about 6 months, although many patients undergoing treatment survive past 2 years. An estimated 35% of SVCS cases are caused by thrombosis or nonmalignant causes.⁵⁸

PATHOPHYSIOLOGY

The SVC is a thin-walled blood vessel. The brachiocephalic veins feed into the SVC, which terminates in the right atrium. An extrinsic chest mass generally to the right of midline (i.e., enlarged lymph nodes, lymphoma, thymoma, inflammatory process, or aortic aneurysm) or internal thrombus compressing on the SVC can easily cause obstruction of blood flow because the chest wall and surrounding organs leave little movement for compensation. Increased venous pressure caused by the obstruction leads to increased flow through collateral blood vessels.

CLINICAL FEATURES

SVCS classically presents as progressive swelling of the head and neck. Symptoms associated with increased venous pressure of the upper body usually develop over a period of 2 weeks and include edema of the face, neck, and arms. Symptoms are severe when the obstruction occurs rapidly or below the level of the azygos vein.⁵⁷ A blanching rash represents the excess development and dilation of compensatory subcutaneous vessels of neck and anterior chest. SVCS can also manifest with cerebral edema, causing headaches, dizziness, and syncope, or laryngopharynx-related compression, causing dysphagia, dyspnea, hoarseness, and cough.^{58–59}

DIAGNOSIS

Chest CT imaging with contrast is the most useful study to detect an impending SVC compression, such as aortic

aneurysm or thrombosis, before symptoms present. MRI can be used when contrast medium is contraindicated. A tissue biopsy is recommended to definitely diagnose malignancy.⁵⁴ In approximately 65% of cases, SVCS is the clinical presentation with malignancy of the lung or mediastinum.⁵⁸

MANAGEMENT STRATEGIES

The American College of Chest Physicians and the National Comprehensive Cancer Network have made general recommendations supporting radiation and stent placement for symptomatic SVC obstruction due to NSCLC.⁶⁰ If thrombus is related to an indwelling catheter, anticoagulation is the primary treatment. Removal of the catheter and balloon dilation or stenting should be considered if fibrosis remains and the procedure is deemed clinically appropriate.⁵⁸ Management of SVCS related to malignancy is guided by the severity of symptoms and anticipated response to the cancer. The prognosis for SVCS correlates with the underlying diagnosis, with better outcomes for hematological malignancies versus solid tumors.⁵⁹ In all cases, the goal of treatment should be to alleviate the bothersome symptoms of the obstruction.

In cases of SCLC and lymphoma, treatment with radiation or chemotherapy alone have been found to be equally effective in relieving symptoms of SVCS. Radiation is best for well-defined tumors that are less chemo-sensitive, such as NSCLC. SVCS symptoms usually show improvement within 72 hours of radiation and resolve within 1–2 weeks after chemotherapy or radiation therapy.⁵⁶

Placement of a stent relieves symptoms within hours and is optimal for recurrent SVCS related to malignancy when the goal is to avoid the toxic effects of repeating chemotherapy or radiation.⁶¹ While rare, complications with stenting the SVC are related to stent misplacement.⁵⁸ Once a stent is placed, consideration should be given to anticoagulation and implications for management of SVCS recurrence, which occurs in an estimated 20–50% of patients. Researchers have used oral aspirin as antiplatelet preventative maintenance therapy after 3–4 days of complete heparinization after stent placement.⁵⁹

The palliative APRN should be vigilant for SVCS in patients with implanted devices, those with malignant conditions, or those with predisposing risks for cancer (smoking, asbestos exposure). Management is focused on determining and treating the root cause of SVCS. Palliative therapy is focused on addressing symptoms and may include elevating the head, diuretics, steroids, stenting, or surgical removal of the offending mass or intravascular device.

SUMMARY

The National Consensus Project for Quality Palliative Care *Clinical Practice Guidelines* Domain 2: Physical Aspects of Care focuses on expert assessment and management of physical aspects of care and screening for and relieving distressing physical symptoms, which includes palliative emergencies.⁶²

The palliative APRN must have knowledge about disease trajectories with the potential for hemorrhage, MSCC, seizures, and SVCS. Caring for patients with these diagnoses, the APRN must understand the assessment, physical examination, and diagnostic procedures that lead to their diagnosis and create a care plan that includes anticipatory management which may depend on the care setting.

When these palliative emergencies do occur, the palliative APRN must collaborate with the palliative interdisciplinary team and other specialties to support the patient and family. Of course, educating the patient, family, and other healthcare staff is critical to understanding the necessity for a proactive rapid response. In cases where emergently distressing symptoms are intractable, the care plan should include medications to relieve suffering and ensure a peaceful, dignified death, including palliative sedation.

CHALLENGING SYMPTOMS

PRURITUS, HICCUPS, DRY MOUTH, FEVERS, AND SLEEP DISORDERS

Barton T. Bobb and Devon S. Wojcikewych

KEY POINTS

- The palliative advanced practice registered nurse (APRN) must have a working knowledge of the symptoms of pruritus, hiccups, dry mouth, fever, and sleep disorders so they can be effectively managed.
- Pruritus can be challenging to treat; determining the cause when possible can help tailor treatment.
- Hiccups are a common symptom; though seemingly benign, they can affect quality of life.
- Dry mouth is a common symptom among palliative care patients, especially cancer patients.
- Fever may require scheduled antipyretic treatment at end of life if it is believed to be distressing.
- Sleep disorders can also cause distress. The most common one, primary insomnia, has a variety of potential treatment options that may require titration/rotation.

CASE STUDY: CHALLENGING SYMPTOMS

Ms. B was a 60-year-old woman with advanced cirrhosis and hepatocellular carcinoma with associated pain. She had been followed by a palliative advanced practice registered nurse (APRN) in a palliative care clinic. The short-acting opioid that best managed her pain after multiple attempts at opioid rotation, immediate-release morphine, unfortunately caused some pruritus. The palliative APRN prescribed oral hydroxyzine 25 mg every 6 hours, as needed.

Ms. B also complained of ongoing dry mouth as well as difficulty sleeping at night. She used sugar-free chewing gum and was prescribed 5 mg oral pilocarpine three times a day to stimulate saliva production. Saliva substitutes were prescribed as well. A variety of sleep hygiene measures were suggested to help her sleep. Oral mirtazapine 7.5 mg nightly was prescribed. With sleep medications, pain medications, changes in sleep hygiene, and improved pain control, Ms. B reported more consecutive hours of uninterrupted sleep. Cholestyramine was added for worsening pruritus that was likely caused by cholestasis.

After several months, Ms. B's disease progressed, and she was actively dying at home with hospice. Because she was running high fevers that appeared to be distressing to her and her family,

the attending hospice APRN ordered scheduled acetaminophen rectal suppositories every 6 hours. Her oral pain medications were switched to home IV fentanyl patient-controlled analgesia (PCA). The palliative APRN made a home visit to check on her and her family. She appeared to be very comfortable. Her family expressed appreciation for all the care the APRN had provided for her and them over the past several months. Ms. B died peacefully 3 days later.

PRURITUS

The word *pruritus* comes from the Latin *prurire*, meaning “to itch.” Pruritus causes a desire to scratch. This scratch reflex is meant to be a protective mechanism, but when this sensation becomes chronic, there can be significant emotional and physical consequences.^{1–5} The impact of itch on quality of life, sleep, anxiety, and depression can be very distressing, and this symptom must not be overlooked.

The physiology of the itch sensation has been increasingly studied over recent years but is proving to be a diverse and complex symptom that is still not completely understood. The mechanism of itch was initially thought to be a subset of the pain transmission pathway but is now thought to be significantly more complicated than this and may differ depending on the underlying cause.^{6–12} Chronic pruritus can also lead to neural sensitization, like that found in chronic pain.¹³ There are increasingly identified neuropeptide targets associated with itch, and, as the understanding of these mechanisms improve, so do the potential targets for its treatment.^{11–14}

ETIOLOGY

Determining the trigger for the itch reflex can be challenging and cannot always be identified. Often patients may have overlapping or multiple causes of pruritus as well. When possible, however, determining the cause can help direct the choice of treatment, especially as different molecular pathways of itch for specific disease states are further identified. As with any assessment, a detailed history and physical exam should be performed because teasing out any primary dermatologic conditions, systemic disease, or neurologic or psychiatric/psychosomatic diseases may help determine referral and treatment options.^{15–18}

Primary Dermatologic Causes

Pruritus is the most commonly reported symptom in dermatologic disorders as a whole.¹⁹ Often itch-producing stimuli are short-lived or self-limiting and usually can be treated effectively by a primary care provider or other first-line providers. Causes of primary dermatologic conditions can range from dry skin and insect bites to dermatologic malignancies. Atopic dermatitis and prurigo nodularis are known to be especially associated with pruritus.⁴ Depending on the severity of the symptoms, the advanced practice registered nurse (APRN) may need to refer to a dermatology specialist.

Systemic Diseases

Pruritus can manifest in many systemic diseases (Table 52.1). A large percentage of patients with cholestatic liver disease report pruritus. Bile salt accumulation was previously thought to be the underlying cause, but more recent studies have increased knowledge of the mechanism of itch in cholestatic liver disease. There are now thought to be multiple potential targets to interrupt the itch pathways in cholestatic liver disease, including endogenous opioid receptors.^{8,17,20–22}

Chronic renal insufficiency is another systemic disease with a high symptom burden from pruritus, especially in patients on chronic hemodialysis.^{19,23–25} As in cholestatic liver disease, activation of endogenous opioid receptors are thought to be important mediators of itch in this patient population.^{23–25} Metabolic derangements in renal disease, such as hypercalcemia, hyperphosphatemia, and hypermagnesemia, seem to contribute independently to pruritus as well.¹⁷ Endocrinopathies such as hyperparathyroidism, both hypothyroidism and hyperthyroidism, and diabetes are all associated with itching as well.^{17,19,26,27}

Multiple hematopoietic disorders, ranging from the more benign iron deficiency anemia and polycythemia vera to malignancies such as lymphoma and multiple myeloma, can cause itching or chronic pruritus. T-cell lymphomas, such as Sézary syndrome, are characterized by a high incidence of pruritus and commonly require the assistance of a palliative provider for more advanced interventions.^{17,28,29}

Multiple infectious diseases can also cause local and systemic pruritus, including hepatitis and herpetic infections. Chronic pruritus is recognized in HIV-positive patients; it appears to be independent of primary dermatologic sources of itch.^{5,30}

Medications

Any medication can cause itching from an allergic reaction or sensitivity. Certain medications or illicit drugs commonly known to cause itching include opiates, amphetamines, cocaine, heparin, niacin, aspirin, certain antibiotics, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors.^{19,31}

Neurologic

Patients with stroke or brain tumor (either primary or due to metastatic disease) can have a centrally mediated itch. There are also peripheral neuropathic itch syndromes, such as postherpetic itch and notalgia paresthetica.^{15,32}

Psychiatric

Pruritus is reported to be common in psychiatric conditions, such as psychosis, delirium, and delusional parasitosis, but epidemiologic data on the actual prevalence are lacking.^{19,33,34} In addition, anxiety and depression are thought to worsen the patient's ability to cope with pruritus of other etiologies.³⁴ The palliative APRN may need to collaborate with psychiatric colleagues to manage these causes for effective treatment.

TREATMENT

Treatment of systemic pruritus is often difficult, likely in part due to its complex and overlapping signaling pathways. Balancing the side effects against the benefit of a treatment is always at the core of the palliative APRN's decision to administer or prescribe therapeutic agents. If the pruritus is from a disease process or a medication that cannot be removed, then treatment modalities range from topical therapies and

Table 52.1 SYSTEMIC CAUSES OF PRURITUS

	ACE inhibitors	

systemic medications to invasive interventions in which the symptom burden should outweigh the risk of treatment. The evidence basis for treatment of pruritus is varied based on cause of pruritus and may be difficult to generalize. The palliative APRN should be prepared for a stepwise trial approach to determine what interventions are effective at relieving pruritus.

Initial nonpharmacologic interventions include patient and family education on methods to decrease itching, such as wearing lightweight clothing and lowering the room temperature and keeping the skin moisturized. The palliative APRN should also continue to monitor the patient's skin for excoriation and secondary infections from scratching as well.^{1,15}

Topical Treatments

Topical barrier creams are often recommended for most causes of itch (Box 52.1). Topical treatments are less likely to be helpful when pruritus is due to a systemic cause, however.^{15,19} Prescription topical therapies include steroids, calcineurin inhibitors such as pimecrolimus and tacrolimus, and crisaborole, a phosphodiesterase-4 inhibitor.¹²

Systemic Treatments

Systemic therapies are varied (Table 52.2), and, when possible, systemic therapy should be directed toward the source of pruritus. Understanding the multiple itch-inducing mechanisms, often different for varying diseases, has led to further targets for symptom management of pruritus in these systemic diseases. Some of the newer targets for pruritus treatment include opioid receptors, tropomyosin receptor kinase A antagonists, voltage-gated sodium channel (Nav 1.7) antagonists, phosphodiesterase-4 inhibitors, interleukin antagonists, janus kinase inhibitors, histamine-4 receptor antagonists, ileal bile acid transporter (IBAT) inhibitors, aryl hydrocarbon receptor (AhR) agonists, and monoclonal Anti-IgE antibodies. There has been an extensive increase in research into this troubling symptom in the past decade, but further understanding is still needed.^{11–13,15,35}

Antihistamines are generally trialed for all types of pruritus at some point due to a relatively benign side-effect profile but are particularly helpful for pruritus that is known to be histamine-mediated, such as that seen in allergy-mediated

Table 52.2 SYSTEMIC TREATMENTS OF PRURITUS

skin diseases. A non-histaminergic mechanism is more commonly seen in chronic pruritus, however.³⁶ Side effects of antihistamines commonly include drowsiness and dry mouth; the former can be helpful if the patient is experiencing pruritus at night affecting sleep but can limit use if causing sedation during the day.³⁵ The second-generation antihistamines may be less sedating.

Opiate rotation should be considered for patients experiencing pruritus associated with opiate use. If this is not possible, the use of an opioid receptor antagonist such as naloxone or naltrexone may be helpful. Intravenous naloxone is not a realistic treatment option for outpatient, home management or long-term use because its half-life is too short, but it can be given by intravenous infusion for acute symptoms.^{13,37} Opiate antagonism can produce side effects similar to opiate withdrawal, and patients should be warned of this prior to use; opiates may not be appropriate for palliative patients on chronic opiate therapy for pain control.³⁶ The increasing understanding of μ - and κ -opioid receptors in the pathologic itch of cholestatic liver disease and chronic kidney disease and the improved symptoms seen with naltrexone warrants consideration of this treatment in certain situations, however.^{23,24,38,39} Newer mixed μ -opioid antagonists/ κ -opioid agonists are also helpful for treatment of opiate-induced pruritus and uremic pruritus specifically.^{24,37,40} κ -opioid receptor antagonists are not available in the United States currently, but some initial studies in other countries and clinical trials are promising, especially for uremia associated pruritus, but potentially for other etiologies as well.^{12,13,35}

Bile sequestrant medications, such as cholestyramine and colestipol, are often used as first-line agents to control pruritus in cholestatic liver disease. Cholestyramine is the only medication approved by the US Food and Drug Administration (FDA) for cholestatic pruritus.⁴¹ It is of note that levels of bile acids do not always correlate with intensity of itch, however, and often these medications are not helpful.^{36,41} Compliance difficulties can arise for these medications because they can be unpleasant to swallow, and there should be a 4-hour interval before taking other oral medications. Ileal bile acid transporter inhibitors are another class

under investigation for treatment of pruritus in cholestatic liver disease.³⁶

Rifampicin has been found to be helpful for pruritus in hepatic cholestasis as a second-line agent. Its utility is limited due to potential hepatotoxicity, but continued studies suggest it may be considered in certain cases.^{42,43}

Neuroleptics like gabapentin, an α -2- δ calcium channel ligand, seem to be effective for neurologic causes of itching. Both gabapentin and pregabalin have increasing data supporting their use in the treatment of pruritus associated with uremia. Both medications can be associated with drowsiness, among other side effects.^{44–46}

Serotonin reuptake inhibitors, such as sertraline, paroxetine, and fluvoxamine, as well as mirtazapine, a tetracyclic antidepressant, and doxepin, a tricyclic antidepressant, have all shown some benefit in pruritus caused by various etiologies.^{35,47–49}

Antiemetics, such as ondansetron, a type 3 (5-HT₃) serotonin receptor antagonist, were previously used to relieve itch because serotonin was thought to play a role in the mechanism of pruritus, but this is controversial and further randomized controlled trials suggest ondansetron may not be as helpful for pruritus related to hepatic cholestatic disease and chronic renal disease.^{44,50}

Aprepitant, a neurokinin receptor-1 (NK-1) antagonist used as an antiemetic, blocks the binding of substance P and has been shown to be helpful in patients with treatment-refractory pruritus from T-cell lymphoma and nodular prurigo, and it does seem to have relatively minimal side effects.⁵¹ Several newer NK-1 receptor antagonists are being researched and show promise for the treatment of pruritus as well.⁵² Due to NK-1 receptor antagonist's cost, the utility in comparison to established treatments for pruritus needs further studies, however, and it may not be superior to these older treatments.⁵³

Due to continued legalization of marijuana in the United States and the potential use for cannabinoids in treating multiple symptoms encountered by the palliative APRN, it is important to be aware of ongoing evaluations of the efficacy and safety of cannabinoids for pruritus, including for topical use.^{36,54,55}

Immunosuppressants such as topical steroids are frequently used for allergic or immune-induced dermatologic disorders, and oral steroids are thought to help reduce itch only if an inflammatory component is present. Because of the side effects of long-term steroid use, providers should exhaust other treatments before using steroids for systemic pruritus. Other immunosuppressants and monoclonal antibodies are not typically used by the palliative APRN, but it is important to be aware of evolving research of the uses for these treatments against pruritus. The APRN may need specialty consultation from subspecialists who regularly use these treatment modalities.^{12,13,15}

Interventional Treatments

Several interventions for pruritus, mostly pruritus caused by liver disease, have been developed for patients with symptoms refractory to less invasive treatments (Box 52.2). A

Box 52.2 INTERVENTIONAL TREATMENTS FOR PRURITUS

Biliary drainage
Hemodialysis
Liver transplantation
Parathyroidectomy
Phototherapy
Plasmapheresis
Transcutaneous nerve stimulation

patient's ability to withstand these interventions depends on overall prognosis and clinical status. Patients with primary biliary cirrhosis with cholestatic disease may be liver transplant candidates based on severe pruritus symptoms alone.⁵⁶ Phototherapy seems to have an increasing evidence basis for treating a variety of primary dermatologic and systemic causes of pruritus.^{17,57–59} Extracorporeal albumin dialysis, nasobiliary drainage, plasmapheresis, and charcoal hemoperfusion may be beneficial in relieving chronic pruritus, but their benefit seems to be short lived and likely the risk and burden of these treatments would outweigh the benefit.³⁶ Therapies such as acupuncture⁶⁰ and transcutaneous nerve stimulation⁶¹ have shown some promise and may be worth exploring; however, currently there is relatively little evidence to support their use.

HICCUPS

Hiccup, or *singultus* in medical terms, is derived from the Latin word *singult*, which means “the act of catching one's breath while sobbing.”⁶² Most people experience hiccups periodically, but when hiccups are persistent (>48 hours) or intractable (>1 month), they can become a burdensome symptom, severely affecting quality of life.^{62,63}

Epidemiologic studies of prevalence are limited, although it is believed that persistent or intractable hiccups are relatively uncommon; as a result, minimal research has been done to test the effectiveness of treatments.⁶⁴ The actual number of patients suffering from hiccups affecting quality of life may be higher in the palliative care population, but it is thought that nearly one-third of patients with esophageal cancer may report this symptom⁶⁵ and by some estimates, hiccups may affect up to 9% of patients treated in palliative care settings.^{66,67} Despite this statistic there are very few palliative-specific studies to help guide management, and most evidence for treatment is derived from non-palliative patient studies.^{66,68,69}

ETIOLOGY

Hiccups represent an involuntary spasm of the diaphragm and accessory respiratory muscles. The hiccup reflex involves the afferent vagal, phrenic, and sympathetic nerves; the brainstem; and the efferent phrenic nerve to the glottis, diaphragm, and inspiratory respiratory muscle. The causes of hiccups can

be varied, but they generally result from an irritation of the diaphragm directly or of the nervous system controlling these muscles.⁶²

Causes of hiccups can be divided into several broad categories (Box 52.3), and identifying the cause can often help treat the symptom. Hiccups can result from direct irritation of the vagus or phrenic nerve reflexes by various causes such as intubation, endoscopy, surgery, radiation, cancer infiltration, or esophageal stenting, as a few examples.^{70,71} Gastric distention and gastroesophageal reflux are among the more common causes of persistent hiccups and should be treated if suspected.^{62,64,71,72} Ruling out serious pathology in cases of persistent hiccups is important. Hiccups have been shown to be the initial presenting symptom for a gastrointestinal malignancy, such as esophageal cancer.⁶² Hiccups have also been reported as a symptom in myocardial infarction and pulmonary embolism.^{65,73,74} Toxic and metabolic causes such as alcohol, infections, and uremia are also reported causes. Central nervous system disorders such as head trauma, stroke,

and intracranial malignancies are thought to be causes of intractable hiccups, with an especially high frequency (20%) in patients with Parkinson's disease.⁷⁵⁻⁷⁷ Medications such as corticosteroids, opiates, benzodiazepines, and chemotherapeutic agents have all been linked with hiccups.^{66,69,78} This knowledge may be beneficial for palliative APRNs working with patients who are often exposed to some or all of these medications for treatment of cancer or end-of-life-related symptoms. Once organic pathology has been ruled out, psychogenic hiccups becomes a potential cause in the differential diagnosis.

TREATMENT

Nonpharmacologic Treatments

Although there are limited prospective studies on the topic, attempting vagal maneuvers and other nonpharmacologic maneuvers have minimal side effects and can potentially be effective so should be tried prior to medication management.^{71,79} Valsalva maneuvers, nasopharyngeal stimulation, and inducing hypercapnia with hyperventilation and potentially even positive pressure ventilation are among the initial physical interventions that may be successful.^{80,81} These maneuvers are potentially less helpful for prolonged or intractable episodes of hiccups, however.⁸²

Pharmacologic Treatments

If symptoms persist or recur at a frequency where the benefit of interventions outweighs the potential side effects, several medications have been tried with some success, although no one medication has been demonstrated to consistently manage hiccups. The exact mechanism of neurotransmitters involved in intractable hiccups is not well understood, and there are many conflicting case reports and studies; therefore, directing pharmacologic treatments has been difficult.^{82,83} Chlorpromazine is the only medication approved by the FDA for the treatment of persistent hiccups. Baclofen, gabapentin, and metoclopramide are the only agents that have been studied in a prospective manner, and only baclofen and metoclopramide have been studied in randomized controlled trials. Due to this, definitive recommendations are difficult to make. Thus, the APRN must consider the patient, the current medication profile, comorbidities, other medications being taken, and goals of care.⁸³⁻⁸⁶

As GI-related pathology is frequently related to recurrent or chronic hiccups, including simple gastrointestinal reflux, use of a proton pump inhibitor as an initial medication is relatively low risk and should be tried if a GI source is in the differential diagnosis as a cause of the hiccups.⁸¹

Metoclopramide, a prokinetic agent with central dopamine receptor antagonist properties, has the strongest evidence basis, although still limited, for treatment of intractable hiccups caused by gastric distention. Side effects include sedation, extrapyramidal symptoms and tardive dyskinesia, elevation in blood pressure, and arrhythmias due to QT prolongation.⁸⁴

From Kaneishi, Kawabata.⁹⁰

Chlorpromazine, a phenothiazine first-generation antipsychotic, is the only medication approved by the FDA for the treatment of persistent hiccups, based on older studies.⁸⁵ It is thought to potentially be effective for hiccup management due to its dopamine antagonism, but this is not well understood. Side effects include drowsiness, agitation, tardive dyskinesia, dizziness, and confusion, which may limit its use in certain patient populations. QTc prolongation may occur, and monitoring may be indicated, especially if the patient is using other medications that may also prolong QTc and increase the risk of arrhythmias.^{64,83}

Baclofen, a γ -aminobutyric acid (GABA) analog used as a muscle relaxant, is emerging as the first-line treatment for central nervous system (CNS)-related intractable hiccups.^{64,66,86} Baclofen's potential side effects include respiratory depression, sedation, and asthenia but are most common in patients with impaired renal function, and the APRN must take care to avoid withdrawal symptoms.

Gabapentin, an α -2- δ calcium channel ligand, has also been identified as a relatively low-burden therapy for intractable hiccups, including in advanced cancer patients.^{66,72} When choosing an agent for treatment of hiccups, gabapentin is thought to be more helpful for hiccups with a CNS cause.⁶⁵ Gabapentin does not have as strong evidence as baclofen to support its use, but it may be worth considering in palliative patients for whom gabapentin may additionally be helpful for an alternative symptom, such as peripheral neuropathy. Sedation and dizziness have been identified as the major potential side effect, and titrating slowly can help avoid these. Pregabalin, another α -2- δ calcium channel ligand, may potentially be helpful for hiccups as well. Emerging concerns regarding the abuse potential and respiratory suppression of both these agents warrants close monitoring, especially if they are used in conjunction with opiates.⁸⁷

Multiple other medications have case reports or case series to support their use, although it is of note that some are contradictory. Despite this, it is helpful to know these alternatives in case first-line medications are not helpful, as even these have relatively limited data for their use. These medications include but are not limited to olanzapine, haloperidol, risperidone, nifedipine, nimodipine, cisapride, carvedilol, midazolam, valproic acid, phenytoin, carbamazepine, amantadine, methylphenidate, and lidocaine.^{64,66,69,72,75,82,88-91}

Interventional Treatments

If hiccups are persisting and affecting quality of life significantly despite the just discussed pharmacologic and non-pharmacologic interventions, several invasive therapeutic interventions have been proposed as alternatives when needed. These include surgical interventions, nerve blocks, ablations,^{66,92-95} and, potentially, diaphragmatic pacing.⁹⁶ Studies evaluating acupuncture as a treatment for hiccups suggest its possible effectiveness as well, but due to the quality of evidence, conclusive recommendations for its use cannot be given; however, it may be worth considering if the burden from intractable hiccups is high.^{64,97}

DRY MOUTH

Dry mouth, or *xerostomia*, is common in cancer patients and patients at the end of life.⁹⁸⁻¹⁰⁰ The differential diagnosis can be broadly divided into decreased saliva secretion and erosion of the buccal mucosa.¹⁰⁰

Saliva secretion is regulated by both sympathetic and parasympathetic processes and involves a number of different pathways, so the pathophysiology of hyposalivation can be traced to several potential causes, including a slight disruption of the muscarinic receptors to outright obliteration of parenchymal tissue.¹⁰¹ The parotid, submandibular, and sublingual glands work together to produce saliva and maintain proper consistency, so damage to any of them will affect not only the amount but also the viscosity of the saliva.¹⁰⁰

Decreased saliva secretion can be caused by radiation to the head and neck, chemotherapy, a variety of medications (e.g., anticholinergics, antihistamines, tricyclic antidepressants, opioids, and sedatives), and some medical conditions (e.g., autoimmune disorders, infections, and sarcoidosis).^{99,100}

Erosion of the buccal mucosa can also be caused by a variety of medical conditions (e.g., HIV/AIDS, Sjögren syndrome, systemic lupus erythematosus, and diabetes mellitus) plus chemotherapy and radiation, where higher doses and more radiation treatments also directly affect the extent and length of impairment in saliva production.^{99,100} Xerostomia from dehydration can occur as a result of vomiting, diarrhea, dysphagia, oxygen use, and fever, while mental health issues, such as depression or anxiety, are potential miscellaneous causes of xerostomia.^{98,100}

For the assessment of xerostomia, the palliative APRN can use several precise ways to make the diagnosis, such as measuring salivary flow or salivary gland scintigraphy, but these are usually not appropriate to the palliative care population.^{98,102} A basic clinical history and focused exam should be sufficient to make the diagnosis and determine the likely etiology.⁹⁸ The inside of the mouth can be examined for signs of xerostomia, such as dry mucosa and tongue and ulceration. Two simple bedside tests to evaluate for xerostomia are the cracker biscuit test, where the patient is diagnosed to have xerostomia if unable to eat a cracker or biscuit without drinking something, and the tongue depressor test, which diagnoses xerostomia if the tongue depressor sticks to the tongue after placement.¹⁰⁰ There are also certain assessment tools, such as the University of Michigan Xerostomia tool, that allow patients to rate their symptoms.¹⁰⁰

The management of xerostomia relies on potentially complex medication use as well as nonpharmacologic interventions (Table 52.3, Box 52.4). A general approach to management involves treating any underlying conditions (e.g., candidiasis), reviewing medications and changing those that may be contributing to xerostomia, finding ways to stimulate salivation, using saliva substitutes to replace lost saliva, and managing the xerostomia holistically in general.¹⁰⁰

Mucin-based saliva substitutes appear to be better tolerated than carboxymethyl-cellulose-based ones, and sprays overall better than gels.^{98,100} Contraindications to taking

Table 52.3 PHARMACOLOGIC XEROSTOMIA TREATMENTS

SALIVA STIMULANTS	SALIVA SUBSTITUTES
Pilocarpine 5–10 mg tid (primarily muscarinic agonist) Cevimeline 15–30 mg tid (muscarinic)	Mucin-based (e.g., Saliva Orthana) Carboxymethyl-cellulose-based (e.g., BioXtra)

From Davies⁹⁸; Klinedinst et al.¹⁰⁰; and Millsop et al.¹⁰²

pilocarpine include asthma, bronchitis/chronic obstructive pulmonary disease, glaucoma, and heart, kidney, or liver disease.^{98,100} Cevimeline should not be used in patients with acute iritis, uncontrolled asthma, or narrow-angle glaucoma.¹⁰²

Preventative oral care interventions for patients with xerostomia should be encouraged. This includes brushing teeth regularly with fluoridated toothpaste, rinsing with a cup of warm water containing ½ teaspoon of baking soda, and using an antimicrobial rinse daily.¹⁰¹ Potential interventional techniques to treat xerostomia are acupuncture and intraductal gene therapy, which is inserted via the parotid gland, but acupuncture does not have sufficient evidence to recommend it and gene therapy is in its early stages of research.¹⁰²

The palliative APRN should focus patient and family education on good preventive and nonpharmacologic measures. Oral care is especially important throughout the disease course, including at end of life for continued comfort.¹⁰⁰ Ensure that the patient and family know how to use any prescription medications or over-the-counter medications. They should also understand any potential side effects, precautions, contraindications, or drug interactions.

FEVERS

Fever is generally defined as a rise in oral body temperature above 38°C (100.4°F).¹ The pathophysiology of fever is based on the presence of *pyrogens*, substances that produce fever, inducing the hypothalamus to reset the body temperature set point.¹⁰³ Pathogens release exogenous pyrogens, and the destruction of pathogens causes the body to produce endogenous pyrogens, namely interleukin-1 and -6, interferons, and tumor necrosis factor, but both types of pyrogens can ultimately induce fever.¹⁰³

Box 52.4 NONPHARMACOLOGIC XEROSTOMIA TREATMENTS

Sugar-free chewing gum Organic acids (ascorbic acid, citric acid, malic acid) Water/peppermint water Electrostimulation (embedded in a custom-made mouthguard) Diet modifications (e.g., soft foods, increased fluid intake with meals, avoiding sugary and spicy foods)

From Davies⁹⁸; Klinedinst et al.¹⁰⁰; and Millsop et al.¹⁰²

Clinically, fever often presents in three stages: chill, fever, and flush.¹ During the chill phase, the body is reacting to the body’s new temperature set point and generates heat through shivering and tries to prevent heat loss through vasoconstriction.¹ During the fever phase, the body raises its temperature to meet the new set point, resulting in a warm feeling, lethargy, and possible dehydration or even seizures. In the flush stage, the body tries to acclimate to the new set point through diaphoresis and vasodilation.¹ Certain populations, such as immunocompromised patients, older adults, newborns, and those taking steroids, may not mount a fever response to an infection.¹⁰⁴

The assessment of patients with fever usually begins with a detailed history and exam, but the extent of evaluation and further workup may vary greatly depending on the patient’s prognosis and established goals.¹⁰⁴ When appropriate, the APRN conducts a thorough examination, looking for signs of infection and possible disease progression in cancer patients, and reviews the patient’s medications; this may be followed by laboratory (e.g., blood and urine cultures, complete blood count) and radiographic (e.g., chest radiograph, computed tomography [CT] scan) testing.¹⁰⁴

Some of the most common differential diagnoses of fever in palliative care patients include infection (by far the most common etiology), medications, paraneoplastic-related fevers, neurologic damage, and inflammation.¹⁰³ Neutropenic patients are particularly susceptible to infections; some common sources include wounds, the bloodstream and urinary tract, implanted vascular access devices, pneumonia, and the gastrointestinal tract.¹⁰³

The palliative APRN must decide whether to treat the source of the fever in the first place. How much workup to pursue will depend on the patient’s prognosis, potential burden versus benefit, and overall goals of care. If a workup is pursued and the source of the fever is identified, treatment of the underlying condition may involve both interventional techniques (e.g., drainage of an abscess) and complex medication options (e.g., intravenous antibiotics). In some instances, the APRN could initiate empiric antibiotics without further workup. This may be appropriate when patients have a colonized infection and antibiotics curb the infection just enough to ward off fevers.

However, when patients are actively dying, even empiric antibiotics are usually no longer indicated.¹ In fact, even symptomatic treatment of fever is not always necessary or appropriate. Fevers may not cause discomfort, but breaking the fever, and the likely resulting sweats, could cause discomfort.¹⁰³ There is also some indication that low-level fevers can have a protective function. It is ultimately the patient’s decision whether the fever is bothering him or her; if the patient can no longer communicate, then the patient’s family can help the palliative APRN with decision-making.¹⁰³

For symptomatic treatment of fever, the major medication options include acetaminophen 325 to 650 mg every 4–6 hours (orally, intravenously, or rectally), nonsteroidal anti-inflammatories (NSAIDs; e.g., naproxen 225–500 mg orally every 12 hours, intravenous ketorolac 15–30 mg every 6 hours, ibuprofen 200–400 mg orally every 4–6 hours, or

indomethacin 50 mg orally or rectally every 8 hours), or aspirin 325–650 mg orally or rectally every 6 hours plus corticosteroids.¹⁰³ Generally speaking, antipyretics' action centers on preventing the production of prostaglandin E2.¹⁰⁴ When antipyretics are administered for symptomatic relief, it is best to schedule them around the clock to avoid fluctuations in body temperature and diaphoresis with fever.¹

Nonpharmacologic interventions to treat fevers need to be chosen carefully. Many of the treatments historically used to bring down fevers, such as ice packs, cooling blankets, cold sponge baths, or a fan blowing directly on the patient, can cause more discomfort by making the patient too cold and inducing shivering.¹ Instead, some measures that can be safely implemented to help maintain patient comfort include keeping the room temperature at a comfortable level, ensuring that the patient's bed linen and clothing are clean and dry, offering cool liquids to drink for those who can drink, and ensuring that the patient's lips are kept moist.^{1,103}

The palliative APRN should be aware of the very severe side effects that can occur with excessive use of acetaminophen (liver failure) or NSAIDs (kidney failure, gastrointestinal bleed—a much higher risk with ketorolac). The patient's prognosis and goals of care could once again affect the risk-benefit ratio of administering either of these medications for symptomatic management of fever. In the actively dying patient who is believed to have discomfort from persistent fevers, the potential benefit of giving either medication on a scheduled basis should outweigh the potential risks. The treatment of any underlying infection with antibiotics may also involve careful evaluation of any potential side effects or drug interactions when prescribing them.

When the palliative APRN is treating a fever in a patient with advanced illness, especially one who is actively dying, careful patient and family education is vital. The APRN must ensure that the approach to treatment is properly established and that the patient does not accidentally receive some of the aforementioned nonpharmacologic interventions that may cause more harm than benefit (e.g., cold packs). Cool, not cold, cloths may help, as well as light bedding. Mouth care should be continued since fever causes dry mouth.¹ Patients and family members may need frequent reinforcement when the decision is made not to treat the underlying cause of a fever or its symptoms if it does not appear to be causing discomfort to the dying patient. However, if family members insist that their loved one receive symptomatic fever treatment, it may be an appropriate and palliative measure to do so.¹⁰³ When patients require symptomatic treatment for fevers earlier in the course of their disease, patients and families may require extensive education and reminders about the potential dangers of excessive NSAID or acetaminophen use.

