CHAPTER 51

Management of Patients with Neurologic Trauma

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the mechanisms of injury, clinical signs and symptoms, diagnostic testing, and treatment options for patients with traumatic brain and spinal cord injuries.
2. Use the nursing process as a framework for care of patients with traumatic brain injury.
3. Identify the population at risk for spinal cord injury.
4. Explain the clinical features and management of the patient with neurogenic shock.
5. Discuss the pathophysiology of autonomic dysreflexia and describe the appropriate nursing interventions.
6. Apply the nursing process as a framework for care of patients with spinal cord injury.
7. Explain the rehabilitation of patients following neurotrauma.

GLOSSARY

autonomic dysreflexia: a life-threatening emergency in patients with spinal cord injury that causes a hypertensive emergency; also called *autonomic hyperreflexia*

complete spinal cord lesion: a condition that involves total loss of sensation and voluntary muscle control below the lesion

concussion: a temporary loss of neurologic function with no apparent structural damage to the brain

contusion: bruising of the brain surface

halo vest: external traction device that encircles the head like a halo and stabilizes the cervical spine

incomplete spinal cord lesion: a condition in which there is preservation of the sensory or motor fibers, or both, below the lesion

neurogenic bladder: bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity

paraplegia: paralysis of the lower extremities with dysfunction of the bowel and bladder from a lesion in the thoracic, lumbar, or sacral region of the spinal cord

primary injury: initial damage to the brain that results from the traumatic event secondary injury; an insult to the brain subsequent to the original traumatic event

spinal cord injury (SCI): an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral discs caused by trauma

tetraplegia: varying degrees of paralysis of both arms and legs, with dysfunction of bowel and bladder from a lesion of the cervical segments of the spinal cord; formerly called *quadriplegia*

transection: severing of the spinal cord itself; transection can be complete (all the way through the cord) or incomplete (partially through)

traumatic brain injury: an injury to the skull or brain that is severe enough to interfere with normal functioning

traumatic brain injury, closed (blunt): occurs when the head accelerates and then rapidly decelerates or collides with another object and brain tissue is damaged, but there is no opening through the skull and dura

traumatic brain injury, open (penetrating): occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain

Introduction

Trauma involving the central nervous system can be life threatening. Even if not life threatening, brain and spinal cord injury (SCI) may result in major physical and psychological dysfunction and can alter the patient's life completely. Neurologic trauma affects the patient, the family, the health care system, and society as a whole because of its major sequelae and the costs of acute and long-term care of patients with trauma to the brain and spinal cord.

Head Injuries

Head injury is a broad classification that encompasses any damage to the head as a result of trauma. A head injury does not necessarily mean a brain injury is present. Traumatic brain injury (TBI) or craniocerebral trauma describes an injury that is the result of an external force and is of sufficient magnitude to interfere with daily life and prompts the seeking of treatment.

The Centers for Disease Control and Prevention (CDC) estimates that there are 2.5 million emergency department (ED) visits in the United States each year, the majority of which are for a mild TBI (CDC, 2016a). As a result of TBI, approximately 52,000 people die (contributing to about 30% of all injury-related deaths), 275,000 are hospitalized, and 80,000 to 90,000 will have long-term disabilities (CDC, 2016a); (Hickey, 2014). Approximately 78% of patients are treated in the ED and released (Hemphill & Phan, 2016). The most common causes of TBIs are falls (35.2%), motor vehicle crashes (17.3%), being struck by objects (16.5%), and assaults (10%). Children 0 to 4 years, adolescents 15 to 19 years, and adults 65 years and older are most likely to sustain a TBI. In every age group, TBI rates are higher for males than for females (Hickey, 2014). An estimated 57 million people worldwide are currently living with a TBI-related disability, producing an annual economic impact of approximately $60 to $75 billion due to medical expenses and the cost of lost productivity (CDC, 2016a). The best approach to head injury is prevention (see Chart 51-1).

Chart 51-1 HEALTH PROMOTION

Preventing Head and Spinal Cord Injuries

- Advise drivers to obey traffic laws and to avoid speeding or driving when under the influence of drugs or alcohol.
- Advise all drivers and passengers to wear seat belts and shoulder harnesses. Children younger than 12 years should use an age/size-appropriate system in the back seat.
- Caution passengers against riding in the back of pickup trucks.
- Advise motorcyclists, scooter riders, bicyclists, skateboarders, and roller skaters to wear helmets.
- Promote educational programs that are directed toward violence and suicide prevention in the community.
- Provide water safety instruction.
- Educate patients about steps that can be taken to prevent falls, particularly in older adults.
- Advise athletes to use protective devices. Recommend that coaches be educated in proper coaching techniques.
- Advise owners of firearms to keep them locked in a secure area where children cannot access them.

India is the seventh largest country by area and the second most populous country. The Ministry of Road Transport, Government of India, statistics (2020) show that 4,49,002 road traffic accidents occurred in 2019 and 3,66,138 accidents occurred in 2020 in various states and union territories of India. The percentage of fatal accidents was 33.7 in 2019 and 36 in 2020. The state of Tamil Nadu stands first in the number of road traffic accident (Government of India, 2020).

Pathophysiology

Research suggests that not all brain damage occurs at the moment of impact. Damage to the brain from traumatic injury takes two forms: primary injury and secondary injury. Primary injury is defined as the consequence of direct contact to the head/brain during the instant of initial injury, causing extracranial focal injuries (e.g., contusions, lacerations, external hematomas, and skull fractures), as well as possible focal brain injuries from sudden movement of the brain within the cranial vault (e.g., subdural hematomas (SDHs), concussion, diffuse axonal injury [DAI]). The greatest opportunity for decreasing TBI is the implementation of prevention strategies (see Chart 51-1).

Secondary injury evolves over the ensuing hours and days after the initial injury and results from inadequate delivery of nutrients and oxygen to the cells. Identification, prevention, and treatment of secondary injury are the main foci of early management of severe TBI. Contributors to this process include intracranial pathologic processes such as intracranial hemorrhage, cerebral edema, intracranial hypertension, hyperemia, seizures, and vasospasm (Bader, Littlejohns, & Olson, 2016); (Hickey, 2014). Systemic effects from hypotension, hyperthermia, hypoxia, hypercarbia, infection, electrolyte imbalances, and anemia can also be factors which add to the complex biochemical, metabolic, and inflammatory changes that further compromise an injured brain (Bader et al., 2016); (Hickey, 2014).

The Monro–Kellie hypothesis, also known as the Monro–Kellie doctrine, explains the dynamic equilibrium of cranial contents. The cranial vault contains three main components: brain, blood, and cerebrospinal fluid (CSF). According to the Monro–Kellie hypothesis, the cranial vault is a closed system, and if one of the three components increases in volume, at least one of the other two must decrease in volume or the pressure will increase. Any bleeding or swelling within the skull

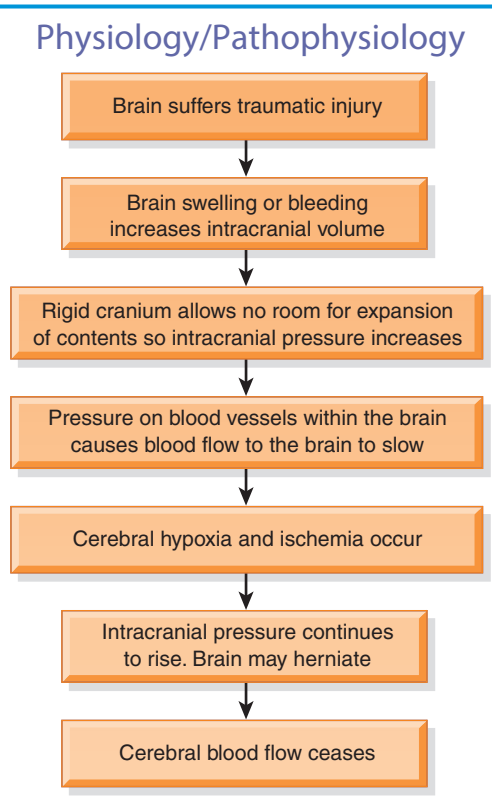

Figure 51-1 • Pathophysiology of traumatic brain injury.

increases the volume of contents within the skull and therefore causes increased intracranial pressure (ICP) (see Chapter 49). If the pressure increases enough, it can cause displacement of the brain through or against the rigid structures of the skull. This causes restriction of blood flow to the brain, decreasing oxygen delivery and waste removal. Cells within the brain become anoxic and cannot metabolize properly, producing ischemia, infarction, irreversible brain damage, and eventually brain death (see Fig. 51-1).

Scalp Injury

Isolated scalp trauma is generally classified as a minor injury. Because its many blood vessels constrict poorly, the scalp bleeds profusely when injured. Trauma may result in an abrasion (brush wound), contusion, laceration, or hematoma beneath the layers of tissue of the scalp (subgaleal hematoma) (Hickey, 2014). A large avulsion (tearing away) of the scalp may be potentially life threatening and is a true emergency. Diagnosis of a scalp injury is based on physical examination, inspection, and palpation. Scalp wounds are potential portals of entry for organisms that cause intracranial infections. Therefore, the area is irrigated before the laceration is sutured to remove foreign material and to reduce the risk for infection (Hollander & Camacho, 2014). Subgaleal hematomas (hematomas below the outer covering of the skull) usually reabsorb and do not require any specific treatment.

Skull Fractures

A skull fracture is a break in the continuity of the skull caused by forceful trauma. It may occur with or without damage to the brain. Skull fractures are classified by type and location. Types include linear, comminuted, and depressed skull fractures, whereas location fractures include frontal, temporal, and basal skull fractures. A simple (linear) fracture is a break in the

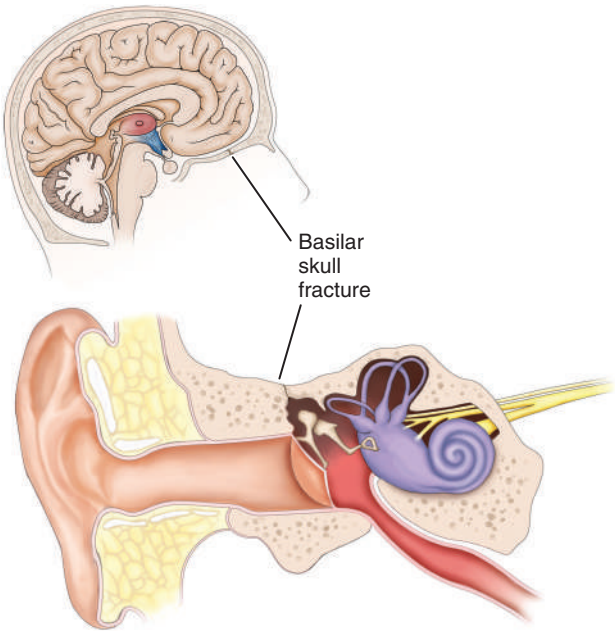

Figure 51-2 • Basal skull fracture allows cerebrospinal fluid to leak from the nose and ears. Adapted from Hickey, J. V. (2009). The clinical practice of neurological & neurosurgical nursing (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

continuity of the bone. A comminuted skull fracture refers to a splintered or multiple fracture line. Depressed skull fractures occur when the bones of the skull are forcefully displaced downward, and can vary from a slight depression to bones of the skull being splintered and embedded within brain tissue. A fracture of the base of the skull is referred to as a basal skull fracture (Hickey, 2014) (see Fig. 51-2). A fracture may be open, indicating a scalp laceration or tear in the dura (e.g., from a bullet or an ice pick), or closed, in which case the dura is intact.

Clinical Manifestations

Symptoms, apart from those of the local injury, depend on the severity and the anatomic location of the underlying brain injury. Persistent, localized pain usually suggests that a fracture is present. Fractures of the cranial vault may or may not produce swelling in the region of the fracture. Fractures of the base of the skull tend to traverse the paranasal sinus of the frontal bone or the middle ear located in the temporal bone (see Fig. 51-2). Therefore, they frequently produce hemorrhage from the nose, pharynx, or ears, and blood may appear under the conjunctiva. An area of ecchymosis (bruising) may be seen over the mastoid (Battle sign). Basal skull fractures are suspected when CSF escapes from the ears (CSF otorrhea) and the nose (CSF rhinorrhea). Drainage of CSF is a serious problem, because meningeal infection can occur if organisms gain access to the cranial contents via the nose, ear, or sinus through a tear in the dura.

Assessment and Diagnostic Findings

A computed tomography (CT) scan can be used to diagnose a skull fracture. The ease with which a diagnosis of skull fracture is made depends on the site of the fracture. If a fracture is found on CT scan, there is always the question of associated brain injury, and a magnetic resonance imaging (MRI) scan provides better resolution and clearer pictures of the injured area (Hickey, 2014).

Gerontologic Considerations

Older patients with head injuries differ from those who are younger in terms of etiology of injury, higher mortality rates, longer lengths of hospital stay, and poorer functional outcomes. Neurologic assessment can be challenging, as the older adult patient with a TBI can have hearing and/or visual deficits or pre-existing dementia or cognitive issues, making establishment of a neurologic baseline difficult. The most common causes of injury in older adult patients are falls and motor vehicle crashes (Stocchetti & Maas, 2014). Approximately 61% of all TBIs among adults aged 65 years and older result from falls (CDC, 2016a). Physiologic changes related to aging may place the older adult at increased risk for injury, alter the type and severity of injury that occurs, or lead to complications. Two major factors place older adults at increased risk for hematomas. First, brain weight decreases, the dura becomes more adherent to the skull, and reaction times slow with increasing age (Eliopoulos, 2018). Second, many older adults take aspirin and anticoagulant agents as part of routine management of chronic conditions.

Medical Management

Nondepressed skull fractures generally do not require surgical treatment; however, close observation of the patient is essential. Nursing personnel may observe the patient in the hospital, but if no underlying brain injury is present, the patient may be allowed to return home. If the patient is discharged home, specific instructions must be given to the family (see later discussion of concussion).

Depressed skull fractures usually require surgery with elevation of the skull and débridement, usually within 24 hours of injury. Skull fractures can be a combination of open, compound, closed, or simple. Associated injuries include concurrent scalp laceration, dural tears, and brain injury directly below the fracture from compression of the tissue below the bony injury and from lacerations produced by the bony fragments (Hickey, 2014).

Brain Injury

The most important consideration in any head injury is whether the brain is injured. Even seemingly minor injury can cause significant brain damage secondary to obstructed blood flow and decreased tissue perfusion. The brain cannot store oxygen or glucose to any significant degree. Because the cerebral cells need an uninterrupted blood supply to obtain these nutrients, irreversible brain damage and cell death occur if the blood supply is interrupted for even a few minutes. A traumatic brain injury, closed (blunt) occurs when the head accelerates and then rapidly decelerates or collides with another object (e.g., a wall, the dashboard of a car) and brain tissue is damaged but there is no opening through the skull and dura. A traumatic brain injury, open (penetrating) occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain.

Types of Brain Injury

Injuries to the brain can be focal or diffuse. Focal injuries include contusions and several types of hematomas. Concussions and diffuse axonal injuries are the major diffuse injuries (Hickey, 2014).

Contusion

In cerebral contusion, the brain is bruised and damaged in a specific area because of severe acceleration–deceleration force or blunt trauma. The impact of the brain against the skull leads to a contusion. Clinical manifestations of a contusion are dependent upon size, location, and the extent of surrounding cerebral edema. Although a contusion may occur in any area of the brain, most are usually located in the anterior portions of the frontal and temporal lobes, around the Sylvian fissure, and at the orbital areas; less commonly, contusions are located at the parietal and occipital areas.

Contusions can be characterized by loss of consciousness associated with stupor and confusion. The effects of injury, particularly hemorrhage and edema, peak after about 18 to 36 hours. These effects, which can cause secondary effects resulting in increased ICP and possible herniation syndromes, are most pronounced in temporal lobe contusions. Patients are most often managed medically with interventions directed toward prevention of additional insults. Deep contusions are more often associated with hemorrhage and destruction of the reticular activating fibers, altering arousal (Hickey, 2014).

Intracranial Hemorrhage

Hematomas are collections of blood in the brain that may be epidural (above the dura), subdural (below the dura), or intracerebral (within the brain) (see Fig. 51-3). Major symptoms are frequently delayed until the hematoma is large enough to cause distortion of the brain and increased ICP. The signs and symptoms of cerebral ischemia resulting from compression by a hematoma are variable and depend on the speed with which vital areas are affected and the area that is injured. A rapidly developing hematoma, even if small, may be fatal, whereas a larger but slowly developing one may allow compensation for increases in ICP.