SLEEP DISORDERS

Sleep disorders, and the associated insomnia or lack of quality sleep, are a potentially very disturbing issue for palliative patients and a challenge for the APRNs treating them. Broadly speaking, the American Academy of Sleep Medicine

classifies sleep disorders into four categories: disorders of extreme somnolence; disorders of the sleep–wake cycle; difficulty initiating or maintaining sleep; and dysfunction of sleep, sleep stages, or incomplete arousal.¹⁰⁵ More specifically, the differential diagnoses among the major sleep disorders include primary insomnia (e.g., acute, life-long or chronic, psychological, or poor sleep hygiene), sleep apnea, restless leg syndrome, parasomnia, and narcolepsy.¹⁰⁶ A workup to differentiate primary insomnia from another specific sleep disorder may include the Epworth Sleepiness Scale questionnaire; an overnight polysomnogram, followed by daytime multiple sleep latency testing if evaluating for narcolepsy; use of an actigraph to study sleep–wake patterns; and other miscellaneous tests.¹⁰⁷ A polysomnogram positive for sleep apnea would likely be followed by a trial of continuous positive airway pressure (CPAP), possibly even done halfway through the night of a polysomnogram if the results are blatantly positive. A survey of 76 palliative care clinic patients indicated that about 40% met criteria for restless leg syndrome that reduced their quality of life negatively¹⁰⁸ (Box 52.5).

The most common sleep disorder is some form of simple/primary insomnia (occurs in 23–61% of cancer patients); it will be the focus of the rest of this section.¹⁰⁵ The normal architecture of sleep involves two major phases, rapid eye movement (REM) and non-rapid eye movement sleep (NREM).¹⁰⁵ During REM sleep, sometimes also called “dream sleep,” the brain is very active, while NREM sleep consists of four increasingly deep, quiet, and restorative periods of sleep that together make up one sleep cycle of approximately 90 minutes.¹⁰⁵ The pathophysiology of insomnia is potentially quite complex involving as it does an increased level of arousal of the brain, including higher activity during NREM sleep. Genetic factors may predispose individuals to be more sensitive to external factors, such as caffeine or stress, that can subsequently disrupt the sleep–wake cycle.¹⁰⁵ Some other biological differences found in patients with chronic insomnia include higher levels of adrenocorticotrophic hormone (ACTH), cortisol, and adrenaline release and increased body temperature compared to patients who sleep normally.¹⁰⁵

The assessment of insomnia begins by obtaining a thorough sleep history from the patient and any sleeping partner and involves an evaluation of sleep chronology, environment, and hygiene in addition to any physical symptoms, medical conditions, and spiritual concerns.¹⁰⁶ The sleep assessment questionnaires that have been used most frequently in research include the Epworth Sleepiness Scale, the Insomnia

Box 52.5 DIFFERENTIAL DIAGNOSIS OF MAJOR SLEEP DISORDERS

Primary insomnia
Sleep apnea
Restless leg syndrome
Narcolepsy
Parasomnia

From Arnold et al.¹⁰⁶

Severity Index, and the Pittsburgh Sleep Quality Index; the Insomnia Severity Index appears to have the most consistency and reliability regarding cancer patients in particular.¹⁰⁹

The palliative APRN should determine whether the patient follows generally accepted sleep hygiene behaviors: (a) a regular sleep time and wake time, (b) using the bed only for sleep and sexual activity, (c) not lying in bed awake for more than about 30 minutes if unable to fall asleep at night, and (d) subsequently not returning to bed again until sleepy. The APRN should ask whether the patient takes naps during the day. Naps should be avoided, except possibly a short one between 2 and 4 PM. The APRN should assess the patient's caffeine intake in food and beverages or the use of alcoholic beverages. Finally, the APRN should assess the patient's activity level. Usually, strenuous exercise from late afternoon on should be avoided unless the patient has a very different sleep cycle. The sleep environment, such as the lighting, an unfamiliar bed, and noises, can also affect the patient's ability to sleep in a strange environment (e.g., a hospital, child's/relative's home).¹⁰⁶

By assessing the sleep chronology, the course of the patient's insomnia can be determined in more detail and the palliative APRN can pinpoint whether the main issue involves sleep onset, maintenance, or both.¹⁰⁶ If the insomnia is an ongoing problem, there is often a medical, psychological, or neurological disorder that is at least partially responsible.¹⁰⁶ Medications may cause frequent awakening throughout the night, and early morning awakening is often related to depression.¹⁰⁶

Medical conditions can also contribute to insomnia, including worsening of a chronic problem, such as chronic obstructive pulmonary disease or congestive heart failure; a recent or deepening depression that may also be accompanied by anxiety; a variety of medications to treat such conditions (e.g., corticosteroids, stimulants); or previously mentioned sleep disorders like restless leg syndrome.¹⁰⁶ Physical symptoms such as pain, shortness of breath, or cough may interfere with sleep initiation or maintenance. Spiritual distress associated with the fear of dying while asleep, together with other anxiety and the fear of uncertainty, may precipitate reluctance to fall asleep and nightmares.¹⁰⁶ The only sleep disorder that routinely uses an interventional technique for management is obstructive sleep apnea, which may be treated with use of a CPAP machine at night or, in some cases, can improve with uvulopalatopharyngoplasty surgery.

The management of insomnia generally consists of complex medication management and nonpharmacologic interventions. The major classes of medications approved by the FDA to treat insomnia are benzodiazepines, benzodiazepine receptor agonists, non-benzodiazepine receptor agonists, and melatonin-receptor agonists.¹⁰⁵ Some of the other major classes of drugs frequently used to treat insomnia include antidepressants, atypical antipsychotics, and antihistamines.¹¹⁰

Benzodiazepine and non-benzodiazepine agonists both act on the GABA receptor complex. The APRN should use caution if a patient already taking opioids is started on benzodiazepines. For some patients, a synergistic effect may occur and more sedation may ensue. Non-benzodiazepine agonists do not affect the sleep architecture and tend to have fewer side effects, especially longer lasting ones (e.g., less risk for abuse, dependence, and lingering oversedation).¹⁰⁵ Melatonin-receptor

Table 52.4 PHARMACOLOGIC OPTIONS TO MANAGE INSOMNIA

MEDICATION AND DOSAGE	MAJOR SIDE EFFECTS
Benzodiazepine receptor agonists	
Temazepam 7.5–15 mg	Drowsiness, confusion
Triazolam 0.125 mg	Amnesia, drowsiness
Lorazepam 0.5–4 mg	Respiratory depression, sedation
Non-benzodiazepine receptor agonists	
Zolpidem 5–10 mg (IR), 6.25–12.5 mg (ER)	Sedation, dizziness
Eszopiclone 1–3 mg	Headache, drowsiness, dizziness
Antidepressants	
Trazodone 25–100 mg	Sedation, confusion, headache
Mirtazapine 7.5–30 mg	Constipation, sedation, xerostomia
Melatonin-receptor agonist	
Ramelteon 8 mg	Central nervous system (CNS) depression, headache
Atypical antipsychotics	
Olanzapine 5–10 mg	Extrapyramidal side effects, drowsiness
Antihistamines	
Diphenhydramine 25–50 mg	Dizziness, headache, sedation
Doxylamine 25 mg	Paradoxical CNS arousal, dizziness, sedation

ER, extended release; IR, immediate release.

From Schroeder¹⁰⁵; Wijemanne, Ondo¹⁰⁷; and Arnold et al.¹¹⁰

agonists act on MT₁ and MT₂ receptors, are believed to be involved in normal sleep–wake cycle regulation, and have fewer side effects and no risk for abuse or dependence; only ramelteon has FDA approval.¹⁰⁵ The other classes of drugs are used due to their sedating properties^{105,110} (Table 52.4).

SUMMARY

Pruritus, hiccups, dry mouth, fevers, and sleep disorders are all distressing and difficult to treat symptoms that negatively impact quality of life. Consistent assessment is essential. While there is often a lack of consensus on evidence-based management, the palliative APRN should be familiar with treatments for these less common and often treatment resistant symptoms. Continued investigation into the mechanisms of action of these symptoms will help guide improved management, and evaluation of novel approaches to treatment is needed and under way.

SECTION IX

ETHICAL CONSIDERATIONS

NAVIGATING ETHICAL DILEMMAS

Nessa Coyle and Timothy W. Kirk

KEY POINTS

- The palliative advanced practice registered nurse (APRN) is uniquely trained and situated within palliative care teams to navigate ethical discussions.
- Professional codes of ethics, bioethical principles, and the defining aims of palliative care are the foundation for such discussions.
- An ethical framework of advocacy, truthfulness, and accommodation guides discussions, highlighting that *process* rather than *outcome* is the appropriate focus.
- Three skill sets—communication, empathy, and moral reflection/deliberation—aid the palliative APRN in facilitating discussions.
- Curiosity, an open mind, and humility are necessary components.

The nursing staff were concerned that Mr. S's wishes regarding end-of-life care were being overridden by his son. A palliative APRN consult was requested to bring clarity to the situation and help with communication. After talking with the nursing staff and other members of the interdisciplinary team, a family meeting was arranged. Mr. S's wife opted not to attend the meeting, stating that her son was the spokesperson for the family. The son, as well as one of the two daughters (a social worker), participated in the meeting alongside involved members of the team. The second daughter opted not to participate in the meeting but to remain with her mother. The palliative APRN led the discussion.

INTRODUCTION

What is an ethical discussion? When the question "What is the 'right' thing to do in this situation?" is asked, it is an ethical question.¹ When a discussion touches on one or more core values of the participants involved, or the core values of their respective traditions or professions, it is likely ethically significant. The context of palliative care, in which patients and their families are faced with many choices and decisions throughout the disease trajectory, but especially during transitions from curative or life-prolonging therapy to end-of-life care, makes such discussions commonplace.² Effective communication skills, empathy, and moral reflection and deliberation are essential ingredients in such conversations. Progressive illness with a long trajectory provides both the opportunity and the obligation for the palliative advanced practice registered nurse (APRN) to have ongoing conversations with patients and their families about their preferences for present and future healthcare interventions.³ The importance of having these conversations and clearly documenting them becomes even more urgent when patients present with advanced disease.⁴

The Institute of Medicine's 2011 report, *The Future of Nursing: Leading Change, Advancing Health*, states that, although physicians have traditionally been responsible for end-of-life conversations, with the advancement of nursing practice, nurses are now taking the lead.⁵ The Hospice and Palliative Nurses Association emphasizes that, due to their advanced training, visibility, and presence at the bedside, APRNs are ideally placed to create an ethical environment in which staff, patients, and families can navigate the difficult decisions to be made.⁶ The palliative APRN's influence in creating an ethical environment is seen not only in the inpatient

CASE STUDY: THE CASE OF MR. S (PART I)

This case will be used to illustrate key principles and skills for navigating ethical discussions.

Mr. S was a 69-year-old Jewish man with refractory leukemia. He was critically ill with bacteremia, multiple organ failure, and hemodynamic instability. Although earlier in his illness he had been considered a candidate for a research protocol, he was no longer eligible. There were no further disease-focused treatment options available.

Mr. S was married with three adult children—two daughters and a son. Shortly after admission to hospital, his medical condition deteriorated. In a discussion with a covering physician, he agreed to a do-not-attempt-resuscitation (DNAR) code status. No family member was present during this conversation. Shortly thereafter, Mr. S lost decision-making capacity.

The following day, in a discussion with the attending physician, the patient's family learned that Mr. S had agreed to a DNAR code status on admission. Despite the wife reporting the patient's decision was consistent with prior conversations between them, there was dissension within the family. Because of this dissension, the patient's wife recused herself from being spokesperson for her husband. The son, with family agreement, assumed this responsibility. After consultation with an outside rabbi, the son revoked his father's DNAR code status. The patient's attending physician honored the son's decision and removed the DNAR order.

setting but also in outpatient clinics, as a clinical palliative care consultant, in home hospice care, and in long-term care facilities. By serving on ethics committees and clinical ethics consultation teams, palliative APRNs can help create ethical environments across their care organizations. By participating in the creation and review of institutional policies and procedures guiding palliative care interventions, APRNs ensure that the perspective of nurses helps to shape such documents. An ethical environment is one in which interactions are characterized by trust and respect, where there is encouragement to “speak up” and psychological safety in doing so, and where differences of opinion are welcomed and discussed.^{7,8}

As you read this chapter, we would like you to reflect on ethical discussions you have navigated with patients, families, or staff. What was it about these discussions that left you with a feeling of satisfaction or failure? Was it in the process, or was it in the outcome? If in the process, what elements of the process contributed to success? If in the outcome, how was success or failure measured? This chapter addresses these questions by providing the palliative APRN with the structure and language that complement the classic patient-centered care model of autonomy, beneficence, nonmaleficence, and justice. The chapter builds on the ethical foundation already inherent in the practice of the palliative APRN, explaining ethical principles and skills to facilitate and guide navigation of ethical discussions. Throughout, the palliative APRN is recognized as being uniquely well-trained and situated within palliative care teams to be an advocate to ensure that the values, goals, perspectives, and concerns of patients, families, and fellow clinicians are appropriately heard in patient care conversations.

The tools and principles we present in this chapter function as guides. However, just as clinicians use their clinical judgment to apply best practice standards in each case, we invite readers to use their ethical judgment when applying the tools and principles in our model. The uncertainty in which clinical practice occurs, and which makes diagnostic and treatment decisions subject to constant revision as new information unfolds, extends to the ethics of clinical situations. How best to apply principles and tools—which principles are most applicable and how to weigh their relative importance—is necessarily (a) specific to the context of each case and (b) subject to interpretation, error, and revision. With this in mind we have included an appendix to provide the APRN with common definitions and distinctions in palliative care ethics. Each of these definitions and distinctions is followed by four questions for the APRN to consider, to be challenged by, and to challenge her team with. Included are decision-making capacity, foregoing medical interventions, discontinuing life-sustaining therapy, palliative sedation, the doctrine of double effect, medically hastened death, moral distress, and conscientious objection.

THE FOUNDATION OF ETHICAL DISCUSSIONS

This section briefly reviews nursing codes of ethics, core principles in healthcare ethics, and the defining aims of palliative

care. All three provide important background knowledge and set the foundation for the ethical framework explained in the fourth part of the chapter.

NURSING CODES OF ETHICS

Nursing codes of ethics articulate defining values that unite individual nurses into a caregiving community with ideals of professional conduct. While ideals cannot always be realized, they nonetheless give nurses a direction toward which practice aspires. The International Council of Nurses (ICN) *Code of Ethics for Nurses*⁹ states in its preamble, “Nurses have four fundamental responsibilities: to promote health, to prevent illness, to restore health and to alleviate suffering.”^(9, p. 1) In addition, the American Nurses Association (ANA) *Code of Ethics* has its tenets consisting of nine statements that describe the commitment of nurses to patients, duty to self and others, and duties beyond individual patient encounters.³ These codes are a reminder to nurses of their special responsibilities in caring for the sick, and they highlight the use of knowledge and skills to help individuals and families when they are at their most vulnerable. We encourage palliative APRNs to familiarize themselves with the both the ICN and the ANA code and the applicable national nursing association codes in their practice locations. The palliative APRN works toward realizing the ideals outlined in these codes at the individual, unit, and institutional levels.

BASIC ETHICAL PRINCIPLES

These four ethical principles inform the broad landscape of nursing ethics^{10,11}:

1. *Autonomy*. This principle is rooted in the notion of self-governance—the belief that individuals should have the strongest voice in making their own healthcare decisions because such decisions have a significant impact on their lives. Respecting autonomy allows persons with decision-making capacity to make healthcare decisions for themselves by giving them the support and information necessary to integrate their values, beliefs, and preferences into the decision-making process.^{10,12} Autonomy has a relational component. Most people live in a cultural and familial context involving obligations, reciprocal relationships, and interdependence. Patients commonly incorporate the impact of their decisions on others into their deliberative process and seek the assistance of loved ones in formulating care preference.¹³
2. *Beneficence*. This principle asserts that a primary ethical obligation of all clinicians is to do good—to provide care and support that enhances patients’ well-being and offers benefit consistent with their goals and values.¹⁰ While clinicians are strongly positioned to determine what biomedical benefits may accrue from certain treatments, patients and family members know

best which outcomes are beneficial in light of patients' goals and values. As such, honoring beneficence requires knowledge about what each patient values in his or her life and discussion with each patient of which treatment options align best with those values. In this setting *non-abandonment*—whether or not clinicians agree with a patient's decision—is a key element of beneficence.

3. *Nonmaleficence*. Minimizing the risk of harm, mitigating or removing preventable harm, and ensuring care interventions have a favorable benefit-harm ratio grounded in the values of the patient are the hallmarks of nonmaleficence.¹² Many treatments cause a degree of harm, but the benefit to patients, on their terms, should outweigh the harm. When a patient's values and preferences are not able to be known, nonmaleficence requires teams to craft plans of care which prioritize minimization of pain and suffering.
4. *Justice*. This principle refers to providing care that is equitable and fair to all and includes the fair distribution of scarce resources. Two types of justice are referred to here, *procedural justice* and *distributive justice*. Procedural justice requires that clinicians engage care processes that elicit the goals and preferences of patients and respect the values and rights of all involved in giving and receiving care. Such processes are considered "fair" when all appropriate voices are heard and considered. Family meetings, for example, benefit from being guided by procedural justice so that patients' and family members' voices are at the forefront when decisions about the type and site of care are made. Distributive justice requires that resources be allocated fairly and equitably, using transparent and appropriate criteria. The availability of palliative care is a good example: all patients and families should have access to palliative care services, interventions, and support, and access to care should be based on transparent, appropriate criteria applied equally to all regardless of socioeconomic state or social status.^{11,12,14} The significance of distributive justice was underscored in the COVID-19 pandemic, when allocation of scarce life-saving resources became a reality.

While discrete conceptually, in practice, these four principles often overlap. Nonmaleficence works in concert with beneficence and autonomy. The patient, family, and clinicians partner together to discern (a) which values and goals of care are most important to the patient and (b) how best to support these values and achieve these goals while at the same time maximizing benefit and minimizing harm. Procedural justice requires that clinicians engage the moral agency of all stakeholders, thereby implicating autonomy. Equitably distributing care resources requires assessing procedural and outcomes-based harms and benefits. When one principle is insufficiently engaged, other principles are often similarly at risk of violation. All four principles resonate strongly with the defining aims of palliative care.

DEFINING AIMS OF PALLIATIVE CARE

Palliative care is an approach that improves the quality of life of patients (adults and children) and their families who are facing problems associated with life-threatening illness. It prevents and relieves suffering through the early identification, correct assessment and treatment of pain and other problems, whether physical, psychosocial or spiritual.¹⁵

As we have written elsewhere,¹⁶ palliative care is an inherently moral enterprise because it seeks to empower the agency of patients and families through the relief of suffering, thereby strengthening their ability to make decisions consistent with their moral values. Agency is a concept that describes one's ability to develop and exercise a sense of self—engaging with the world in a manner that sets and achieves goals by doing what one can for oneself. It is linked to concepts like self-efficacy and autonomy and is predictive of improved health outcomes via variables like treatment adherence, self-care, hope, and ability to cope.¹⁷ A person's *moral* agency is the ability to identify and embrace guiding values in life and to execute decisions, participate in actions, and develop character traits that reflect and express those values.¹⁸ For persons who need assistance, moral agency can be respected by ensuring that the actions of caregivers are consistent with the values and preferences of patients, even if patients are not able to exercise their agency independently.

Suffering that arises in the context of life-limiting illness can constitute a threat to the agency of patients and families.^{19,20} One important way that palliative APRNs can address the suffering of their patients while concurrently honoring the four ethical principles of autonomy, beneficence, nonmaleficence and justice is to offer support and interventions that restore and engage patients' moral agency. Doing so resonates strongly with the philosophy underpinning palliative care as a model of care.^{21,22} Therefore, relieving suffering and empowering moral agency should be primary aims in advanced practice palliative nursing, informing how palliative APRNs navigate ethical discussions.

AN ETHICAL FRAMEWORK FOR NAVIGATING ETHICAL DISCUSSIONS

Advocacy, truthfulness, and accommodation provide an ethical framework to guide the palliative APRN in navigating ethical discussions informed by the ultimate goal of palliative care: reducing suffering by supporting and engaging moral agency.²² The unique balance among these principles will vary in each discussion, paralleling the unique blend of persons, goals, and values involved.

ADVOCACY

Advocacy is frequently cited as the primary—perhaps even the defining—role of the nurse in the context of healthcare

ethics.²³ Two models of advocacy are presented in this section: existential advocacy and advocacy as rights protection.

EXISTENTIAL ADVOCACY

Gadow's model of *existential advocacy* is an apt model for the palliative APRN when a patient has decision-making capacity and is able to participate in the decision-making process.²⁴ This chapter adapts the model to include patients and families, insofar as palliative care is patient- and family-centered care. The nurse as advocate offers care focused on restoring and empowering patients' moral agency as well as fostering and respecting the agency of family members. This is done through providing therapeutic presence to create conditions in which a patient and family can partner with clinicians to (a) discern the meaning of clinical changes in the patient's condition, (b) explore how such changes interact with their values and goals, and (c) appreciate together which care options might best honor those values and goals.

Explaining the role of existential advocacy in nursing care, Gadow writes:

The ideal which existential advocacy expresses is this: that individuals be assisted by nursing to authentically exercise their freedom of self-determination. By authentic is meant a way of reaching decisions which are truly one's own decisions that express all that one believes important about oneself and the world, the entire complexity of one's values.

Individuals can express their wholeness and uniqueness as valuing beings only if their full complexity of values—including contradictions and conflicts—is clearly in mind, having been reexamined and clarified in the new context. Yet, that clarification is the most difficult precisely when it is most needed, when a situation arises which threatens to overturn previously stable values. In such situations, of which health impairment is a paradigm, individuals face the necessity of either recreating their values or recreating their situation according to their existing hierarchy of values.²⁴ (p. 85)

As Gadow makes clear, the goal in existential advocacy is not for the nurse to put herself in the place of *speaking for* patients. Rather, it is to provide the supportive presence and facilitate the empowering conditions necessary for patients to restore their sense of self by (a) understanding the facts and experiences of their illness, (b) appreciating what they mean in the larger context of their lives, (c) reconnecting to the values that are most important to them and most directly relevant to the situation at hand, and (d) engaging in a decision-making process that integrates such understanding, appreciation, and reconnection. The palliative APRN as a moral advocate directs attention not toward specific decisions or outcomes, but to the ongoing discussion *process* itself—a process that promotes and engages the moral agency of all involved. Humility,

openness, and an ability to listen and to let go of preconceived ideas are key components.

ADVOCACY AS RIGHTS PROTECTION

A *rights protection* model of advocacy is a common approach to nursing advocacy in which the nurse represents the wishes of the patient when he or she is in danger of being subsumed to the wishes of someone else—most commonly clinicians or family members.³ In this model, the nurse functions in the healthcare system in a manner similar to that of a legal advocate in the legal system—protecting the rights of his or her client. This notion of advocacy has two main elements: (a) speaking up for others who cannot speak for themselves (a process element) and (b) seeking to achieve a particular outcome, presumed to be in the best interest of the party being spoken for (an outcome element).²³ These elements also imply a context in which advocacy occurs: there is some threat in the environment that increases the risk of (a) the voice of the patient or family not being heard and (b) an outcome consistent with the patient's best interest not being prioritized. In other words, the assumed condition in which this model of advocacy is needed is when there is an imbalance of power that creates vulnerability. The role of the nurse advocate is to protect the rights of the vulnerable. Again humility, openness, letting go of preconceived ideas, and an ability to listen are key components.

The rights protection model assumes that the patient needs someone else to speak *for* him or her and that the primary ethical risk in such discussions is that the patient's preferences will be overridden by the preferences of others. Such risks may well be present for certain palliative care patients for whom this model of advocacy is appropriate. An example is when a patient loses decision-making capacity and his or her advance directive is not being honored, as is seen in our case study. Another example is advocating for an unrepresented patient whose values and preferences may be unknown despite extensive attempts to do so.

Discerning the best way to advocate for patients and families requires curiosity, empathy, and good communication skills. We know so little about the full and many-faceted lives of our patients and families and we may make assumptions that cloud our ability to listen—especially when faced with a stressed family whose actions seem counterproductive to the wishes and best interests of the patient.

TRUTHFULNESS

The dominant model of truth-telling in healthcare ethics is the *disclosure model*.²⁵ The disclosure model begins with the assumption that healthcare providers have access to important information—a diagnosis or prognosis, for example—that patients need to make decisions about their care. Telling the truth, then, focuses on effectively communicating this information to patients so that it can be used in the decision-making process. Hallmarks of truth-telling in this model are (a) accuracy (Is what is communicated to the patient consistent with

what is known by the provider?), (b) sufficiency (Is the provider telling the patient all of the relevant information?), (c) coherence (Is what is being communicated by the provider integrated with other relevant facts and circumstances such that the patient understands the context of the disclosure?), (d) timeliness (Is the disclosure shared with the patient at a point in time when it can be effectively integrated into the decision-making process?), and (e) uncertainty (How is the relative certainty/uncertainty of the situation being communicated to the patient)?

It is a common but misinformed belief among healthcare providers that telling a patient the truth is harmful. In fact, in research primarily done with cancer patients, the opposite has been found to be true.^{26,27} Telling the truth fosters trust and demonstrates respect when it is told in a compassionate and sensitive manner and titrated to the patient's ability to absorb the information.²⁸ The purpose of sharing information with patients and families is to enable the kind of understanding, reflection, and deliberation necessary to make informed care decisions that resonate with their goals, values, and beliefs.

While the spirit of the disclosure model of truth telling is important, we have intentionally opted for the term "truthfulness." As noted earlier, palliative care is family-centered care that seeks to support the moral agency of patients by acknowledging and caring for the web of intimate relationships through which patients already find and create meaning. That relational structure is all the more important in times of distress and serious illness. Patients, loved ones, and clinicians work together in palliative care to interpret the meaning of clinical developments and integrate that meaning into the larger life horizon of the patient.²⁹ Truth, in other words, is not something possessed by clinicians and disclosed to patients. Rather, the truth of patients' situations is discerned through a shared process of enquiry, discovery, and meaning making.^{30,31}

Truthfulness promotes patterns of engagement that create a supportive environment in which all parties can explore, share, and integrate their points of view. The goal is to achieve the fullest understanding of a patient's situation and develop a plan of care driven by the values of the patient. Such integration is likely to require some accommodation—the final element of the ethical framework.

ACCOMMODATION

Originally developed in the context of home care, the principle of accommodation is a very helpful guide in palliative care.³² Palliative care clinicians are frequently invited into the circle of care for patients whose clinical care is managed by other primary teams. Patients are often in the late stages of progressive illness and may have become dependent on loved ones for rides to appointments, upkeep of their homes, and activities of daily living. As their ability to live independently has slowly eroded, patients have had to accommodate the schedules, preferences, and abilities of others, even when conflicting with their own. Families, in turn, have had to accommodate in similar ways. This is an example of a mutual

and reciprocal process that the principle of accommodation acknowledges and promotes.

Sometimes, however, accommodation can be one-sided or gradually erode into one-sidedness. Collopy and colleagues, in addressing this phenomenon, strive to correct ways in which one-sided accommodation by patients can gradually erode their autonomy:

In practice, such erosion of autonomy is often incremental. Caregivers intervene when clients function slowly and imperfectly. In the basic, repeated routine of care clients' preferences are not elicited; their efforts to be autonomous are waved aside by paternalistic soothing or efficient impatience on the part of caregivers. The dominant interactive pattern is frequently one in which progressive physical and mental incapacity is expected in clients and is equated with progressive inability to be autonomous.³² (p. 8)

These words may seem lacking in sensitivity to the needs of family members, discounting the significant accommodations they have had to make in their lives to care for the sick person. Indeed, family members may have many responsibilities to self and others that have been set aside to meet the needs of a seriously ill loved one. It may seem intuitive that healthy family members must do all of the accommodating because they are well. However, this one-sided approach can be destructive for both patients and families. It can be harmful for patients because failing to ask them to accommodate the needs and abilities of loved ones can constitute a significant departure from their usual role in relationships. This can result in a loss of self as a responsible member of a family, with the give and take that such a role entails. Similarly, a one-sided model of accommodation can harm family members and their relationships with a sick loved one—they may become overwhelmed and resentful.

Accommodation in the palliative care arena is complex. Many different players are involved, including the patient, family members, friends, and members of the healthcare team. Sensitivity and awareness of the ethical issues and complexities implicit in the principle of accommodation will allow the palliative APRN to navigate discussions and make visible the accommodation each person or group is making or being asked to make. This acknowledgment allows people to feel heard and to believe that what they say matters. Because people with advanced disease can be so frail, their voice and agency may be lost inadvertently to the strength of others. It is important that their agency is recognized and re-engaged.

In sum, advocacy, truthfulness, and accommodation constitute an ethical framework guiding palliative APRNs in navigating ethical discussions. While there are surely other principles that would be helpful guides, we have chosen these three because they (a) explicitly and effectively support the moral agency of patients, families, and clinicians and (b) are particularly well matched to the training and role of the palliative APRN.

SKILLS TO NAVIGATE ETHICAL DISCUSSIONS

COMMUNICATION SKILLS

Principles of communication (discussed in depth in Chapter 32, “Advance Care Planning”; Chapter 33, “Family Meetings”; and Chapter 34, “Communication Near End of Life”), are essential for the palliative APRN’s approach when navigating ethical discussions. They include where possible (1) making sure that the patient’s symptoms are under control and that some privacy has been provided; (2) eliciting, understanding, and validating the patient’s perspective of the situation (concerns, feelings, expectations, goals, and values); (3) understanding the patient within his or her own psychological, cultural, social, and spiritual context; (4) reaching a shared understanding of the patient’s situation; and (5) supporting the patient or surrogate in the decision made.^{33–35} These principles of communication are enhanced by certain APRN behaviors, both nonverbal and verbal. Nonverbal behaviors include maintaining eye contact if culturally appropriate, leaning forward to indicate attentiveness, avoiding interrupting the patient, tolerating silence, and refraining from distracting behavior such as glancing at a cellphone. Verbal behaviors include soliciting the beliefs, values, and preferences of the patient; exploring the family’s social and spiritual context and their explanatory model of health and disease; checking the patient’s understanding of what has been said; validating the patient’s emotions; and offering reassurance, non-abandonment, and support.^{34–36}

Understanding the patient’s explanatory model of disease—for example, the patient’s beliefs about what has caused the illness and, therefore, what kinds of treatments may or may not work—is important as it may shape the patient’s response to illness.^{37,38} Such an explanatory model may be learned from multiple sources, including culture, mass media, friends, and family. However, the patient is the best source of such information.

EMPATHY SKILLS

Empathy is a skill that can be taught.³⁹ Empathy has three components: affective, cognitive, and behavioral.^{40,41} Affectively, empathy enables us to have a sense of fellow-feeling with others; to appreciate their lived experience by using imagination to connect it to our own. This fellow-feeling can be a valuable motivator to respond to the suffering of patients and families. The affective component of empathy also carries with it the risk of projective identification. A palliative APRN’s emotional response to a patient’s situation can become overwhelming, directing attention to the APRN’s emotional activation rather than the patient and family. Risk of distortion can be reduced by emphasizing the cognitive and behavioral elements of empathy.

Cognitively, empathy enables the palliative APRN to understand conceptually (a) the elements of others’ experiences and circumstances—the “facts of the matter” and

(b) the *meaning* of those experiences and circumstances *for them*. Such meaning can be elicited through exploration with patients and families of the psychosocial implications of their situations.⁴² Attentive listening, engaging all relevant parties, and facilitation of shared discussion among all those involved contribute to obtaining a fuller understanding of the situation at hand.

Behaviorally, palliative APRNs can communicate with empathy by demonstrating to patients and families that “We have heard and appreciate the significance of what you are going through.” Verbal and nonverbal behaviors which acknowledge patients’ and families’ experience validate and normalize the feelings and significance of that experience and praise their efforts to engage and cope with serious illness. These are key components of behavioral empathy.⁴¹ Active listening and engaging the communication skills explained in the previous section help shape behaviors which create a supportive presence with patients and families.

CASE STUDY: THE CASE OF MR. S (PART II: APPLYING THE FRAMEWORK)

The circumstances of Mr. S were as follows: soon after admission to the hospital, when he was gravely ill and medically unstable, Mr. S’s code status was discussed with him by the admitting physician—no family member was present. He agreed to a DNAR code status. The following day, Mr. S was found to be delirious and without decision-making capacity. His son, who was the family spokesperson and surrogate decision-maker, learned of his father’s code status and asked that the DNAR order be rescinded. The request was honored, and the patient reverted to a full code.

Mr. S’s care team asked the palliative APRN to address this primary question: *How do you proceed when a healthcare agent or surrogate decision-maker challenges a patient’s advance directive after decision-making capacity has been lost?*

Although the team was clear that autonomy, beneficence, and nonmaleficence all support continuing to honor a patient’s documented preferences after decision-making capacity is lost, the reality was that Mr. S’s decision about his code status had been reversed after he lost capacity and the validity of his decision was challenged by his son.

With this as a background, the palliative APRN used communication and empathy skills to engage a process guided by advocacy, accommodation, and truthfulness. In modeling this process the APRN also created a template for a pattern of engagement between the team and the patient’s son that could be used going forward.

Listening to the Narratives

The palliative APRN wanted to have a context within which to frame and understand the son’s position regarding his father’s code status. She therefore needed to hear the narratives of the son and other members of the family. In addition, although the teams’ question to her was quite specific, she wanted to learn more about their concerns.

In this first step, the APRN attentively listened to separate narratives—that of the primary team and that of the family. The patient was unable to participate. It was understood that there might be different narratives among the family members and among the team members. If that were the case, the different narratives would need to be heard.

The Team's Narrative

The patient has far-advanced disease, no further disease-focused treatment options were available to him, and he had agreed to a DNAR code status on admission. No family member had been present at the time of the discussion. The following day after Mr. S had lost decision-making capacity, the physician was challenged by Mr. S's son saying that his father was a religious Jew, had not understood what he was agreeing to, had not consulted with his rabbi, and that his mind had been clouded by pain medications. The DNAR code status was rescinded at the son's request.

The team was concerned that the patient's autonomy and right to self-determination was being violated. At the same time, they fully acknowledged that their knowledge of Jewish law around end-of-life care was limited. The team expressed ambivalence as to whether or not to be guided by the son's knowledge in this area, specifically how it applied to his father's end-of-life care as death drew near. The team wanted to respect the patient's autonomy; they were unsure how best to integrate the patient's stated preferences with the son's knowledge of his father. This concern reflected patient- and family-centered care.

The Wife's Narrative

There was dissension among the family about the patient's code status. The dissension was unsettling to all of them and would have been distressing to her husband. Having the family united had always been important to Mr. S. The family was in agreement that the son should be their spokesperson and surrogate decision-maker.

The Son's Narrative

His father was a Jew and lived his life according to a Jewish code of ethics. His father's consent to a DNAR code status on time of admission was not authentic. He had been under the influence of opioid medications when the discussion had taken place and had not understood the implications of the decision in the context of Jewish law. In addition, no family member had been present at the time the code status discussion took place. He stated that his father would want his care at the end of life to be consistent with Jewish law—guided by his rabbi.

Integrating the Narratives

Eliciting and integrating narratives from key participants in a patient's care provides a background through which the APRN can guide discussions within the framework and ethical principles previously outlined.

What was Mr. S's authentic preference regarding resuscitation? Perceptions and claims by different parties may conflict. Respect for autonomy strongly favors privileging the values and preferences of the patient unless there is a

compelling reason to do otherwise. The son's claims that the father's expressed preferences were not authentic challenged the team's commitment to honor Mr. S's DNAR code status. They were conflicted as to what was the "right" thing to do. They took seriously several of the son's points: (a) that Mr. S had been medically unstable and receiving opioids for pain when the code discussion took place; (b) that he had not had a formal capacity assessment at the time (as his capacity had not been called into question); and (c) that, in an ideal situation, a family member would have been present for the discussion. The team was uncertain if they should honor Mr. S's advance directive in the face of his son's challenge, conceding the preceding points, and aware that their knowledge of the patient and his values was limited compared to the decades-long relationship between Mr. S and his family.

Because the patient's DNAR code status had already been rescinded, the team made the decision to accept in good faith the son's report that his father would want his end-of-life care to conform with Jewish law as directed by the rabbi, swiftly moving forward with the son and rabbi to clarifying the care parameters.

The Family Meeting

Having integrated the narratives, the palliative APRN led a family meeting. The attending physician provided a clear and candid review of Mr. S's medical situation, rapid deterioration, and likely end-of-life scenario with and without attempted resuscitation. The son indicated that he understood the clinical situation, did not want his father to suffer, but wanted his father's death to conform with Jewish law. He again stated it was "what his father would want." The son asked for very specific medical information that he could share with the rabbi: evidence of his father's progressive deterioration, evidence of progressive organ failure, and evidence that death was imminent. Although both Mr. S's attending physician and the palliative APRN offered to speak directly with the consulting rabbi, the son said that he preferred to do so. The requested information was provided to the son both verbally and in written form. Based on this information, the rabbi stated that, according to Jewish law, it was appropriate for Mr. S's code status to be DNAR—but that all other life-sustaining treatments should be continued^{43,44} (see also Chapter 33, "Family Meetings").

By taking such an intentional approach to the *process* of eliciting and integrating everyone's narrative—using the skills and principles outlined in this chapter—the APRN facilitated a discussion notable for its mutual respect, careful listening, and ability to find common ground. Mr. S's care plan was modified to reinstate the DNAR order and maintain other life-sustaining interventions. He died peacefully 48 hours later.

Moral Reflection and Deliberation

Following Mr. S's death, the team and the APRN set aside time for moral reflection and deliberation. Reflection and deliberation can be an important way for team members to maintain connection with each other, restoring focus on the moral foundation and framework of their work.⁷ This approach is grounded on the assumption that good care is defined and redefined in

concrete situations wherein a dialogue occurs involving ethical principles, professional standards, constraints, and the unique circumstances of each narrative.