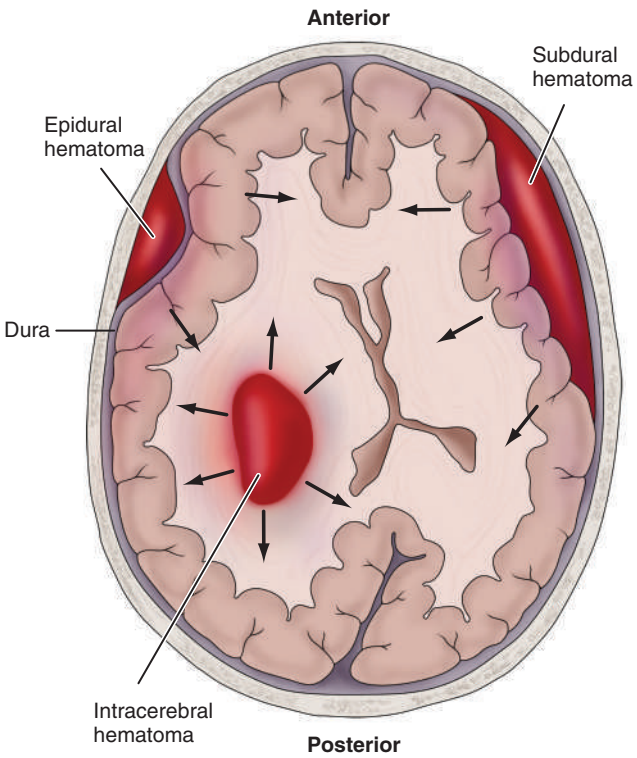

Figure 51-3 • Location of epidural, subdural, and intracerebral hematomas.

Epidural Hematoma

After a head injury, blood may collect in the epidural (extradural) space between the skull and the dura mater. This can result from a skull fracture that causes a rupture or laceration of the middle meningeal artery, the artery that runs between the dura and the skull inferior to a thin portion of temporal bone. Hemorrhage from this artery causes rapid pressure on the brain. Epidural hematomas (EDHs) account for approximately 2.7% to 4% of traumatic head injuries (Hickey, 2014).

Symptoms are caused by the expanding hematoma. EDHs are often characterized by a brief loss of consciousness, followed by a lucid interval in which the patient is awake and conversant. During this lucid interval, compensation for the expanding hematoma takes place by rapid absorption of CSF and decreased intravascular volume, both of which help to maintain the ICP within normal limits. When these mechanisms can no longer compensate, even a small increase in the volume of the blood clot produces a marked elevation in ICP. The patient then becomes increasingly restless, agitated, and confused as the condition progresses to coma. Then, often suddenly, signs of herniation appear (usually deterioration of consciousness and signs of focal neurologic deficits, such as dilation and fixation of a pupil or paralysis of an extremity), and the patient's condition deteriorates rapidly. The most common type of herniation syndrome associated with an EDH is uncal herniation causing pressure on the midbrain (Hickey, 2014).

An EDH is considered an extreme emergency; marked neurologic deficit or even respiratory arrest can occur within minutes. Treatment consists of making openings through the skull (burr holes; see Chapter 49, Fig. 49-10) to decrease ICP emergently, remove the clot, and control the bleeding. A craniotomy may be required to remove the clot and control the bleeding. A drain is usually inserted after creation of burr holes or a craniotomy to prevent reaccumulation of blood.

Subdural Hematoma

An SDH is a collection of blood between the dura and the brain, a space normally occupied by a thin cushion of fluid. The most common cause is trauma, but it can also occur as a result of coagulopathies or rupture of an aneurysm. An SDH is more frequently venous in origin and is caused by the rupture of small vessels that bridge the subdural space (Bauman & McCourt, 2014). SDHs may be acute or chronic depending on the size of the involved vessel and the amount of bleeding on CT scan.

Acute SDH

Approximately 50% of brain injuries and 60% of deaths in patients with brain injuries result from acute SDHs and are associated with major head injury involving contusion or laceration. Clinical symptoms develop rapidly (Bauman & McCourt, 2014). Signs and symptoms include changes in the level of consciousness (LOC), pupillary signs, and hemiparesis. There may be minor or even no symptoms with small collections of blood. Coma, increasing blood pressure, decreasing heart rate, and slowing respiratory rate are all signs of a rapidly expanding mass requiring immediate intervention.

If the patient can be transported rapidly to the hospital, an immediate craniotomy is performed to open the dura, allowing the subdural clot to be evacuated. Successful outcome also depends on the control of ICP and careful monitoring of

respiratory function (see Chapter 49). The mortality rate for patients with acute SDH is high because of associated brain damage (Bauman & McCourt, 2014).

Chronic SDH

A chronic SDH can develop from seemingly minor head injuries and is seen most frequently in older adults who are prone to this type of head injury due to brain atrophy, which is a consequence of the aging process (Bauman & McCourt, 2014). Seemingly minor head trauma may produce enough impact to shift the brain contents abnormally. The time between injury and onset of symptoms can be lengthy (e.g., 3 weeks to months), so the actual injury may be forgotten.

A chronic SDH can resemble other conditions—for example, it may be mistaken for a stroke. The bleeding is less profuse, but compression of the intracranial contents still occurs. The blood within the brain changes in character in 2 to 4 days, becoming thicker and darker. In a few weeks, the clot breaks down and has the color and consistency of motor oil. Eventually, calcification or ossification of the clot takes place. The brain adapts to this foreign body invasion, and the clinical signs and symptoms fluctuate. Symptoms include severe headache, which tends to come and go; alternating focal neurologic signs; personality changes; mental deterioration; and focal seizures (Bauman & McCourt, 2014).

The treatment for a chronic SDH consists of surgical evaluation for evacuation of the clot. Consideration must be made for reversal of coagulopathies and iatrogenic anticoagulation (Bauman & McCourt, 2014). The operative procedure may be carried out through multiple burr holes, or a craniotomy may be performed for a sizable subdural mass that cannot be suctioned or drained through burr holes.

Intracerebral Hemorrhage and Hematoma

Intracerebral hemorrhage is bleeding into the parenchyma of the brain. It is commonly seen in head injuries when force is exerted to the head over a small area (e.g., missile injuries, bullet wounds, stab injuries). These hemorrhages within the brain may also result from the following:

- Systemic hypertension, which causes degeneration and rupture of a vessel
- Rupture of an aneurysm
- Vascular anomalies
- Intracranial tumors
- Bleeding disorders such as leukemia, hemophilia, aplastic anemia, and thrombocytopenia
- Complications of anticoagulant therapy

Nontraumatic causes of intracerebral hemorrhage are discussed in Chapter 50.

The onset may be insidious, beginning with the development of neurologic deficits, followed by headache. Management includes supportive care; control of ICP; and careful administration of fluids, electrolytes, and antihypertensive medications. Surgical intervention by craniotomy or craniectomy permits removal of the blood clot and control of hemorrhage, but may not be possible because of the inaccessible location of the bleeding or the lack of a clearly circumscribed area of blood that can be removed.

Concussion

A concussion is a temporary loss of neurologic function with no apparent structural damage to the brain. Of the 1.7 million TBIs that occur in the United States each year, it is estimated that approximately 80% of them are concussions, also referred to as "mild TBI" (Hyatt, 2014); (CDC, 2016b). The mechanism of injury is usually blunt trauma from an acceleration–deceleration force, a direct blow, or a blast injury. If brain tissue in the frontal lobe is affected, the patient may exhibit bizarre irrational behavior, whereas involvement of the temporal lobe can produce temporary amnesia or disorientation.

The duration of mental status abnormalities is an indicator of the grade of the concussion. The patient is discharged from the hospital or ED once he or she returns to baseline after a concussion. Monitoring includes observing the patient for a decrease in LOC, worsening headache, dizziness, seizures, abnormal pupil response, vomiting, irritability, slurred speech, and numbness or weakness in the arms or legs (West, Bergman, Biggins, et al., 2011). The occurrence of these symptoms is a red flag indicating the need for further intervention. Recovery may appear complete, but long-term sequelae are possible and repeat injuries common.

Repeated concussive incidents can lead to a syndrome known as chronic traumatic encephalopathy. This syndrome has been recognized in those participating in contact sports such as football and boxing. The presentation is similar to Alzheimer disease, characterized by personality changes, memory impairment, and speech and gait disturbances. Imaging findings show gross cerebral, particularly temporal lobe, atrophy (Bailes, Petraglia, Omalu, et al., 2013); (Hickey, 2014).

Diffuse Axonal Injury

DAI results from widespread shearing and rotational forces that produce damage throughout the brain—to axons in the cerebral hemispheres, corpus callosum, and brainstem. The injured area may be diffuse with no identifiable focal lesion. DAI is associated with prolonged traumatic coma; it is more serious and is associated with a poorer prognosis than a focal lesion. The patient with DAI in severe head trauma experiences no lucid interval, immediate coma, decorticate and decerebrate posturing (see Chapter 49, Fig. 49-2), and global cerebral edema. Diagnosis is made by clinical signs in conjunction with a CT or MRI scan (Bodanapally, Sours, Zhuo, et al., 2015). Recovery depends on the severity of the axonal injury.