Although the team expressed relief at the eventual outcome of the case, they described the tension, conflict, and moral distress they had experienced. By accommodating Mr. S's son as an advocate for his father, were they violating the patient's autonomy by negating his advance directive? As they struggled with this tension a question arose: Was it possible that Mr. S's long-standing value of living and dying according to Jewish law had changed when faced with the immediacy of death and associated suffering? Had this change in values led to his agreeing to a DNAR code status without consulting his rabbi? In addition, they wondered if there was some validity to the son's claim that his father's judgment had been impaired by pain and/or opioid administration and that he had not realized the implications of what he was agreeing to. Should they have performed or requested a formal decision-making capacity assessment? Had they been lacking in not doing so?

Creating space for moral reflection and deliberation provided the palliative APRN with a format for educating, debriefing, and supporting the staff following their challenging interactions with the patient's son.

SUMMARY

This chapter has provided the APRN with a structure and language that complement the classic patient-centered care model of autonomy, beneficence, nonmaleficence, and justice. It articulated the ethical foundation of palliative care, explaining further ethical principles and skills to navigate ethical discussions. Throughout, the palliative APRN was recognized as being uniquely well-trained and situated to be an advocate to ensure that the values, goals, perspectives, and concerns of patients, families, and fellow clinicians are appropriately heard in patient care conversations.

APPENDIX A-COMMON DEFINITIONS AND DISTINCTIONS IN PALLIATIVE CARE ETHICS

DECISION-MAKING CAPACITY

Decision-making capacity is a situation-specific clinical determination that a patient is able to make their own healthcare decisions. Capacity has four elements. A patient must be able to

- (a) understand the relevant information,
- (b) appreciate the current situation and its consequences,
- (c) reason about treatment choices; and
- (d) communicate a consistent choice.

The assumption is that a patient has capacity unless indications suggest otherwise.^{45,46} If a patient is found not to have capacity and an immediate decision is not required, clinicians must make a good faith attempt to restore the patient's capacity. If restoring capacity is not possible, a surrogate decision-maker—appointed by the patient or identified per applicable law—makes decisions on behalf of the patient. Any treatment decisions made on behalf of the patient must be shared with the patient. If the patient objects to the determination of incapacity or the surrogate's decision, the care team must seek additional assistance before proceeding.

Questions to consider:

1. What ethical principles are embedded in the concept of decision-making capacity?
2. What are the triggers for a capacity assessment?
3. Does our responsibility end with the initial capacity assessment?
4. How do we mitigate the risk that the initial capacity assessment is inappropriately expanded to all decisions?

FOREGOING MEDICAL INTERVENTIONS

The correlate of a capable patient's right to consent to a medical intervention is the right to refuse such an intervention. It is an established principle of law and ethics that capable patients have the right to refuse any proposed medical treatment.¹⁰ Respecting the patient's treatment refusal, like seeking the patient's consent, is an aspect of honoring the patient's autonomy. For patients to make informed decisions to accept or refuse healthcare interventions, special attention should be given to (a) the adequacy of the information presented and the quality of the explanation; (b) possible language or cultural barriers to understanding; and (c) the patient's appreciation of the consequences, both positive and negative, of all options available to them. When a patient lacks decision-making capacity, surrogates may exercise a patient's right to refuse treatment consistent with the patient's known wishes.

WITHHOLDING AND DISCONTINUING LIFE-SUSTAINING THERAPIES

Palliative APRNs are often part of discussions about starting and stopping life-sustaining treatment. In the ethics literature, decisions to limit life-sustaining treatment are often categorized as either (a) withholding treatment or (b) discontinuing (or withdrawing) treatment. *Withholding* such treatment is a decision "not to start or increase a life-sustaining

treatment.⁴⁷ (p. 859) Whereas *discontinuing* such treatment is a decision “to actively stop a life-sustaining treatment presently being given.”⁴⁷ (p. 860) The prevailing position in the ethics literature is that decisions to withhold and discontinue life-sustaining treatment are considered ethically equivalent, meaning that the same ethical reasoning that would justify withholding a treatment also justifies withdrawing that treatment after it has begun.⁴⁸ However, actions that are conceptually equivalent in the ethics literature don’t always feel equivalent in clinical practice. Some clinicians—especially those new to the field—report that discontinuing a life-sustaining treatment after it has been initiated “feels” different from never beginning such a treatment. Rules may differ among religions in regard to withholding and discontinuing life-prolonging therapy.^{43,44}

Questions to consider:

1. Which ethical principles and values are most helpful when making decisions about withholding or discontinuing life-sustaining treatment with patients and families?
2. How is withdrawing or discontinuing life-sustaining treatment ethically distinct from medical aid in dying?
3. Does a decision to discontinue a life-sustaining treatment require a stronger/different ethical justification than a decision to withhold a life-sustaining treatment? Why or why not?
4. If a palliative APRN has a personal moral objection to discontinuing life-sustaining treatments, is she obliged to explain the option of discontinuing treatment to the patient even if she is not willing, personally, to participate in such discontinuation? (See also the later discussion on conscientious objection.)

PALLIATIVE SEDATION

Palliative sedation is the administration of sedative medications to reduce awareness of suffering which has been refractory to other interventions.^{49,50} While there is some variation across regions and institutions regarding the conditions in which sedation is administered,⁵¹ the defining element of palliative sedation is that it targets a patient’s conscious awareness of distress because more precise targeting of the cause of distress via other interventions has not worked. Sedation can be appropriate for patients who are imminently dying and patients who are not close to death. Considerations for both groups of patients are offered here.

Informed consent for sedation includes discussion of whether concurrently administered treatments—including nutrition and hydration—will continue. There remains a lack of consensus in the literature regarding whether sedation is an appropriate intervention for symptoms which are primarily non-physical, such as existential distress.^{52,53} Some guidelines indicate that sedation is only appropriate when patients are imminently dying—in a matter of days. Others posit that

the aim of reducing refractory suffering is sufficient justification for initiating sedation regardless of a patient’s projected time until death. The most prevalent concern regarding timing is that sedation of patients who are not imminently dying may hasten their death if sedation precludes oral intake and nutrition and/or hydration are not concurrently administered via an alternate route.⁵⁴ Sedation is a distinct intervention from resuscitation; code status for patients considering sedation must be clarified. Palliative APRNs are encouraged to consult their institutional policies and procedures regarding sedation.

PALLIATIVE SEDATION AT END OF LIFE

Palliative sedation is a medical therapy for the imminently dying. The intent is to relieve intractable pain and other symptoms where pain and suffering are intolerable. All parties agree that, because palliative interventions which compromise consciousness have been ineffective, reducing consciousness to reduce awareness of symptoms is acceptable. This is with the consent of the patient or surrogate decision-maker. Sedation is increased until the patient is without evidence of distress and then no further. Clear parameters for increasing the level of sedation are set and documentation is specific. The intent is not to hasten death but to control symptoms. Indeed, when carefully titrated there is no evidence that imminently dying patients who are sedated die more quickly than those who are not sedated.⁵⁵

SEDATION FOR INTRACTABLE SYMPTOMS

In contrast to palliative sedation in the imminently dying, some patients may have intractable symptoms but are not within the last few days of life. At the same time an intensive effort is made to find other means for controlling the symptoms with the patient remaining awake and alert. As previously described, sedation is increased until the patient is without evidence of distress and then no further. Clear parameters for increasing the level of sedation are set and documentation is specific. The intent is to control symptoms while other means to control the symptoms with the patient remaining more awake and alert are sought. All life-preserving measures continue. In contrast to palliative sedation in the imminently dying, there is the luxury of time to explore different approaches to manage the patient’s symptoms.

Questions to consider:

1. How does one determine the harm-benefit ratio of sedation?
2. What are important elements of consent for sedation?
3. Does sedation hasten death? How does one engage this question?
4. How does one ensure that sedation is for the treatment of the patient’s suffering and not the suffering of family/clinicians?

DOCTRINE OF DOUBLE EFFECT

Though there is considerable debate as to its usefulness,^{56,57} the doctrine of double effect remains commonly used and taught in healthcare ethics, especially in end-of-life decision-making.⁵⁸ Rooted in Catholic moral theology, the doctrine presents conditions in which interventions that carry the likelihood of both good and bad effects (outcomes) may be morally justified. Mangan's⁵⁹ formulation of the conditions is most frequently cited, modified here for clarity and simplicity.

- A. The good effects are intended. The bad effects are foreseen but not intended.
- B. The act itself is morally good or neutral.
- C. The bad effect is not the means of producing the good effect.
- D. The good of the good effect must proportionately outweigh the bad of the bad effect.

The doctrine has been used in discussion of opioid titration, palliative sedation, and discontinuation of some burdensome life-sustaining treatments to argue that relief of suffering (intended effect) can justify a perceived risk of hastened death (foreseen effect). Careful use of the doctrine requires (a) engaging all four conditions in the doctrine, (b) agreement regarding which actions and effects are "good" and "bad," (c) ability to discern which effects of an action are intended and which are merely foreseen, and (d) careful clinical assessment of the likely effects of an intervention, ensuring that any possible steps to mitigate the bad effects have been taken.

Questions to consider:

1. Is it necessary to evoke the doctrine of double effect when titrating treatments in response symptom distress?
2. Does proportionality (balancing benefits and harms) and the relationship between beneficence and non-maleficence render the doctrine of double effect unnecessary?
3. How does one identify interventions which are and are not intrinsically good or neutral?
4. How does one distinguish between intended and foreseen effects?

MEDICALLY HASTENED DEATH

Physician-assisted dying (PAD), physician-assisted suicide (PAS), or medical aid-in-dying (MAID) is a practice whereby a physician provides a capacitated, terminally ill patient with a prescription for a lethal dose of medication, upon the patient's request, to end their own life.⁶⁰ Patients self-administer the lethal dose of medication at a time of their choosing. (In some

countries, the term also includes lethal doses of a medication directly administered by a clinician, a practice currently not legal in the United States.) The intended goal is to prevent or relieve intractable suffering through the person's death. As of 2021, the legality of this practice varies across jurisdictions. There is considerable debate over whether PAD/PAS/MAID should be considered a "palliative" intervention. Given societal trends and the leadership role of APRNs in healthcare, it is likely that in the future palliative APRNs (as is the case in Canada) will be authorized to be the prescribing clinician, making knowledge about and careful consideration of the practice essential.

Questions to consider:

1. How does one determine the harm-benefit ratio of medically hastened dying?
2. What are important elements of informed consent for medically hastened dying?
3. How does one ensure that medically hastened dying intended to relieve patients' suffering is not primarily directed by the suffering of family/clinicians?
4. In jurisdictions where the practice is legal, can palliative APRNs morally opposed to medically hastened dying refuse to provide information about the practice to eligible patients?

MORAL DISTRESS

Moral distress can be experienced by clinicians when their ability to practice in accordance with accepted professional values and standards is compromised by factors perceived as outside of their control.⁶¹ It is a relational experience shaped by multiple contexts, including the sociopolitical and cultural context of the workplace environment.⁶² For example, a nurse follows a medical order to increase administration of vasopressors, all the while believing that (a) doing so is violating nonmaleficence and (b) she has no choice but to administer the prescribed treatment. Common causes of moral distress are lack of clarity about goals of care among family members and healthcare providers, disagreement within the team about goals of care, voice not heard, fragmentation of care, and inadequate communication. By identifying the existence of moral distress and talking about it—giving a name to the phenomenon, recognizing it as a multidisciplinary problem—reduces the threat to the individual clinician's moral integrity and can be an instigator for change.⁶³

Questions to consider:

1. Is the experience and acknowledgment of moral distress ethically significant in healthcare, and, if so, why?
2. What are the personal ramifications to the nurse of repeated exposure to situations causing moral distress?

3. Does the experience of moral distress always indicate the patient is receiving inappropriate care? If yes, why? If not, why not?
4. If, as stated earlier, palliative APRNs have a responsibility as clinical leaders to create an ethical climate, how can palliative APRNs help teams identify and address conditions which lead to repeated episodes of moral distress?

CONSCIENTIOUS OBJECTION

Conscientious objection in healthcare refers to a situation where a clinician opts out of participating in a plan of care or providing a particular medical service on personal moral or religious grounds.⁶⁴ The intent of recognizing the right of clinicians to engage conscientious objection is to protect clinicians' ability to practice professionally without damaging their personal moral integrity.^{3,65} Individual moral and religious convictions represent what a clinician stands for on a deep level, constituting their identity as responsible individuals accountable for their actions. To violate such convictions can damage clinicians' moral and religious identities; to bar an individual from engaging in conscientious objection is to put him or her in the position either of resigning or violating his or her conscience.³ As conscientious objection is grounded in personal moral beliefs, it is distinct from a palliative APRN refusing to participate in a clinical intervention because such an intervention is contrary to best practice. When clinicians object to participating in a clinical intervention on personal moral grounds, several conditions must be met to ensure that exercising such objection does not violate the rights of the patient and the accepted norms of nursing practice.⁶⁶

Questions to consider:

1. What are the key differences in refusing to participate in a clinical intervention when based on a personal moral belief or on professional judgment?
2. Are both valid grounds for conscientious objection?
3. If a nurse objects to participating in a clinical intervention based on personal moral grounds, what conditions must be met to ensure that the rights of the patient and accepted norms of nursing practice are not violated?
4. Is it important that an organization has a transparent process/formal policy for engaging conscientious objection? If so, why?

COMMON QUESTIONS FROM PATIENTS AND FAMILIES

Sometimes opportunities for ethical engagement arise not in the form of full discussion but in short—perhaps unforeseen—questions from patients and families. Box 53.1 lists some difficult questions and statements from the patient and/or family that the APRN may be confronted with and on which it can be useful to reflect. Common fears associated with these, and pitfalls to avoid, are also included.

Box 53.1 QUESTIONS TO EXPECT AND PITFALLS TO AVOID

Questions/statements that may arise while navigating ethical discussions:

1. How long do I have to live?
2. Tell me that everything is going to be all right.
3. Are you saying that I am going to die?
4. Is there no hope for me?
5. Don't tell XX (the patient) that he is dying.
6. If you don't feed her, she will starve to death.
7. If this were your mother, what would you do?
8. There must be something you can do.
9. She is going to die anyway, so why not give more chemo?
10. Withdrawing the machine is the same as killing her—euthanasia. Call it what it is.
11. Why can't you just dial up the morphine? Why does she have to linger this way? Why does she have to suffer?
12. How can I tell my children that I am dying?
13. How will I die?
14. What is it like to die?
15. I don't like Dr. Q; is he always so rude?

Common fears when navigating ethical discussions:

1. Being blamed—"shooting the messenger"
2. Saying the wrong thing
3. Eliciting strong emotional responses
4. Not knowing the answer—not being comfortable saying "I don't know"
5. Expressing one's own emotions (crying)
6. Anxiety about one's own mortality

Pitfalls to avoid:

1. Making promises you can't keep
2. Giving information when you don't have the facts
3. Giving premature reassurance

There is an abundance of literature suggesting phrases to use in responding to such questions and statements, and the reader is referred to this literature.^{25,31,67–69}

DISCONTINUATION OF CARDIAC THERAPIES

Patricia Maani Fogelman and Janine A. Gerringer

KEY POINTS

- Heart failure and cardiac advanced practice registered nurses (APRNs) are vital members of the management team for patients with heart failure. APRNs are primarily the providers following patients through trajectories of long-term chronic disease management and progression.
- The heart failure and cardiac APRN is often the primary provider who maintains responsibility for managing the treatment of complex and advancing heart failure.
- Ongoing assessment, medication management, symptom management, care planning, goals-of-care discussions, and end-of-life planning are all under the purview of the APRN.
- Heart failure, cardiac, and palliative APRNs provide medical care and disease management, education, patient and family counseling, and overall health promotion for patients with advancing and/or terminal heart failure.

meeting including the palliative advanced practice registered nurse (APRN), cardiology, Mrs. X and family were informed that once the LVAD was disabled, death would occur within hours. Mrs. X verbalized understanding of these implications and emphasized her poor quality of life. She was particularly distressed by her continued weakness, air hunger, and loss of dignity. Mrs. X declared her desire for deactivation of her device with the transition to comfort care. Her family was tearful but supportive, acknowledging she had struggled for a long time and wanted to avoid prolonging her suffering. The heart failure and palliative APRNs reviewed the procedure for device discontinuation. They planned the deactivation and medications were administered to relieve any respiratory distress or anxiety. Later that afternoon, her LVAD was disabled. The palliative APRN and ICU nurses provided supportive care for Mrs. X, ensuring that her dyspnea, anxiety, and agitation were well controlled. She died peacefully 2 hours later, surrounded by her family.

CASE STUDY: A PATIENT WITH HEART FAILURE

Mrs. X was a 73-year-old woman with an extensive history of heart disease with resulting severe heart failure, chronic kidney disease Stage III, diabetes, hypothyroidism, and osteoporosis. She underwent triple-vessel coronary artery bypass graft (CABG) surgery 15 years prior with two myocardial infarctions in the past 3 years. Her quality of life was deteriorating due to her increasing need for assistance with her daily activities. Mrs. X was not a candidate for heart transplantation. She resided with her husband in their home, and two adult children lived nearby. Approximately 5 months prior, her doctors implanted a left ventricular assist device (LVAD) as destination therapy for her very debilitating Stage IV heart failure, with the hopes that this device would maximize the volume of blood pumped by her heart into her body.

Following device implantation, Mrs. X was in the intensive care unit (ICU) for approximately 2 months due to complications of chronic wound infections, kidney failure, and sepsis. She was discharged from the hospital to a nursing home for short-term rehabilitation and returned home 8 weeks later. Her quality of life did not appreciably improve. After 3 weeks, Mrs. X was readmitted due to significant weakness, fatigue, air hunger, pain, nausea, anorexia, and declining performance status bordering on a performance status of 4. Palliative care was consulted as she began to ask questions about device deactivation. In a family

INTRODUCTION

There are many challenges to the integration of palliative care in the care of heart failure patients, likely due in part to the difficulty of prognostication in a population with exacerbations and a high risk for sudden death, as well as deficits in provider knowledge. Patients with advanced heart failure have demonstrated preferences to discontinue therapies or procedures they deem to be ineffective or burdensome, and they may ask about deactivating devices that had been placed earlier in their disease course, when there was more benefit to be gained. As their disease trajectory evolves, patients demonstrate a desire and willingness to discuss end-of-life planning, redefine the goals of care, and establish a plan for pain and symptom management when their disease can no longer be controlled or managed by their present medical regimen. Healthcare providers, often perceiving death as a “failure,” tend to avoid these discussions. The key to breaking down these barriers is continued promotion of palliative care education and awareness. Palliative advanced practice registered nurses (APRNs) can facilitate the delivery of palliative care to heart failure patients by promoting educational activities on their units and using resources from the American Association of the Colleges of Nursing’s End of Life Nursing Education Consortium (AACN-ELNEC). This national education initiative strives to enhance the delivery of palliative care by providing education and development tools for

nursing staff. The ELNEC project provides APRNs with education in palliative care and advanced disease management and allows these nurse educators to “teach it forward” to their staff, peers, and healthcare colleagues.

DISCONTINUATION OF VASOPRESSORS

Vasopressors are medications delivered intravenously to support blood pressure during periods of hemodynamic instability in the acute care setting, most notably in the treatment of shock. Examples of vasopressors are epinephrine, norepinephrine, phenylephrine, and vasopressin.¹ Vasopressors induce vasoconstriction and elevate arterial pressure.

The general practice is to stop these medications when their desired effects are no longer elicited. Vasopressors are generally discontinued when other forms of life support, such as ventilator support or renal dialysis, are discontinued after the patient, patient’s family, and medical teams have deemed their use to have no further benefit. The role of the palliative APRN is to offer treatment to relieve and anticipate distressing symptoms before discontinuing vasopressors and other forms of life support. In the acute care setting, medications are often stopped either at the same time or before or after ventilator support. It is critical to anticipate the provision of palliative management of terminal heart failure symptoms (pain, dyspnea, nausea, anxiety). To ensure a peaceful death, palliative APRNs should educate the patient and family about the dying process, including signs and symptoms and how they will be managed. This includes sudden cardiac death, hypotension with loss of perfusion (skin changes, mottling, and cyanosis), somnolence, disorientation when awake, restlessness, diminished senses and inability to respond to stimulus (although awareness remains intact longer), coma, changes in body temperature, respiratory pattern changes, and changes in oral secretions.

Palliative APRNs should refer to organizational policies regarding discontinuation of vasopressors. Heart failure and palliative APRNs are often critical players in developing these protocols. If there are complicated circumstances, an ethics consultation should be initiated. The heart failure APRN should rapidly assess the patient to ensure that appropriate care is provided. The palliative care team is especially important in situations where the patient’s acute decline was not expected, thereby exacerbating the period of crisis. Palliative care consultation will help family members decide what the patient would want under the circumstances and will help the family understand the discontinuation process, including how they can keep the patient comfortable during the dying process (see Box 54.1 for discontinuation steps).

DISCONTINUATION OF INOTROPES

Intravenous inotropic agents are used in acutely ill, hospitalized heart failure patients with a severely reduced ejection fraction. In the acute setting, inotropes are used to establish

Box 54.1 DISCONTINUATION OF VASOPRESSORS AND INOTROPES

1. Patient and family discussion regarding goals of care
 - a. Include who would like to be present with the patient during discontinuation
2. Team meeting
 - a. Sequence of medication discontinuation if more than one
 - b. Any other life-saving measures that need to be addressed
3. Room preparation
 - a. Clearing of unnecessary or distracting items
 - b. Prepare the patient; reposition for comfort
4. Interdisciplinary team presence (e.g., spiritual care, respiratory therapy for ventilator)
5. Premedication
6. Discontinuation of medication
7. Monitor until death
 - a. Treat any perceived patient discomfort
8. Death pronouncement per facility guidelines
9. Support for the family and staff
10. Care of the body per facility guidelines

hemodynamic stability by increasing systemic perfusion and preserving end-organ function. The use of inotropes focuses on clinical improvement or as a bridge to a more permanent treatment, such as surgery, cardiac transplant, or left ventricular assist device (LVAD) placement. In rare circumstances, patients at home may receive short-term initiation of inotropes under palliative home care or hospice.

In an acute situation, a discussion should be held with the patient and family regarding the limited options available should inotrope therapy be unsuccessful. Treatment goals should be discussed so that appropriate steps can be taken regarding the patient’s plan of care.² Inotropes may also be used as a long-term palliative treatment in patients whose advanced heart failure is refractory to other guideline-directed oral medications and who are not candidates for a ventricular assist device (VAD) or a cardiac transplant. The goal of chronic inotropic therapy is symptom relief. Inotrope treatment is initiated based on hemodynamic evidence of clinical benefit and on the patient’s wishes. Goals of care and possible end-of-life scenarios should be discussed before starting continuous inotrope therapy.²

The most common inotropes used in the home setting are milrinone, dobutamine, and dopamine. These inotropes can be administered intravenously through a small pump, which allows the patient to remain at home during treatment.³ Palliative APRNs should monitor patients for the risks of continuous inotropic therapy, such as central line

infection, hypotension, and arrhythmias.⁴ To minimize the risk of adverse effects such as arrhythmias, the lowest dose needed for symptom relief should be used.² Inotropes can help reduce hospitalizations and reduce symptoms in advanced heart failure patients. It is important to note that chronic inotrope therapy in patients who are not candidates for cardiac transplant or LVAD results in poor survival outcomes.⁵

APRNs should monitor the patient for changes in clinical status and goals of care. If the patient is no longer benefiting from inotrope therapy, the palliative APRN should revisit the goals of care. APRNs can manage heart failure patients with the right medications and can perform the tasks associated with discontinuation (if allowed in their practice setting), including writing orders to discontinue medications. Again, the palliative APRN should discuss the signs and symptoms of the dying process and should establish mutual goals with the family regarding a peaceful death for the patient. Many patients express their desire to be at home during the final stages of dying. Taitel and colleagues⁶ found that patients who participated in a home inotrope infusion program were more likely to die at home than in the hospital. Patients may be discharged to hospice as well.

DISCONTINUATION OF VENTRICULAR ASSIST DEVICES

Mechanical circulatory support is becoming a widely accepted treatment for patients with advanced (stage D) heart failure with a reduced ejection fraction refractory to guideline-directed oral medications and cardiac device intervention. VADs are designed to assist the patient's failing native ventricle by improving cardiac output.

VADs can serve patients in both the short term, when patients are acutely decompensated and hemodynamically unstable, and in the long term, when patients have chronic advanced heart failure. VADs can stabilize the patient so decisions can be made regarding the plan of care, such as the need for surgical intervention (e.g., revascularization, correction of valve abnormalities, permanent pump placement, or, when appropriate, pump explant).²

Patients who are waiting for a cardiac transplant and need additional support until a donor heart becomes available can receive an LVAD as a bridge to transplant. If the patient's heart failure is severe and irreversible and the patient is not a cardiac transplant candidate, he or she can receive an LVAD as destination therapy. Destination therapy with an LVAD has proved to prolong survival and improve both quality of life and functional status in select patients with end-stage heart failure.⁷

Long-term LVADs are surgically implanted pumps that connect from the left ventricle to the ascending aorta to assist with systemic circulation. Blood exits the left ventricle through the inflow cannula, enters the pump, and is then directed through an outflow cannula to the aorta. An external driveline and power source are connected to the body to power the pump.⁸

Hospitals that offer LVAD therapy have an interdisciplinary team that participates in the patient's pre-implant and long-term care. In October 2014, the Joint Commission mandated that certified destination therapy VAD programs have a palliative care representative who has experience with the VAD population on the institution's interdisciplinary team.⁹ Palliative care services should be initiated early on, when the patient is undergoing evaluation prior to implantation. The role of the palliative care team is to promote goals-of-care discussions, ensuring the inclusion of both the patient and the surrogate decision-makers. Palliative care should be available to support patients who have decided to undergo LVAD implantation, as well as patients who have been deemed ineligible for an LVAD or who decline implantation in favor of optimal medical management alone. The palliative APRN provides ongoing assessment of quality of life, goals of care, and health status. Major changes in health status due to device-related complications or other comorbidities not related to the device may lead to revisiting end-of-life discussions. Potential complications that may result in death include stroke, infection, and multiple-organ failure.⁸ Again, partnership with the palliative care team is vital in managing patients with an LVAD and approaching the end of life.¹⁰

When deactivating an LVAD, many issues need to be considered. Of primary importance is the patient's wishes, expressed either directly or through advance care planning documents such as a living will or surrogate decision-maker. The medical team must agree on the lack of benefit and a minimal chance of meaningful recovery to continuing device therapy. APRNs are integral members of this team as they develop an intimate relationship with heart failure patients and families due to the chronicity of the disease. Caring for these patients at the end of life is just as important as caring for them through their life. If the interdisciplinary medical team cannot reach a consensus regarding device discontinuation, consultation with a hospital ethicist or ethics committee may be necessary.¹¹

Swetz and colleagues¹² found that consultation with palliative care before patients received an LVAD for destination therapy was conducive to developing *personal preparedness plans*, which are expanded advance directives for patients with LVADs. Personal preparedness planning focuses on points unique to treatment with an LVAD, including situations where the heart can be supported by the device but other medical conditions or functional limitations may have a significant negative effect on the patient's health status and quality of life. Preparedness planning can be particularly advantageous if a major adverse event or change in quality of life occurs because palliative care already established a rapport with the patient and family and can focus on the situation at hand.

Various models have evolved for addressing ethical concerns in the treatment of VAD patients.¹³ Key elements note that advance directives are particularly important in VAD patients because most patients and families are not aware of the issues that may arise while the patient is supported with a VAD. For example, the VAD can continue to mechanically support the blood pressure in an otherwise fatal situation.

Box 54.2 TECHNICAL LEFT VENTRICULAR ASSIST DEVICE (LVAD) DEACTIVATION STEPS

1. The APRN should be familiar with the system's alarms and how to turn them off, so as not to cause any additional distress to the patient and the patient's family members.
2. The APRN should order, assist in administration of, and monitor the efficacy of medications directed toward patient comfort prior to LVAD device deactivation because the cardiovascular circulation may significantly decrease when the LVAD ceases to function.
3. Removal of the power sources and the driveline from the controller will cause the LVAD to stop functioning. As with ventilator discontinuation, the APRN should be prepared to act quickly to prevent and treat signs and symptoms of discomfort.

Discussion should be based on the type of support the VAD will offer, either as destination therapy or a bridge to transplant, keeping in mind that the patient can transition between the two types of support under certain circumstances. The model further states that discussion should occur before an advance directive is formulated regarding complications related to the implant procedure and to VAD therapy, such as bleeding, neurological events, and infection. This is the time to address any major conflicts between the patient and designated decision-makers.

Prior to deactivation of the LVAD, the following points should be discussed with the patient and a surrogate decision-maker: current condition and prognosis, change in benefit of current therapy, how the device will be halted, how symptoms will be treated, patient and surrogate decision-maker's readiness to proceed, and the anticipated outcome.¹⁴ There are models of LVADs which have different steps for deactivation. Healthcare professionals should first refer to any institutional protocols regarding VAD deactivation. In the absence of a formal institutional protocol, Gafford and colleagues¹⁵ have outlined key points for LVAD withdrawal so that the patient can die peacefully (Box 54.2).

Deactivation can occur in the hospital or at home, depending on the patient's medical condition, preference and wishes for site of death, and whether the event is acute or chronic. In the hospital, the APRN can oversee the process and be available to support the patient, the patient's family, and the staff. This includes writing orders for discontinuation of the device and administering medications for comfort. If deactivation is to occur at home, the process will depend on whether hospice is involved and state advanced practice nurse statutes. The palliative APRN may be responsible for overseeing the deactivation from start to finish. Or they may teach the patient's family or hospice staff how to deactivate the device and how to administer medication for the patient's comfort to ensure a peaceful death. Both in the hospital and at home, the palliative APRN acts as a liaison between the patient and the heart failure team to determine how to dispose of the external

Box 54.3 COMPREHENSIVE LEFT VENTRICULAR ASSIST DEVICE (LVAD) DEACTIVATION STEPS

1. Patient and family discussion regarding goals of care¹⁴
 - a. Include who would like to be present with the patient during deactivation
2. Team meeting
 - a. Who will deactivate the device?
 - b. Any other life-saving measures that need to be addressed
3. Room preparation
 - a. Clearing of unnecessary or distracting items
 - b. Prepare the patient; reposition for comfort
4. Interdisciplinary team presence (e.g., spiritual care, respiratory therapy for ventilator)
5. Premedication¹⁵
6. Deactivation of LVAD¹⁴
 - a. Attempt to limit device noise to decrease anxiety for patient and family
7. Monitor until death¹⁵
8. Death pronouncement per facility guidelines
9. Support for the family and staff
10. Care of the body per facility guidelines

LVAD equipment according to local regulations for biological medical equipment (see Box 54.3).

DISCONTINUATION OF EXTRACORPOREAL MEMBRANE OXYGENATION

Extracorporeal membrane oxygenation (ECMO) is a form of temporary mechanical circulatory support used in critically ill patients with respiratory and/or cardiac failure. It is connected to the patient via cannulas in the large arteries and veins, removing blood from the body and transporting it to an oxygenator that adds oxygen and removes carbon dioxide (lung function). It then returns blood to the heart through a pump with the same force as the heart (cardiac function).¹⁶

Venoarterial (VA)- ECMO is used in patients with acute cardiogenic shock and/or cardiac arrest as either a bridge to recovery or other treatment. It does not cure the patient of the underlying condition. It provides time for the patient to heal or acts as a bridge to another long-term solution such as LVAD or heart transplant, staying in place for days to weeks until a decision can be made.¹⁷ Ethically, it may be more beneficial to discontinue ECMO support after a prognosis becomes clear instead of withholding treatment under acute clinical conditions in which the outcome is uncertain.¹⁸

Critically ill patients requiring ECMO are usually cared for by a multidisciplinary team including critical care, cardiology, cardiothoracic surgery, perfusion, and anesthesia. Core ECMO teams usually consist of specially trained physicians, an ECMO coordinator, nurse practitioners, staff nurses, perfusionists, and respiratory therapists.¹⁹ Potential complications can include pulmonary edema, limb ischemia, ischemic stroke, intracranial bleed, severe bleeding, and infection.²⁰

The acute need associated with ECMO can leave little time for detailed discussions regarding goals of care. The patient being placed on ECMO may not be able to participate in decision-making. In this case, the medical team and surrogate decision-maker often need to make complex decisions based on clinical outcomes that are not entirely clear.²¹ If recovery becomes unlikely, the palliative APRN can support both the clinical team and family as the goals of care are discussed and plans for termination of therapy are made. If discontinuation of ECMO is likely to result in immediate death, surrogate decision-makers and even staff members may perceive this decision-making as a profound burden.²²

The palliative APRN can support the ECMO patient and families as they would any other acutely ill patient at a high risk of dying by continually assessing and clarifying the patient's and family's understanding, providing emotional and spiritual care, supporting conversations regarding patient-centered goals of care, and helping to provide comfort to the dying patient.²³ They also collaborate with their interdisciplinary team members, such as social work and chaplaincy, to provide support to patients, families, and health colleagues.

Often, the patient does not have the capacity to request or participate in the decision to discontinue ECMO support.²⁴ The palliative APRN may facilitate communication between the surrogate decision-makers and clinical team by organizing and leading family meetings to discuss clinical progress and goals of care. When patients are transitioning from a process of living to a process of dying, they or their family may decide to stop life-prolonging measures, and direct communication with the decision-makers is important to decrease the burden associated with making decisions for a patient unable to participate. Again, the palliative APRN can oversee the process and support the patient, surrogate decision-makers, and staff by writing orders for discontinuation of the device and administering medications for comfort.

DISCONTINUATION OF PACEMAKERS/ AUTOMATIC IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Implantable pacemakers are commonly used to treat patients with symptomatic bradycardia and sinus node dysfunction. Current pacing systems have one or two leads that are positioned in the right atrium and right ventricle and a small computerized pulse generator that is placed under subcutaneous tissue in the shoulder area. The pacemaker can deliver an electrical pulse to the heart, leading to cardiac muscle contraction.²⁵

Implantable cardioverter-defibrillators (ICDs) are devices that increase survival by terminating life-threatening

arrhythmias. ICDs do not treat heart failure by improving cardiac function or decreasing symptom burden, but they decrease the risk of sudden cardiac death.²⁶ The 2017 American College of Cardiology Foundation/American Heart Association/Heart Rhythm Society *Guidelines for the Management of Patients with Ventricular Arrhythmias and Prevention of Sudden Cardiac Death* address the specific criteria, determined through clinical trials, to identify those patients most at risk and make recommendations for the proper use of ICD devices.

Cardiac resynchronization therapy (CRT), on the other hand, synchronizes segmental and global contraction of the left as well as the right ventricle in patients with systolic heart failure who have a left bundle-type wide QRS complex and clinical symptoms of heart failure despite optimal medical therapy.²⁷ CRT can be combined with a pacemaker or ICD.²⁸

CRT and ICD therapy may be available in the same device, but they offer very different options. CRT reduces the altered electrical activation of the left and right ventricles. This sometimes leads to favorable reverse remodeling and decreased severity of mitral regurgitation and left ventricular hypertrophy. CRT has been shown to improve survival and can significantly reduce symptoms and improve quality of life in end-stage heart failure patients. ICDs treat life-threatening tachyarrhythmias but do not improve symptoms. CRT-D (CRT with an ICD) implantation should prompt discussion regarding deactivation of either or both functions.²⁹

The patient's goals of care should be assessed prior to implantation of a cardiovascular implantable electronic device (CIED), such as a pacemaker or ICD. The health-care provider is responsible for discussing both the risks and benefits of CIED therapy. The palliative APRN can initiate discussion regarding deactivation and scenarios for the end of life prior to CIED implantation. The APRN may recommend that the patient complete an advance directive to outline his or her wishes at the end of life and designate a surrogate decision-maker. Deactivation should be readdressed should any major changes occur in the patient's health status,³⁰ as when prompted for a generator change, notification of device recall, diagnosis of another life-limiting illness, and when a decision is made for hospice care.³¹ Sometimes, it is necessary to remove a CIED system, the generator, or the leads due to complications such as a CIED infection or structure failure of the CIED (e.g., lead fracture). When a pacemaker is removed, the indication for pacing versus risks of reimplantation should be discussed. When an ICD is removed, the patient is no longer protected from sudden cardiac death and a discussion regarding if and when to place a new ICD should occur.³²

Prior to device deactivation, the patient should understand his or her prognosis, any treatment options, and what will happen when the device is discontinued. For example, the palliative APRN should discuss with the patient how deactivation of an automatic ICD may lead to death if a life-threatening arrhythmia occurs.³³

Any provider or institution that implants CIEDs should have a protocol in place that clearly outlines the process for deactivating CIEDs when withdrawal of such care is

appropriate. Palliative care professionals can facilitate discussions regarding deactivation of CIEDs, including the patient's and family's wishes as well as expected symptom management.³⁴ The final decision as to whether an ICD is burdensome should be made by the patient or a surrogate decision-maker.³³ A study by Buchhalter and colleagues³⁵ of patients who underwent cardiac device deactivation revealed that more than half of the requests for device deactivation came from surrogate decision-makers.