Medical Management

Assessment and diagnosis of the extent of injury are accomplished by the initial physical and neurologic examinations. CT and MRI scans are the main neuroimaging diagnostic tools and are useful in evaluating the brain structure (Bodanapally et al., 2015). Positron emission tomography (PET) is available in some trauma centers for assessing brain function.

Any patient with a head injury is presumed to have a cervical spine injury until proven otherwise. The patient is transported from the scene of the injury on a board with the head and neck maintained in alignment with the axis of the body. A cervical collar should be applied and maintained until cervical spine x-rays have been obtained and the absence of cervical SCI documented.

All therapy is directed toward preserving brain homeostasis and preventing secondary brain injury, which is injury to the brain that occurs after the original traumatic event (Bader et al., 2016). Common causes of secondary injury are cerebral edema, hypotension, and respiratory depression that may lead to hypoxemia and electrolyte imbalance. Treatments to prevent secondary injury include stabilization of cardiovascular and respiratory function to maintain adequate cerebral perfusion, control of hemorrhage and hypovolemia, and maintenance of optimal blood gas values.

Treatment of Increased Intracranial Pressure

As the damaged brain swells with edema or as blood collects within the brain, an increase in ICP occurs; this requires aggressive treatment (see Chapter 49 for a discussion of the relationship between ICP and cerebral perfusion pressure [CPP]). If the ICP remains elevated, it can decrease the CPP. Initial management is based on preventing secondary injury and maintaining adequate cerebral oxygenation.

Surgery is required for evacuation of blood clots, débridement and elevation of depressed fractures of the skull, and suture of severe scalp lacerations. ICP is monitored closely; if increased, it is managed by maintaining adequate oxygenation, elevating the head of the bed, and maintaining normal blood volume (Stocchetti & Maas, 2014). Devices to monitor ICP or drain CSF can be inserted during surgery or at the bedside using aseptic technique. The patient is cared for in the intensive care unit (ICU), where expert nursing care and medical treatment are readily available.

Supportive Measures

Treatment also includes ventilatory support, seizure prevention, fluid and electrolyte maintenance, nutritional support, and management of pain and anxiety. Patients who are comatose are intubated and mechanically ventilated to ensure adequate oxygenation and protect the airway.

Because seizures can occur after head injury and can cause secondary brain damage from hypoxia, anticonvulsant agents may be given. If the patient is very agitated, benzodiazepines are the most commonly used sedative agents and do not affect cerebral blood flow or ICP. Lorazepam (Ativan) and midazolam (Versed) are frequently used but have active metabolites that may cause prolonged sedation, making it difficult to conduct a neurologic assessment. Propofol (Diprivan), a sedative–hypnotic agent that is supplied in an intralipid emulsion for intravenous (IV) use, is the sedative of choice. It is an ultra-short acting, rapid onset drug with elimination half-life of less than an hour. It has a major advantage of being titratable to its desired clinical effect but still provides the opportunity for an accurate neurologic assessment (Hickey, 2014). A nasogastric tube may be inserted, because reduced gastric motility and reverse peristalsis are associated with head injury, making regurgitation and aspiration common in the first few hours.

Brain Death

When a patient has sustained a severe head injury incompatible with life, the patient is a potential organ donor. The nurse may assist in the clinical examination for determination of brain death and in the process of organ procurement. The three cardinal signs of brain death on clinical examination are coma, the absence of brainstem reflexes, and apnea. Adjunctive tests, such as cerebral blood flow studies, electroencephalogram (EEG), transcranial Doppler, and brainstem auditory-evoked potential, are often used to confirm brain death (Hickey, 2014). The health care team provides information to the family and assists them with the decision-making process about end-of-life care.

NURSING PROCESS

The Patient with a Traumatic Brain Injury

Assessment

Depending on the patient's neurologic status, the nurse may elicit information from the patient, from the family, or from witnesses or emergency rescue personnel. Although all usual baseline data may not be collected initially, the immediate health history should include the following questions:

- When did the injury occur?
- What caused the injury? A high-velocity missile? An object striking the head? A fall?
- What was the direction and force of the blow?

A history of unconsciousness or amnesia after a head injury indicates a significant degree of brain damage, and changes that occur minutes to hours after the initial injury can reflect recovery or indicate the development of secondary brain damage. The nurse should determine if there was a loss of consciousness, the duration of the unconscious period, and if the patient could be aroused.

In addition to asking questions that establish the nature of the injury and the patient's condition immediately after the injury, the nurse examines the patient thoroughly. This assessment includes determining the patient's LOC using the Glasgow Coma Scale (GCS) and assessing the patient's response to tactile stimuli (if unconscious), pupillary response to light, corneal and gag reflexes, and motor function (Teasdale & Jennett, 1974). The GCS (see Chart 51-2) is based on the three criteria of eye opening, verbal responses, and motor responses to verbal commands or painful stimuli. It is particularly useful for monitoring changes during the acute phase, the first few days after a head injury. It does not take the place of an in-depth neurologic assessment.

Detailed assessments are made initially and at frequent intervals throughout the acute phase of care (Hickey, 2014). Monitoring of ICP is crucial to decision making for patients with neurologic injuries, yet research findings indicate that practices for the measurement of ICP vary widely (Olson, Rogers, & Stutzman, 2015) (see Chart 51-3). Baseline and ongoing assessments are critical in nursing assessment of the patient with brain injury, whose condition can worsen

Chart 51-2 ASSESSMENT

Glasgow Coma Scale

The Glasgow Coma Scale is a tool for assessing a patient's response to stimuli. Scores range from 3 (deep coma) to 15 (normal).

Eye-opening response	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Best motor response	Obeys command	6
	Localizes pain	5
	Withdraws	4
	Flexion	3
	Extension	2
	None	1
Total		3 to 15

Chart 51-3 NURSING RESEARCH PROFILE

Validating the Electronic Medical Record for Measuring Increased Intracranial Pressure

Olson, D. M., Rogers, M. S., & Stutzman, S. (2015). Electronic medical record validation: Exploring the reliability of intracranial pressure data abstracted from the electronic medical record-pilot. Journal of Nursing Measurement, 23(3), 532–540.

Purpose

The most reliable and valid methods of measuring and documenting intracranial pressure (ICP) monitoring for patients with neurologic injuries are not known. The purpose of this pilot study was to compare different methods of ICP monitoring.

Design

This was a nonrandomized, unblinded, observational study that compared three different technologies. The technologies for recording ICP included pen and paper (P&P), electronic medical record (EMR), and video data with continuous data acquisition (CDA).

Findings

Data were obtained from 11 patients who had ICP monitoring and 26 nurses who provided care to these patients. Patients' mean age was 50.7 years, 6 (54.4%) were female, and 8 (72.7%) were White (two Black, and one not declared). Patient diagnoses included subarachnoid hemorrhage (six), intracranial hemorrhage (two), neoplasm (two), and one patient with cerebral edema following ischemic stroke. Nurses were primarily baccalaureate prepared (*n* 22, 84.6%) with a mean of 8.3 (*SD* 9.8) years of nursing experience and 7.5 (*SD* 1.7) years of experience in critical care. ICP values did not significantly differ between EMR and P&P records, despite an average of 16 minutes' difference in reporting times. ICP values did vary significantly when comparing CDA data to EMR or paper.

Nursing Implications

This pilot study called into question the validity of ICP values as they are currently recorded. Nurses caring for patients with neurologic injuries need to know that significant practice variation exists and there are no best practice standards for recording ICP. With EMRs becoming pervasive, more nursing research is essential in this area.

dramatically and irrevocably if subtle signs are overlooked (Arciniegas, Zasler, Vanderploeg, et al., 2013); (Booker, 2015). More information on assessment is provided in the following sections and in Figure 51-4 and Table 51-1.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Ineffective airway clearance and impaired gas exchange related to brain injury
- Risk for ineffective cerebral tissue perfusion related to increased ICP, decreased CPP, and possible seizures
- Deficient fluid volume related to decreased LOC and hormonal dysfunction
- Imbalanced nutrition: less than body requirements related to increased metabolic demands, fluid restriction, and inadequate intake
- Risk for injury (self-directed and directed at others) related to seizures, disorientation, restlessness, or brain damage
- Risk for imbalanced body temperature related to damaged temperature-regulating mechanisms in the brain
- Risk for impaired skin integrity related to bed rest, hemiparesis, hemiplegia, immobility, or restlessness
- Ineffective coping related to brain injury
- Disturbed sleep pattern related to brain injury and frequent neurologic checks
- Risk for dysfunctional family processes related to unresponsiveness of patient, unpredictability of outcome, prolonged recovery period, and the patient's residual physical disability and emotional deficit
- Deficient knowledge about brain injury, recovery, and the rehabilitation process

The nursing diagnoses for the patient who is unconscious and the patient with increased ICP also apply (see Chapter 49).