Whenever possible, deactivation should be performed by healthcare professionals with electrophysiology experience. This may include physicians and device-trained APRNs or technologists. In the absence of a device-trained specialist, deactivation can be performed by a healthcare professional such as a physician or an APRN under the guidance of an industry representative.³⁶ When a patient is at home with hospice or home health, a pacemaker magnet can be used to deactivate an ICD generator if a programmer is unavailable.³⁴ These general steps can be followed in any setting in which deactivation occurs, including acute care hospitals, patient care facilities, or the patient's home. Pacemakers may be discontinued by changing the programming mode, or the rate may be lowered and the output adjusted so that the device is no longer functional. ICD deactivation can be performed by changing the programming or, for certain pulse generators, constant application of a magnet over the device. Placement of a magnet over a pulse generator of most ICDs will temporarily cease the anti-tachycardia therapies while not affecting the pacemaker function. To spare the patient from multiple painful shocks, a doughnut magnet and instructions for use should be provided to patients with a terminal diagnosis.² The patient should be reassured that deactivation of the ICD through reprogramming is not painful.³⁷ The defibrillator function of an ICD is separate from the pacing function. Pacing does not need to be disabled when the ICD is reprogrammed. Pacing may treat bradyarrhythmias and cardiac resynchronization at the end of life for symptomatic relief in patients without causing discomfort (Box 54.4).³⁸

**Box 54.4 AUTOMATIC IMPLANTABLE
CARDIOVERTER-DEFIBRILLATOR (AICD)
DEACTIVATION STEPS**

3. Deactivation of the AICD
4. Support for the patient, family, and staff

**PALLIATIVE CARE AND THE
ADVANCED HEART FAILURE PATIENT**

Patients with advanced heart failure are living longer and with far more advanced modalities than once thought possible. Medical innovation highlights its intention to prolong life, but without attention to the truth that, for all of us, the natural endpoint of all life—death—will eventually arrive. APRNs are often the primary providers for these patients over their disease continuum, and it is the time-tested strength of this patient-APRN partnership that builds trust and therapeutic rapport and facilitates discussions about difficult but necessary end-of-life topics. The APRN can initiate the discussion about advance illness planning and revisit this discussion during clinic appointments throughout the disease management trajectory.

APRNs can initiate the referral to palliative care for early, upstream involvement to ensure comprehensive, patient-focused care that is not solely “disease-focused” but involves critically assessing the overall needs of the patient, family, and caregivers while allowing for periodic reassessment of needs and preferences. Considerable discussion and attention tends to be given to life-sustaining treatment while end-of-life issues are often considered the bane of patient-provider dialogue.²⁶ Advanced illness discussions are often deferred or avoided for a multitude of reasons including provider discomfort, patient fears, and inconsistent prognostication, as well as a shortage of trained palliative care clinicians. For this latter reason, earlier integration of palliative care principles into medical school, residency, and fellowship education will increase awareness of and understanding about palliative care in advanced diseases, with the hopeful goal of leading to earlier utilization of palliative care in the trajectory of chronically, progressive heart failure.^{39,40} Advanced illness management requires ongoing goals-of-care discussions and shared decision-making as crucial to navigating the divergence between patient and provider ideals on perceived quality of care. For patients with advanced heart failure, especially those with assistive devices, early palliative care discussions and interventions are critical.^{40,41}

Thanks to progress in bioengineering, devices can be used as destination therapy, aiming for stable provision of cardiac function; to this end, devices are now able to be successfully implanted in the human body. With this advanced technology, however, comes the responsibility to ensure that patients are aware of the risks, complications, and adverse outcomes. Medical technology fosters the conviction that one does not have to die “yet,” which further solidifies an existing resistance or reluctance to discuss advanced illness planning, symptom management needs, goals of care, end-of-life care preferences, and code status.^{42,43} National nursing and medical professional organizations have taken up the call to advocate for earlier and more appropriate involvement of palliative care in the care of patients with advanced disease.^{44–47}

In palliative care, these challenging discussions provide the foundation for optimizing comprehensive “whole-person” care of the cardiac failure patient, especially those with

implanted devices. Withdrawal of device support is an issue rampant with ethical and moral conflict, further emphasizing the need for early involvement of palliative care in partnership with cardiology so that effective, comprehensive care can be delivered to patients with advanced heart failure.⁴⁸ Palliative care assists patients across their continuum of illness, regardless of whether therapy is curative in intent, offering clinician and patient/family centered perspectives on a barrier-breaking approach to care with education, resources for support, frank but compassionate conversations about symptoms, advance illness planning and a framework for re-evaluation of goals as the disease progresses over time which integrates teaching from national models of care such as ELNEC.^{49–54}

SYMPTOM MANAGEMENT

The predominant symptoms of distress for most dying patients, and especially those with cardiopulmonary organ failure, are pain, anxiety, and dyspnea. The goal of therapy for these symptoms is to ensure relief from suffering while allowing the desired level of interaction for as long as possible. Opioids such as morphine have been foundational medications to providing relief from the more severe symptoms of end-stage heart failure, such as dyspnea and pain.⁵⁵ It is important to bear in mind that there is no maximum dose of opioids for patients with end-of-life symptoms: patients must receive the dose that controls and relieves their distress and suffering and provides maximal comfort—sometimes in the necessary form of palliative sedation. Stronger medications may be necessary (see Chapter 43, “Pain” and Chapter 44, “Respiratory Symptoms” for more information).

The American Pain Society provides excellent guidelines and dosing recommendations for opioid medication management for end-stage or advanced illness.^{55,56} *Principles of Analgesic Use in the Treatment of Acute Pain and Cancer Pain*⁴³ is a clinical resource that provides well-established guidelines for opioid initiation and management. This publication provides a solid framework and guidance for safe medication administration that can be useful for all practitioners.

The palliative APRN’s goals for palliative care of the end-stage heart failure patient are to ensure clear patient and family communication, provide psychosocial support, and, when indicated, relieve pain, dyspnea, nausea, and any other distress. The APRN facilitates discussions to determine the goals of care by direct communication with the patient and family, by arranging a family meeting with palliative care and medical teams, or perhaps, if early in the disease trajectory, by simply initiating the referral to palliative care, with a preliminary patient discussion about the importance of planning for advanced illness and the services offered by additional consultants. Common symptoms to anticipate include chest pain, shortness of breath/dyspnea, air hunger, anxiety, nausea, and, later in the process, hallucinations. For patients with an LVAD, one of the most serious risk factors is a traumatic brain bleed leading to death. For these patients, control of neurotrauma-related symptoms is of utmost importance as

they can often be most distressing to the family. Symptoms can include increased secretions, agitation, and myoclonic or seizure-like activity.

PAIN AND DYSPNEA

Pain and dyspnea are best relieved using a multimodal approach: relief of pain and dyspnea with opioid therapy,^{55–56} mindful breathing practice,⁵⁷ and the additional control of air hunger via enhanced air movement modalities such as a ceiling or oscillating fan because air movement across one’s face often reduces the sensation of breathlessness, leading to a decreased sense of air hunger/dyspnea and anxiety.⁵⁴ A cooler temperature may also add to comfort and provide relief, as the reduction of humidity can remove it as a trigger for shortness of breath. The primary goal is to always assure the temperature of the room is comfortable for the patient. For patients who are awake and alert, the use of oral opioids for pain and dyspnea is preferred; for those with refractory or uncontrolled symptoms, escalation to intravenous or continuous therapy is preferred.^{55–57}

MEDICATIONS USED AT END OF LIFE FOR PATIENTS WITH END-STAGE CARDIAC DISEASE

Patients with end stage cardiac diagnoses struggle with symptoms that may be physical, psychological, and spiritual. The APRN should bear in mind that not all suffering is physical, but the physical symptoms may often cause the most initial distress to the patient and will be what the family members remember after death. In heart failure, the symptom prevalence is as follows: pain (78%), dyspnea (61%), depression (59%), insomnia (45%), anorexia (43%), anxiety (30%), constipation (37%), nausea/vomiting (32%), fatigue, difficulty ambulating, and edema.^{53,54} The APRN should continue to evaluate the patient’s comfort and symptom burden and determine when/if additional interventions are warranted.

Diuretics: Furosemide (Lasix) and Torsemide (Demadex)

Heart failure patients at the end of life often have fluid overload, and diuretics are the core treatment of hypervolemia in these patients. Fluid status should be assessed prior to device removal. If a volume overload state is assessed, additional diuretic should be provided prior to withdrawal. Doses will vary because heart failure patients through the course of their illness tend to tolerate relatively high doses of diuretics; it is recommended that dosing be –initiated at the patient’s last known dose and increased in 10–20 mg increments from their baseline dose. Advanced heart failure patients develop diuretic resistance over time, which requires rotation to a new diuretic (e.g., from furosemide to torsemide, which has been shown to have a better reduction in brain natriuretic peptide [BNP] level, collagen volume fraction [CVF], and edema). However,

no meaningful difference between the agents concerning glomerular filtration rate (GFR), water extraction, and sodium excretion was demonstrated.⁵⁸ Regarding side effects, no significant difference among diuretics was observed in terms of hospital readmission and mortality rates. Therefore, there is no “correct” dose, but instead there is a “right dose for the patient.” A urinary catheter should be in place for comfort, as frequent urination could create more distress than relief. To further reduce fluid overload, the palliative APRN should stop therapies that do not provide or contribute to comfort (e.g., intravenous fluids, continuous infusions). Opioids, when given as an infusion, can be concentrated to limit unnecessary fluids: the pharmacy can assist with this higher concentration.⁵⁵

Lorazepam (Ativan)

Patients with end-stage cardiac diagnoses become more dyspneic with disease progression, leading to increasing levels of anxiety. Lorazepam is used to treat anxiety due to disease progression, uncontrolled dyspnea, or fear of dying. In addition, heart failure patients experience nausea from the effects of hypoperfusion and hypotension, for which lorazepam may also provide relief.⁴⁶ It can be given as an elixir, subcutaneously, intravenously, or as a continuous infusion for management of nausea, agitation, anxiety, myoclonus, or seizures. Dosing varies based on the patient’s history and needs. Begin at 0.5 mg intravenously or orally every 4 hours as needed and rapidly titrate up to an effective dose; doses may be needed every hour for some patients.

Olanzapine (Zyprexa)

Olanzapine is a second-generation atypical antipsychotic that has shown off-label efficacy for the treatment of nausea, delirium, anxiety, insomnia, and cachexia in adults. This capacity for multisymptom relief allows it to be preferable to other alternatives such as haloperidol because it has a less significant impact on QTc intervals. Dosing begins at 2.5 mg daily and can be increased in 2.5 mg increments up to 20 mg daily.^{59,60}

Hyoscyamine (Levsin)

As their level of consciousness decreases, dying patients lose their ability to swallow and clear oral secretions. As air moves over the secretions, which have pooled in the oropharynx and bronchi, the resulting turbulence produces noisy ventilation with each breath, described as “gurgling” or “rattling” noises. While there is no evidence that patients find this “death rattle” disturbing, the noises may be disturbing to family, visitors, or caregivers, who worry the patient is choking to death. The death rattle is a good predictor of approaching death; one study indicated that the median time from onset of the death rattle to death was 16 hours.

Hyoscyamine should be given as an intravenous or subcutaneous injection for the management of oral secretions and is preferred over suctioning, which can cause further damage, swelling, edema, and secretions in the posterior airway and

increase patient distress. Dosing generally begins at 0.125 mg given intravenously every 4 hours.⁶¹

Scopolamine (Transderm Scop)

An option for oral secretion management is scopolamine. Scopolamine patches decrease secretions over a longer period of time. Scopolamine should not be used for acute symptoms because it takes an hour or so to take effect, but it does have the benefit of a steady state of symptom management. The usual dose for scopolamine is a 1.5 mg patch placed on the hairless area of skin just behind one ear. The patch needs to be replaced every 72 hours.⁶²

Glycopyrrolate (Robinul)

Glycopyrrolate is an anticholinergic agent with approximately five times the anti-secretory potency of medications such as atropine, but it can have issues with erratic absorption. When administered intravenously, its onset of action is usually noted within a few minutes; dosing begins at 0.2 mg and can be increased to 0.4 mg every 1–4 hours as needed. It is especially helpful when administered 15 minutes prior to extubation in cases of compassionate extubation with transition to comfort care. For this reason, it can be a highly effective option for rapid improvement of distressing death rattle secretions for the patient’s family and caregivers.⁶³

Haloperidol (Haldol)

Haloperidol can be given as a liquid or as a subcutaneous or intravenous injection for management of agitation, restlessness, nausea, or terminal delirium. Delirium can be seen in a disproportionate amount of patients in end-of-life care; Terminal delirium is an acute change in the level of arousal; features include an altered sleep–wake cycle, mumbling speech, disturbance of memory and attention, and perceptual disturbances accompanied by delusions and hallucinations. Haloperidol is commonly used for sedation. Haloperidol is administered in a dose-escalation process similar to that used to treat pain: the starting dose is 0.5–2 mg given orally or intravenously every hour as needed.⁶⁴

Medical Cannabis

There is an increasing interest in the use of medical cannabis largely due to its potential to help reduce opioid dose requirements. There are variations in state and federal regulations as well as global views. It may not be available in the acute care setting but rather in the home setting. The data remain mixed, with no irrefutable evidence that medical cannabis diminished pain severity or yielded an opioid-sparing effect. Systematic reviews show doubt and bias, and conclusions had Grading of Recommendations, Assessment, Development and Evaluations (GRADE) rating of low- to very-low-quality evidence. As medical cannabis use increases, it is vital that well-constructed clinical trials, inclusive of patients with complex comorbidities, be performed (Table 54.1).^{65–67}

Table 54.1 SYMPTOM MANAGEMENT MEDICATIONS

MEDICATION	PURPOSE	ROUTES	DOSE RANGES
Furosemide, Torsemide ⁵⁸	Fluid volume management, relief of swelling, dyspnea/	IV, oral	Begin at patient's baseline dose and increase by 10–20 mg increments.
Lorazepam ⁴⁶	Anxiety	IV, oral	0.5 mg IV or PO q4h as needed; rapidly titrate up to an effective dose. Doses may be needed every hour for some patients.
Olanzapine ^{59,60}	Nausea	Oral	Begin 2.5 mg PO daily, increase in 2.5 mg increments to max dose of 20 mg/day.
Hyoscyamine ⁶¹	Anti-secretory	IV	Dosing generally begins at 0.125 mg given IV q4h
Scopolamine ⁶²	Long-acting drug for secretion management	Transdermal	1.5 mg patch placed on the hairless area of skin just behind one ear and changed ever q72h. May be increased to 2 patches (one behind each ear) if no improvement in 72 hours.
Glycopyrrrolate ⁶³	Anti-secretory	IV: Onset of action is usually noted within a few minutes.	0.2 to >0.4 mg every 1–4 hours as needed <i>or</i> start 15 min prior to compassionate extubation.
Haloperidol ⁶⁴	Agitation, restlessness, nausea, or terminal delirium	IV, SQ, or oral	0.5–2 mg PO, IV, or SQ every hour as needed
Medical Cannabis	Pain, nausea	Edibles, inhalational, tinctures	Availability varies with state policies governing use. Check your state's rules.

CARE TO PROMOTE HUMAN DIGNITY

Many nonpharmacological yet therapeutic options promote human dignity in caring for patients who are dying with end-stage cardiac diagnoses.

- *If a patient is feeling warm or uncomfortable:* Cool mouth swabs, cool compress to forehead. Families can be encouraged to participate in this care.
- *For mild dyspnea:* An oscillating fan, promoting air movement across the face can be helpful. Facilities may not allow fans if there is the potential to spread viruses and bacteria, particularly with new procedures with the onset of COVID-19. However, in the home setting, this is a preferred strategy to ameliorate shortness of breath
- *For increased oral secretions (or those not yet controlled by medications like hyoscyamine):* Position or instruct the family to position the patient on his or her side or in a semi-prone position to facilitate postural drainage.
- *Encourage a peaceful atmosphere and family participation:* Use gentle massage, soft music, comforting stimuli (e.g., reading favorite poems or stories, religious music, aromatherapy).
- *Promote a calm environment and healing environment:* Food, support of a vigil volunteer, continued presence, and ask the family members or caregivers “What helps you relax? What would help you feel more comfortable?” (Try to meet their requests whenever possible within the means and resources of your organization.)⁴⁰

SUMMARY

Mark Lazenby, APRN, once wrote: “Nursing imagination establishes the hope of health promoted, health restored, or life safely passing. When we are able to help our patients achieve that, through our imagination, we have resisted the threat of becoming an automaton. This is the ethical significance of imagination in our everyday lives as nurses. Through the habit of imagination, we preserve our patients’ humanity in the world of automation and technology. We preserve our own as well.”⁶⁸

The management of heart failure begins with advance care planning: for patients with advanced heart failure, early palliative care intervention embodies an alliance between cardiology and palliative care with the shared goal of optimizing heart failure patients’ care and well-being. Ongoing supportive care, with multimodality approaches including telephonic support, counseling, or medication management for effective symptom relief will all contribute to reducing both patient and caregiver burden and improving their quality of life.⁶⁹ Truly patient-centered planning entails timely referral to and partnership with palliative care so that the plan of care can be customized. Early and ongoing discussions with patients and families are vital elements to assuring ongoing, goal-concordant care. As heart failure worsens, the patient’s needs will change as existing symptoms will intensify and new symptoms develop, and the goals of care need to be modified.

The palliative APRN can advocate for patients with heart failure and their families to ensure they receive excellent care throughout the illness and at the end of life. Palliative APRNs can manage cardiac medications and partner with palliative care for advanced modalities when the symptom

burden intensifies or becomes refractory. Palliative APRNs caring for these patients must remember that end-of-life care is an art as well as a science, balancing the needs of the patient and effective symptom management.

DISCONTINUATION OF RESPIRATORY THERAPIES

Brenna Winn

KEY POINTS

- The palliative advanced practice registered nurse (APRN) must have clinical knowledge of respiratory conditions that warrant advanced respiratory support.
- The palliative APRN must understand the importance of mastering effective communication with the family and/or patient regarding decisions to discontinue respiratory support/technology.
- The palliative APRN should anticipate and proactively manage symptoms associated with discontinuing respiratory support/technology at end of life.
- The palliative APRN must have an understanding of and take necessary precautions for withdrawing respiratory support in the setting of COVID-19.
- The palliative APRN must understand the clinical, ethical, and legal aspects of discontinuing respiratory support/technology.

CASE STUDY: DISCONTINUING RESPIRATORY SUPPORT

LM was an 81-year-old man with a past medical history significant for chronic obstructive pulmonary disease (COPD); diabetes type 2; coronary artery disease, status post double coronary artery bypass surgery in 1994; and a cerebrovascular accident (CVA) in 2013, leaving him with right-sided weakness and mild dysphagia. His dysphagia and right-sided weakness improved after his stay in inpatient rehabilitation. LM was recently admitted to the hospital with acute respiratory distress and fever. He was found to have pneumonia on chest radiograph and was started on oxygen as well as intravenous antibiotics.

LM had a rapid response called early the next morning; he was tachycardic, hypoxic, and minimally responsive. He was transferred to the intensive care unit (ICU) and emergently intubated for airway protection. LM's morning labs revealed a significant drop in his hemoglobin. A gastroenterology consult was placed. Further lab tests were ordered which raised concern for possible leukemia. An esophagogastroduodenoscopy revealed a gastrointestinal bleed. Hematology-oncology were consulted for further workup. Further testing confirmed an acute leukemia diagnosis. The palliative care team was consulted on hospital Day 11, intubation Day 10. LM lived with his wife of 63 years, and they had two grown children; all family members were involved in his care. The palliative advanced practice registered nurse (APRN)

was in daily communication with the intensivist in the ICU as well as the hematology/oncology team. Both ICU and hematology/oncology had discussed the patient's new diagnosis with the family as well as LM's overall prognosis.

Unfortunately, LM had difficulty weaning from the ventilator due to severe delirium and agitation thought to have been encephalopathy secondary to his acute pneumonia infection. The weaning process went on for several days during which the palliative APRN met daily with the family and continued ongoing discussions regarding their goals of care. LM's wife expressed that LM "would never want to live like this nor would he ever want to go through any sort of chemo treatment. I know he would rather just be comfortable. His only request has only ever been that he does not die in the hospital. Do you think he can make it home?" LM's wife was elderly herself and taking care of him at home would have been incredibly difficult for her.

The discussion regarding transitioning to comfort care was held with the goal being to transfer to the hospice house nearby. As part of the conversation of transitioning to comfort care, the procedure of palliatively extubating LM was described in detail to the family. There was emphasis placed on ensuring that LM would be calm and comfortable prior to beginning the procedure and throughout the end of his life.

The family made the decision to stay in the room for the procedure, the palliative APRN was present for emotional support and to assist in expert symptom management during extubation and afterward. LM received a bolus of morphine 2 mg IV and lorazepam 1 mg IV prior to extubating. He remained comfortable during the procedure. He received an additional three doses of morphine 2 mg IV and one additional dose of lorazepam 1 mg IV prior to transferring to the hospice house later that afternoon. His symptoms were well-managed at the hospice house by the hospice nurses. LM died 2 days later with his entire family at his bedside.

INTRODUCTION

Discontinuation of respiratory technology is a frequent occurrence in intensive care units (ICUs) all over the world. This procedure may be referred to as *compassionate extubation* or *palliative extubation*. In fact, 40% of ICU deaths typically involve palliative extubation, removal, or discontinuation of respiratory support.¹ *Respiratory technology* is a broad term that includes mechanical ventilation, noninvasive positive-pressure ventilation (NPPV), extracorporeal membrane oxygenation (ECMO), and high-flow nasal

**Box 55.1 ACRONYMS FOR TYPES OF
SUPPLEMENTAL OXYGEN**

AIRVO: High-flow nasal oxygen
NPPV: Noninvasive positive-pressure ventilation
ECMO: Extracorporeal membrane oxygenation
BiPAP: Bilevel positive airway pressure
CPAP: Continuous positive airway pressure

oxygen (AIRVO). NPPV includes modalities such as continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and delivered oxygen (see Box 55.1). There are very few standards or protocols for discontinuing respiratory technology.² However, there are a multitude of research and case studies to guide APRNs when faced with patients in respiratory failure.

Discontinuing advanced respiratory technology is a carefully planned process that can occur when all efforts of weaning ventilation have failed, treatments may be nonbeneficial, and death is expected. When discussions regarding discontinuation of respiratory support arise, palliative advanced practice registered nurses (APRNs) and care team members have acknowledged that death is probable and that continuation of life-sustaining treatment may be prolonging the patient's dying process.³ Typically, multiorgan failure is also a common factor that further validates poor prognosis and further warrants these discussions with families.⁴ This chapter promotes a better understanding of the clinical, ethical, and legal aspects of discontinuing respiratory technology as well as improving symptom management skills associated with end of life in these patients.

RESPIRATORY FAILURE AND TYPES OF RESPIRATORY SUPPORT/TECHNOLOGY

Acute respiratory distress syndrome (ARDS), also known as hypoxic respiratory failure (AHRF), is one of the most common causes of critical illness requiring intensive care unit (ICU)-level care and advanced respiratory support.⁴ ARDS is defined clinically as acute arterial hypoxemia, with a minimum requirement of 5 cm H₂O positive end-expiratory pressure (PEEP). Patients who meet this criteria typically exhibit signs on chest radiograph (CXR) such as bilateral opacities not exclusive to fluid overload⁵ or cardiogenic pulmonary edema.⁴

OXYGEN

Oxygen is often used in patients with chronic obstructive pulmonary disease (COPD) or ARDS to alleviate dyspnea. However, there is little evidence proving that the addition of medical oxygen alleviates feelings of breathlessness. Supplemental oxygen is often part of palliative care or comfort care order sets, but it may not always be helpful. Some patients can report subjective improvement in symptoms

with addition of oxygen, and it can also lend psychological benefit to some patients and their families. However, oxygen can be uncomfortable for some patients, causing discomfort to the patient's nose; it can interfere with eating and talking and can cause dryness as well as bleeding. Opioids are proved to be more effective in relieving severe dyspnea than is higher flow oxygen. In fact, oxygen may prolong the patient's dying process. At end of life, the body's oxygen requirements change as the body begins to slow down.⁶ High-flow oxygen may be discontinued as a way to improve a patient's comfort at end of life.

MECHANICAL VENTILATION

Mechanical ventilation includes respiratory support from an external machine to help patients in respiratory failure effectively breathe. This can be done using aggressive measures such as an endotracheal (ET) tube and ventilator or through less invasive methods involving NPPV. Any decision involving the need to initiate any form of mechanical ventilation warrants a conversation with the patient and/or family to review the medical condition, establish goals of care, discuss risks and benefits, and discuss alternative options to proceeding with aggressive measures.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

NPPV includes AIRVO, CPAP, and BiPAP. Patients who require mechanical ventilation are typically in acute hypercapnic respiratory failure,² having difficulty adequately oxygenating and eliminating carbon dioxide. Common conditions that support use of NPPV include acute exacerbations of COPD, hypoxic respiratory failure in immunocompromised patient, acute respiratory failure with cardiogenic pulmonary edema, and neuromuscular diseases.⁷ Patients who are on NPPV are generally able to have a conversation with the palliative APRN. Ideally, goals of care should be established prior to initiating NPPV.² It is important to address goals of care and ask questions regarding quality of life and if this type of intervention is causing discomfort or undesirable life prolongation. NPPV can be bothersome to patients, causing claustrophobia and anxiety, and, over time, it can lead to skin breakdown. It also negatively impacts goals of comfort at end of life. NPPV is used in both home and critical care settings, and the option of discontinuing this therapy presents itself in both settings. When death is expected, the palliative APRN should continuously assess the advantages and disadvantages of NPPV and the patient's physical symptoms and determine if these interventions are prolonging the patient's dying process.²

There are differing perspectives regarding NPPV at end of life; some suggest that offering NPPV can give the patient time with family or to finalize personal affairs.⁷ Another perspective is that if a patient has decided to forgo intubation and mechanical ventilation, NPPV can prolong the dying process because NPPV is considered a form of life support.⁷ The Society of Critical Care Medicine Task Force developed

an approach for providers considering initiating NPPV in critical care settings using three categories.⁷

Category 1: NPPV as life support with no limitations on life-sustaining treatment, including escalation of care to ET intubation and ventilation.⁷

Category 2: NPPV as life support with the limitation of “do not intubate.” The patient’s goals of care are consistent with alleviating dyspnea, improving comfort, and restoring health. Improved oxygenation and little discomfort are signs of success. The patient will be able to wean from the machine and breathe on their own, or the patient will have difficulty tolerating NPPV. If there is difficulty tolerating, discussion should be initiated and transitioning to comfort care should be recommended.⁷

Category 3: NPPV as a comfort measure only in patients who are dying. The goal in this category is palliation of the patient’s work of breathing.⁵ This can minimize usage of opioids and increase wakefulness at end of life, which some patients prefer.^{5,7} If the patient is unable to tolerate NPPV, symptoms should continue to be managed and NPPV should be discontinued.

There are no evidence-based guidelines for weaning NPPV at end of life. However, for quality and consistency, it is helpful for an organization to develop a policy and procedure. It should include medicine, nursing, respiratory therapy, social work, and chaplaincy to ensure that all the domains of care are met. If the decision is made to discontinue NPPV, symptoms should be closely monitored because severe dyspnea and anxiety can occur after removing NPPV. Initiating opioids and/or anxiolytics prior to discontinuing NPPV may help ensure the patient’s comfort. Table 55.1 provides dosing details on opioids and anxiolytics.

INVASIVE MECHANICAL VENTILATION

Invasive mechanical ventilation refers to an artificial airway via an endotracheal or a tracheal tube that is then attached to a ventilator which in turn provides proper gas exchange and ventilation for the patient. ET tubes are meant to be temporary: the goal is to continue working with the patient to wean from the ventilator as their condition improves.⁸ When attempts at weaning begin to fail and continued ventilator support becomes medically nonbeneficial, the option of palliative extubation should be presented to the patient, if able to speak for themselves, or to the family as surrogate decision-makers.⁸ The palliative APRN should reinforce that mechanical ventilatory support is a treatment that can be forgone or discontinued. Moreover, palliative extubation is not hastening death. Rather, the process allows a dignified death consistent with a patient’s values, preferences, and beliefs as stated in advance care planning documents. As well, palliative extubation may be viewed as promoting a more natural death without technology rather than a prolonged dying process (see Chapter 53, “Navigating Ethical Dilemmas”). The outcome

**Table 55.1 SYMPTOM MANAGEMENT GUIDE
OPIOIDS: MODERATE TO SEVERE DYSPNEA IN
OPIOID-NAÏVE PATIENTS**

MEDICATION	GUIDELINES
Morphine	2–5 mg IV q10–15 min PRN If two doses in an hour are providing little relief but are tolerated well, double the dose. Consider initiating continuous infusion if 2 bolus doses are required in 1 hour after increasing bolus dose. Typical starting continuous infusion rate is 4 mg/h. If the patient receives 2 bolus doses in an hour after initiating infusion, consider doubling the infusion rate. (Same titration rules apply to hydromorphone and fentanyl.)
Hydromorphone	0.5–1 mg IV q10–15 min PRN Typical starting continuous infusion rate is 0.5 mg/h
Fentanyl	50–100 µg IV q30min–1 h Typical starting continuous infusion rate is 25 µg/h

BENZODIAZEPINES: MODERATE TO SEVERE ANXIETY

MEDICATIONS	GUIDELINES
Lorazepam	1–2 mg IV q4h PRN If infusion is needed, typical starting infusion rate is 0.5–1 µg/h
Midazolam	2 mg q4h PRN 0.02–0.1 mg/kg/h infusion Patients can receive 1–2× the hourly infusion rate as bolus dose

From Yeow, Chen¹; Coradazzi et al.⁸; Blinderman⁹; and Dudgeon.¹⁰

of palliative extubation is reduced unnecessary suffering on behalf of the patient as well as the family.⁸

EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO is a type of aggressive respiratory support that is typically reserved for the most severe cases of respiratory failure.⁵ This is a temporary and aggressive form of life support technology that allows a patient’s failing heart or lungs to fully rest and hopefully recover during a life-threatening illness.¹¹ ECMO has advanced over the past several years from being primarily used in the pediatric population to use among adults as well.¹² ECMO is initiated in addition to mechanical ventilation and should only be considered in the most severe cases.⁵ Patients who are on ECMO are already at high risk of death based on their clinical condition. ECMO should fully be discussed in detail with the patient’s family prior to initiating the therapy: this communication should involve the purpose and goals of ECMO, the risks and potential benefits, and the possibility of needing to discontinue ECMO. There

are two different types of ECMO, *venovenous* (VV), which is used in patients with severe respiratory failure, and *venoarterial* (VA), which is used for patients with combined respiratory and cardiac failure or post-cardiac arrest.¹³

ECMO functions to remove blood from the venous system through a negative pressure machine outside the body which oxygenates the blood and circulates it back to either the venous or arterial system (VV or VA, respectively). The flow rate of the blood determines the oxygenation and CO₂ removal. Vascular access is obtained via two large-bore canulas, typically placed in the groin or neck depending on the type of ECMO being done.¹¹ The ECMO circuit functions as a heart-lung bypass machine, allowing the patient's heart and lungs to rest with the intention of recovery. Life-threatening complications may occur with ECMO such as bleeding, thromboembolism, infection, cerebral hemorrhage, and neurological devastation.¹¹

Patients can be on ECMO for days to long weeks (>14 days); prolonged ECMO support is associated with a lower hospital survival rate.¹⁴ If organ recovery fails or other serious complications arise, discontinuing ECMO should be

considered and discussed open and honestly with the family or surrogate decision-maker if the patient lacks decision-making capacity. Discussions surrounding discontinuing ECMO can be complex and emotional given the technology of ECMO itself. The decision requires the care team to work together in determining what is best for the patient. The Extracorporeal Life Support Organization (ELSO) has a set criteria for determining medical futility; this includes little hope for survival, severe brain damage, no hope for heart or lung transplant, no hope for heart or lung recovery or transplant, and/or fixed pulmonary hypertension.¹⁵ There are slight differences in end-of-life symptom management for patients on ECMO because ECMO can slightly alter the pharmacokinetics of certain medications, causing the need for dose adjustments. The ECMO circuit can also affect the lipophilicity of a drug and extend its absorption time. Morphine may be preferred over fentanyl in these patients because it is a hydrophilic drug.¹⁶

Discontinuing invasive mechanical ventilation is a complex process that requires careful planning by the palliative APRN and the care team. Table 55.2 outlines this process.

Table 55.2 PROCESS OF DISCONTINUATION OF RESPIRATORY SUPPORT

Prepare When continued aggressive medical interventions are unlikely to reverse the patient's condition and death is expected	Meetings: Ensure interdisciplinary meetings are occurring days prior and the day of with the palliative team as well as with the medical team prior to having discussions with the patient and/or family; this is <i>key</i> to ensuring that a consistent message is being relayed. Discuss terminal weaning vs. palliative or compassionate extubation and decide which process is right for the patient based on their clinical condition. Support: Offer social work or spiritual support services to the patient and/or family. Prepare the room: Clear the room of any unnecessary medical devices, ensure the patient is clean, sheets are clean and straight, and that the environment is as comfortable as possible. Ensure all comfort care orders are in place and the bedside RN has comfort medications readily available in the room.
Pre-Medication Anxiety Dyspnea Pain	If dyspnea is anticipated (dosages can vary based on patient's opioid tolerance): Morphine 2–5 mg IV ×1 <i>or</i> Hydromorphone 0.5–1 mg IV ×1 <i>or</i> Fentanyl 50–100 µg IV ×1 <i>or</i> If anxiety is anticipated: Lorazepam 1 mg IV ×1 for pre-medication
Discontinuation of Respiratory Support Removal mechanical ventilation	Ensure patient's surroundings are peaceful and comfortable; turn off all alarms and monitors. Ensure that family is present if they request. <i>Terminal weaning</i> : Slowly reduce the ventilator settings over the course of 10–30 minutes. <i>Palliative/compassionate extubation</i> : Stop ventilator support and remove ET tube all in one process. The patient may be at higher risk for rapid respiratory distress, but this option may offer a more natural, peaceful death. Offer support to the family by staying close by the room or at bedside if appropriate.
Post-Discontinuation of Respiratory Support	Monitor patient's condition closely. If appropriate, consider transfer to private room or hospice inpatient facility. If death occurs shortly after discontinuation of respiratory support, follow proper institutional/state guidelines for pronouncement process and communicate with the family. Pronouncement of death occurs by assessing that respirations and heartbeat have ceased via auscultation as well as noting the time. Communicating the death of a loved one demands sensitivity, a calm presence, comfort, and kindness. Conduct postmortem care per unit/RN guidelines. If present, offer to assist the RN in bathing the body and making the environment comfortable and peaceful for the family. If necessary, provide education to the family regarding things to anticipate immediately following death (muscles relax, relaxation of the jaw) so that they are assured that things they might observe are normal. Offer spiritual support at time of death.

From Yeow, Chen¹; Coradazzi et al.⁸; Blinderman⁹; Dudgeon¹⁰; White et al.¹⁷; and Kok.¹⁹

SYMPTOM CONTROL DURING DISCONTINUATION OF RESPIRATORY TECHNOLOGY AND SUPPORT

It is essential that the palliative APRN have expert symptom management skills at end of life, especially in the situation where respiratory technology is being discontinued or withdrawn. Common symptoms include dyspnea, anxiety, increased pulmonary secretions, and dry mouth. Many patients will not be able to express discomfort or distressing symptoms, so it is recommended that the palliative APRN uses validated assessment tools to effectively assess and manage symptoms. Table 55.3 outlines validated tools that are commonly used in the ICU setting to assess pain, dyspnea, agitation, and delirium.

It is imperative that the patient's symptoms are effectively managed for their own comfort but also for the family's comfort. Observing signs of suffering can be distressing for the family. For pain, the use of the Behavioral Pain Scale, Critical Care Pain Observation Tool, or Pain Assessment Behavior Scale is recommended. The palliative APRN assesses the presence of pain behaviors including grimacing, rigidity, squinting of the eyes, clenching of fists, and moaning. The Richmond Agitation Sedation Scale (RASS) or Sedation Agitation Scale (SAS) is recommended in assessing agitation. The CAM-ICU tool is recommended when assessing degree of delirium. The Respiratory Distress Observation Scale is suggested for dyspnea.¹ To accurately assess the patient, discontinuation of neuromuscular blocking agents is recommended. These medications can interfere with the ability to accurately assess patient comfort and could result in unnecessary suffering.^{1,23}

Opioids are considered first-line therapy for managing dyspnea. No opioid is superior to another in managing dyspnea.^{1,2,23} However, morphine, fentanyl, and hydromorphone

are the most commonly used opioids in the critical care setting.²⁴ There are many guidelines and protocols available for symptom control at end of life and during discontinuation of respiratory support. Many institutions and healthcare systems have their own versions of these orders sets that are initiated when the decision has been made to transition to comfort care. Many guidelines suggest premedicating the patient with an opioid and benzodiazepine prior to extubation.^{1,23,25} Opioids and benzodiazepines assist in minimizing the degree of respiratory distress and anxiety as extubation occurs. Table 55.1 outlines opioid and benzodiazepine usage and dosages.