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Decreased cerebral perfusion
- Cerebral edema and herniation
- Impaired oxygenation and ventilation
- Impaired fluid, electrolyte, and nutritional balance
- Risk of posttraumatic seizures

Planning and Goals

The goals for the patient may include maintenance of a patent airway, adequate CPP, fluid and electrolyte balance, adequate nutritional status, prevention of secondary injury, maintenance of body temperature within normal limits, maintenance of skin integrity, improvement of coping, prevention of sleep deprivation, effective family coping, increased knowledge about the rehabilitation process, and absence of complications.

Nursing Interventions

The nursing interventions for the patient with a TBI are extensive and diverse. They include making nursing assessments, setting priorities for nursing interventions, anticipating needs and complications, and initiating rehabilitation.

Maintaining the Airway

One of the most important nursing goals in the management of head injury is to establish and maintain an adequate airway. The brain is extremely sensitive to hypoxia, and a neurologic deficit can worsen if the patient is hypoxic. Therapy is directed toward maintaining optimal oxygenation to preserve cerebral function. An obstructed airway causes carbon dioxide retention and hypoventilation, which can produce cerebral vessel dilation and increased ICP (McNett & Olson, 2013); (Mitchell, Kirkness, & Blissitt, 2015).

Interventions to ensure an adequate exchange of air are discussed in Chapter 49 and include the following:

- Maintaining the patient who is unconscious in a position that facilitates drainage of oral secretions, with the head of the bed elevated about 30 degrees to decrease intracranial venous pressure
- Establishing effective suctioning procedures (pulmonary secretions produce coughing and straining, which increase ICP)
- Guarding against aspiration and respiratory insufficiency

Figure 51-4 • Assessment parameters for the patient with a head injury include eye opening and responsiveness (**A**), vital signs (**B**), and motor response reflected in hand strength or response to painful stimulus (**C**, **D**). Photos by B. Proud.

TABLE 51-1 Multisystem Assessment Measures for the Patient with Traumatic Brain Injury

System-Specific Considerations	Assessment Data
Neurologic System	
• Severe TBI results in unconsciousness and alters many neurologic functions. • All body functions must be supported. • Increased ICP and herniation syndromes are life threatening. • Measures are instituted to control elevated ICP.	• Assessment of neurologic status • Assessment for signs and symptoms of ICP elevation • Calculation of cerebral perfusion pressure if ICP monitor is in place • Monitoring of anticonvulsant medication blood levels
Integumentary System (Skin and Mucous Membranes)	
• Immobility secondary to TBI and unconsciousness contributes to the development of pressure areas and skin breakdown. • Intubation causes irritation of the mucous membrane and deterioration of oral health.	• Assessment of skin integrity and character of the skin • Assessment of oral mucous membrane and oral health
Musculoskeletal System	
• Immobility contributes to musculoskeletal changes. • Decerebrate or decorticate posturing makes proper positioning difficult.	• Assessment of range of motion of joints and development of deformities or spasticity
Gastrointestinal System	
• Injury to the GI tract can result in paralytic ileus. • Constipation can result from bed rest, NPO status, fluid restriction, and opioids given for pain control. • Bowel incontinence is related to the patient's unconscious state or altered mental state.	• Assessment of abdomen for bowel sounds and distention • Monitoring for decreased hemoglobin
Genitourinary System	
• Fluid restriction or the use of diuretic agents can alter the amount of urinary output. • Urinary incontinence is related to the patient's unconscious state.	• Intake and output record

(*Continued*)

(*Continued*)

Metabolic (Nutritional) System	
• The patient receives all fluids IV for the first few days until the GI tract is functioning. • A nutritional consultation is initiated within the first 24–48 hours; parenteral or enteral nutrition may be started.	• Assessment of fluid and electrolyte balance • Recording of weight, if possible • Hematocrit • Electrolyte studies
Respiratory System	
• Complete or partial airway obstruction will compromise the oxygen supply to the brain. • An altered respiratory pattern can result in cerebral hypoxia. • A short period of apnea at the moment of impact can result in spotty atelectasis. • Systemic disturbances from head injury can cause hypoxemia. • Brain injury can alter brainstem respiratory function. • Shunting of blood to the lungs as a result of a sympathetic discharge at the time of injury can cause neurogenic pulmonary edema.	• Assessment of respiratory function: – Auscultate chest for breath sounds – Note the respiratory pattern, if possible (not possible if a ventilator is being used) – Note the respiratory rate – Note whether the cough reflex is intact • Arterial blood gas levels • Complete blood count • Chest x-ray studies • Sputum cultures • Oxygen saturation using pulse oximetry
Cardiovascular System	
• The patient may develop cardiac dysrhythmias, tachycardia, or bradycardia. • The patient may develop hypotension or hypertension. • Because of immobility and unconsciousness, the patient is at high risk for DVT and PE. • Fluid and electrolyte imbalance can be related to several problems, including alterations in antidiuretic hormone secretion, the stress response, or fluid restriction. • Specific conditions may occur: – Diabetes insipidus – Syndrome of inappropriate secretion of antidiuretic hormone – Electrolyte imbalance – Hyperglycemic hyperosmolar syndrome	• Assessment of vital signs • Monitoring for cardiac dysrhythmias • Assessment for venous thromboembolism including PE and DVT • Electrocardiogram • Electrolyte studies • Blood coagulation studies • Blood glucose level • Blood acetone level • Blood osmolality • Urine-specific gravity
Psychological/Emotional Response	
• The patient with TBI is unconscious. • The family needs emotional support to deal with the crisis.	• Alternative methods of assessment for pain are indicated in the patient who is unconscious (see Chapter 48, Chart 48-2) • Collection of information about the family and the role within the family of the person with head injury • Assessment of the family to determine how functional it was before the injury occurred

DVT, deep vein thrombosis; GI, gastrointestinal; ICP, intracranial pressure; IV, intravenous; NPO, nothing by mouth; PE, pulmonary embolism; TBI, traumatic brain injury.
Adapted from Booker, K. (2015). Critical care nursing: Monitoring and treatment for advanced nursing practice. Oxford: Wiley Blackwell.

- Closely monitoring arterial blood gas values to assess the adequacy of ventilation. The goal is to keep blood gas values within normal limits to ensure adequate cerebral blood flow.
- Monitoring the patient who is receiving mechanical ventilation for pulmonary complications such as acute respiratory distress syndrome and pneumonia (Hickey, 2014)

The patient who is intubated is at high risk for ventilator-associated pneumonia, and providing good oral hygiene can help prevent this complication (Larrow & Klich-Heartt, 2016).

Monitoring Neurologic Function

Patients with severe TBI are admitted to the ICU for close assessment and monitoring (cardiac monitoring, pulse oximetry, invasive arterial blood pressure monitoring, end-tidal CO_2, and temperature monitoring). Parameters are assessed initially and as frequently as the patient's condition requires. As soon as the initial assessment is made, the use of a neurologic observational flow record is started and maintained.

The importance of ongoing assessment and monitoring of the patient with brain injury cannot be overstated.

Level of Consciousness. The GCS is used to assess LOC at regular intervals, because changes in the LOC precede all other changes in vital and neurologic signs. The patient's best responses to predetermined stimuli are recorded (see Chart 51-2). Each response is scored (the greater the number, the better the functioning), and the sum of these scores gives an indication of the severity of coma and a prediction of possible outcome. The lowest score is 3 (least responsive); the highest is 15 (most responsive). A GCS score between 3 and 8 is generally accepted as indicating a severe head injury (Bader et al., 2016).

Nursing Alert: The GCS is considered the most sensitive indicator of a lapse in neurologic functioning in patients with TBI and is often the earliest sign of acute change in ICP.

Vital Signs. Although a change in LOC is the most sensitive neurologic indication of deterioration of the patient's condition, vital signs also are monitored at frequent intervals to assess the intracranial status. Table 51-1 depicts the general assessment parameters for the patient with a head injury.

Signs of increasing ICP include slowing of the heart rate (bradycardia), increasing systolic blood pressure, and widening

pulse pressure (Cushing reflex). As brain compression increases, respirations become rapid, the blood pressure may decrease, and the pulse slows further. This is an ominous development, as is a rapid fluctuation of vital signs (Hickey, 2014). The temperature is maintained at less than 38°C (100.4°F) (Perez-Barcena, Llompart-Pou, & O'Phelan, 2014). Tachycardia and arterial hypotension may indicate that bleeding is occurring elsewhere in the body.

Nursing Alert: In a patient with a head injury, a rapid increase in body temperature is regarded as unfavorable because hyperthermia increases the metabolic demands of the brain and may indicate brainstem damage—a poor prognostic sign.

Motor Function. Motor function is assessed frequently by observing spontaneous movements, asking the patient to raise and lower the extremities, and comparing the strength and equality of the upper and lower extremities at periodic intervals. To assess upper extremity strength, the nurse instructs the patient to squeeze the examiner's fingers tightly. The nurse assesses lower extremity motor strength by placing the hands on the soles of the patient's feet and asking the patient to push down against the examiner's hands. Examination of the motor system is discussed in more detail in Chapter 48. The presence or absence of spontaneous movement of each extremity is also noted, and speech and eye signs are assessed.

If the patient does not demonstrate spontaneous movement, responses to painful stimuli are assessed (Hickey, 2014). Motor response to pain is assessed by applying a central stimulus, such as pinching the pectoralis major muscle, to determine the patient's best response. Peripheral stimulation may provide inaccurate assessment data because it may result in a reflex movement rather than a voluntary motor response. Abnormal responses (lack of motor response; extension responses) are associated with a poorer prognosis.

Other Neurologic Signs. In addition to the patient's spontaneous eye opening, which is evaluated with the GCS, the size and equality of the pupils and their reaction to light are assessed (Booker, 2015). A unilaterally dilated and poorly responding pupil may indicate a developing hematoma, with subsequent pressure on the third cranial nerve due to shifting of the brain. If both pupils become fixed and dilated, this indicates acute injury and intrinsic damage to the upper brainstem and is a poor prognostic sign (Bader et al., 2016).

The patient with a head injury may develop deficits such as anosmia (lack of sense of smell), eye movement abnormalities, aphasia, memory deficits, and posttraumatic seizures or epilepsy. Patients may be left with residual psychological deficits (impulsiveness; emotional lability; or uninhibited, aggressive behaviors) and, as a consequence of the impairment, may lack insight into their emotional responses.

Monitoring Fluid and Electrolyte Balance

Brain damage can produce metabolic and hormonal dysfunctions. The monitoring of serum electrolyte levels is important, especially in patients receiving osmotic diuretics, those with syndrome of inappropriate antidiuretic hormone (SIADH) secretion, and those with posttraumatic diabetes insipidus.

Serial studies of blood and urine electrolytes and osmolality are carried out because head injuries may be accompanied by disorders of sodium regulation. Hyponatremia is common after head injury due to shifts in extracellular fluid, electrolytes, and volume. Hyperglycemia, for example, can cause an increase in extracellular fluid that lowers sodium. Hypernatremia may also occur as a result of sodium retention that may last several days, followed by sodium diuresis. Increasing lethargy, confusion, and seizures may be the result of electrolyte imbalance.

Endocrine function is evaluated by monitoring serum electrolytes, blood glucose values, and intake and output. Urine is tested regularly for acetone. A record of daily weights is maintained, especially if the patient has hypothalamic involvement and is at risk for the development of diabetes insipidus.

Promoting Adequate Nutrition

Head injury results in metabolic changes that increase calorie consumption and nitrogen excretion. Protein demand increases. Early initiation of nutritional therapy has been shown to improve outcomes in patients with head injury. Patients with brain injury are assumed to be catabolic, and nutritional support consultation should be considered as soon as the patient is admitted. Parenteral nutrition via a central line or enteral feedings given via a nasogastric or nasojejunal feeding tube should be considered, though enteral is the preferred route (Hickey, 2014). If CSF rhinorrhea occurs or if there is any suspicion of disruption to the skull base, an oral feeding tube should be inserted instead of a nasal tube.

Laboratory values should be monitored closely in patients receiving parenteral nutrition. Elevating the head of the bed can help prevent distention, regurgitation, and aspiration. A continuous-drip infusion or pump may be used to regulate the feeding. Enteral or parenteral feedings are usually continued until the swallowing reflex returns and the patient can meet caloric requirements orally. See Chapter 15 for the principles and technique of enteral feedings.

Preventing Injury

Often, as the patient emerges from coma, a period of lethargy and stupor is followed by a period of agitation. Each phase is variable and depends on the person, the location of the injury, the depth and duration of coma, and the patient's age. Restlessness may be caused by hypoxia, fever, pain, or a full bladder. It may indicate injury to the brain but may also be a sign that the patient is regaining consciousness. (Some restlessness may be beneficial because the lungs and extremities are exercised.) Agitation may also be the result of discomfort from catheters, IV lines, restraints, and repeated neurologic checks. Alternatives to restraints must be used whenever possible.

Strategies to prevent injury include the following:

- Assessing the patient to ensure that oxygenation is adequate and the bladder is not distended. Dressings and casts are checked for constriction
- Using padded side rails or wrapping the patient's hands in mitts to protect the patient from self-injury and dislodging of tubes. Restraints are used judiciously, because straining against them can increase ICP or cause other injury. Enclosed or floor-level specialty beds may be indicated (see Chart 51-4)
- Avoiding opioids as a means of controlling restlessness, because they depress respiration, constrict the pupils, and alter responsiveness
- Reducing environmental stimuli by keeping the room quiet, limiting visitors, speaking calmly, and providing frequent orientation information (e.g., explaining where the patient is and what is being done)

Chart 51-4 ETHICAL DILEMMA

When is it Appropriate to Use Restraints?

Case Scenario

You work as a staff nurse on a rehabilitation unit. A 23-year-old man is admitted to the unit with a brain injury, which occurred as a result of a motorcycle crash. His severe brain injuries caused cerebral hypoxia and ischemia to occur. He has periods of severe agitation, has fallen out of bed twice, and an enclosed bed has been prescribed for his safety.

Discussion

Nurses must weigh carefully the risks of limiting autonomy and increasing the risks of injury by using restraints against the risks of injury if not using restraints, which have been documented as resulting in physical harm and death.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have pre-eminence when a treatment plan is devised for this patient?
- What are your professional obligations in this case? What steps might you take to ensure that the patient's autonomy is preserved?

Resources

See Chapter 2, Chart 2-6 for ethics resources.

- Providing adequate lighting to prevent visual hallucinations
- Minimizing disruption of the patient's sleep–wake cycles
- Lubricating the patient's skin with oil or emollient lotion to prevent irritation due to rubbing against the sheet
- Using an external sheath catheter for a male patient if incontinence occurs. Because prolonged use of an indwelling catheter inevitably produces infection, the patient may be placed on an intermittent catheterization schedule.

Maintaining Body Temperature

Fever in the patient with a TBI can be the result of damage to the hypothalamus, cerebral irritation from hemorrhage, or infection. The nurse monitors the patient's temperature every 2 to 4 hours. If the temperature increases, efforts are made to identify the cause and to control it using acetaminophen/paracetamol and cooling devices to maintain normothermia (Madden & DeVon, 2015); (Wilson & DellaPenna, 2015). Cooling devices should be used with caution so as not to induce shivering, which increases ICP. If infection is suspected, potential sites of infection are cultured and antibiotic agents are prescribed and given. Research about intentional hypothermia for patients with TBI suggests there is no clear evidence to guide therapy (Madden & DeVon, 2015); (Wilson & DellaPenna, 2015).

Maintaining Skin Integrity

Patients with TBI often require assistance in turning and positioning because of immobility or unconsciousness. Prolonged pressure on the tissues decreases circulation and leads to tissue necrosis. Potential areas of breakdown need to be identified early to avoid the development of pressure ulcers. Specific nursing measures include the following:

- Assessing all body surfaces and documenting skin integrity every 8 hours
- Turning and repositioning the patient every 2 hours (Larrow & Klich-Heartt, 2016)
- Providing skin care every 4 hours
- Assisting the patient to get out of bed to a chair three times a day

Improving Coping

Although many patients with head injury survive because of resuscitative and supportive technology, they frequently have ineffective coping due to cognitive sequelae. Cognitive impairment includes memory deficits; decreased ability to focus and sustain attention to a task (distractibility); impulsivity; egocentricity; and slowness in thinking, perceiving, communicating, reading, and writing. Psychiatric, emotional, and relationship problems develop in many patients after head injury. Resulting psychosocial, behavioral, emotional, and cognitive impairments are devastating to the family as well as to the patient (Tam, McKay, Sloan, et al., 2015).