The dose requirement will vary from patient to patient based on their previous opioid usage. In an opioid-naïve patient, a starting bolus dose of IV morphine is 2 mg. Bolus dosing of morphine is typically 2–4 mg IV every 10–15 minutes as needed. Initiating a continuous infusion may be necessary. Consider starting a continuous infusion if the patient is expected to survive after the discontinuation of ventilatory support or two or more bolus doses are given in 1 hour with little relief.^{1,8,9,10} Patients may continue to require bolus dosing of an opioid for dyspnea and/or pain. If dyspnea continues and opioid doses are providing little efficacy, initiating an opioid infusion should be considered. Anxiety is another common symptom at end of life, especially in patients who also are suffering from severe dyspnea. If anxiety is anticipated, lorazepam 1 mg IV often is recommended prior to extubation and can be additionally be given at 1–2 mg IV every 4 hours as needed.²⁵ Midazolam is another appropriate alternate benzodiazepine that can be started at 2 mg IV, followed by an infusion of 1 mg per hour if necessary, based on the patient's response to the initial dose.¹ Once the patient is extubated, careful symptom management should continue.

Table 55.3 DISTRESS ASSESSMENT TOOLS

SYMPTOM	TOOL
Pain	Behavioral Pain Scale (BPS) Critical care pain observation tool Pain can be objectively assessed based on signs of tachypnea, tachycardia, diaphoresis, facial grimacing, clenching fists, and moaning. ¹
Dyspnea	Respiratory Distress Observation Scale (RDOS) Objective assessments include tachypnea, increased respiratory rate (sometimes double from baseline), tachycardia, use of accessory muscles, nasal flaring, paradoxical breathing. ¹
Agitation	Sedation-Agitation Score (SAS) Ramsay Agitation Sedation Scale (RASS) 10-point scale used to assess patient's agitation level ranging from –5 to +4. –1 to –5 ranges from awake to unarousable +1 to +4 ranges from anxious to combative ^{20,21}
Delirium	CAM-ICU Assesses for acute changes in mental status, inattentiveness, disorganized thoughts, and altered level of consciousness ²²

COVID-19: IMPLICATIONS AND PRECAUTIONS

CASE STUDY: COVID 19 COMPASSIONATE EXTUBATION

KT was a 41-year-old African American man with a relatively negative past medical history except for obesity (body mass index [BMI] 31). He was admitted to the hospital for respiratory distress and tested positive for COVID-19. On Day 5, KT became increasingly hypoxic; he was transferred to the medical ICU and required emergent intubation. Over the course of the next 21 days he failed weaning trials and eventually required transfer to the cardiovascular ICU (CVICU), where he was placed on VV ECMO. KT was closely monitored and treated for COVID-19 per hospital protocols. The palliative care team was consulted on Day 16 to begin assisting with family communication and goals-of-care conversations.

KT was married and had three children ages 12, 16, and 20. He also had a brother and sister who lived out of state and were involved in the telephone conferences. The palliative APRN organized and led multiple family conferences via telephone as well as video conference with KT's family. She explained that KT

was not showing any signs of improvement on Day 67 of ECMO. She reviewed the goals of care and his poor outcomes. She asked what KT's wishes would be, knowing he was in a situation with such a poor prognosis.

The family was offered the option of transitioning to comfort care. KT's family verbalized their understanding but wanted a couple of days to process and finalize a decision. During this time, KT was noted to have severe neurological dysfunction and was eventually found to have suffered a stroke while on ECMO. The family decided it was time to transition to comfort care.

On Day 81, KT had his ECMO discontinued. He was placed on comfort care and symptoms were managed appropriately per the hospital's comfort care order set. KT was compassionately extubated with the proper COVID-19 precautions. Although the family was unable to be at KT's bedside when he died, the family greatly appreciated the palliative APRN's compassion and extra time spent arranging family phone conferences to update them and provide them with additional options when things seemed to be getting worse.

The coronavirus disease 2019 (COVID-19) pandemic has without a doubt disrupted every aspect of our country's healthcare system and has affected every healthcare provider, especially palliative care providers and teams. The need for palliative care in the inpatient setting, especially in ICUs, has substantially increased during the COVID pandemic.²⁶ Patients who are critically ill and hospitalized with COVID-19 typically have an exceptionally long course of illness and, if intubated, a prolonged need for mechanical ventilation.²⁶

All previously described advanced respiratory treatment modalities pose an extremely high risk for COVID-19 transmission. AIRVO, CPAP, BiPAP, and tracheal mechanical ventilation are all considered to be high-risk aerosolizing procedures. It is important to note that bronchoscopy and nebulizer treatments expose clinicians to the same risk of exposure, transmission, and infection.²⁷ It is imperative that the palliative APRN takes proper precautions when present in a room with a patient who is COVID-19-positive.

Goals-of-care conversations are necessary with any hospitalized COVID-19 patient due to the uncertainty of their disease trajectory.²⁶ The conversations are no longer theoretical but are part of the care plan. Patients and family may not understand the high respiratory support necessary for severe cases of COVID-19. They may also be unaware that it is common that no visitors are allowed in the clinical setting.

Prior to extubation, the palliative APRN should have the same goals-of-care discussions with the patient's family as previously discussed when considering discontinuation of respiratory support. It is important to identify who is the patient's surrogate decision-maker for health as well a backup decision-maker in case the surrogate falls ill.²⁸ Due to the strict visitor restrictions most institutions have in place, the palliative APRN must often perform this virtually. Ideally, it is important to have goals-of-care discussions upon hospital admission because COVID-19 is unpredictable.

All clinicians should be aware of the necessary special precautions with palliative or compassionate extubation. The procedure of extubating a patient poses significant risk of COVID-19 transmission due to the high risk of cough aerosolization.

Most hospital systems will have their own protocols for extubating a COVID-19-positive patient based on current research. Excess coughing should be kept to a minimum if possible due to the aerosolization risk. If possible, extubation should occur in a negative-pressure room with minimal staff present for the procedure to minimize transmission risk. There have been reports that the COVID-19 virus can remain airborne in aerosols for up to 3 hours.²⁷ Staff present in the room must be wearing all appropriate personal protective equipment (PPE) including an N-95 mask or powered air-purifying respiratory (PAPR), a gown, gloves, and eye protection.²⁹ To date, no consensus guidelines for extubation of COVID-19 patients have been developed.²⁹ However, oxygen via nasal cannula or mask should be placed on the patient following extubation. There are some centers that are using barrier hoods made from PVC or clear rigid plastic. The one principle is that NPPV should be avoided post extubation due to risk of aerosolization.

In some cases, traditional ventilatory support fails, eventually requiring patients to receive ECMO support. There is little research at this point regarding COVID-19 and ECMO efficacy.³⁰ The studies that have been done so far demonstrate an extremely poor survival rate.³⁰ This scenario further supports the need for earlier palliative care consults in COVID patients to assist in goals-of-care discussions with the patient before their condition deteriorates so rapidly that they are intubated and placed on ECMO.

ETHICAL CONSIDERATIONS

Discontinuation of life-sustaining therapies, including respiratory technology, often raises ethical concerns. Palliative APRNs, along with their team, have a duty to ensure patients are comfortable and that their dying process is not prolonged. There is also the legal obligation to avoid hastening a patient's death.²³ The following ethical issues surround palliative or compassionate extubation or discontinuing or withdrawing respiratory ventilation (see also Chapter 53, "Navigating Ethical Dilemmas," for further discussion).

1. *Abandonment*: The ability to breathe is seen as a core requirement of life. There may be the perspective that discontinuation of ventilatory support is a form of patient abandonment. The perception arises from the concern that the palliative APRN will stop caring for the patient and that the established patient-provider relationship has ceased without notice. Discontinuation of mechanical ventilation at end of life is not considered abandonment because the APRN continues a therapeutic relationship and will provide proper symptom management.^{17,18}
2. *Beneficence*: The best interest and well-being of a patient is the core of healthcare. There are limitations to what

medicine can accomplish, and allowing the patient to die in a controlled manner consistent with their values, wishes, and goals of care is promoting beneficence.¹⁷ Beneficence requires the palliative APRN to facilitate the patient's best interest in considering the benefits and burdens of treatments. In patients who are critically ill, it is important to acknowledge that continued mechanical ventilation and other aggressive therapies may not be in the patient's best interest.

3. *Hastening death*: Patient have a choice to decline or stop treatments that are life-sustaining. Patients, families, and even some clinicians believe that providing sedatives or opioids at the end of life unnecessarily hastens death. The palliative APRN has ethical obligation to alleviate uncontrolled symptoms at end of life. Severe dyspnea can cause tremendous suffering at end of life that is distressing for families to witness at the bedside. In this situation, managing potential suffering of end-of-life symptoms is paramount even if death occurs as a consequence.^{17,30} This leads to the principle of the *double effect*, which differentiates intended "good" versus unintended "bad" effects. The discussion of intentions and goals with the use of medications is imperative with patients, families, and staff and should be documented.³⁰
4. *Nonbeneficial care/futility*: Medical technology has advanced to the point where there is always something that can be done. The question is whether it should be. *Nonbeneficial care or futility* refers to the failure of a specific intervention to lead to the intended outcome. This may be gauged by unintended consequences or suffering. There may be situations in which the palliative APRN is faced with discussing therapies or interventions with patients and/or family members that are providing little to no benefits to the patient and some that may potentially cause a great deal of harm.³⁰

Ethics and legal consults should be considered in particularly challenging cases. It is critical to know the institution's guidelines, policies, and resources as well as one's state regulations. There are many resources for the palliative APRN (Box 55.2).

SUMMARY

All palliative care teams will be involved in the discontinuation of respiratory technology. The palliative APRN is an integral member of the palliative care team in this process. It is essential that care teams understand the ethical principles behind discontinuation. Moreover, the team must develop a collaborative process delineating each member's roles, responsibilities, and process consistent with the resources of the setting. The palliative APRN can lead the development in policies and procedures appropriate to the acute care, rehabilitation, and home settings. Procedures should include clarity of the role of each team member, medications to use, who orders medications, and who discontinues oxygen therapy. To ensure a dignified end of life for a patient, the APRN is responsible for

collaboratively developing a proactive care plan that supports the needs of the patient and family. The care plan requires effective communication to plan the event with the team members; pre-meet prior to the event to consider how dyspnea, anxiety, and secretions will be managed; prepare the family and the patient (as able) for the process; support the staff involved with the process; facilitate the process as necessary; and debrief the event afterward. The palliative APRN can offer resources to support the family in their bereavement as well.

DISCONTINUATION OF OTHER LIFE-SUSTAINING THERAPIES

Kathy Plakovic and Jennifer Donoghue

KEY POINTS

- Withholding, withdrawing, and discontinuing antibiotics, blood products, dialysis, and medically administered nutrition are important topics that require the palliative advanced practice registered nurse (APRN) to provide information and participate in shared decision-making.
- The APRN should explain the benefits and burdens of treatment versus no treatment to the patient and family, along with the ethical framework that supports them.
- If treatment is withheld, withdrawn, or discontinued, discussions should include the expected course of the dying process.
- Although the phrase “withdrawal of care” is often heard, it is important to distinguish between the withdrawal of life-sustaining interventions and the withdrawal of care. While the former is common, the latter should never occur. Language is important, particularly to patients and their families,^{1 (p. 956)} which is why more teams are using the term discontinuation.

the medical team’s recommendation for comfort-focused care. Betty verbalized her inability to make such a difficult decision without the input of her two siblings. The palliative APRN coordinated a virtual call with the Mr. R’s three children to achieve consensus. After much discussion, the family agreed that quality of life was more important and gave permission for no resuscitation or intubation. Mr. R’s family requested visitation to see their father before he died. Due to COVID-19 visitor restrictions within the intensive care unit (ICU) and Betty and her sibling’s own health issues, the decision was made to coordinate video visitation with Mr. R.

The evening of Mr. R’s hospital admission, a video call was held at his bedside where his children were able to say goodbye and play his favorite hymns. The patient was started on a morphine drip for respiratory distress and any potential pain and discomfort. The palliative APRN continued to monitor him, and Mr. R died within 24 hours. The palliative care team provided bereavement follow-up to the family.

INTRODUCTION

Technological and medical advancements have led to dilemmas surrounding decisions to withhold, withdraw, or discontinue life-sustaining treatment. For patients with advanced illness, technology has often served to only prolong the dying process. While many patients and loved ones see medical intervention as a human right, it is important to remember that the first obligation of a provider is to do no harm. The ethical principles of *beneficence* and *nonmaleficence* support a provider’s right to refuse treatment that may cause harm. *Autonomy* is the ethical principle that allows patients or their assigned decision-maker the right to accept or refuse any treatment that may not align with their personal health wishes.²

While withholding, withdrawing, or discontinuing interventions are legally and ethically equivalent, withdrawal or discontinuation of life-sustaining interventions, especially in the intensive care unit (ICU), is harder for both providers and family members. Family members are often burdened with “what ifs” and feel greater responsibility for the outcome when treatment is withdrawn or discontinued versus withheld.³ Families often associate withdrawal with active participation in death, misunderstanding that the true intention is to allow for a natural dying process. Palliative advanced practice registered nurses (APRNs) ease patient and family

CASE STUDY: CONSENSUS WITH COVID-19 PROGNOSIS

Mr. R is a 78-year-old man with advanced dementia who presented to the hospital from a local nursing home with shortness of breath. A rapid COVID-19 test was positive. The palliative APRN was consulted immediately upon admission to discuss goals of care with his family because Mr. R did not have any advance directives. He was decompensating quickly and required high-flow oxygen via nasal cannula for respiratory support. He was alert to voice but lethargic and did not appear to be in any distress.

Prior to calling the family, the palliative APRN reviewed the case with the attending physician and intensive care specialist. The APRN, attending, and intensivist agreed that, given Mr. R’s underlying terminal diagnosis and frail state, intubation was not recommended. This multidisciplinary medical team was unable to meet in person due to COVID-19 restrictions but held a phone consultation to reach consensus.

The palliative APRN called the Mr. R’s daughter and primary surrogate, Betty, to discuss next steps in care. Betty was informed of Mr. R’s positive COVID-19 status along with the best and worst case outcomes. In addition, the APRN conveyed

distress when decisions on withdrawal or discontinuation of life-sustaining treatments are indicated. Specifically, palliative APRNs can help patients and families better understand the dying process by discussing the nature of the underlying illness, including the expected prognosis and the benefits and burdens of treatment. This allows patients and families to make informed decisions about treatments.

While withdrawal of treatment is most often associated with removal of mechanical ventilation, there are several other life-sustaining interventions that should be addressed in the dying patient. This chapter focuses on the withdrawal or discontinuation of antibiotics, blood products, dialysis, and medically administered nutrition in the terminally ill. It will provide case scenarios for each intervention to aid in understanding and discuss the burdens and benefits of continuing treatment versus stopping. The normal dying process when these therapies are discontinued will be reviewed.

Decisions regarding life-sustaining treatments regularly happen in the ICU. The aim of ICU-level care is to treat acute illness with the goal of returning patients to a level of function that offers an acceptable quality of life. Unfortunately, ICU admissions tend to be prolonged, complex, and often delay death instead of supporting life in patients with terminal illness. With a mortality rate of up to 20%, it is important for palliative care providers not only to be present, but also skilled at navigating end-of-life discussions in this setting.⁴

Conversations surrounding life-sustaining treatments are often difficult and emotionally charged even for the most skilled providers. Prognostic uncertainty in the ICU has made it challenging for palliative APRNs to navigate end-of-life discussions with patients and family members. The current recommendations support a multidisciplinary approach to family meetings.⁵ While multiple prognostic scoring systems are available, they are not often applied in the ICU setting. Prognosis tends to be overestimated, and there are commonly conflicting opinions on prognosis from different specialty groups.⁴ When the multidisciplinary team is not on the same page, the palliative APRN plays an important role in bringing the team together prior to meeting with the family to present a united front. Consensus among the medical team regarding prognosis is key to effective end-of-life discussions. The team must also have an understanding of how the patient's and family's culture, religion, and ethnicity may affect decisions (see Chapter 35, "Culturally Respectful Palliative Care," and Chapter 53, "Navigating Ethical Dilemmas").

The coronavirus pandemic has forced medical providers to face end-of-life conversations in a rapidly changing environment. It has highlighted the important role that palliative APRNs play in critical care situations and helped medical providers understand why the "big picture" of patient care is just as important as managing the acute illness, especially when it comes to clinical outcomes and accurate prognostication. COVID-19 has forced providers to question the almost 20 years of research that has gone into improving patient and provider communication at the end of life. It has physically separated the patient, provider, and family and led many to question their ethical beliefs.⁶ Navigating goals-of-care discussions with providers and

family members via telehealth has proved challenging for palliative APRNs, especially in environments where access to smart devices and training for patients, loved ones, and providers is limited. Consensus and a team-based approach have been more important now than ever.

The ability to navigate complex, interdisciplinary patient- and family-centered goals-of-care conversations is a key skill that palliative APRNs must possess. Family members often rely on palliative APRNs as the primary source of information and support when loved ones are terminally ill. Building rapport with patients and families allows palliative providers to lead effective team meetings once consensus among the team has been established. Palliative APRNs play a key role in educating patients and loved ones on prognosis and expectations with and without treatment. They ensure that decisions made by loved ones for patients who are incapacitated have the patient's preferences for care as the primary focus. When the decision is made to withdraw or discontinue life-sustaining treatment, the palliative APRN should also discuss expectations for the dying process.

ANTIBIOTICS

Antibiotic use is common for infections and is considered the standard of care. As patients near the end of life, antibiotic use may become a life-sustaining or a death-prolonging treatment. Using antimicrobial medications at the end of life is a common practice.^{7,8} Albrecht and colleagues evaluated 3,884 hospice patients and found that 27% received antibiotics in the last week of life, but only 15% of those patients had a documented infectious diagnosis.⁹ Merel et al. reported that 15–20% of patients remained on antibiotics after comfort care was started.⁷ As with other life-sustaining treatments, the decision to either withhold or withdraw or discontinue antibiotics requires informed decision-making based on the goals of care for the individual patient.

Many families and healthcare professionals fail to see dementia as a terminal illness, however, patients with all types of dementia have a median survival of 5 years from diagnosis to death.¹⁰ Dementia is the sixth leading cause of death in the United States for all ages and the fifth leading cause of death for those 65 and older.^{11,12} As dementia progresses, patients lose their ability to swallow food and manage their own secretions, which can lead to aspiration pneumonia. In a study of nursing home patients with dementia (FAST 6e and above), 42% had swallowing issues at the start of the study. Of the patients that died, 20% had aspiration and 47% had breathing difficulties at the end of life.¹³ Several studies have shown pneumonia to be one of the leading causes of death in patients with dementia.^{14,15} Manabe and colleagues reported that patients with dementia are two times more likely to die of pneumonia.¹⁶ Patients with Lewy body dementia are twice as likely as those with Alzheimer's disease to have a respiratory death.¹⁷

Patients with other disease processes, such as advanced cancer, are at risk for infection due to immune suppression from the disease or neutropenia as a result of cancer

treatment. Among hospitalized advanced cancer patients, nearly 90% received antibiotics in their last week of life.¹⁸ Even when patients are transitioned to comfort-focused care, many patients continue to receive antimicrobial therapy.^{19,20} One study showed that almost 80% of dying patients received antimicrobial therapy in the 24 hours before and after being transitioned to comfort care. That number decreased to 20% when patients had been on comfort measures for more than 24 hours.⁷

A growing body of evidence suggests that antibiotic prescribing frequently occurs at end of life and often is nonbeneficial.^{21,22} However, many healthcare providers believe that because infection is a reversible problem, it should always be treated. Decisions to withhold, withdraw, or discontinue antibiotics at the end of life can also be stressful for families. A study looking at antimicrobial use when patients are transitioned to hospice showed that 19% of patients were sent with a prescription because of a family request.²³

A common belief is that the treatment of an infection provides comfort by decreasing fever and other distressing symptoms, such as shortness of breath. Symptoms like confusion, dyspnea, fever, and hypotension can also occur. However, a study conducted by Givens and colleagues²⁴ showed that comfort scores for patients receiving antibiotics were worse than those for patients not receiving treatment in pneumonia patients with severe dementia. Data from another study showed that antimicrobial use in hospice patients had little effect in relieving symptoms for patients with infections, including bacteremia and pneumonia, although it did decrease symptoms in patients with urinary tract infections.²⁵ Interestingly, that study also showed no difference in median survival in those patients with an infection versus those without infection: 29.1 and 30.5 days, respectively. Survival was the same for patients treated with antibiotics and those with no antibiotics: 29.3 and 30.7 days, respectively. For patients near the end of life, there is little evidence that survival is prolonged with antibiotic therapy.¹⁴ Palliation of

infection-related symptoms at the end of life, such as dyspnea, can be managed by opioids and other, nonpharmacologic treatments (see Section VIII, “Symptoms”).²⁶

The burdens of using antimicrobial therapy should also be considered when choosing whether to treat an infection. Antibiotic stewardship programs seek to improve appropriate use in an effort to decrease adverse effects and antimicrobial resistance. Pasay and colleagues implemented a stewardship program that significantly reduced urine culture testing and antimicrobial prescriptions with no increase in hospital admission or mortality.²¹ Other potential harms include the potential for *Clostridium difficile* infection, side effects or adverse reactions to the medication, and the need for intravenous access, which can be difficult to obtain in patients near the end of life. The volume of fluid required to deliver intravenous antibiotics can also place a burden on patients with impaired kidney function or with edema due to hypoalbuminemia. Tamma et al. reported that 20% of hospitalized patients experienced an adverse event related to antimicrobial therapy.²⁷ The healthcare cost, especially for patients on newer antimicrobial medications or those prescribed multiple agents, can place a financial burden on patients, healthcare institutions, and society.²⁸

Ethical considerations can assist in guiding decision-making. Eliciting the patient and family perspective of quality versus quantity of life, including their belief system and other values, supports patient autonomy.²⁹ When the expressed goal is comfort at the end of life, antibiotic use should be reduced. Figure 56.1⁸ proposes an algorithm for antibiotic use at the end of life. Sinert and colleagues recommend using a decision support tool to help guide use of antibiotics for patients in hospice care (see Table 56.1).³⁰

Palliative APRNs can explain that most symptoms can be successfully managed at the end of life. They can also educate families that hypotension in the dying patient is normal and that giving medications like vasopressors or fluid boluses will only prolong the dying process and potentially prolong suffering,

Figure 56.1 Goals of care discussion.⁸

Table 56.1 STAMPS: A HOSPICE DECISION SUPPORT TOOL FOR ANTIBIOTIC USE

DESCRIPTION		ACTION
S	Symptom assessment	When infection is suspected, determine symptoms impacting comfort or quality of life. If asymptomatic or if symptoms do not significantly impair comfort/quality of life, no antibiotic is indicated.
T	Targets/goals of therapy	Review specific goals for infection and symptom management with the patient and caregiver.
A	Alternative treatment options	Based on patient-specific goals, determine what other nonantibiotic treatment options exist and compare expected outcomes.
M	Medication factors	Review drug allergies, drug interactions, and anticipated adverse effect/risks. Assess swallowing function and other factors that affecting antibiotic selection and administration.
P	Prognosis	Evaluated estimated prognosis versus necessary treatment duration and anticipated time to symptom resolution.
S	Stewardship	Avoid bug-drug, infection-drug, or patient-drug mismatch. If antibiotic therapy is chosen, ensure the use of correct drug, dose, route of administration, and therapy duration.

From Sinert et al.³⁰ (table 2)

which is not recommended. The decision to proceed with, withhold, withdraw, or discontinue treatment should be individualized for each patient based on the goals of care. Determining the goals of care for patients with advanced disease can help guide antibiotic use. If the goal is to prolong life at any cost, then family members may elect to proceed with antimicrobial therapy. However, if comfort is the primary focus, families should be educated on the burdens of antibiotic treatment, including a prolonged dying process and potentially worse symptoms.

family members initially, they were able to come to a consensus with guidance from the APRN to discontinue antibiotics. The patient’s orders for life sustaining treatments or POLST form was updated to reflect the goal of comfort care. Mrs. F was admitted to hospice care and died 1 week later.

CASE STUDY: USE OF ANTIBIOTICS

Mrs. F was an 87-year-old woman with Parkinson’s disease, chronic obstructive pulmonary disease (COPD), and Alzheimer’s disease. The patient and family had decided to proceed with enteral feeding after multiple admissions for aspiration pneumonia and a percutaneous endoscopic gastrostomy (PEG) tube was placed. Mrs. F was admitted to a long-term care facility when her care needs became too much for her family.

The palliative APRN at the nursing home met with the patient and family to address goals of care. They completed a provider/physician’s orders for life-sustaining treatment (POLST) form indicating (a) do not attempt resuscitation, (b) selective medical treatments with no intubation, and (c) long-term medically administered nutrition. The palliative APRN discussed that the risk for aspiration was still a concern as the patient could aspirate her tube feeding or her own secretions. She discussed that Mrs. F may continue to have frequent cases of pneumonia. The family insisted on continued hospitalizations and antibiotics because “you can treat an infection.” They remained hopeful that Mrs. F would make it to her 90th birthday.

Mrs. F was hospitalized three more times over the next 5 weeks for aspiration pneumonia. With each admission her functional and cognitive status declined. The palliative APRN met with the family again after the third discharge and recommended comfort-focused care. While there was disagreement among

BLOOD PRODUCTS

Transfusions of blood products, including red blood cells and platelets, are life-sustaining treatments for patients with anemia and thrombocytopenia caused by the disease process or treatment-related cytopenias. Many patients with advanced disease become transfusion-dependent due to bone marrow infiltration or chronic bleeding from tumor invasion. For these patients, continued transfusions are used not as a bridge to wellness but as a temporizing measure.

Many providers, especially ones with a long-term relationship with a patient, have difficulty discussing goals of care when there are no further treatment options. Aggressive care is often continued when patients are actively dying. This can lead to patients and families not having the time to attend to unfinished business prior to death. While some patients and families will continue to request ongoing care despite a poor prognosis,^{31,32} they must receive honest, direct information about treatment options—including no treatment—so they can make informed decisions about the goals of care.

Advances in medicine have improved survival rates for patients with hematological malignancies, but some patients will succumb to their disease despite aggressive management.^{33,34} Many of these patients are transfusion-dependent due to bone marrow failure or infiltration. These patients often die on the hematology ward or in the ICU.^{35,36,37,38} Forty-eight percent of hospitalized patients who died with hematological malignancies received a blood transfusion during their terminal admission.³⁸

Patients with hematological cancers are commonly referred to palliative care too late when they are actively dying even though treatment of their disease entails a high symptom burden and psychosocial and spiritual distress.³⁹ Reasons for the late referral to palliative care include the aggressive nature of treatment, including chemotherapy, transfusions, and antibiotics until the end of life. Blood and platelet transfusions become a “normal” part of the patient’s life; stopping them is a difficult decision, not only for the patient but also for the hematologist.

Transfusions are often not allowed in hospice programs, which makes providers reluctant to refer patients who are transfusion-dependent.^{37,40} Patients with multiple myeloma who were transfusion-dependent were three times more likely to be referred late to hospice.⁴¹ Patients with hematologic malignancies are often symptomatic and could benefit from the services provided by hospice. Of those patients who are referred, they are significantly sicker and usually have a hospice length of stay measured in days.^{34,36}

Patients with acute myelocytic leukemia (AML) in particular appear to use hospice services less, and those that do often transfer in and out of hospice care in order to receive disease-directed care such as transfusions.⁴² A small study of patients with AML showed that most patients continue cancer-related care until the end of life.⁴³ Older adults diagnosed with AML spent more than a quarter of their life in the hospital.³⁹ These patients have a much greater likelihood of dying hospitalized.⁴⁴

Recognizing when patients are near the end of life becomes particularly important in this patient population. Kripp and colleagues⁴⁵ looked at five factors—low performance status, low platelet count, opioid therapy, high lactate dehydrogenase (LDH), and low albumin—that would identify patients with a high risk of death (Box 56.1). Patients with four or five risk factors had a median survival of 10 days. Median survival for those with two or three risk factors was 63 days. This information can assist healthcare providers in identifying patients at risk of death so they can have in-depth discussions with patients and families regarding goals of care. Other factors associated with mortality in hematologic malignancies include declining performance, treatment limitations of the hematological malignancy, relapse, refractory or persistent disease, presence of two or more comorbidities, invasive fungal infections, and persistent infections.⁴⁶ Most studies looking at prognostication in hematologic malignancies have focused on

Box 56.1 PROGNOSTIC FACTORS IN PATIENTS WITH HEMATOLOGIC MALIGNANCIES

Eastern Cooperative Oncology Group (ECOG) status >2
Platelet count <90 × 10⁹/L
Lactate dehydrogenase (LDH) >248 U/L
Opioid use per World Health Organization (WHO) level 3
Albumin <30 g/L
Median survival with no or one risk factor is 440 days; two or three risk factors, 63 days; four or five risk factors, 10 days.

Adapted from Kripp et al.⁴⁵

patients who are receiving aggressive ICU-level care. There is little information to help guide clinicians on predicting survival for patients receiving palliative-focused care.⁴⁷

It is important to look at patient and family goals of care in regard to continued transfusions. The patient’s perceived and desired quality of life should be considered.⁴⁶ Transfusions can palliate symptoms, but the benefit is usually not durable.^{48,49} The risks and benefits should be carefully weighed. Continuing transfusions in terminally ill patients can place a tremendous burden on the patient and family and usually requires frequent clinic visits for laboratory tests and transfusions, which can also result in unplanned hospitalizations. Patients requiring frequent transfusions are at risk for fluid overload, transfusion reactions, and alloimmunization, making matched transfusions more difficult. Routine transfusions based on complete blood count results showing anemia or thrombocytopenia should be discouraged. Given the national shortage of blood products, thoughtful consideration should be given before transfusing patients in the terminal phase of their disease.⁵⁰ Suggested guidelines for transfusions at the end of life can be found in Box 56.2. Symptomatic treatment for fatigue or active bleeding should guide clinical practice.

Box 56.2 GUIDELINES FOR BLOOD PRODUCT USE AT END OF LIFE

1. Exceedingly scarce resources, such as cross-matched and HLA-matched platelets, granulocytes, and rare units of blood should not be used in patients who have transitioned to palliative or comfort care. Routine blood products should be used sparingly, and requests should be reviewed by the transfusion medicine service.
2. Transfusions in medically nonbeneficial situations should be avoided if possible and limited to the minimum number of red blood cell transfusions necessary to ameliorate symptoms of anemia. Platelets should also be limited to the minimum necessary to control bleeding (if it is causing significant patient distress, such as upper airway bleeding). If the frequency of transfusions has an impact on the resources available for other patients (i.e., more than twice a week), the request should be reviewed by the transfusion medicine service.
3. If shortages of blood products arise, attempts should be made to defer transfusion in patients at the end of life so the products can be used for other patients. Unusual requests, such as massive transfusion in a nonbeneficial situation, should not be filled. If agreement cannot be reached on this, an ethics consult should be requested.
4. Transfusion in stable, terminally ill patients requires a careful analysis of the goals of care. Transfusions should not be discouraged in patients for whom an occasional transfusion is likely to alleviate primary symptoms, such as extreme fatigue. Large numbers of transfusions, however, should be reviewed by the transfusion medicine service.

Adapted from Smith, Cooling.⁵⁰

CASE STUDY: BLOOD TRANSFUSIONS

Mr. J was a 59-year-old man with relapsed AML with complex cytogenetics. He had failed to obtain remission with multiple chemotherapy regimens and opted for best supportive care, including ongoing blood transfusions. He had many short- and long-term goals including making it to his birthday (2 months away), wedding anniversary (3 months away), and birth of his first grandchild (6 months away). Mr. J met with the outpatient palliative APRN to discuss goals of care.

The palliative APRN outlined options for care with Mr. J and his family, including continued aggressive care or comfort-focused care with home hospice. She explained to Mr. J and his family the risks and benefits of continued transfusions versus stopping transfusions, and they decided to continue transfusions as long as the benefits outweighed the burdens.

Mr. J was able to celebrate his milestone birthday and anniversary. His transfusion requirement increased to needing platelets once a week and blood twice a week. He became increasingly more fatigued and was not getting the “bump” in energy that he previously did after receiving blood. The palliative APRN readdressed goals of care, and Mr. J elected to continue as he was still able to spend quality time with his family.

After the birth of his grandson, he decided to forgo further transfusions. The palliative APRN facilitated a referral to hospice. Over the next 2 weeks, Mr. J became increasingly fatigued and somnolent. His family reported he died peacefully at home with hospice care.

DIALYSIS

The primary goal of renal replacement therapy (RRT) is to prolong life. Initially, dialysis was used to either bridge patients to transplant or allow time for renal recovery in patients with acute kidney injury (AKI).⁵¹ Due to the aging population and advancements in technology, dialysis has now become a destination therapy. According to the US Renal Data System, in 2017, there were 746,557 patients with end-stage renal disease (ESRD). Roughly 70% of these patients received either peritoneal or hemodialysis, and the majority of these patients were older than 65.⁵² With the number of patients over 65 expected to triple in the next 30 years, there is rising concern about the burden such treatment places on an already fragile patient population.⁵³

The mortality rate of patients with Stage 5 chronic kidney disease (CKD) in the first year of maintenance of dialysis exceeds 20%.⁵⁴ For patients older than 75, the risk of death in the first year is 40%.⁵⁵ Elderly patients on dialysis experience higher rates of hospitalizations, intensive care admissions, invasive procedures, and death in a hospital setting in the last month of their life as compared to cancer or heart failure patients.⁵⁵ A study by Brown and colleagues showed that elderly patients with CKD who choose not to initiate dialysis survived a median of 16 months past the time dialysis was recommended and had marked improvements in symptom management with the initiation of palliative care.⁵⁶ While

dialysis may be an option for elderly CKD patients, it is not the only option. When RRT is initiated in this population, it has a significant negative impact on quality of life.⁵³

A reported 60% of dialysis patients feel regret after initiating treatment.⁵⁵ Patients often feel ill-prepared for the physical and psychological toll dialysis takes on the body.⁵⁴ The lack of conversations on realistic expectations both with and without dialysis contribute to this problem. Only 10% of ESRD patients report having goals-of-care conversations with their nephrologist while up to 90% wanted them.⁵⁵ Prognostic uncertainty and unfamiliarity in leading complex discussions contribute to miscommunications between ESRD patients and their providers. While dialysis is meant to lower the symptom burden associated with advanced kidney disease, research has shown that patients undergoing maintenance dialysis suffer from a symptom burden comparable to patients who have not yet started treatment.⁵⁴

Dialysis survival rates have increased in the past 2 years, leading to more uncertainty on prognosis in patients who have initiated treatment.⁵¹ Discussing short-term prognosis with patients and family members can aid in decision-making. Several risk factors have been linked to increased mortality in ESRD patients. These risk factors have been used to develop prognostication tools that help providers determine which patients should initiate dialysis versus conservative management. One system, shown in Table 56.2 and developed by Santos and colleagues,⁵⁷ uses readily available clinical and laboratory data to predict which elderly patients have the highest 6-month mortality. Points are assigned based on five common risk factors. The higher the score, the greater the mortality risk. Patients with a score of 2 had a 10% risk of death in the first 6 months, while patients with a score of 6 had a 70% risk. Prognostication tools such as this can be useful to palliative APRNs as they identify which patients are at risk of death so they can help patients and families navigate difficult decisions surrounding initiation of dialysis.⁵⁷

Withdrawal or discontinuation of RRT also occurs in patients with acute kidney injury (AKI). AKI affects up to 57% of patients in the ICU with 10–15% of these patients

Table 56.2 PREDICTORS OF 6-MONTH MORTALITY IN PATIENTS WITH END-STAGE RENAL DISEASE (ESRD)

RISK FACTOR		POINTS
Age >75		2
Coronary artery disease		2
Cerebrovascular disease with hemiplegia		2
Time of nephrology care before dialysis	< 3.0 months	2
	> 3.0 to < 12 months	1
Serum albumin	3.0–3.49 g/dL	1
	< 3.0 g/dL	2

The higher the score, the greater the mortality risk. Patients with a score of 2 had a 10% risk of death in the first 6 months, while patients with a score of 6 had a 70% risk.

From Santos et al.⁵⁷ (fig. 2)

requiring RRT. The mortality rate in this population is high. Only 50% of AKI patients who start dialysis survive to discharge and of those who do, up to 14% require it long term.⁵⁸ Current guidelines recommend withholding dialysis in acutely ill patients who have an underlying terminal condition, advanced dementia, and in patients older than 75 years. Unfortunately, these guidelines are often ignored as the acute illness takes precedence, which leads to prolonged suffering in terminally ill patients in the ICU.⁵⁹ Palliative APRNs play an important role in educating patients, families, and collaborating providers on prognosis with and without dialysis. This type of informed discussion allows patients and families to better understand the burdens of dialysis in the final days to weeks of life and can lead to reduced initiation in this population or increased discontinuation of dialysis.

At this time, there are no standardized criteria for withdrawal or discontinuation of RRT. Research suggests dialysis should be stopped when the burdens of treatment outweigh the benefits, when the goals of treatment are not being met, and when a competent patient or surrogate decision-maker decide to forgo treatment.⁵⁹ Conversations regarding withdrawal and discontinuation should start prior to initiation of RRT and continue throughout treatment, as recommended by the American Society of Nephrology.⁶⁰ When the recommendations are followed, patients and their loved ones feel more prepared for the end of life and have realistic expectations after withdrawal or discontinuation. Unfortunately, lack of training on serious illness conversations for nephrologists often leaves these conversations to the last minute, when they are most difficult.⁵⁵ Palliative APRNs can help fill this gap in knowledge to ensure that all ESRD patients are making the most informed decisions.

Palliative APRNs play an important role in educating patients and families on the normal dying process. While many fear cessation of dialysis will lead to increased symptoms, death from uremia is often peaceful. Withdrawal or discontinuation from dialysis is the third leading cause of death in ESRD patients. The mean survival after withdrawal or discontinuation is approximately 7 days in this population.⁶¹ Survival is even shorter for AKI patients in the ICU setting. Approximately 50% of deaths after withdrawal or discontinuation occur in a hospital setting without hospice care, which has been shown to increase patient and family suffering at the end of life.^{55,62} Schmidt and colleagues linked early palliative referrals and advance care planning to a higher use of hospice in ESRD patients and improved quality of death.⁶²

Discussions on withdrawal or discontinuation of life-sustaining treatment are difficult. Advance directives, when completed early, can help guide patient, family, and provider conversations on end of life. While advance directives appoint a decision-maker and give guidance on patient's preferences for resuscitation, intubation, and medically administered nutrition, they do not address dialysis at the end of life.⁵⁵ This is one reason that palliative APRNs are so important to this population. Patients who utilize palliative services in coordination with RRT report a lower symptom burden, improved quality of life, and better coping with the stressors associated

with treatment.⁵¹ Because palliative APRNs are skilled in complex discussions and prognostication, they can initiate discussions on withdrawal or discontinuation of RRT early and help patients and families understand kidney failure as a normal part of the dying process.

CASE STUDY 4: DIALYSIS

Mrs. M was a 66-year-old woman with a history of hypertension and triple negative Stage IV breast cancer. Her course is complicated by bilateral hydronephrosis with bilateral ureteral stents. She was currently on palliative chemotherapy and presented to the hospital after falling at home. Mrs. M was found to have lower extremity cellulitis on admission and was initiated on IV antibiotics. Her hospitalization was complicated by persistent hypotension not responsive to fluid resuscitation, worsening leukocytosis, and increasing blood urea nitrogen (BUN) and creatinine levels with decreased urine output. She was transferred to the ICU for further care and initiation of vasopressors. Her renal function continued to fluctuate throughout a prolonged ICU course, but it was ultimately unable to recover despite maximal treatment. Mrs. M required initiation of dialysis 2 weeks after hospital admission.

Prior to initiation of dialysis, palliative care was consulted. Mrs. M and her brother, John, met with the palliative APRN, Amy, to discuss next steps in care. The discussion included risks and benefits of dialysis, expectations given her advanced cancer diagnosis, and advance directives including power of attorney for healthcare (POAHC) and provider order for life-sustaining treatment (POLST) forms. She identified her brother as her chosen agent, and the POAHC form was completed with assistance from the social worker. At that time, Mrs. M was not interested in limiting any life-sustaining interventions. Her goals were to recover her renal status and work on regaining her functional status with intense physical therapy, hoping she could continue palliative chemo in the near future. However, Mrs. M did state that she would not want her life prolonged if she was going to be dependent on machines long term.

Mrs. M took a turn for the worse during her third week in the hospital. She became progressively thrombocytopenic, intermittently confused, and unable to meaningfully participate in therapy. Her body was unable to maintain fluid balance without IV supplementation. Mrs. M also became less tolerant of dialysis and required premedication with midodrine. Amy suggested a family meeting to readdress goals of care.

Mrs. M and her brother met with Amy, and the oncologist, hospitalist, and nephrologist. Mrs. M was alert and oriented enough to participate in the meeting. Both she and her brother were updated on her current status, prognosis, and goals of care were readdressed. Amy, with consensus from the multidisciplinary team, expressed concern that further dialysis would only prolong suffering and not enhance quality of life. Mrs. M and her family were informed that renal recovery was not possible and discontinuation of dialysis was recommended. Mrs. M and her brother were reminded of her previously verbalized wish to not be dependent on machines if there was no meaningful chance of recovery. It was eventually decided to move Mrs. M into inpatient hospice, where dialysis would be discontinued. Mrs. M died comfortably 3 days later with her brother at her bedside.

NUTRITION

Medically administered nutrition is a medical intervention used in patients who have difficulty swallowing or maintaining adequate nutrition as a result of a number of medical conditions. For patients with functioning gastrointestinal (GI) tracts, nutrition can be administered through a percutaneous endoscopy gastrostomy (PEG) tube or a nasogastric tube (NG). For patients without a functioning GI tract, total parenteral nutrition (TPN) is usually indicated. While all methods of medically administered nutrition carry risks and benefits, as a whole it has not been shown to prolong patients' lives as they near the end of life regardless of the route of administration or cause.⁶³

Nearly 50 million people worldwide are suffering from dementia with an expected 10 million new cases each year.⁶⁴ Dementia is characterized by a progressive decline in mental, functional, and nutritional status ultimately leading to the end of life. Because anorexia is a normal part of the disease process, the risks and benefits of medically administered nutrition in this population have been widely researched. At this time, there are no prospective randomized control trials that demonstrate that artificial nutrition benefits patients with advanced dementia.⁶⁵ Consensus statements from both the American Geriatric Society and American Academy of Hospice and Palliative Medicine recommend against medically administered nutrition in advanced dementia. The Hospice and Palliative Nurses Association (HPNA) does not recommend medically administered nutrition in patients with a prognosis of 6 months or less but acknowledges the right for competent patients and family members to choose it with guidance from palliative APRNs.⁶⁶

Placement of feeding tubes in advanced dementia patients remains controversial despite the overwhelming evidence against the benefits and clear recommendations.² This can be attributed to cultural and familial beliefs, lack of advance directives in this population, and misinterpretation of preferences by loved ones. Medically administered nutrition is often seen as a necessity and not a life-prolonging intervention. Family members tend to separate interventions for nutrition and hydration from "more invasive" end-of-life interventions such as mechanical ventilation and intubation.^{67,68} A study by Tsai and colleagues showed that only 35–45% of patients with dementia had disclosed their preferences on end-of-life decisions. Of the patients who had, almost 50% of caregivers disagreed with or misunderstood the patient's preference. This, in turn, led to a high percentage of caregiver distress. Their research showed that comprehensive education on advanced dementia starting at diagnosis significantly reduced caregiver depression and use of medically administered nutrition in this patient population.⁶⁷

Malnutrition impacts between 40% and 80% of cancer patients. It most commonly occurs in patients with late-stage disease and/or disease affecting the GI tract, lung, head, neck, and liver. While medically administered nutrition is recommended in cancer patients who are unable to meet 60% of nutritional needs despite nutritional counseling, there is no

evidence that supports its use in advanced cancer patients, especially in the last weeks of life.⁶⁹ Though malnutrition in cancer patients is linked to higher mortality, oral feeding is recommended over medically administered nutrition and has been shown to provide just as much benefit without the risks.⁷⁰ Much like dementia, research has shown that early palliative care referrals significantly decreased the use of medically administered nutrition in this population.⁷¹

TPN is most commonly used in cancer patients suffering from radiation enteritis, chronic bowel obstruction, peritoneal carcinomatosis, and short bowel syndrome. While evidence on the benefit of such intervention is lacking, the current recommendation is to only initiate TPN in patients who are expected to be cured or live longer than 2–3 months.⁶⁹ When anorexia is caused by cancer cachexia syndrome rather than decreased oral intake, medically administered nutrition will not change the course and is associated with higher treatment-related complications, including sepsis. TPN has also been linked to poor quality of life and disruption in sleep, work, travel, fluid balance, and electrolyte abnormalities. Because TPN requires close monitoring both in the hospital and out, it is often seen as a burden for patients with advanced malignancies.⁷²

Communication plays an important role in the patient's and family's understanding of nutrition at the end of life, regardless of the diagnosis. There is overwhelming evidence that early screening for malnutrition, consistent discussion on expectations throughout the disease course, and early advance directives reduce the use of artificial nutrition in patients with end-stage disease.^{2,65,66,70} When families understand anorexia as a normal, natural part of the disease process, there is less report of suffering and improved promotion of patient-centered care.^{2,65} One barrier to education and effective communication is lack of provider and nursing experience caring for terminally ill patients and overestimation of prognosis.^{71,73,74} Palliative services have been demonstrated to break down these barriers, reduce the use of medically administered nutrition, improve overall quality of life, and reduce suffering associated with cessation of feeding for terminally ill patients.^{67,70}

The role of the palliative APRN is to ensure providers, patients, and loved ones understand that medically administered nutrition is a medical intervention and not a basic provision of comfort. Withdrawal or discontinuation of medically administered nutrition is ethically justified when continuing treatment cannot achieve the intended benefit, the burdens of treatment outweigh the benefits, and/or when a competent patient or designated decision-maker chooses to discontinue treatment.⁷⁵ The dying process is characterized by diminished oral intake, diminished awareness, and decreased perception of hunger.² When the dying process has begun, medically administered nutrition has not been shown to provide benefit regardless of the cause. Despite the evidence, conversations regarding withdrawal, discontinuation, or withholding medically administered nutrition remain highly charged. Palliative care programs not only improve patient, caregiver, and provider understanding and

acceptance of withdrawing, withholding, or discontinuing medically administered nutrition at end of life, but also protect patients from harm and ensure that patients' advance health wishes are respected.² Once a patient or family member has decided to withdraw or discontinue it, it is important that advance directives are updated accordingly.

CASE STUDY 5: MEDICALLY ADMINISTERED NUTRITION

Mrs. D was an 82-year-old Cantonese-speaking woman with history of cerebrovascular accident, coronary artery disease, COPD on 2 L nasal cannula, type 2 diabetes, CKD Stage IV, and hypertension who presented from a nursing home with hyperkalemia and hypoxia, her fifth admission for abnormal blood values. She was bedbound and could not provide any care for herself at baseline. On admission, Mrs. D was awake and alert to voice, oriented only to herself. She received nutrition through a PEG tube. While her hyperkalemia was quickly resolved, her hospitalization was complicated by worsening respiratory failure unresponsive to IV diuresis and requiring noninvasive ventilatory support.

Palliative APRN Sarah was consulted to discuss goals of care with Mrs. D's family. Sarah began working with Mrs. D and her five children after she was admitted a year ago for a stroke. Mrs. D did not have any advance directives in place. During one of the previous palliative meetings, her son Huang was established as the primary surrogate decision-maker and a POLST form was completed. With consensus among her children, the decision was for no resuscitation or intubation; however, long-term medically administered nutrition could be initiated. Because Mrs. D could no longer safely take oral nutrition, discussion turned to a feeding tube. Despite discussions on risks and benefits of a feeding tube, her family decided to proceed with placement in hopes it would aid in her recovery. Unfortunately, the last year of Mrs. D's care had been marked by progressive functional, cognitive, and nutritional decline; opportunistic infections; and repeated hospitalizations. Up to this point, Mrs. D's family have declined

discussions on end of life and hospice care and have verbalized preferences to continue hospitalizations.

Given Mrs. D's clinical condition, another family meeting was held to discuss next steps in her care. Palliative APRN Sarah knew this was Mrs. D's last hospitalization because she was unresponsive, hypotensive, and her breathing was irregular. Given COVID-19 restrictions, only two of her five children were allowed in the meeting room. The rest of the family joined via videoconference. Mrs. D's prognosis of hours to days was discussed, as well as discontinuation of medically administered nutrition and hydration and expectations for a normal dying process. Initially, Mrs. D's family was hesitant to withhold food and fluids. They were concerned that she would starve, die faster, and be more uncomfortable without nutrition. Sarah educated the family on the harms of nutrition at the end of life and addressed concerns about the cessation of food and fluids. Ultimately, her family agreed to withdrawal of further life-sustaining interventions, including tube feedings, and Mrs. D was moved to the inpatient hospice unit. Her POLST form was updated to reflect the new goals of comfort care. Mrs. D died 2 days later, comfortably, with family at her side.

SUMMARY

Life-sustaining treatments, such as antibiotics, blood products, dialysis, and medically administered nutrition, can prolong the dying process in critically and terminally ill patients. These treatments may provide little benefit, and the burdens of these interventions can increase suffering. Families are often faced with decisions regarding withholding, withdrawing, or discontinuing life-sustaining treatment as patients near the end of life. Recommendations regarding withholding, withdrawing, or discontinuing treatments should be made based on medical knowledge and evidence-based practice.

The palliative APRN must be adept at using communication skills to navigate these often emotionally charged conversations. Careful attention should be paid to avoid using

Table 56.3 SUGGESTED PALLIATIVE APRN COMMUNICATION REGARDING LIFE-SUSTAINING THERAPIES AT END OF LIFE

CLINICAL SITUATION	SUGGESTED WORDING AND/OR MESSAGES
Infection in advanced disease	Your father is dying from advanced cancer and has no further treatment options. Antibiotics may prolong the dying process and cause unnecessary suffering. I recommend withholding or discontinuing antibiotic therapy.
Blood products in advanced hematological malignancies	Your loved one is anemic because the disease has worsened and is no longer responding to treatment. Transfusions may sustain or prolong life for some time but will not help the underlying disease.
Kidney failure in sepsis with underlying terminal illness	Your mother's kidneys are shutting down as a part of the dying process, and dialysis will not be beneficial. As the toxins she normally urinates out build up in her system, she will become more sleepy, then comatose. It is usually a peaceful death.
Total parenteral nutrition (TPN) for malignant gastrointestinal failure	TPN is not likely to prolong life or improve quality of life. Medically administered nutrition is not recommended. Most patients with advanced disease do not feel hunger. We can offer pleasure feeds if the patient wants to eat.

judgmental terms such as “inappropriate” and “futile.” The current terminology is the wording “nonbeneficial care,” which implies less judgment. Sensitivity to cultural and religious beliefs is also key (see Section VI, “Communication”). Suggested messaging and wording for these conversations can be found in Table 56.3.

Palliative APRNs can play a key role in explaining the underlying disease process and prognosis to patients and families. They must also educate colleagues about prognostic tools that enable clinicians to identify patients who are nearing the end of life. Their role includes facilitating team and family meetings to encourage informed decision-making. Palliative APRNs can also educate colleagues, patients, and families regarding what to expect during the normal process of dying when treatments are discontinued.

PALLIATIVE SEDATION

David Collett and Kelly Baxter

KEY POINTS

- Palliative sedation is an important therapy of last resort to relieve suffering in patients who have intractable pain and/or other symptoms.
- The palliative advanced practice registered nurse (APRN) must understand the ethical framework of palliative sedation as well their institutional and jurisdiction's context.
- The palliative APRN should be familiar with the various medications and monitoring guidelines that are used to provide safe and effective sedation.
- Palliative sedation necessitates interdisciplinary team involvement, utilization of evidence-based practice, and knowledge of ethical principles, as well as practice guidelines.

CASE STUDY

Miguel is a 30-year-old man who was diagnosed 2 years prior with metastatic osteosarcoma. He had recently finished business school and was advancing in his company when he was diagnosed. Miguel had initially presented to his family nurse practitioner with a history of persistent and worsening knee pain, weight loss, and fatigue that was interfering with his workouts as well as his daily activities. After being ruled out for other causes, he underwent imaging that showed a femur mass concerning for malignancy, and a subsequent biopsy confirmed metastatic sarcoma involving bone, soft tissue, and liver.

Miguel underwent several lines of chemotherapy and radiation with ongoing progression of disease. Because of his continued high functional status and tolerance of treatment, he was able to continue to receive disease-directed treatment. However, he continued to have neuropathic and somatic right lower extremity pain. His medical oncologist referred him to the palliative nurse practitioner who was embedded as part of the oncology practice. She initiated a pain regimen of morphine and gabapentin, although, over the next several months, he required increases in doses and initiation of long-acting morphine.

Miguel continued to be followed by palliative care, who also engaged him in advance care planning and referred him for chaplaincy for spiritual support. The palliative social worker also held sessions with both Miguel as well as his parents to help them process his advanced illness. As his disease progressed, he required rotation to methadone due to tolerance at significantly higher

doses of opioids, and he received some benefit from a short course of palliative radiation. Several months later, his oncologist asked palliative care to participate in a goals-of-care meeting to share that Miguel's disease had continued to progress and that there were no further treatments. A recommendation for home hospice services was provided, and a prognosis of 6 months was given. Miguel initially declined home hospice services, stating that he was hopeful to continue to receive disease-directed treatment.

Miguel enrolled in a Phase I clinical trial at a nearby academic medical center. However, he had an adverse reaction to one of the trial drugs and was forced to disenroll in the trial. A week later, he presented to the oncology center's emergency department with severe pain, nausea, and failure to thrive. He was admitted by the oncology hospitalist team, and palliative care was consulted. His clinical status continued to decline, with continued severe pain. Miguel's nausea interfered with his ability to take oral medications, and his oral methadone was converted to intravenous (IV) form. Eventually, he required the addition of patient-controlled analgesia with hydromorphone, and he also received ketamine as an adjuvant analgesic.

Miguel continued to have moderate-severe pain, though the pain was tolerable. He preferred to remain as alert as possible to spend time with his friends and family who were frequently at bedside. He continued to decline, and there were multiple discussions regarding goals of care. Miguel elected to have a do-not-resuscitate (DNR) order placed. Though Miguel shared he would prefer to be at home, he expressed understanding that his opioid regimen and IV requirement would require inpatient services. Social work was involved, and a referral was made for a local inpatient hospice that had an adequate supply of the opioids Miguel required.

Unfortunately, the inpatient hospice had a waitlist. Miguel declined further, with increasing pain and frequent pain crises that required extensive titration under the guidance of the palliative care team's pharmacist. It was shared with him and his family that his prognosis was likely short – death was probable within days. Miguel's intractable pain was distressing to him as well as his family, as he would often wake up screaming and boluses were providing less and less relief. The palliative care team discussed the potential of using palliative sedation as a way to control his refractory pain. Miguel expressed interest in this, although he shared that he was hopeful to see his brother who was traveling to the hospital to see him. After discussion, it was decided by Miguel to pursue palliative sedation until his brother was able to be present bedside. A clinical meeting was held with Miguel's primary hospital team, nursing staff, and the palliative

care interdisciplinary team. One nurse shared that he felt ethically uncomfortable with palliative sedation because of religious beliefs, and a change in nursing staff was made. An overview was provided to Miguel and his family, and his DNR code status was reconfirmed. Later that evening, a midazolam infusion was started that relieved Miguel's symptoms, with his family staying close. His opioid regimen was continued concurrently, and he was monitored closely for signs of pain.

His family stayed at his bedside. The next night, Miguel's brother arrived, and sedation was paused. Miguel awoke in severe pain and again received boluses for breakthrough pain with minimal relief. He was able to spend an hour with his brother and family and say goodbye to them. The palliative chaplain provided prayers and spiritual support before Miguel requested that sedation be restarted. The infusion was restarted and Miguel continued to be monitored by nursing and his medical teams, with his family present at bedside until he died the following afternoon.

INTRODUCTION

Every individual hopes for a peaceful death. When a serious illness becomes a terminal illness, the goals of care may shift from curative or life-prolonging to an exclusive focus on comfort. When someone transitions to the end of life, physical comfort can be achieved for many people. With physical symptoms controlled, the dying experience may become a time for personal growth, reconciliation, strengthening of relationships, and spiritual enrichment. However, there are rare circumstances when, despite best efforts, distressing symptoms may not be fully managed. This results in not only physical suffering but can also cause psychological and existential suffering that may interfere with a peaceful death. When patients have intractable symptoms, palliative sedation is offered as a treatment of last resort when all other expert palliative care treatments have failed.⁶ The process of deciding to offer palliative sedation is multifaceted, but its intention—to relieve suffering and not to hasten death—is clear.¹

Critical and systematic review of the palliative sedation literature reveals differences in the concepts and practice of palliative sedation.⁶ The lack of consensus among experts demonstrates that even experienced palliative care clinicians may be uncomfortable with palliative sedation—whether based on personal beliefs, unfamiliarity, or a lack of guidelines. The focus of this chapter is the role of the palliative advanced practice registered nurse (APRN) in palliative sedation based on expert opinion and evidence-based practice.

TERMS AND PREVALENCE OF USE

Palliative sedation has also been described as “controlled sedation” “terminal sedation,” “sedation for intractable symptoms,” “continuous sedation,” “sedation at end of life,” “total sedation,” and “prolonged sedation.”^{1,6,7} The Hospice and Palliative Nurses Association uses the term “palliative

sedation” rather than “terminal sedation” in its position statement regarding the practice because “the name was modified to more accurately reflect the intent and application of its use—to palliate the patient’s experience of symptoms rather than to cause or hasten death.”¹

Even though there is no universal terminology of palliative sedation, and even some disagreement on its conceptual foundation, there is some agreement that it involves the monitored use of medications to induce controlled sedation to the point of unconsciousness in a dying patient to relieve distress caused by otherwise uncontrolled pain and symptoms and that it is used as a last resort.^{8,9} It is typically continued until the patient dies. Palliative sedation is different from *procedural sedation* or *conscious sedation*, in which time-limited use of sedation decreases awareness and pain during an anticipated painful procedure in a patient who is going to survive. Palliative sedation also includes *respite sedation* and *emergency sedation*. Respite sedation is a time-limited use of sedative medications in dying patients with the goal of providing reprieve from distress and suffering for a period of time and then returning the patient to consciousness. Emergency sedation is utilized in patients who experience an emergent, symptomatic crisis at the end of life that causes severe distress—such as a hemorrhage or profound hemoptysis.

Palliative sedation is not a veiled type of euthanasia or aid in dying. Clearly, the intent and practice of palliative sedation are to reduce suffering by inducing an altered consciousness, not by precipitating death. *Voluntary active euthanasia* is when a clinician *administers* a lethal dose of medication in response to a request from a competent patient for help in ending life.² *Assisted death* (i.e., medical aid in dying or physician-assisted dying) is when a patient is prescribed a lethal dose of medication that is self-administered by a patient who has requested the means to end their own life (Table 57.1). The American Nurses Association (ANA) position statement, *The Nurse’s Role When a Patient Requests Medical Aid in Dying*, states that nurses are “ethically prohibited from administering medical aid in dying medication.” However, the statement also states that nurses need to “remain objective when discussing end-of-life options with patients who are exploring medical aid in dying” and to also advocate for palliative care³ (see Chapter 53, “Navigating Ethical Dilemmas”).

The literature reports wide variation in the use of palliative sedation, although, when it is utilized, it is often in cancer patients.¹⁰ Frequency of palliative sedation is broad, with studies showing use ranging from 1% to 80% of study population patients.⁷ The lack of consensus on the definition of palliative sedation, the retrospective nature of palliative sedation studies, and the settings that palliative sedation takes place in may contribute to this variation.¹¹ Other hypotheses for the wide deviation in its reported use include varied cultural, religious, and ethnic values and beliefs about the ethics and appropriateness of its use. Research has found an increase in the use of palliative sedation in recent years in some countries, which may be a result of increased recognition of palliative sedation by clinicians and/or by patients and families.⁷

Table 57.1 COMMON TERMS RELATED TO PALLIATIVE SEDATION

INTERVENTION	DEFINITION	TYPICAL SCENARIO	LEGALITY
Palliative sedation	Sedation provided to a terminally ill patient near end of life with goal of reducing suffering. The controlled induction of sedation to the point of unconsciousness in a patient at end of life to relieve otherwise refractory pain, symptoms, and emotional suffering (though this is more controversial).	End of life with intractable symptoms continued through death Could be planned or emergent	Legal in the United States
Respite sedation	Temporary or time-limited sedation provided to a terminally ill patient with goal of giving respite from symptoms for a period of time and then returning the patient to consciousness.	End of life with intractable symptoms	Legal in the United States
Urgent or emergency palliative sedation	An emergent use of palliative sedation medications provided in a crisis for patients at end of life with the goal of giving respite from urgently arising symptoms.	End of life with a symptomatic crisis (e.g., hemorrhage, acute respiratory distress from lung shift)	Legal in the United States
Procedural sedation	The time-limited or temporary use of sedation to decrease awareness and prevent pain during a medical procedure or surgery in a patient who is going to survive.	Surgical settings, other procedures (e.g., intubation, wound packing for ENT issues)	Legal in the United States
Voluntary active euthanasia	Administration of an agent by a third party to a patient by request with goal of ending life.	Varies depending on locale, typically in terminally ill patients	Not legal in the United States and not recognized by most discipline-specific organizations in the United States (i.e., American Medical Association, American Nurses Association)
Assisted death	Self-administration of an agent prescribed by a medical provider with goal of ending own life	Varies depending on locale, typically in terminally ill patients	Legal in some states throughout the United States. In most states, APRNs are not authorized to prescribe medications for this procedure

From Hospice and Palliative Nurses Association¹, Billings², American Nurses Association³, Cherny⁴.

LEGAL JUSTIFICATION FOR THE USE OF PALLIATIVE SEDATION

Several important legal cases set the support and precedent for the use of palliative sedation. In the 1997 US Supreme Court decisions in *Vacco v. Quill* and *Washington v. Glucksberg*, Justice O'Connor stated that "a patient who is suffering from a terminal illness and who is experiencing great pain has no legal barriers to obtaining medication, from qualified physicians, to alleviate that suffering, even to the point of causing unconsciousness and hastening death."^{12,13} O'Connor went further to describe the end of life: "Death will be different for each of us. For many, the last days will be spent in physical pain and perhaps the despair that accompanies physical deterioration and a loss of control of basic bodily and mental functions. Some will seek medication to alleviate that pain and other symptoms." Justice O'Connor affirmed the distinction between intentionally hastening death and the justifiable use of medication to alleviate suffering, even to the point of unconsciousness and hastening death.

Multiple ethical concepts support the use of palliative sedation. Principles of dignity, autonomy, fidelity, beneficence, nonmaleficence, and the rule of double effect are often used. A palliative APRN must be familiar with how these concepts relate to decision-making about palliative sedation and be able to counsel, educate, and support their team. The ANA's *Code of Ethics for Nurses* states that "A fundamental principle that underlies all nursing practice is respect for the inherent dignity, worth, unique attributes and human rights of all individuals."¹⁴ Palliative sedation frees a patient from suffering and thereby preserves his or her dignity and self-worth. The ANA's *Nurses' Roles and Responsibilities in Providing Care and Support at the End of Life* exhorts all nurses to have a basic understanding of palliative care, how to advocate for palliative care for patients, and basic symptom recognition and management. Nurses are also to be able to engage with patients and their families on advance care planning and discussing with them their goals and values in the context of their medical care, including do-not-resuscitate orders.^{15,16} By respecting the values, beliefs, goals, privacy,

actions, priorities, and body of an autonomous adult, the palliative APRN respects the dignity of that person.¹⁴

Autonomy or self-determination is derived from the principle of respect for persons. It is the right of a capable person to decide their own course of action based on their own personal values and goals of life.¹⁷ Informed consent derives from self-determination. It requires that the patient has the capacity and sufficient information to understand the risks and potential benefits of palliative sedation before it is started. The patient without the capacity to make decisions has the same right to informed consent before treatment, but decisions should be made through a surrogate decision-maker who is substituting for the patient.¹⁸

The principle of fidelity is also an ethical imperative that ensures that healthcare providers keep promises and faithfully act in the correct manner toward the patient. The commitment to not abandon our patients or their families at the end of life, even in the face of great suffering, is based on fidelity. Beneficence is the ethical duty to act to the benefit or good for the person under our care.¹⁷ Treating physical and psychological distress, promoting comfort, and honoring the wishes of our patients are perceived as beneficial. Nonmaleficence is historically linked to the Hippocratic Oath and its stated imperative of doing no harm.¹⁷ This principle is often used as a moral argument against the practice of palliative sedation, as some believe that harm is incurred in the potential for hastening death. The validity of this argument is contradicted by Maltoni and colleagues who reviewed 30 years of data in patient cohorts matched for prognostic variables. They demonstrated that patients receiving palliative sedation did not die sooner than those not receiving sedation.¹⁹ Moreover, careful use of the therapy in terms of patient selection and close monitoring limit potential harm.

The ANA's *Code of Ethics for Nurses* states that "the nurse should provide interventions to relieve pain and other symptoms in the dying patient even if those interventions entail the risk of hastening death. However, nurses may not act

with the sole intent to end a patient's life even if motivated by compassion, respect for patient autonomy, and quality of life considerations."¹⁴ This reflects the principle of double effect. Billings points out that solely relying on this precept ignores the issue that although the intended effect of palliative sedation is to reduce suffering, it often involves withholding fluids and other life-supporting measures and that death from the underlying disease or condition is actually inevitable^{2,20} (Table 57.2).

The Hospice and Palliative Nurses Association, the American Academy of Hospice and Palliative Medicine, the National Hospice and Palliative Care Organization, and other professional organizations endorse palliative sedation for intractable symptoms to relieve suffering.^{1,21-24} Despite this general acceptance in the healthcare community for the use of palliative sedation, it is important to understand and acknowledge the concerns of those who do not agree that the practice is morally acceptable. Objections include the fear that the practice is part of a slippery slope that will lead to hastening death or euthanasia, violating the sanctity of life, or a belief that a higher power or deity alone should choose when a patient dies. Also, the withdrawal of life support or withholding of nutrition, although legally permissible and ethically supported in nursing and medicine, may be unacceptable for someone's moral framework.² Team members, patients, and families may differ in their opinions based on their cultural norms and religious beliefs. The palliative APRN must explore these values while offering nonjudgmental support and negotiating a care plan that is respectful of these other opinions but consistent with the patient's wishes and codes of professional conduct. This may result in the APRN assuming the responsibility of care for others who are uncomfortable with palliative sedation. Such actions include offering to take the lead in care, writing orders, directly initiating the medication administration, and providing ongoing support of the family and staff.

In the final analysis, each team member must create his or her own personal ethical and moral framework to work

Table 57.2 PALLIATIVE SEDATION AND DOUBLE EFFECT

DOUBLE EFFECT	PALLIATIVE SEDATION
The act itself is morally good or indifferent.	Giving medication to relieve suffering is good.
The intent of the act is only to cause a good effect.	The intent is to alleviate suffering and distress from intractable pain and suffering.
A bad effect may be foreseen but is not intended and would have been avoided if a satisfactory alternative method to achieve the good effect could be found.	Death is foreseen but is not intended with palliative sedation.
The desirable effect follows from the intended effect and not from the bad effect (death).	Relief of pain and symptoms and the subsequent suffering is achieved through sedation, not death.
A proportionately grave reason exists for seeking the good effect and thus compensates for risking or permitting the bad effect.	The use of palliative sedation to relieve intolerable suffering from intractable pain and symptoms outweighs the risk of hastening death.

Adapted from Billings²; and Billings, Churchill.²⁰

with the patient, family, and other team members to come to a mutually supportive plan that is respectful of each person's values. The use of palliative sedation, although supported by the law and leading organizations in the science, will not be morally or ethically permissible to some patients and families and some members of the healthcare team. Thus, the palliative APRN needs to understand the legal and ethical doctrines that support and challenge the use of palliative sedation as well as the institution's guidelines while simultaneously initiating and participating in discussions about its use, with sensitivity to the concerns and perspectives of all: patients, families, and members of the healthcare team.

CREATING A MODEL OF CARE FOR PALLIATIVE SEDATION THERAPY

There are three types of sedation: palliative sedation for symptoms, palliative sedation for existential issues, and respite sedation. To create a model of safe, effective, high-quality care, best practice in the following six areas listed in must be delineated:

- Patient eligibility
- Clinician/team member competence, involvement, and care
- Informed consent and decision-making about continued treatments (including the use of life support and nutrition and hydration)
- Team preplanning: who will lead the process, who will write orders, who will support the family and the care team
- Family involvement and care
- Medications and procedure of palliative sedation
- Post-sedation debrief

PATIENT ELIGIBILITY

For the use of palliative sedation to be considered, the patient must have a terminal condition with imminent death anticipated and must be experiencing severe symptoms and suffering, often described as intolerable, intractable, or refractory to aggressive standard palliative interventions. Imminent death is defined as a life expectancy of hours to days based on the person's physical exam, the progression of disease, and the symptom constellation.^{25,26}

Cherny and Portenoy define a refractory symptom as having these attributes: (1) aggressive palliative care interventions short of sedation fail to provide relief, (2) additional invasive or noninvasive treatments are unlikely to provide relief, and (3) additional therapies are likely to be associated with excessive or unacceptable morbidity or are unlikely to provide relief within a reasonable timeframe⁴ (e.g., a patient in the last few days of life with severe neoplasm-related pain unrelieved by

escalating multidrug analgesic regimens despite the involvement and evaluation of palliative specialists).

The type of refractory patient suffering (physical vs. existential) for which palliative sedation therapy may be considered is another factor. The term "existential suffering" can also include spiritual suffering and typically relates to nonphysical symptoms, including the inability to find meaning, purpose, and fulfillment in one's life, a loss of dignity, fear of death, hopelessness, and loneliness.^{27,28} Prevalence of existential distress for patients with terminal illness is 13–18%, and potential risk factors for existential distress include lack of social support, uncontrolled physical symptoms, reduced physical activity, and coping through blaming oneself.^{29,30} Additionally, it is important to consider posttraumatic stress disorder (PTSD) as a precipitating factor in existential distress as well as physical symptoms and to identify patients who are at increased risk.³¹

For some patients, such existential distress can be intolerable. The use of palliative sedation for existential distress is controversial and views vary widely, even among palliative care providers.³² One argument against its use is the difficulty of defining the intractability of existential distress. While there are objective criteria for quantifying and treating physical distress, evaluating existential distress is more difficult and exposed to clinician subjectivity.³³ Additionally, there is a lack of research to provide evidence and evolving guidelines for patients with existential distress.³⁴ Some experts argue that it is not about the cause of the suffering. It is the degree of the distress and the proximity of death that should be considered when determining whether to use palliative sedation. Nonetheless, many clinicians find the idea of sedation for existential suffering to be morally and ethically challenging.³³ Refractory psychological distress must be distinguished from other treatable problems, such as depression, anxiety, delirium, other psychiatric illness, and family conflict. The American Medical Association's Opinion 2.201: *Sedation to Unconsciousness in End-of-Life Care* recommends against the use of palliative sedation for existential distress.²³ The Veterans' Administration (VA) Ethics Committee report explores this issue and concludes, "When the patient's suffering is interpersonal, existential, or spiritual, the tasks of the clinician are to remain present, to 'suffer with' the patient in compassion, and to enlist the support of clergy, social workers, family, and friends in healing the aspects of suffering that are beyond the legitimate scope of medical care."²⁴

Specific clinical guidelines for the use of palliative sedation in the patient with existential suffering include^{5,35}:

- Ensuring it is utilized in a patient with advanced terminal disease, with informed consent from the patient or surrogate decision-maker.
- Exhausting all palliative treatments, including treatment for depression, delirium, anxiety, and any other contributing psychiatric illnesses.
- Completing a psychological assessment by a skilled clinician. If applicable, spiritual assessment should also be done by a skilled clinician or clergy member.

- Initially starting with a trial of respite sedation, ranging from 6 to 24 hours, with ongoing re-evaluation prior to continuous sedation.

Respite palliative sedation has been found to be helpful for the patient, family, and healthcare team in re-evaluating the decision for and benefit of palliative sedation. Some patients who were provided with short periods of sedation have been found to be able to break the cycle of anxiety and distress that created the request for palliative sedation in the first place—as a result, further palliative sedation was unnecessary.³⁶ These criteria seem prudent and appropriate for evaluating the use of palliative sedation not only in patients with existential distress but also in all patients with severe uncontrolled symptoms who are considering palliative sedation.

In practice, some clinicians and protocols limit the use of palliative sedation to only physical distress (or symptoms that are somatic in nature), whereas others include existential and psychological distress, though typically only under special circumstances or for short periods (respite sedation). Although only the patient can determine if a symptom is intolerable, and although the patient has a right to request sedation, the clinician does not have to act to provide sedation. Severe distress in itself should always create urgency for palliative care clinicians to attempt to reduce the suffering. If the treatment of severe symptoms is not successful, the team may consider palliative sedation as an option only if the patient's condition, in terms of both the immediacy of expected death and the intractability of the symptoms and distress, meets established criteria for palliative sedation (Box 57.1).

There is general acceptance that when palliative sedation is considered, whether continuously or intermittently, there should be specific policies, procedures, and protocols for its use.²⁸ All treatment and diagnostic options for the previously discussed problems must be addressed adequately before palliative sedation is considered and provided. The decision to begin sedation is often difficult for clinicians, requiring thorough patient assessment and discussions with the patient, family, and other team members.