These problems require collaboration among many disciplines. A neuropsychologist (specialist in evaluating and treating cognitive problems) plans a program and initiates therapy or counseling to help the patient reach maximal potential. Cognitive rehabilitation activities help the patient devise new problem-solving strategies. The retraining is carried out over an extended period and may include the use of sensory stimulation and reinforcement, behavior modification, reality orientation, computer training programs, and video games. Assistance from many disciplines is necessary during this phase of recovery. Even if intellectual ability does not improve, social and behavioral abilities may improve.

The patient recovering from a TBI may experience fluctuations in the level of cognitive function, with orientation, attention, and memory frequently affected. Many types of sensory stimulation programs have been tried, and research on these programs is ongoing (Hickey, 2014). When pushed to a level greater than the impaired cortical functioning allows, the patient may show symptoms of fatigue, anger, and stress (headache, dizziness). The Rancho Los Amigos Scale: Levels of Cognitive Functioning is frequently used to assess cognitive function and evaluate ongoing recovery from head injury. Progress through the levels of cognitive function can vary widely for individual patients (Hagen, Malkmus, & Durham, 1972). Nursing management and a description of each level are included in Table 51-2.

Preventing Sleep Pattern Disturbance

Patients who require frequent monitoring of neurologic status may experience sleep deprivation as they are awakened hourly for assessment of LOC. To allow the patient longer times of uninterrupted sleep and rest, the nurse can group nursing care activities so that the patient is disturbed less frequently. Environmental noise is decreased, and the room lights are dimmed. Measures to increase comfort may promote sleep and rest (Giusti, Tuteri, & Mirella, 2016).

Supporting Family Coping

Having a loved one sustain a TBI produces a great deal of stress in the family. This stress can result from the patient's physical and emotional deficits, the unpredictable outcome, and altered

TABLE 51-2 Rancho Los Amigos Scale: Levels of Cognitive Function

Cognitive Level	Description	Nursing Management
For levels I–III, the key approach is to *provide stimulation.*		
I: No response	Completely unresponsive to all stimuli, including painful stimuli	Multiple modalities of sensory input should be used. Examples are listed here, but management should be individualized and expanded based on available materials and patient preferences (determined by obtaining information from the family).
II: Generalized response	Nonpurposeful response; responds to pain but in a nonpurposeful manner	*Olfactory*: Perfumes, flowers, shaving lotion. *Visual*: Family pictures, card, personal items.
III: Localized response	Responses more focused—withdraws to pain; turns toward sound; follows moving objects that pass within visual field; pulls on sources of discomfort (e.g., tubes, restraints); may follow simple commands but inconsistently and in a delayed manner	*Auditory*: Radio, television, tapes of family voices or favorite recordings, talking to patient (nurse, family members). The nurse should tell patient what is going to be done, discuss the environment, provide encouragement. *Tactile*: Touching of skin, rubbing various textures on skin *Movement*: Range-of-motion exercises, turning, repositioning, the use of water mattress.
For levels IV–VI, the key approach is to *provide structure.*		
IV: Confused, agitated response	Alert, hyperactive state in which patient responds to internal confusion/agitation; behavior nonpurposeful in relation to the environment; aggressive, bizarre behavior common	For level IV, which lasts 2–4 weeks, interventions are directed at decreasing agitation, increasing environmental awareness, and promoting safety. • Approach patient in a calm manner, and use a soft voice. • Screen patient from environmental stimuli (e.g., sounds, sights); provide a quiet, controlled environment. • Remove devices that contribute to agitation (e.g., tubes), if possible. • Functional goals cannot be set because the patient is unable to cooperate.
V: Confused, inappropriate response	When agitation occurs, it is the result of external rather than internal stimuli; focused attention is difficult; memory is severely impaired; responses are fragmented and inappropriate to the situation; there is no carryover of learning from one situation to the other	For levels V and VI, interventions are directed at decreasing confusion, improving cognitive function, and improving independence in performing ADLs. • Provide supervision. • Use repetition and cues to educate about ADLs. Focus the patient's attention, and help to increase their concentration. • Help the patient organize activity. • Clarify misinformation and reorient when confused. • Provide a consistent, predictable schedule (e.g., post daily schedule on large poster board).
VI: Confused, appropriate response	Follows simple directions consistently but is inconsistently oriented to time and place; short-term memory worse than long-term memory; can perform some ADLs	
For levels VII–X, the key approach is *integration into the community.*		
VII: Automatic, appropriate response	Appropriately responsive and oriented within the hospital setting; needs little supervision in ADLs; some carryover of learning; patient has superficial insight into disabilities; has decreased judgment and problem-solving abilities; lacks realistic planning for future	For levels VII–X, interventions are directed at increasing the patient's ability to function with minimal or no supervision in the community. • Reduce environmental structure. • Help the patient plan for adapting ADLs for self into the home environment. • Discuss and adapt home-living skills (e.g., cleaning, cooking) to patient's ability. • Provide standby assistance, as needed, for ADLs and home-living skills.
VIII: Purposeful, appropriate	Alert, oriented, intact memory; has realistic goals for the future. Able to complete familiar tasks for 1 hour in a distracting environment; overestimates or underestimates abilities, argumentative, easily frustrated, self-centered; uncharacteristically dependent/independent	
IX: Purposeful, appropriate	Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours; uses assistive memory devices to recall schedule and activities; aware of and acknowledges impairments and disabilities when they interfere with task completion; depression may continue; may be easily irritable and have a low frustration tolerance	• Provide assistance on request for adapting ADLs and home-living skills.

(*Continued*)

(*Continued*)

X: Purposeful, appropriate	Able to handle multiple tasks simultaneously in all environments but may require periodic breaks; independently initiates and carries out familiar and unfamiliar tasks but may require more than usual amount of time and/or compensatory strategies to complete them; accurately estimates abilities and independently adjusts to task demands; periodic periods of depression may occur; irritability and low frustration tolerance when sick, fatigued, and/or under stress	• Monitor for signs and symptoms of depression. • Help the patient plan, anticipate concerns, and solve problems.

ADLs, activities of daily living.

Adapted from Los Amigos Research and Education Institute, Inc., Downey, CA, 2002. Used with permission.

family relationships. Families report difficulties in coping with changes in the patient's temperament, behavior, and personality (Tam et al., 2015). Such changes are associated with disruption in family cohesion, loss of leisure pursuits, and loss of work capacity, as well as social isolation of the caretaker. The family may experience marital disruption, anger, grief, guilt, and denial in recurring cycles.

To promote effective coping, the nurse can ask the family how the patient is different now, what has been lost, and what is most difficult about coping with this situation. Helpful interventions include providing family members with accurate and honest information and encouraging them to continue to set well-defined short-term goals. Family counseling helps address the family members' acute feelings of loss and helplessness and gives them guidance for the management of inappropriate behaviors. Support groups help the family members share problems, develop insight, gain information, network, and gain assistance in maintaining realistic expectations, hope, and a good quality of life (Tam et al., 2015).

Many patients with severe head injury die of their injuries, and many of those who survive experience long-term disabilities that prevent them from resuming their previous roles and functions. During the most acute phase of injury, family members need factual information and support from the health care team.

Many patients with severe head injuries that result in brain death are young and otherwise healthy and are therefore considered for organ donation. Family members of patients with such injuries need support during this extremely stressful time and assistance in making decisions to end life support and permit donation of organs. They need to know that the patient who is brain dead and whose respiratory and cardiovascular systems are maintained through life support is not going to survive and that the severe head injury, not the removal of the patient's organs or the removal of life support, is the cause of the patient's death. Bereavement counselors and members of the organ procurement team are often very helpful to family members in making decisions about organ donation and in helping them cope with stress.

Monitoring and Managing Potential Complications

Decreased Cerebral Perfusion Pressure. Maintenance of adequate CPP is important to prevent serious complications of head injury due to decreased cerebral perfusion. Adequate CPP is greater than 50 mm Hg. If CPP falls below a patient's threshold, a vasodilating cascade occurs, causing the volume of blood to increase inside the brain, which causes ICP to increase. Measures to maintain adequate CPP are essential because a decrease in CPP can impair cerebral perfusion and cause brain hypoxia and ischemia, leading to permanent brain damage. Once the threshold CPP is reached, vasoconstriction of the cerebral blood vessels occurs, causing ICP to decrease. Therapy (e.g., elevation of the head of the bed, increased IV fluids, CSF drainage) is directed toward decreasing cerebral edema and increasing venous outflow from the brain. Systemic hypotension, which causes vasoconstriction and a significant decrease in CPP, is treated with increased IV fluids or vasopressors (Griesdale, Ortenwall, Norena, et al., 2015); (Perez-Barcena et al., 2014).