The literature cites many different reasons palliative sedation has been used. While Muller-Busch, in their analysis of 7 years of data, found anxiety and existential distress (40% anxiety/psychological distress, 35% dyspnea, and 14% delirium/agitation) to be the most commonly cited reason for the use of palliative sedation, another study that looked at 30 years of palliative sedation practice reported delirium as the most common reason for its use (54%), followed by dyspnea (30%), psychological distress (19%), pain (17%), and vomiting (5%).³⁷ They also reported that some programs never provided palliative sedation for patients with existential psychological distress while others included it, and it was one of the most often-cited reasons for its use. A recent systematic review found dyspnea, agitation/delirium, and pain to be the most common reasons for use.⁷

Box 57.1 PATIENT ELIGIBILITY FOR PALLIATIVE SEDATION

- Interdisciplinary assessment of the patient includes nursing, medical, social work, chaplaincy providers.
- The patient must be imminently dying.
 - Life expectancy is hours to days.
 - There is a do-not-resuscitate order in place.
- The patient has severe, intolerable pain and/or symptoms refractory to treatment.
 - Aggressive palliative care management fails to provide relief.
 - Additional invasive/noninvasive treatment cannot provide relief.
 - Additional therapies are associated with excessive/unacceptable morbidity or are unlikely to provide relief within a reasonable time.
- All palliative treatments must be exhausted, including treatment for depression, delirium, anxiety, and any other contributing psychiatric illnesses.
- Expert consultations from other specialties (i.e., psychiatry for delirium, pain service for pain syndromes, pulmonology for respiratory issues) offer no other alternatives.
- A psychological assessment has been completed by a skilled clinician.
- A spiritual assessment has been completed by a skilled clinician or member of the clergy.
- Trial of respite sedation may be considered before palliative sedation is provided.

Adapted from Cherny, Portenoy⁴; and Rosseau.⁵

INTERDISCIPLINARY TEAM MEMBER COMPETENCE, INVOLVEMENT, AND CARE

Interdisciplinary assessment determines the refractory nature of the symptoms. Key roles of the palliative APRN, along with the physician, pharmacist, and nurse, include (1) a thorough review that all potential treatments have been pursued and all other potential specialties have offered an opinion, thus ensuring that all standard treatments have been aggressively used, and (2) determining that the symptom is truly refractory despite adjustments in regimens. The involvement of a pharmacist, optimally a palliative care-trained pharmacist, can help with symptom assessment and recommendations for regimen changes or alternative therapeutics.³⁸ Involving the social worker and the chaplain assists with the assessment and management of the patient's psychological, existential, and spiritual distress (which also affects their physical distress) and family and patient well-being and coping.^{39,40} The importance of addressing and treating the nonphysical distress that contributes to the patient's total pain expression cannot be overemphasized. A multidimensional approach is important

to prevent, detect, and manage risk factors for intractable pain, including psychosocial distress, addictive behavior, and delirium in patients with terminal disease.

Even with specialist-level palliative care, pain and other distress can be difficult to treat, especially when complicated by profound suffering. Interdisciplinary collaboration among the primary care providers, the palliative care interdisciplinary experts, and other team members confirms the patient's condition and assists in the essential aspects of care planning, including assessment (making sure patients meet the conditions of imminently dying, refractory symptoms, assessment of distress), goals-of-care establishment, and care delivery during the sedation period.

An additional aspect has to do with the competence of the palliative APRN and their team in performing the palliative sedation, including their knowledge, critical thinking, and experience. A team should be part of developing a protocol and discussing their personal comfort with the process, ethically and morally. It can be difficult if this is not done and a team member surprises the team by opting out at the last minute. Most protocols involve the interdisciplinary team in decision-making about palliative sedation. This includes the attending or primary care physician who consults and/or receives advice from a palliative care clinical expert (typically an experienced palliative physician and/or a palliative APRN), a pain specialist who has interventional expertise, a palliative pharmacist, or another expert specialty clinician as appropriate to the symptoms being managed (e.g., pulmonary or cardiology for dyspnea, psychiatry for delirium and to assess for depression and anxiety). The palliative APRN and bedside nurses are critical in the support and coaching of other direct-care providers and each other to ensure that the patient and family members are given the psychosocial care they need.

Collaboration with the interdisciplinary team not only validates the appropriateness of palliative sedation and facilitates the informed consent process but also reduces the emotional burden for the healthcare providers. Palliative care team members work in a specialty that has significant factors for burnout.⁴¹ Team members have said that one of the worst aspects of their jobs is when they cannot treat a patient's symptoms, especially pain and existential suffering.⁵ For care team members, managing the multiple, complex, and overlapping aspects of palliative sedation—from recognizing symptoms to managing family distress and interdisciplinary team dynamics—can be emotionally challenging.⁴²

One study found that palliative sedation caused team members to have doubts about their professional competence and that bedside nurses were especially susceptible, due to their role in palliative sedation.⁴³ Ongoing care of all members of the team is crucial and should be part of the formal protocols for providing palliative sedation. During the process of palliative sedation, as well as before and after, there should be opportunities for team members to debrief, share concerns, and discuss personal distress. Debriefing models may vary based on type of setting but are typically voluntary, led

by a trained facilitator (often a palliative care social worker), and allow team members to talk through their emotional experiences as they relate to the clinical situation; debriefing discussions have the added benefit of helping build clinician resilience.^{44,45}

In addition to ongoing team support, policies must also state how to handle conscientious objection by any member of the team to participating in palliative sedation and give procedures to transfer care to another available team member of equal competence while ensuring ongoing patient care. There should be mechanisms to discuss and resolve conflicts or concerns raised by anyone involved, along with consistent consultation with ethics committees and legal counsel. This promotes open communication within the organization.

Care of patients with life-limiting illness has always been at the core of the practice of professional nursing. Florence Nightingale observed that nursing relieves a patient's suffering from an illness, even when the disease itself cannot be treated, and that suffering includes more than the physical body's response to disease.⁴⁶ Ferrell and Coyle further describe a patient's suffering as a personal and multidimensional experience that is expressed in many ways, including grief, loss, pain, discomfort, loss of control or helplessness, hopelessness, inability to cope, loneliness, isolation, and loss of meaning.⁴⁷

Thus, the palliative APRN may first recognize the need to consider palliative sedation in the face of intractable suffering. Collaboration with other clinicians ensures that all reasonable treatment options to manage the distress have been exhausted and that the patient truly is near death. Depending on institution and state regulations, the palliative APRN may initiate the sedation, which means that they must have knowledge of the medications commonly used to ensure safe and effective therapy and understand monitoring requirements. For safe and consistent practice, the palliative APRN should follow a palliative sedation policy, collaborating with other clinicians. They must inform and educate colleagues and team members about the process of decision-making and implementing palliative sedation. The palliative APRN must collaborate with the interdisciplinary team to support the patient, family, and other team members. When palliative sedation is part of a treatment plan, the palliative APRN often leads and/or participates in multiple meetings with staff before, during, and after the procedure to ensure the success of the intervention and to provide ongoing support to team members.

INFORMED CONSENT AND DECISION-MAKING

Informed consent requires the clinician to provide key information to the patient so that the patient can weigh the risks and benefits of a procedure or treatment before reaching a voluntary decision about its use in the individual's care.⁴⁸ The palliative APRN has an essential role in explaining palliative sedation to patients, family, and staff. It is important to review prior symptom management regimes trialed and to be certain that all other options have been explored. Once this has been

determined, an agreement between provider, patient, and family is required to proceed with palliative sedation. Some palliative sedation protocols require written consent and some accept verbal consent, but all require that the discussion must occur before palliative sedation starts and must be documented in detail. This discussion should include acknowledgment of the terminal disease, review of the patient's goals of care, identification of the intractable symptom/symptoms and regimes trialed, education surrounding the option of palliative sedation, medication selection, and a review of the side-effect profile and plan for titration (respite sedation or continuous).

When discussing the option of palliative sedation, it is very important to determine the patient's capacity to make informed decisions—that the patient is able to receive information, understand and apply the information to their context, and communicate this decision.⁴⁹ If a patient is deemed to lack decision-making capacity, the surrogate decision-maker or healthcare proxy becomes the voice for the patient. Even if the patient is capable of making a decision, most protocols mention the importance of family members' being involved with the informed consent discussion along with the patient. Some protocols even require consent from the family.⁵⁰ Specific benefits of palliative sedation are relief of suffering and distress and a controlled environment. Burdens include loss of consciousness and awareness and an inability to relate to family and others. As discussed earlier in the chapter, the distinction between palliative sedation and euthanasia is subtle but real. It relies on the intention of the provider who is administering treatment. The goal of palliative sedation is to relieve suffering. The goal of euthanasia is to cause death. Causation is not the key issue, intent is. Clinicians have the moral obligation to do no harm and relieve suffering.²¹

Before palliative sedation is to be initiated, decisions regarding the use of life support, resuscitation, and medically administered nutrition and hydration need to be determined separately from the decision for palliative sedation. Since palliative sedation is only used for the imminently dying, there should be a clear understanding that no attempt at cardiopulmonary resuscitation will occur and that the appropriate order (do-not-resuscitate [DNR], do-not-intubate [DNI], do-not-attempt-resuscitation [DNAR]) will be in place before palliative sedation is provided. Other life-prolonging treatments, such as medically administered nutrition and hydration, are typically also withdrawn before beginning palliative sedation, except for cases when respite sedation is being considered. Refer to Box 57.2 for guidelines for a comprehensive approach regarding the use of palliative sedation.

FAMILY INVOLVEMENT AND CARE

The palliative APRN should seek to elicit an understanding of the suffering of family members and provide careful, compassionate, and ongoing communication with them. Interdisciplinary care is critical during this time. Clear, comprehensive communication detailing the purpose of palliative sedation, the risks and benefits of therapy, and the plan

Box 57.2 GUIDELINES FOR A COMPREHENSIVE APPROACH REGARDING THE USE OF PALLIATIVE SEDATION

1. Multidimensional evaluation and determination of refractory suffering and consultation procedures and consult to palliative care for palliative sedation.
2. Palliative care team discusses on role of sedation in end-of-life care and contingency planning, and clarification of indications in which sedation may or should be considered.
3. Palliative care team engages with the patient and family, and education about the option of palliative sedation and purpose of its use. Promote shared decision-making.
4. Palliative care team ensures a do-not-resuscitate order is in place with documented decisions regarding hydration, nutrition, and concomitant medications.
5. Palliative care team elicits and documents patient/family consent.
6. Palliative care team convenes clinical meeting about selection of the sedation method, staff education regarding guidelines and protocol.
7. Palliative care team initiates therapy, dose titration, patient monitoring, and care.
8. Palliative care team provides information, care, and support to the patient, the patient's family, and the staff.
9. Post procedure, provide support and debrief with staff and interdisciplinary team.

Adapted from Cherny et al.³⁵

for assessing comfort and titrating sedation should be clearly outlined to both family and staff. When patients are considering or undergoing palliative sedation, family distress may stem from many factors, including inability to interact with patient, anticipatory grief, disagreement or confusion regarding the use of sedation, perceptions that the use of sedation was precipitous or inappropriately delayed, and impressions that sedation hastened or actually caused the death or that death did not follow sedation as quickly as hoped.^{51–53} Communication and trust building are essential. Experts in palliative nursing stress the importance of deliberate, careful, and compassionate communication. Successful communication involves the principles listed in Chapter 33, “Family Meetings” and Chapter 53, “Navigating Ethical Dilemmas.”

MEDICATIONS AND PROCEDURE OF SEDATION

Palliative sedation is an option of last resort when treating refractory symptoms. Refractory symptoms differ from difficult or “difficult-to-treat” symptoms in that, despite the multiple efforts of clinical experts, they cannot be adequately treated

without compromising the consciousness of the patient.⁵⁴ Indications for palliative sedation may include delirium, dyspnea, pain, agitation, nausea, vomiting, and existential suffering. Administering palliative sedation to alleviate psycho-existential suffering remains a controversial issue partly because it is difficult to determine when this type of suffering is refractory.³⁴

Drug selection is based on the type of suffering present, current medications, response to past medications, the patient's medical problems, and the drug's efficacy, side-effect profile, and potential for success.⁵⁰ Consultation with a palliative care pharmacist, if available, is recommended. Although the intravenous (IV) route is preferred because it allows for quick titration and safety, subcutaneous (SC) and rectal administration (PR) are acceptable alternatives for some of the common medications. The clinical, ethical, and legal decision-making for the use of palliative sedation includes determining the best type of sedative to use.

In 1958, Dame Cecily Saunders advocated for the use of non-opioid sedative therapy to reduce anxiety and induce a sense of relaxation.⁵⁵ She was clear that the use of opioids as analgesia was beneficial but advised against their use to induce drowsiness.⁵⁶ Even today, opioids are not recommended as a sedative drug. However, they are often used alongside sedatives as part of the management of pain or dyspnea, and it is recommended that they not be stopped prior to palliative sedation and they should be continued.⁵⁷ The most common medications used for palliative sedation are benzodiazepines, barbiturates, and anesthetics. Patient assessment and clinical protocols developed by the interdisciplinary team, including pharmacists, guide drug selection, initial dosing, dose titration, and route of administration.^{38,50} Additionally, complications of the sedation process may include respiratory depression, aspiration, or hemodynamic compromise. Although patients who are candidates for palliative sedation are imminently dying and in severe distress, the palliative APRN must discuss death as a potential effect.

Benzodiazepines are the most common medications used for palliative sedation. Midazolam is the drug of choice due to its rapid onset and shorter duration, allowing for greater flexibility in dosing than other benzodiazepines. Also, it can be combined with other drugs used in palliative care. The typical starting dose of midazolam in an acute care setting is 1–5 mg IV bolus every 5 minutes until the patient is comfortable or a maximum of 20 mg. Continuous infusion is started generally at 0.5–1 mg/h. Usual effective dose range is 1–20 mg/h SC or IV.⁵⁸ In the community setting, midazolam can be given SC as a 1–5 mg bolus every 5 minutes until the patient is comfortable, followed by a continuous infusion of 0.5–1 mg/h, or diazepam suppositories given PR may be used. Clinical trials show that midazolam is safe to give with opiates for the treatment of dyspnea in advanced illness.⁵⁸ Other drugs used either alone or in combination with midazolam are haloperidol, phenobarbital, and opioids.

Barbiturates have been used for many years for palliative sedation. Thiopental, pentobarbital, and phenobarbital also have quick onsets of action and short durations so they can be easily titrated. The starting dose for thiopental is an IV bolus

of 5–7 mg/kg and then 20 mg/h as a continuous infusion. The usual maintenance dose is 70–180 mg/h. Pentobarbital can be given rectally at 60–200 mg every 2–4 hours in the community setting or IV in the inpatient setting at 1–3 mg/kg bolus followed by a continuous infusion of 1 mg/kg/h. Titrate for appropriate level of sedation. Pentobarbital may offer antiemetic and anticonvulsant effects, making it more advantageous in patients at risk for vomiting and seizures. Phenobarbital is given as an IV/SC bolus of 200 mg and then with a continuous infusion of 600 mg/day. Usual maintenance dose is 600–1,600 mg/day. Side effects include the irritant nature of the injection.⁵⁹ For home use, phenobarbital or pentobarbital may be compounded into a suppository.

Anesthetics such as propofol (Diprivan) are considered excellent agents for palliative sedation.⁶⁰ This classification of medications can only be used in the acute care setting because they require frequent monitoring. Propofol can be used safely in patients who have renal or liver disease; it has an extremely short onset of action, duration of action, and half-life (shorter than the benzodiazepines and barbiturates), and is very easy to titrate. It provides anxiolytic, antiemetic, antipruritic, anticonvulsant, antimyoclonic, and muscle relaxant effects.⁶⁰ Dosing for propofol is initially based on weight; a continuous infusion of 2.5–5 µg/kg/min can be increased by 2.5–5 µg/kg/min every hour to the desired level of sedation. During the infusion, the palliative APRN may also give bolus doses of propofol (2.5–5 µg/kg) by IV push every 10 minutes as needed for rapid control of severe symptoms.⁶⁰ This is a suggested option for respite or temporary palliative sedation because the sedation effects can be reversed quickly with decreased titrations or discontinuation of the medication.

Dexmedetomidine (Precedex) is a newer sedative agent that could be beneficial in palliative sedation, although it has not been studied extensively for this indication. It is an α -2 agonist that may induce unconsciousness without causing respiratory depression.⁶¹ It is a potent sedative that also possesses analgesic and opioid-sparing properties. Its sedative effects induce a state of non-rapid eye movement (NREM)-like sleep that fosters easy awakening if desired.⁶² It may reduce the likelihood of delirium in comparison to benzodiazepines. Moreover, it is reported to possess anxiolytic and anti-sialagogue properties.⁶¹ The dosing range is typically 0.2–1.4 µg/kg/h. Loading or IV push doses are not needed. Avoiding a loading dose minimizes the risk of developing hypotension or bradycardia. The onset of effect for dexmedetomidine after beginning infusion is 5–10 minutes, with action lasting for approximately 60 minutes once the infusion is discontinued.^{58,63}

Ketamine (Ketalar) is classified as an anesthetic and centrally acting non-opiate. It is an N-methyl-D-aspartate (NMDA) receptor antagonist known for its analgesic and anesthetic properties. It is used in the inpatient setting for the management of pain and refractory symptoms related to terminal illness. Starting dose is 1–4.5 mg/kg/dose IV; 3–5 mg/kg/dose IM; infusion 0.5–2 mg/kg/h. An adjuvant anti-sialagogue and benzodiazepine are recommended. Oral, sublingual, and intranasal doses of ketamine are available but not indicated by this route for palliative sedation purposes.^{64,65}

Antipsychotics are not traditionally used for initiation of palliative sedation, but they play an important role as adjuvants in the treatment of terminal delirium. Haloperidol is not a sedative and therefore should not be used to induce sedation. However, studies show that it is used in combination with benzodiazepines in the treatment of refractory agitated delirium.⁵⁴ Suggested starting dose for haloperidol is 0.5–5 mg PO/SC every 2–4 hours or 1–5 mg bolus IV/SC followed by continuous infusion totaling 5–15 mg/day.⁵⁹ In the community setting, PO, SL, SC routes are used with similar dosing patterns as in the inpatient setting.

Although many patients are on opioids prior to the initiation of palliative sedation, opioids are not effective at producing sustained sedation. However, opioids should be continued, along with the sedating drug, to avoid opioid withdrawal and to treat unobserved pain (Table 57.3).

CONTINUOUS VERSUS INTERMITTENT SEDATION

A modified Delphi study concluded that experts agreed to the use of sedatives, continuous or temporary, for patients with refractory dyspnea and delirium at end of life. Conversely, there was wide variation in opinions on the appropriateness of sedation in dementia patients and existential suffering.⁶⁶ Continuous versus intermittent sedation are suggested depending on the refractory symptom and goals of care. *Proportional sedation* is suggested as the best description for sedation types.⁶⁷ Sedation should be performed proportionately, appropriate to the patient's situation. The intensity and nature of the suffering determines which form of sedation and, more specifically, whether it will be intermittent versus continuous sedation and what dosage of sedatives will be administered to the patient. Thus, palliative sedation does not

Table 57.3 RECOMMENDED MEDICATIONS FOR PALLIATIVE SEDATION

MEDICATION	ACUTE CARE	COMMUNITY
Benzodiazepines	<i>Midazolam</i> (SC/IV) 1–5 mg bolus q 5min until comfortable or maximum of 20 mg Continuous infusion is started generally 0.5–1 mg/h Usual effective dose range is 1–20 mg/h	<i>Midazolam</i> (SC) 1–5 mg bolus q5min until comfortable or maximum of 20 mg Continuous SC infusion is started generally at 0.5–1 mg/h Midazolam is available in IM and intranasal formulations (limited data support these formulations for palliative sedation purposes)
	<i>Lorazepam</i> (SC/IV) 2–5 mg bolus Continuous infusion is 0.5–1.0 mg/h	<i>Lorazepam</i> (SC) 2–5 mg bolus; continuous infusion 0.5–1.0 mg/h
Barbiturates	<i>Thiopental</i> (IV) 5–7 mg/kg bolus and then 20 mg/h as a continuous infusion Usual maintenance dose is 70–180 mg/h.	
	<i>Pentobarbital</i> (IV) 1–3 mg/kg bolus and then continuous infusion of 1 mg/kg/h.	<i>Pentobarbital</i> (PR) 60–200 mg q4–8h
	<i>Phenobarbital</i> (IV/SC) 200 mg bolus (can repeat q10–15min) then continuous infusion of 25 mg/h (or 600 mg/day) Usual maintenance dose is 600–1,600 mg/day.	<i>Phenobarbital</i> (SC) 200 mg bolus (can repeat q10–15min) then continuous infusion of 25 mg/h (or 600 mg/day)
Anesthetics	<i>Diprivan</i> (IV) 20–50 mg bolus (may repeat) then a continuous infusion of 2.5–5 µg/kg/min can be increased by 2.5–5 µg/kg/min every hour to the desired level of sedation. During the infusion, the palliative APRN may also give bolus doses of propofol (2.5–5 µg/kg) by IV push every 10 minutes as needed for rapid control of severe symptoms	This class of medications is not recommended for use in the home or community setting
	<i>Dexmedetomidine</i> (IV) 0.2–1.4 µg/kg/h. Loading or IV push doses are not needed.	
	<i>Ketamine</i> (IV) 1–4.5 mg/kg/dose IV; 3–5 mg/kg/dose IM; infusion 0.5–2 mg/kg/h. Adjuvant anti-sialagogue and benzodiazepine are recommended. Oral, sublingual, and intranasal doses of ketamine are available but not indicated by this route for palliative sedation purposes.	
Antipsychotics	<i>Haldol</i> (should not be used to induce sedation, but as an adjuvant in the treatment of terminal delirium) <i>Haldol</i> (IV/SC) 0.5–5 mg bolus followed by continuous infusion totaling 5–15 mg/day	<i>Haldol</i> * (PO, SL, SC) 0.5–5 mg loading dose, followed by 1–5 mg q4h scheduled <i>or</i> 1–5 mg/h by continuous SC infusion * doses are the same despite route

presuppose that a patient is sedated until unconscious; palliative sedation means that sedative drugs are administered in dosages and combinations required to reduce consciousness as much as necessary to adequately relieve one or more refractory symptom.⁶⁷ This illustrates how important the principle of proportionality is in the decision-making process.

Once the palliative medication has been chosen, generally the infusion is initiated and then titrated to a point where the patient appears to be comfortable. Care should be taken to make further adjustments when necessary to facilitate palliative nursing care. Other reported strategies include varying the depth of sedation during the day, providing deeper sedation at night to ensure peaceful rest.⁶⁸ Sedation should not be increased unless the patient shows signs of distress, such as restlessness, grimacing, or findings that could reasonably be interpreted as evidence of suffering (including tachypnea and tachycardia). Invasive assessment tools to monitor conscious sedation in hospitals are not appropriate for the dying patient, though frequent assessment of pain and consciousness is recommended. Two tools, the Critical Care Pain Observation Tool (CPOT) and the Richmond Agitation Sedation Scale, are frequently used, though other tools exist in the literature.⁶⁹ The level of sedation needed varies with each patient and is based on the achievement of comfort and predetermined goals.

Once palliative sedation is initiated, survival can be quite variable but generally is brief because it is utilized for patients who are already at the end of life. Muller-Busch and colleagues reported survival of 58–63 hours after initiation of sedation; Sykes reported that 56% of patients survived less than 48 hours.^{37,70} Another study showed that the mean survival of patients after the onset of palliative sedation ranged from 1 to 6 days.⁵⁴ A prospective multicenter study of 518 patients found that the overall survival between a cohort receiving palliative sedation and a cohort not receiving palliative sedation was not statistically significant, providing evidence that the intervention does not hasten death.¹⁹ Additionally, a secondary analysis of a prospective cohort study found that palliative sedation did not hasten death for oncology patients receiving palliative care services.⁷¹ Given the lack of uniformity surrounding the process around palliative sedation, outcomes remain quite variable.

EFFICACY

More than 80% of families stated that palliative sedation resulted in adequate relief of their loved one's suffering.⁷² Eighty-eight percent of families felt that palliative sedation helped to considerably decrease symptom distress.⁷² Morita et al. reported that palliative sedation adequately relieved symptoms in 83% of the cases studied.⁵³

CARE OF THE DYING PATIENT RECEIVING PALLIATIVE SEDATION

As the patient nears death, all members of the clinical team apply their own special skills and abilities to guiding the

family and supporting the patient on this final journey.⁷³ End-of-life care for the dying is an interdisciplinary effort that includes anticipatory counseling, symptom management, and comprehensive psychosocial, spiritual, and bereavement care.⁷⁴ Although basic to nursing care, the care of the imminently dying is a fundamental element of the total care of a patient undergoing palliative sedation. Since most palliative sedation is done in the impersonal often sterile environment of a facility, the use of favorite music, special clothes, colorful blankets, supportive aromas, and personal mementos in the room can create an environment that supports the patient's comfort, is unique to the individual, and is soothing to the family and patient (see Chapter 38, "Grief and Bereavement").

In addition to addressing and acknowledging the family's grief, it is equally important to debrief the patient case with staff. This provides an opportunity to emphasize moral reflectiveness and the impact of nursing practice in end-of-life care.⁷⁵ Allowing time to process, reflect on, and review the experience is essential to supporting the clinical aspects of care we provide, as well as the emotional and moral components.

The case study at the beginning of the chapter illustrates the mixed physical and existential components of suffering that patients often experience and the palliative APRN's role in advocating for the patient while providing physical, psychological, spiritual, and emotional support.

SUMMARY

Although palliative sedation is used only when patients experience the most extreme distress, it is a therapy that is a core competency of the palliative APRN. A palliative APRN must be able to demonstrate how he or she uses the fundamental elements of the safe and effective provision of palliative sedation in practice. This begins with a basic competency in understanding the complex issues surrounding palliative sedation decision-making. Ideally, palliative sedation is done with the support of a palliative care team and follows a policy or protocol. Development of policies and procedures around the use of palliative sedation is recommended in your practice setting. Refer to Boxes 57.1 and 57.2 for a framework for procedural guidelines. If one does not exist, the palliative APRN must garner support from a team to develop a policy for palliative sedation. The salient points of each step of palliative sedation can be used to develop these protocols and policies and will assist in the provision of palliative sedation.

In addition, the palliative APRN will need to gain trust from the staff. This often begins with education and requires an individual commitment to be present with nursing and other team members during the often-complex process of considering and delivering palliative sedation. Finally, although palliative care exists to ensure the comfort of patients at the end of their lives and their families, even an experienced APRN may never be wholly comfortable with palliative sedation. Open dialogue and collaboration with all team members will reduce the emotional burden and create an environment of mutual support and personal growth. Palliative sedation is

an option of last resort for patients experiencing the most suffering, and it requires the skills and commitment of the palliative APRN.

APPENDIX I

Palliative APRN Billing and Coding

Constance Dahlin

Palliative advanced practice registered nurses (APRNs) are eligible for reimbursement based on the requirements of their graduate education coursework, as set forth in Chapter 3, “Credentialing, Certification, and Scope of Practice Issues for the Palliative APRN.” Palliative services performed by APRNs are a valuable commodity in financial and business planning and healthcare savings in settings including the home, long-term care facilities, clinics, hospitals, and prisons and via telehealth. Optimizing reimbursement through effective billing and coding supports the financial sustainability of

the palliative care program and the palliative APRN’s utilization within a team specifically since a portion of their salary can be recaptured through reimbursement.

It is essential for palliative APRNs to have a working knowledge of billing and coding and the necessary documentation. It is also important to keep abreast of the Centers for Medicare and Medicaid Services (CMS) updates on Medicare and Medicaid billing. Commercial insurers will often follow suit. Finally, it is in the best interest of the palliative APRN to meet with their organizational biller and

Table I.1 PALLIATIVE APRN CHECKLIST FOR ELIGIBILITY FOR REIMBURSEMENT

Education and certification	<i>Graduate Nursing Education</i>—Master’s or clinical doctorate with coursework in advanced health assessment, advanced pharmacology, and advanced pathophysiology in one of the four roles: clinical nurse specialist (CNS), nurse practitioner (NP), certified midwife (CNM), or certified nurse anesthetist (CRNA). For palliative care, it is a CNS or NP. <i>National primary certification</i> from a nationally recognized certification organization related to population focus of graduate education as specified by the National Council of State Boards of Nursing in either the acute care or primary care setting: (1) family/individual across the lifespan, (2) adult/gerontology, (3) neonatal, (4) pediatrics, (5) women’s health/gender-related, and (6) psychiatric/mental health. <i>Note:</i> Speciality certification in palliative nursing (ACHPN) as a primary certification is rare and only possible in two areas (New York, District of Columbia).
Authority to practice in the APRN role	<i>State license</i> to practice as APRN (most commonly NP or CNS) <i>State APRN practice act, statutes, or regulations</i> within state APRN practices that grant authority to practice in the advanced role
Role delineation of the APRN	<i>A job description</i> that delineates APRN practice For APRNs in states where there is no independent practice, it is helpful to have a <i>collaborative agreement</i> or <i>joint protocol</i>, which is a practice agreement outlining tasks the palliative APRN may perform in a particular setting, under what circumstances the palliative APRN would refer to a physician, and the level of physician involvement or oversight. This can be part of the palliative APRN’s job description.
Basis of the APRN’s salary	All or a <i>percentage of salary</i> (usually percentage of patient care hours) must not be part of a Medicare Part A Cost Report from an organization (i.e., the APRN cannot be under the organization’s nursing department where their care would be included as part of Medicare payment for nursing services). <i>Note:</i> The palliative APRN can have a percentage of their salary be part of a physician group and a percentage of a health system to account for clinical care and education to the organization.
Healthcare employer organizational credentialing	Occurs at organization or <i>institution where APRN will provide services</i>. For hospitals, this must be through a medical staff office, not a human resources department. <i>National Provider Identification (NPI) number</i> Acceptance on Medicare, Medicaid, and commercial panels
APRN prescriptive authority	<i>State</i> prescribing license and/or state-controlled substances registration Drug Enforcement Administration (DEA) registration for controlled substances.

From Dahlin.^{1–4}

- I. A professional scope of practice delineates the legal limits of the services the palliative APRN can provide. Specific regulatory elements include graduate nursing education, licensure as an APRN, certification for practice, professional credentialing and privileging within an organization, and the specific description of the level of patient care the palliative APRN can provide.
- A. Regulatory elements delineated by both the Centers for Medicare and Medicaid Services (CMS) and the National Council of State Boards of Nursing (NCSBN): The APRN must have education beyond a bachelor's degree; specifically a master's, post-master's, or doctorate in nursing. The APRN Consensus Model implements population-based specialty areas: (i) family/individual across the life span, (ii) adult/gerontology, (iii) neonatal, (iv) pediatrics, (v) women's health/gender-related, and (vi) psychiatric/mental health.^{5,6}
- B. Legal Authority: In order for the palliative APRN to seek reimbursement from the CMS, the state scope of practice where the palliative APRN delivers patient care must allow the APRN to practice in the advanced role. This means:
 1. The palliative APRN must have the legal authority within the state, where service occurs, to practice beyond the RN level and have the legal authority to practice at the level of a physician. Specifically, this means the work of the palliative APRN would be performed by an MD/DO in his or her absence, not by a hospice or palliative RN.
 2. Advanced tasks and services include the ability to take a patient history, complete a review of systems, perform physical examinations, diagnose, and treat according to Medicare guidelines.
 3. Prescriptive authority is an aspect of advanced practice. In many states, palliative APRNs are permitted to practice at the physician level except related to prescriptive privileges for the various classifications of pharmacotherapeutics and controlled substances.
- C. Licensure: The palliative APRN must have a license beyond an RN level of practice (i.e., licensed as NP or CNS).
- D. Certification: The palliative APRN must have passed an advanced practice nursing examination through a recognized national body, demonstrating competence within a specific population of advanced nursing practice.
 1. This means the APRN must take a certification examination that matches the area of specialty previously mentioned in regulatory areas.
- E. Credentialing (the process of privileging to practice at a setting): The CMS requires that the palliative APRN must have applied for and been granted institutional privileges to practice at a healthcare organization. The Joint Commission requires that APRNs be credentialed through medical credentialing offices for advanced practice, rather than nursing offices (76 Fed. Reg. 210, 2011).
- F. Scope of Practice: If the palliative APRN is able to practice to the full scope of their practice, then the federal guidelines delineate:
 1. How the palliative APRN provides services for Medicare patients;
 2. How the palliative APRN provides services for Medicaid patients (if allowable in a particular state);
 3. How the palliative APRN can provide services for hospitalized patients;
 4. Whether the palliative APRN can prescribe controlled substances or different levels of controlled substances;
 5. How Medicare billing and reimbursement should occur; and
 6. The use of electronic prescriptive privileges

From Dahlin.¹⁻⁴

Table I.2 PALLIATIVE CARE ESSENTIAL COMPONENTS OF DOCUMENTATION FOR REIMBURSEMENT

The purpose of documentation is to establish the health record and chronicle important facts, findings, and observations pertinent to the patient's health and illness. Documentation of the medical record promotes communication and continuity between healthcare providers and highlights the work of the palliative care team. Last, it is a legal document that serves to verify care and support billing and coding. The following is the *who, what, where, when, why, and how*, of documentation, but in the order of hierarchy.

ELEMENT	DESCRIPTION	IDENTIFYING DATA
Who	Who was the patient that was seen? Who was the clinician who saw the patient?	Patient identification: Name, medical record number, date of birth Palliative APRN identification: Name, credentials, contact information Identify service line: Palliative care and hospice team Affiliation Attestation of a note through a legible electronic or written signature
Why	Why was the palliative care consult requested (specifically explaining the medical reason for a consult request or a follow-up visit)?	Medical reason, such as pain or symptom Clarification of goals of care Potential for rapid change New diagnosis Referring clinician Palliative trigger
How	How was the time spent for the palliative care visit?	History-taking Physical examination Review of procedures, diagnostic testing, and laboratory testing Family meeting * Counseling* Goals of care* Advance care planning* Out-of-hospital orders for life-sustaining treatments or provider/physician orders for life-sustaining treatment (POLST) forms * Need to document start and stop time of these elements within a comprehensive visit * Need to specify the topics covered
What	What type of in-person visit occurred (a consultation/initial visit vs. a subsequent or follow-up visit)? What was done during the palliative care visit? What type of non-face-to-face work was done?	Consultation versus ongoing management Elements of visit: history, physical examination, medication review, review of systems Discussion with other health providers, review of records, review of diagnostics, care plan development
Where	Where or in what setting did the palliative care visit occur?	Inpatient: Acute care or rehabilitation hospital Clinic, ambulatory, or outpatient setting Residential home Skilled nursing facility, subacute or long-term care Assisted-living facility Hospice setting Telehealth
When	When did the palliative care visit occur, and how long was it?	Date, time, and year Start and end time of visit: Assists in determining the level Start and end time of in-person visit: Assists in determining whether goals-of-care discussion is added to diagnosis codes Total time of counseling and topics discussed in that time: Determines time-based billing Total Time (see Table for more explanation of coding)

From Dahlin.^{2,3}

- A. Effective documentation is essential to support optimal coding and billing by the APRN. With electronic health records, there are often templates and prompts for notes to assure that all the work done is captured.
- B. It is helpful to understand necessary documentation elements prior to a visit to assure a comprehensive review, history, physical examination, and treatment plan.
- C. General documentation includes^{2,3}:
1. Identifying data: Patient name, medical record number
 2. Requesting provider for consultation
 3. Specialty code of APRN (e.g., hospice, palliative care)
 4. Service or procedural codes (evaluation and management codes)
 5. Diagnoses: Diagnosis by International Classification of Diseases (ICD); ICD-10 codes (10th version of the codes)
- D. Documentation demonstrates evaluation and management⁷:
1. Chief concern/nature of presenting problem
 2. History of present illness, with a focus on a symptom(s) and the description capturing as many as possible of the following details:
 - a. Location
 - b. Quality
 - c. Severity
 - d. Duration
 - e. Timing
 - f. Context
 - g. Modifying factors
 - h. Associated signs and symptoms.
 3. Review of Systems (ROS), delineated in one of the following categories:
 - a. Problem: Based on 1–5 problems within an organ specific system;
 - b. Extended: Based on specific problem and 2–9 other organ systems;
 - c. Comprehensive: Based on the specific issue and a minimum of 10 other organ systems, or critical care billing as per Centers for Medicare and Medicaid Services (CMS) guidelines
 4. Past medical, family, and social history: This includes social determinants of health and a cultural history (one line from each):
 - a. Past history, including experiences with illnesses and treatments
 - b. Past surgeries, injuries, and treatments
 - c. Family history including a review of medical events, diseases, and hereditary conditions that may place the patient at risk
 - d. Social history including an age-appropriate review of past and current activities
 5. Examination: 2–8 systems (constitutional; eyes; ear, nose, mouth, and throat [EENMT]; cardiovascular; respiratory; gastrointestinal; genitourinary; musculoskeletal; skin; neurologic; hematologic/lymph/immunologic; psychiatric) depending on level of visit
- Palliative care observation alone: Includes constitutional (1 system), HEENT (5 systems), respiratory, neuro, psychiatric
6. Medical decision-making
 - a. Diagnoses managed
 - b. Data reviewed: Laboratory, radiology, chart review, medications
 - c. Risk: Methadone, opioid infusions, benzodiazepines, code status discussion and DNR, de-escalation of care
 7. Counseling
 8. Coordination of care
 9. Time spent on the visit

From Dahlin¹⁻³ National Council of State Boards of Nursing.⁷

Although initial palliative care visits are reimbursed as “consultations” per the Centers for Medicare and Medicaid Services (CMS), there are four elements of documentation to attend to within an initial palliative care visit that are part of best practice.

- I. *Request:* This is the request for a palliative care consultation. It can be a verbal or written request via a specific order or note in the chart. More often, these are now placed as orders within a healthcare record as non-medication orders. Remember, the CMS allows a variety of providers to request a palliative consult including osteopaths, APRNs, physician assistants, rehabilitation therapists, psychologists, and social workers, as well as physicians. The requesting provider must be identified and documented in the APRN consultation or initial evaluation note.
- II. *Reason:* The reason for the palliative consult should accompany the request. The most common reasons are pain and symptom management, advance care planning, goals of care, considerations of treatments, psychosocial or spiritual support, or discharge planning. The reason for the request should be documented in the palliative APRN’s initial consultation note.
- III. *Render service:* The palliative care consultation must be rendered. Thus, the APRN preforms the patient consultation, documents the examination and findings, and offers suggestions to managing the problem. This includes the development of diagnoses and a recommended individualized treatment plan.
- IV. *Report:* The palliative APRN must complete a written record or report of the consultation for the requesting provider. There are several ways this can occur. If within the same health organization, the consult note can be completed in the shared electronic health record. If out of a health system, this can be a consultative note or letter, available to the referring provider who made the original request.

From Dahlin.^{1,2}

Table I.3 PALLIATIVE BILLING AND CODING 101: PRINCIPLES

TYPE OF CODE	DESCRIPTION
ICD-10 codes: Diagnosis International Classification of Disease and Health-Related Conditions, 10th revision	Codes for diseases, signs and symptoms, abnormal findings, complaints, social circumstances, educational needs, and external causes of injury or diseases
ICD-10 code: Palliative Care Identifier: Z51.5	The Z51.5 is the code for all palliative care encounters, regardless of setting. Other ICD-10 codes speak to the symptoms the palliative care provider is addressing within the diagnosis on which the palliative care provider is focused.
Current Procedural Technology (CPT) codes: Level of service provided The CPT code set is a medical code set maintained by the American Medical Association and designed to communicate uniform information about medical services and procedures. CPT codes apply to any type of care and delineate location, intensity, and duration of services. Billing can be complexity-based or time-based	1. Location of service a. Acute care setting b. Office or clinic c. Home d. Nursing home e. Assisted living f. Skilled nursing facility g. Telehealth, telephonic 2. Type of patient: New vs. established 3. Type of visit: Initial vs. subsequent 4. Duration of visit: Time period of visit 5. Complexity of service: Medical decision-making aspect of visit Most palliative care visits meet the criteria for the visit levels at 3, 4, 5.
Evaluation and Management (E/M) codes: Level of complexity	Documentation of key components: 1. History 2. Exam 3. Level of complexity of medical decision-making • Number and complexity of problems addressed • Amount of data to be reviewed and analyzed • Risk of complications, morbidity, and/or mortality 4. Time (time of beginning and end of encounter)

(continued)

Table I.3 CONTINUED

TYPE OF CODE	DESCRIPTION						
Time codes: These now include total time for date of encounter (preparation, review, history, counseling, examination, orders, coordination, etc.).							
<i>Palliative care subsequent visits:</i> If less than 20 minutes, bill on medical decision-making If greater than 20 minutes, give exact time and start and end times							
Prolonged Physician Service with Direct Patient Contact series	<i>Prolonged service</i> involving direct (face-to-face) patient contact beyond the usual service (typical time) in setting. Criteria include: 1. Specific time intervals that qualify for these codes 2. Documentation that includes the exact start and stop time for the visit 3. Specific codes for the prolonged time intervals <i>Outpatient time</i> applies to day of service (same or different) with face-to-face and non-face-to-face contact. Includes the following activities, when performed: • Preparing to see the patient (e.g., review of tests) • Obtaining and/or reviewing separately obtained history • Performing a medically appropriate examination and/or evaluation • Counseling and educating the patient/family/caregiver • Ordering medications, tests, or procedures • Referring and communicating with other healthcare professionals (when not separately reported) • Documenting clinical information in the electronic or other health record • Independently interpreting results (not separately reported) and communicating results to the patient/family/caregiver • Care coordination (not separately reported)						
Point of Service (POS) codes: Setting POS codes are used only by coders and billers, however, the APRN must indicate in the documentation where the patient was located during the encounter.							
Telehealth codes ⁸	Available for: Video visits (vVisit): Connecting via video Telephone call (tVisit): Call via the telephone Secure messaging (eVisit): Connecting via secure patient portal or telehealth platform Remote patient monitoring (RPM)						
Care coordination codes							
Care Plan Oversight (CPO) codes apply to the supervision of patients under either the home health or hospice benefit where the patient requires complex or multidisciplinary care requiring ongoing physician involvement.	Billed by physicians and advanced practice providers who are part of the same team. Occurs for patients under home health or hospice: Home health (GO181) Hospice (GO182) Includes: • 30 minutes of time • Frequent update and review of patient status • Frequent review of laboratory and other studies • Frequent adjustment of medical therapies • Frequent revision of care plans or development of new plans with integration of updated information and ongoing laboratory studies • Communication with other health providers involved in the patient’s care who are outside the practice (e.g., physical therapy, pharmacy regarding pharmaceutical options)						
Transitional Care Management (TCM) codes represent the clinical interactive process in which there is consistent coverage in the “home” setting to help prevent hospital readmission. For patients being discharged or returned to home/assisted living facility/domiciliary or other community-based setting. Patient cannot be in an inpatient setting such as hospital or skilled nursing facility.	<table><tr><th colspan="3">THREE COMPONENTS</th></tr><tr><td>A required interactive contact with patient or other providers: • Phone • Telehealth • Direct exchange of information </td><td>Certain non-face-to-face services: • Obtain and review discharge information • Review diagnostic tests and treatments • Referrals • Interaction with other health providers </td><td>A face-to-face visit: • A first visit is required but not reported or billed separately • This first visit is made within required 7- or 14-day period • Cannot be billed during same period of care plan oversight or chronic care management </td></tr></table>	THREE COMPONENTS			A required interactive contact with patient or other providers: • Phone • Telehealth • Direct exchange of information	Certain non-face-to-face services: • Obtain and review discharge information • Review diagnostic tests and treatments • Referrals • Interaction with other health providers	A face-to-face visit: • A first visit is required but not reported or billed separately • This first visit is made within required 7- or 14-day period • Cannot be billed during same period of care plan oversight or chronic care management
THREE COMPONENTS							
A required interactive contact with patient or other providers: • Phone • Telehealth • Direct exchange of information	Certain non-face-to-face services: • Obtain and review discharge information • Review diagnostic tests and treatments • Referrals • Interaction with other health providers	A face-to-face visit: • A first visit is required but not reported or billed separately • This first visit is made within required 7- or 14-day period • Cannot be billed during same period of care plan oversight or chronic care management					

Table I.3 CONTINUED

TYPE OF CODE	DESCRIPTION
Chronic Care Management (CCM) codes and Chronic and Complex Management (CCCM) codes	CCM and CCCM: Multiple chronic conditions expected to last 12 months or until death. Chronic conditions place the patient at significant risk of death, acute exacerbation, decompensation, or functional decline. CCCM: Moderate or high decision-making Requires: • Patient consent • Comprehensive plan of care • 24/7 access • Use of Centers for Medicare and Medicaid Services (CMS) certified electronic health record (EHR)
ACP Codes ⁹	Advance care planning includes the explanation and discussion of advance directives, which is in conjunction with another visit—whether inpatient, outpatient, home, or telehealth. • 99498: Codes added to E/M when performing initial consultations, follow-up visits, or care coordination codes for more than 16 minutes or when there is specific discussion on surrogate decision-makers, living wills, advance directives, out-of-hospital orders for life-sustaining treatment, provider/physician orders for life sustaining treatments (POLST) Time is longer than 16 minutes with a threshold of 16–45 min • 99497: Second 30 minutes Time over 45 minutes with a threshold of 46–74 min (See Chapter 32, “Advance Care Planning”)
Non–Face-to-Face Codes ¹⁰	Non–face-to-face codes • Greater than 31 minutes spent on patient care • In preparation of seeing the patients • Does not require face-to-face contact; could include a telephone call • Review of records, phone calls to other providers, coordinating care • Doesn’t need to be continuous

There are general principles to the skill of billing and coding. However, billing and coding varies based on organization and region of the country. It is important to understand billing and coding concepts, as well as the regional environment of billing and coding. Most important is to work with the billers and coders of your organization.

Box I.4 SUMMARY OF PALLIATIVE APRN REIMBURSEMENT BY TYPE AND SETTING

I. Palliative APRNs have the potential to bill for visits across settings.

A. Community settings

1. Home visits: Consult for palliative care services or initial palliative care visit
 - a. A palliative APRN may bill independently for these services.
 - b. A palliative APRN may not bill a consult as a shared visit for a consult (i.e., patient is seen by both an MD and APRN).
2. Subsequent home visits for palliative care follow-up
 - a. A palliative APRN may bill independently for these services.
 - b. A palliative APRN may bill incident to the visit if a physician was present at the visit.
 - c. Shared visits are not allowed in the home setting.
3. Ambulatory setting: Outpatient clinics
 - a. Outpatient clinic consult for palliative care services or initial palliative care visit
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may not bill a new patient consult as a shared visit (i.e., patient is seen by both an MD and APRN).
 - b. Subsequent clinic outpatient visit for a palliative care follow-up
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may bill subsequent care with a shared visit (i.e., patient is seen by both an MD and an APRN) if the plan of treatment has been established by the physician.

B. Hospital care

1. Acute inpatient setting

- a. Consult for palliative care services or initial palliative care visit
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may not bill a consult as a shared visit for a consult (i.e., patient is seen by both an MD and APRN).
- b. Initial hospital care for patient admitted as a palliative care patient
 - i. A palliative APRN may not bill a hospital admission visit independently unless serving as the Attending of Record.
 - ii. A palliative APRN may bill an admission with a shared visit (i.e., patient is seen by both an MD and APRN).
- c. Subsequent hospital visit for a palliative care follow-up
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may bill subsequent care as a shared visit (i.e., patient is seen by both an MD and APRN).
- d. Critical care for a palliative care symptom
 - i. A palliative APRN may bill independently for these services as a palliative care consultant.
 - ii. A palliative APRN may not bill critical care as a shared visit (i.e., patient is seen by both an MD and APRN).
- e. Discharge services for a palliative care patient
 - i. A palliative APRN may bill independently for these services if the APRN is the Attending of Record and admitted the patient to the facility.
 - ii. A palliative APRN may bill discharge services as a shared visit (i.e., patient is seen by both an MD and APRN).
 - iii. Both of these scenarios are submitted under the discharge management code.
- f. Death pronouncement and certification of a palliative care patient
 - i. A palliative APRN may bill independently for these services under the discharge management code if state statute allows the APRN to perform a death pronouncement and complete a death certificate.
 - ii. If allowed by state statutes to perform these services and the APRN performs the “final examination” to pronounce the death and complete a death certificate, services would be billed under the discharge management code.

2. Acute rehabilitation settings

- a. Consult for palliative care services or initial palliative care visit
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may not bill a consult as a shared visit (i.e., patient is seen by both an MD and APRN).
- b. Initial hospital care for a palliative care patients
 - i. A palliative APRN may not bill an admission independently unless serving as Attending of Record.
 - ii. A palliative APRN may bill an admission as a shared visit (i.e., patient is seen by both an MD and APRN).
- c. Subsequent hospital visit for palliative care follow-up
 - i. A palliative APRN may bill independently for these services.
 - ii. A palliative APRN may bill subsequent care as a shared visit (i.e., patient is seen by both an MD and APRN).
- d. Discharge services of a palliative patient
 - i. A palliative APRN may bill independently for these services if the APRN is the Attending of Record and admitted the patient to the facility.
 - ii. A palliative APRN may bill discharge services as a shared visit (i.e., patient is seen by both an MD and APRN).
- e. Death pronouncement and certification of a palliative patient
 - i. A palliative APRN may bill independently for these services under the discharge management code if state statute allows the APRN to perform a death pronouncement and complete a death certificate.
 - ii. If allowed by state statutes to perform these services and the APRN performs the “final examination” to pronounce the death and complete a death certificate, services would be billed under the discharge management code.

C. In-patient hospice units with the APRN serving as the Attending of Record

1. The hospice APRN may bill for the initial admission as the admitting Attending of Record.
2. The hospice APRN may bill for subsequent visits independently as the Attending of Record
3. The hospice APRN may bill for discharge services under the discharge management code, if the APRN admitted the patient to the unit.
4. The hospice APRN may bill for death pronouncement and certification, under the discharge management code, if allowed by state statutes to do so and if she or he performs the “final examination” to pronounce the death.

D. Telehealth codes

1. The palliative APRN in the acute care setting, clinic setting, or home setting may bill for initial palliative consultations.
2. The Palliative APRN in the acute care setting, clinic setting, or home setting may bill for subsequent visits.

Table I.4 THE FOUR PARTS OF MEDICARE

MEDICARE BENEFIT	PART A HOSPITAL INSURANCE	PART B MEDICAL INSURANCE	PART C MEDICARE ADVANTAGE PLANS	PART D PRESCRIPTION DRUG COVERAGE
Type of services	Hospital/Inpatient coverage	Professional outpatient services	Health programs that replace Medicare (Medicare Advantage plans)	Prescription drug programs
Universal or voluntary	Universal coverage	Voluntary; premium payment	Voluntary; premium payment	Voluntary; premium
Coverage	Fully covered: However, there may be a deductible amount per admission.	Covered 80%: However, there may be an annual deductible	Varies by plan	Varies by plan: May have a premium and limits of dollar amounts of medications

From Centers for Medicare and Medicaid Services^{13,14,16}; and Bunis.¹⁵

Table I.5 MEDICARE PART A AND PART B

PART A	PART B
Institutional services	Professional services of clinicians
<i>Eligibility:</i> Universal coverage for people ≥65 years and people with certain disabilities. No copayments.	<i>Eligibility:</i> Voluntary. Coinsurance. People ≥65 years and people with certain disabilities. Copayments required.
Sites of care where services are covered:	Types of services covered:
Hospital care	Physicians, APRNs, PAs, psychologists, clinical social workers
Skilled nursing facility	Durable Medical Equipment
Nursing home care (above custodial care)	Outpatient dialysis
Hospice	Mental health services
Home healthcare	Outpatient hospital
Inpatient rehabilitation	Ambulance services
Inpatient dialysis	Rural health clinic and federally qualified health center services

From Centers for Medicare and Medicaid Services.^{13,14,16}

Box I.5 PALLIATIVE APRN AND HOSPICE ORDERS AND HOME HEALTH ORDERS

Home Health Orders: Under CARES Act of 2021, Palliative NPs can order home health as allowed by state regulations.
Hospice Orders: Palliative APRNs may write the order for hospice. However, only a physician may complete the certification for terminal illness. Nurse practitioners (NPs) and physician assistants (PAs) may serve as attendings of record.

APPENDIX II

Perinatal and Pediatric Pain and Symptom Tables

*Maggie C. Root, Mallory Fossa, Gina Santucci, Nicole Sartor, Faith Kinnear, Alice Bass,
Jaime Hensel, Amy Corey Haskamp, Joanne M. Greene, Cheryl Ann Thaxton,
Joan “Jody” Chrastek, Vanessa Battista, and Constance Dahlin*

Infants, children, and adolescents with serious illnesses experience a myriad of pain syndromes and symptoms. It is essential that the pediatric palliative APRN evaluate each symptom through exquisite assessment, physical examination, and review of diagnostic information. To understand the pathophysiology of pain and symptoms, the reader is referred to the Section VIII “Symptoms” in this book. Chapters 39 through 44 provide information on the etiology, pathophysiology, assessment, and management of pain, anorexia and cachexia, bowel symptoms, fatigue, nausea and vomiting, and respiratory symptoms. Chapters 45 through 50 provide information on the etiology, pathophysiology, assessment, and management of anxiety, delirium, and other challenging symptoms. This appendix offers suggestions for the medical management of common infant and pediatric palliative care symptoms. However, it is not meant as medical advice. The pediatric palliative APRN should always review the literature and consult pharmacology databases and palliative care colleagues to ensure that the most current information on medication use and dosages is being used. Additionally, the pediatric palliative APRN should consider consulting other specialists, which may include anesthesia/pain management, psychiatry, neurology, and gastroenterology to name a few.

There are few guidelines for pediatric medications in palliative care. Most of the literature focuses on the adaptation of medications used in the adult population to the pediatric

population.¹ Per the World Health Organization (WHO) and the US Centers for Disease Control and Prevention (CDC), when treating pediatric patients, it is wise to avoid the unnecessary use of medications and be aware of the potential for medication overdoses.^{2,3} Therefore, a step-wise approach to management is appropriate.

Step 1 is the use of nonpharmacological strategies listed in Table II.1.^{4,5,6} This includes a range of interventions. For the infant, the focus is often on adjusting the environment of care to maximize comfort and reduce overstimulation. For the child and adolescent, it moves beyond managing the environment to initiating cognitive, rehabilitative, expressive, and integrative therapies, as available and affordable to families.

Step 2 is pharmacological management of pain and symptoms (Table II.2). Although there are guidelines for the use of medications in the pediatric population (see Table 10), there are limited randomized trials specifically in this population. In children, medication use is frequently based on the opinions and guidelines of experts. Medication management must be individualized to the infant, child, and adolescent based on age, weight, metabolism, and development. Dosing of medications is based on either weight or age. The pediatric palliative APRN should always consult the most recent literature for dosing guidelines. In addition, the APRN must consider regional access to medications, health organization formularies, and the insurance coverage of any therapeutics. The

Table II.1 NONPHARMACOLOGICAL INTERVENTIONS

ENVIRONMENTAL STRATEGIES	COGNITIVE THERAPIES	REHABILITATIVE THERAPIES	EXPRESSIVE THERAPIES	INTEGRATIVE
Swaddling/cuddling	Cognitive-behavioral therapy	Physical therapy	Art therapy	Acupuncture
Heating pads	Hypnosis	Massage	Music therapy	Yoga
Cold packs	Guided imagery	Occupational therapy	Dance and movement therapy	Reiki
Distraction	Counseling		Bibliotherapy or poetry therapy	Biofeedback

Table II.2 NOCICEPTIVE AND NEUROPATHIC PAIN: CAUSES AND DESCRIPTORS

CAUSES	DESCRIPTORS
Nociceptive: Somatic tissues	
Increased pressure, bony invasion or metastases, mucositis, skin breakdown, radiation skin burns, vaso-occlusive crisis in sickle cell disease	Well-localized, sharp/stabbing (if superficial) or dull/throbbing (if deep tissue), constant but worse with movement, point tenderness common
Nociceptive: Visceral organs	
Tumor invasion resulting in organ distention, infiltration, necrosis, or obstruction such as intestine, kidneys, liver, or peritoneum	Poorly localized, dull, deep pressure, spasm or cramping
Neuropathic: Peripheral or central nervous system	
Nerve compression or injury due to tumor or metastatic invasion to the brain, spinal cord, or nerve roots; peripheral neuropathy caused from chemotherapy such as vincristine, phantom limb pain	Difficult to describe or localize, associated with paresthesia or dysesthesia. Tingling, burning, shooting, electric/shooting, prickly

From Postovsky et al.⁸; and Hauer.⁹

Table II.3 PAIN MANAGEMENT: SUGGESTED DOSING FOR INITIATION OF OPIOIDS IN OPIOID-NAÏVE INFANTS AND CHILDREN

OPIOID	COMMON DOSING BASED ON WEIGHT AND AGE
Oxycodone	<i>Weight-based dosing</i> <i>Infants <6 months:</i> Not recommended due to wide variability in drug conversion and clearance ¹⁰ <i>Children >6 months</i> ^{8,10,11,12} : <50 kg: 0.1–0.2 mg/kg q4–6h PO prn, maximum 5–10 mg/dose >50 kg: 5–10 mg q4–6h PO prn
Morphine	<i>Weight-based dosing</i> <i>Neonates <1 month</i> ⁷ : Use preservative-free formulation. 0.025–0.05 mg/kg/dose IV q4–8h prn <i>or</i> 0.08 mg/kg/dose PO q4–6h prn <i>Infants >1 month and ≤6 months</i> ³ : <i>Nonventilated:</i> 0.025–0.03 mg/kg IV q4h prn <i>or</i> 0.08–0.1 mg/kg PO q4h prn <i>Ventilated:</i> 0.05 mg/kg/dose q2–4h prn <i>Continuous IV infusion (initial dosing):</i> 0.008–0.02 mg/kg/hr, titrate carefully to effect <i>Infants >6 months, children and adolescents</i> ^{3,8} : <50 kg: 0.05–0.1 mg/kg/dose IV q4h prn maximum 1–2 mg/dose <i>or</i> 0.15–0.3 mg/kg PO q4h prn usual maximum 7.5–15 mg every 4 hours >50 kg: 2–5 mg IV q4h prn <i>or</i> 15–20 mg PO q4h prn

Table II.3 CONTINUED

OPIOID	COMMON DOSING BASED ON WEIGHT AND AGE
Fentanyl	<i>Weight-based dosing</i> <i>Infants ≤12 months</i> ¹¹ : <i>Infants 0–5 months</i> 0.5–1 mcg/kg/hr with the bolus dose being the same 1–2 mcg/kg IV/SC q2–4h prn <i>Children and adolescents</i> ^{2,3,8} : <50 kg: 0.5–1 mcg/kg IV q1–2h prn (maximum 25–50 mcg) administer slowly over 3–5 minutes) >50 kg: 25–50 mcg /dose IV q1– 2 h prn Continuous infusion 0.5–1 mcg/kg/hr (maximum 25–50 mcg/h) Transdermal Patch 12 mcg/hr patch *Must be using minimum of 30 mg oral morphine/24 hours before initiating patch.
Hydromorphone	<i>Age- and weight-based dosing</i> ¹² : <i>Infants 6 months and >10 kg</i> : 0.01 mg/kg/dose IV q3–6h prn <i>or</i> 0.03 mg/kg/dose PO q4h prn <i>Children and adolescents <50 kg</i> ⁸ : 0.015 mg/kg IV q4h prn <i>or</i> 0.04–0.06 mg/kg PO q4h prn <i>Children and adolescents 50 kg</i> ⁷ : 0.2–0.6 mg IV q4h prn <i>or</i> 1–2 mg PO q4h prn
Methadone	<i>Opioid-naïve children and adolescents</i> ^{8,11} : Wide dosing ranges: 0.05–0.1 mg/kg/dose (maximum 2.5–5 mg PO q8–12h)

Note: Best practice is to cross check dosing with a palliative care colleague or a pharmacist.

Infants are at high risk of respiratory depression from opioids. Metabolism and excretion can vary widely in infants. Use caution when prescribing in this population.

From Wren et al.⁶; Hauer⁸; Friedrichsdorf¹¹; and Taketomo, Hodding.¹³

Table II.4 MANAGEMENT OF NEUROPATHIC PAIN

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
ANTICONVULSANTS	
Gabapentin	<i>Age- and weight-based dosing:</i> <i>Infants</i> ^{14–17} : 2.5–5 mg/kg/day PO, titrate every 3–5 days <i>Children and adolescents (neuropathic pain)</i> ¹¹ : 2 mg/kg PO qhs Slow titration to initial target dose of 6 mg/kg/dose tid (maximum 300 mg/dose tid) Titrate to effect (maximum dose 24 mg/kg/dose tid or 1,200 mg/dose tid) <i>Children and adolescents with severe neurologic impairment (dosing for peripheral and central neuropathic pain, spasticity and visceral hyperalgesia)</i> ^{9,16,18} : Days 1–2: 2 mg/kg (100 mg maximum) PO tid Days 4–6: 4 mg/kg PO tid Titrate to effect every 2–4 days by 5–6 mg/kg/day until any of the following: Analgesia is effective (often noted at 30–45 mg/kg/day) Side effects experienced (nystagmus, sedation, tremor, ataxia, swelling) Maximum dose per day is reached (50–72 mg/kg/day <i>or</i> 2,400–3,600 mg/day) <i>Note:</i> Younger children (<5 years) may require a 30% higher mg/kg/day dosing, such as a total dose of 45–60 mg/kg/day <i>Sedation is more common with rapid titration. Adjust dose in renal impairment.</i>
Pregabalin	<i>Weight-based dosing:</i> <i>Children</i> ¹⁸ : Days 1–3: 1 mg/kg (maximum 50 mg), enterally, every night Days 4–6: 1 mg/kg, enterally, bid Increase every 2–4 days up to 3 mg/kg/dose, enterally, given 2 or 3 times daily (maximum 6 mg/kg/dose)

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
TRICYCLIC ANTIDEPRESSANTS	
Amitriptyline	<i>Age-based dosing</i> <i>Children and Adolescents <50 kg</i>¹⁸: Days 1–4: 0.2 mg/kg (maximum 10 mg), enterally, qhs Days 5–8: 0.4 mg/kg, enterally, every night Increase every 4–5 days by 0.2 mg/kg/day until desired effect (maximum 50 mg/day) OR Initial: 0.1 mg/kg at bedtime, may advance as tolerated over 2–3 weeks to 0.5–2 mg/kg at bedtime. Max: 50 mg/day <i>Adolescents and adults >50 kg</i>^{9,18}: Oral: Initial: 10–25 mg qhs; gradually increase dose based on response and tolerability in 10–25 mg increments at intervals ≥1 week up to 150 mg/day given once daily at bedtime or in 2 divided doses
CENTRALLY ACTING A-AGONIST	
Clonidine	<i>Weight-based dosing</i> <i>For children and adolescents</i>^{3,7–18}: Day 1–3: 0.002 mg/kg (maximum 0.1 mg), enterally at night Days 4–6: 0.002 mg/kg (maximum 0.1 mg), enterally, bid Days 7–9: 0.002 mg/kg (maximum 0.1 mg), enterally tid Increase every 2–4 days by 0.002 mg/kg to effect Can consider clonidine patch when at stable enteral dosing For episodic dosing - 0.002–0.004 mg/kg every 4 hours as needed for autonomic storm events (suggested by facial flushing, muscle stiffening and tremors, hyperthermia)

From Hauer⁹; Friedrichsdorf¹¹; and Taketomo, Hodding.¹³

Table II.5 MANAGEMENT OF CONSTIPATION

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE ³
Docusate	<i>Age-based dosing:</i> <i>Children:</i> Docusate alone is not an effective bowel regimen¹⁹
Docusate and senna	<i>Age-based dosing:</i> <i>Infants:</i> No recommendations <i>Children:</i> 2–6 years: ½ tablet (25 mg docusate/4.3 mg sennosides) PO qhs maximum 1 tab bid 6–12 years: 1 tablet (50 mg docusate/8.6 mg sennosides) PO qhs maximum 2 tabs bid > 12 years: 2 tablets (100 mg docusate/17.2 mg sennosides) PO qhs maximum 4 tabs bid
Senna	<i>Age-based dosing:</i> <i>Infants:</i> No recommendations <i>Children:</i> 2–6 years: 2.5–3.75 mL PO qhs, maximum 3.75 mL bid 6–12 years: 5–7.5 mL PO qhs, maximum 7.5 mL bid >12 years: 10–15 mL PO qhs, maximum 15 mL bid
Lactulose	<i>Infants:</i> Use caution with infants as they are at risk for dehydration and hyponatremia²⁰ <i>Children:</i> <i>Weight-based dosing:</i> 1–2 g/kg/day (1.5–3 mL/kg/day) PO divided 1–2 times per day, maximum 60 mL/day
Methylnaltrexone	<i>Infants:</i> Little evidence exists on the use of methylnaltrexone in infants and neonates.²¹ <i>Children:</i> Consultation with a neonatal pharmacist is recommended for use in children under 2 years old.²² <i>Weight-based dosing</i>^{22,23}: < 38 kg: 0.15 mg/kg SC every other day, maximum 8–12 mg, once daily 38–62 kg: 8 mg SC every other day, maximum once daily 62–114 kg: 12 mg SC every other day maximum once daily >114 kg: 0.15 mg/kg SC every other day maximum once daily
Polyethylene glycol	<i>Children:</i> <i>Weight-based dosing:</i> ≥6 months: 0.2–0.8 g/kg PO Q day, starting dose 17 g/day to maximum dose of 32 g/day

From Komatz, Carter.²⁴

Table II.6 MANAGEMENT OF DELIRIUM

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
Risperidone	<i>Age-based dosing</i> <i>Infants >6 months</i> ²⁵ : Oral: 0.05 mg PO qhs <i>Children <5 yrs. of age</i> ²⁶ : Oral: Initial: 0.1–0.2 mg qhs; doses may be increased based upon response <i>Children >5 yr. and adolescents</i> ²⁶ : Oral: Initial: 0.2–0.5 mg once daily at bedtime May titrate every 1–2 days; usual range: 0.2–2.5 mg/day in divided doses 2–4 times daily Some have suggested maximum daily dose depending on patient weight: <20 kg: 1 mg/day; 20–45 kg: 2.5 mg/day; >45 kg: 3 mg/day
Olanzapine	<i>Age-based dosing (very limited data)</i> <i>Infants</i> ²⁷ : Olanzapine 0.625 mg PO qhs <i>Infants ≥7 months to children <3 years</i> ²⁶ : Oral disintegrating tablet (ODT): Reported range: 0.625–1.25 mg once daily qhs or bid <i>Children ≥3 years and adolescents</i> : <30 kg: 1.25 mg po q hs 30–60 kg: 2.5 mg po q hs >60 kg: 5 mg po q hs ODT: Usual initial range: 1.25–5 mg once daily qhs or bid; should be initiated at low dose and then titrated as needed (maximum 10 mg).
Quetiapine	<i>Age- and weight-based dosing (very limited data)</i> <i>Infants</i> ²⁸ : Ventilated infants: Quetiapine 0.5 mg/kg PO q8h <i>Children and adolescents <50 kg</i> ^{26–28} : Initial dose range 0.43–0.7 mg/kg/dose <i>Adolescents >50 kg</i> ²⁶ : Initial: 50 mg bid; suggested increase by 100 mg at intervals ≥1 day up to a maximum dose of 400 mg/day

From Taketomo, Hodding.¹³

Table II.7 TREATMENT OF NAUSEA AND VOMITING

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
<i>Benzodiazepines</i>	
Lorazepam	<i>Weight-based dosing:</i> <i>Infants and children:</i> 0.025–0.05 mg/kg/dose PO or IV q6h, maximum 2 mg/dose
<i>Dopamine antagonists: Atypical antipsychotic</i>	
Olanzapine	<i>Weight-based dosing:</i> <i>Infants and children</i> ²⁹ : 0.1–0.14 mg/kg/dose PO every day, maximum 10 mg/dose
<i>Serotonin (5-HT₃) antagonists</i>	
Ondansetron	<i>Weight-based dosing:</i> <i>Infants and children:</i> 0.15 mg/kg/dose IV or PO q8h, maximum 8 mg/dose
Granisetron	<i>Age- and weight-based dosing</i> <i>Infants:</i> No guidelines for infants with nausea for non-chemotherapy-related vomiting For infants and children receiving highly emetogenic chemotherapy <i>Infants ≤ 6 months:</i> 40 mcg/kg IV once daily prior to chemotherapy <i>Children:</i> >6 months: 40 mcg/kg IV or PO q12h, maximum 1 mg/dose

(continued)

Table II.7 CONTINUED

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
<i>Antimuscarinics</i>	
Scopolamine patch	Age-based dosing based on prevention of postop nausea³: <i>Children <2 years</i>: Apply 1/4 patch <i>Children ≥2 to 6 years</i>: Apply 1/2 patch <i>Children ≥6 to 12 years</i>: Apply 1/2 to 1 patch <i>Children ≥12 years and adolescents</i>: Apply 1 patch <i>Weight-based dosing</i>: >40 kg: 1.5 mg transdermal patch q72h <i>Note</i>: Patches should not be cut. A reduced dose may be achieved by the placement of an impermeable material under the scopolamine patch.
<i>Neurokinin-1 antagonists</i>	
Aprepitant	<i>Age-based dosing</i>: <i>6 months—12 years (6–30 kg)</i>: Day 1: 3 mg/kg PO, maximum 125 mg Days 2 and 3: 2 mg/kg PO, maximum 80 mg <i>12 years or >30 kg</i>: Day 1: 125 mg PO Days 2 and 3: 80 mg PO once daily
<i>Corticosteroids</i>	
Dexamethasone for chemotherapy-induced nausea and vomiting (CINV)	<i>Age-based dosing</i>: <i>Infants</i>: No dosing guidelines exist for <6 months <i>Child <1 year</i>: 250 mg to 1 mg, enterally tid¹⁴ <i>6 months</i>: 6–10 mg/m² IV or PO every day; maximum 20 mg/dose <i>Note</i>: Reduce dose by 50% if administered concomitantly with aprepitant.
<i>Cannabinoids</i>	
Dronabinol	<i>Age-based dosing</i>: Recommend use in age ≥6 years: 2.5 mg/m²/dose PO q4–6h <i>Adolescents</i>: 2.5 mg PO q6–8h 0.05–0.1 mg/kg PO q 12hr (2.5–5 mg) May increase if tolerated to maximum of 10 mg bid

From Taketomo, Hodding.¹³

Table II.8 TREATMENT OF FATIGUE AND INSOMNIA IN PEDIATRICS

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
Sleep agents	
Melatonin	<i>Age-based dosing</i>: <i>Infants ≥ 6 months</i>²⁰: 1 mg <i>Children</i>: Initially 2–3 mg PO qhs, increase every 1–2 weeks by 1 mg to a maximum of 10 mg/day¹⁴
Trazodone	<i>Age-based dosing</i>: > 5 years: 0.75–1 mg/kg/dose (25–50 mg) PO qhs (maximum 200 mg/day)
Zolpidem	<i>Age-based dosing</i>: <i>2–18 years limited data</i>: 0.25 mg/kg PO qhs (maximum 10 mg/dose) >18 years: 5 mg (females) or 5–10 mg (males) PO qhs (maximum 10 mg/dose)
Psychostimulants	
Methylphenidate	<i>Age-based dosing</i>: <i>Infants</i>: No indication for use <i>Children</i>: 2.5–5 mg PO 1–4 times/day prn up to 20 mg twice daily

From Taketomo, Hodding.¹³

Table II.9 TREATMENT FOR ANOREXIA/CACHEXIA IN PEDIATRICS

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
Megestrol acetate	<i>Weight-based dosing</i>: >8 months—<i>Adolescents</i>: 75–10 mg/kg/day PO in 1–2 divided doses (maximum 800 mg/day)
Dexamethasone	<i>Weight-based dosing</i>: 0.05–0.5 mg/kg/day PO (maximum 4 mg/day)
Dronabinol	<i>Adolescents</i>: 2.5 mg PO 1–2 times/day, may increase to 5 mg/dose

From Anekar, Cascalla³; Davis⁵; Taketomo, Hodding¹³; Flank et al.²⁹; Loprinzi & Jatoi³⁰ and Schack, Wholihan.³¹

Table II.10 SECRETION MANAGEMENT

MEDICATIONS	COMMON DOSING BASED ON WEIGHT AND AGE
Atropine ophthalmic drops	<i>Weight-based dosing:</i> ≤ 10 kg: 1 drop SL of 0.25% solution q6h prn > 10 kg: 1 drop SL of 0.5% solution q6h prn > 25 kg or adolescents: 1 drop of SL 1% solution q6h prn
Glycopyrrolate	<i>Weight-based dosing:</i> 4–10 mg/kg/dose IV q3–4h 20–100 mg/kg/dose PO q6–8h 0.05–0.1 mg/kg PO q 12 hr (2.5–5 mg). May increase if tolerated to maximum of 10 mg bid
Scopolamine transdermal patch	<i>Weight-based dosing:</i> > 40 kg or > 12 years: 1.5 mg transdermal patch q72h; may consider partial patch for younger populations to titrate as needed <i>Note:</i> Scopolamine patch takes approximately 12 hours to peak effect

From Hunt et al.²⁰

Table II.11 AGITATION MANAGEMENT

MEDICATION	COMMON DOSING BASED ON WEIGHT AND AGE
Lorazepam	<i>Weight-based dosing:</i> 0.05 mg/kg IV/PO for agitation (consult with neurology in an infant with known neurological condition/seizure disorder; maximum 2 mg)
Diazepam	<i>Weight-based dosing:</i> > 6 months: 0.12–0.8 mg/kg/day divided PO (long-acting) > 13 years: 2–10 mg PO bid-qid
Midazolam	<i>Weight-based dosing:</i> > 6 months: Intranasal 0.2 mg/kg (divided between nares) PO/PR: 0.2–0.5 mg/kg IV: 0.05 mg/kg Rarely used for agitation; infants < 6 months at higher risk for airway obstruction and hypoventilation
Haloperidol	<i>Weight-based dosing</i> (limited data available): <i>Children ≥ 3 years and adolescents:</i> 0.01 mg/kg/dose PO/IV tid prn; To manage new-onset acute episode: 0.025–0.05 mg/kg once; may repeat 0.025 mg/kg/dose in 1 hour prn
Gabapentin	For use in chronic agitation in children with severe neurologic impairment See dosing recommendations under “Pain”

From Taketomo, Hodding¹³; and Hunt et al.²⁰

following tables offer evidence-based medications to use for common symptoms based on both age and weight.