Cerebral Edema and Herniation. The patient with a head injury is at risk for additional complications such as increased ICP and brainstem herniation. Cerebral edema is the most common cause of increased ICP in the patient with a head injury, with the swelling peaking approximately 48 to 72 hours after injury. Bleeding also may increase the volume of contents within the rigid, closed compartment of the skull, causing increased ICP and herniation of the brainstem and resulting in irreversible brain anoxia and brain death (Hickey, 2014); (Perez-Barcena et al., 2014). Measures to control ICP are listed in Chart 51-5 and discussed in Chapter 49.

Impaired Oxygenation and Ventilation. Impaired oxygen and ventilation may require mechanical ventilatory support. The patient must be monitored for a patent airway, altered breathing patterns, and hypoxemia and pneumonia. Interventions may include endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure. See Chapters 11 and 49 for a detailed discussion of these topics.

Impaired Fluid, Electrolyte, and Nutritional Balance. Fluid, electrolyte, and nutritional imbalances are common in the patient with a head injury. Common imbalances include hyponatremia,

Chart 51-5

Controlling ICP in Patients with Severe Brain Injury

- Elevate the head of the bed as prescribed.
- Maintain the patient's head and neck in neutral alignment (no twisting or flexing the neck).
- Initiate measures to prevent the Valsalva maneuver (e.g., stool softeners).
- Maintain body temperature within normal limits.
- Administer oxygen (O_2) to maintain partial pressure of arterial oxygen (PaO_2) >90 mm Hg.
- Maintain fluid balance with normal saline solution.
- Avoid noxious stimuli (e.g., excessive suctioning, painful procedures).
- Administer sedation to reduce agitation.
- Maintain cerebral perfusion pressure of 50–70 mm Hg.

Adapted from Bader, M. K., Littlejohns, L. R., & Olson, D. (2016). AANN core curriculum for neuroscience nursing. (6th ed). Chicago, IL: American Association of Neuroscience Nurses.

which is often associated with SIADH (see Chapters 7 and 32), hypokalemia, and hyperglycemia. Modifications in fluid intake with tube feedings or IV fluids, including hypertonic saline, may be necessary to treat these imbalances (Hickey, 2014). Insulin administration may be prescribed to treat hyperglycemia; blood glucose levels are maintained between 80 and 160 mg/dL (Perez-Barcena et al., 2014).

Undernutrition is also a common problem in response to the increased metabolic needs associated with severe head injury. Decisions about early feeding should be individualized; options include IV hyperalimentation or placement of a feeding tube (jejunal or gastric). Caloric expenditure can increase up to 120% to 140% with TBI, requiring close monitoring of nutritional status, with a higher concentration of protein if tolerated (Horn, Kinikini, Moore, et al., 2015).

Posttraumatic Seizures. Patients with head injury are at an increased risk for posttraumatic seizures. Posttraumatic seizures are classified as immediate (within 24 hours after injury), early (within 1 to 7 days after injury), or late (more than 7 days after injury) (Hickey, 2014). Seizure prophylaxis is the practice of administering anticonvulsant medications to patients with head injury to prevent seizures. It is important to prevent posttraumatic seizures, especially in the immediate and early phases of recovery, because seizures may increase ICP and decrease oxygenation (Zaman, Dubiel, Driver, et al., 2017). However, many anticonvulsant medications impair cognitive performance and can prolong the duration of rehabilitation. Therefore, the overall benefits of these medications must be weighed against their side effects. Research evidence supports the use of prophylactic anticonvulsant agents to prevent immediate and early seizures after head injury, but not for prevention of late seizures (Hickey, 2014); (Zaman et al., 2017). See Chapter 49 for the nursing management of seizures.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Education early in the course of head injury often focuses on reinforcing information given to the family about the patient's condition and prognosis. As the patient's status and expected outcome change over time, family education may focus on interpretation and explanation of changes in the patient's physical and psychological responses.

Once the patient's physical status allows discharge to home, a rehabilitation center, or a subacute care facility, the patient and family are educated about limitations that can be expected and complications that may occur. The nurse explains to the patient and family, verbally and in writing, how to monitor for complications that merit contacting the primary provider. Depending on the patient's prognosis and physical and cognitive status, the patient may be included in education about self-care management strategies.

If the patient is at risk for late posttraumatic seizures, anticonvulsant medications may be prescribed at discharge. The patient and family require education about the side effects of these medications and the importance of continuing to take them as prescribed.

Continuing and Transitional Care. The rehabilitation phase of care for the patient with a TBI begins at hospital admission. Admission to the rehabilitation unit is a milestone in a patient's recovery and requires intense work by the patient to complete the daily schedule of therapies. The goals of rehabilitation are to maximize the patient's ability to return to their highest level of functioning and to their home and the community, address concerns before discharge for a smooth transition to home or rehabilitation, and promote independence with adaptation to deficits. The patient is encouraged to continue the rehabilitation program after discharge, because improvement in status may continue 3 or more years after injury. Changes in the patient with a TBI and the effects of long-term rehabilitation on the family and their coping abilities need ongoing assessment. Continued education and support of the patient and family are essential as their needs and the patient's status change. Education to address with the family of the patient who is about to return home is described in Chart 51-6.

Depending on status, the patient is encouraged to return to usual activities gradually. During the acute and rehabilitation phases of care, the focus of education is on obvious needs, issues, deficits, and complications. Complications after TBI include infections (e.g., pneumonia, urinary tract infection [UTI], sepsis, wound infection, osteomyelitis, meningitis,

Chart 51-6 HOME CARE CHECKLIST

The Patient with a TBI

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of TBI and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., ADLs, IADLs, activity) necessary for recovery and health maintenance, as applicable.
  - Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation.
  - Demonstrate safe techniques for eating, feeding patient, or assisting patient with eating.
  - Identify need for close monitoring of behavior due to changes in cognitive functioning.
  - Describe strategies for reinforcing positive behaviors.
  - Describe household modifications needed to ensure safe environment for the patient.
- Explain the need for monitoring for changes in neurologic status and for complications.
- Identify changes in neurologic status and signs and symptoms of complications (e.g., pneumonia, urinary tract infection, meningitis) that should be reported to the neurosurgeon or nurse.
- Relate how to reach primary provider with questions or complications.
- State importance of continuing follow-up by health care team.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, brain injury support groups, caregiver support).
- Identify the need for health-promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living; TBI, traumatic brain injury.

ventriculitis, brain abscess) and heterotopic ossification (painful bone overgrowth in weight-bearing joints).

The nurse needs to remind the patient and family of the need for continuing health promotion and screening practices after the initial phase of care. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

Evaluation

Expected patient outcomes may include:

1. Attains or maintains effective airway clearance, ventilation, and brain oxygenation
   a. Achieves blood gas values within normal limits and has breath sounds clear on auscultation
   b. Mobilizes and clears secretions
2. Achieves satisfactory fluid and electrolyte balance
   a. Demonstrates serum electrolytes within normal limits
   b. Has no clinical signs of dehydration or overhydration
3. Attains adequate nutritional status
   a. Is free of gastric distention and vomiting
   b. Shows minimal weight loss
4. Avoids injury
   a. Shows lessening agitation and restlessness
   b. Is oriented to person, place, and time
5. Maintains body temperature within normal limits
   a. Absence of fever
   b. Absence of hypothermia
6. Demonstrates intact skin integrity
   a. Exhibits no redness or breaks in skin integrity
   b. Exhibits no pressure ulcers
7. Shows improvement in coping
8. Demonstrates usual sleep–wake cycle
9. Family demonstrates adaptive family processes
   a. Joins support group
   b. Shares feelings with appropriate health care personnel
   c. Makes end-of-life decisions, if needed
10. Demonstrates absence of complications
    a. Demonstrates ICP within normal limits
    b. Exhibits vital signs and body temperature within normal limits and increases orientation to person, place, and time
11. Experiences no posttraumatic seizures
    a. Takes anticonvulsant medications as prescribed
    b. Identifies side effects/adverse effects of anticonvulsant medications
12. Participates in rehabilitation process as indicated for patient and family members
    a. Takes active role in identifying rehabilitation goals and participating in recommended patient care activities
    b. Prepares for discharge

Spinal Cord Injury

Spinal cord injury (SCI), an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral discs caused by trauma is a major health disorder. Incidence rates of spinal cord injury range from 12.06 to 61.6 per million, and the average age of SCI is 26.8 to 56.6 years old in Asian countries (Ning, Wu, Li, & Feng, 2012), whereas in India, the age group of 20–49 years is most affected by SCI (Mathur et al., 2015). Furthermore, men are at higher risk than women (Ning et al., 2012; Singh, Sharma, Mittal, & Sharma, 2003). Major causes of SCI are motor vehicle accidents (59.5%) and fall injury (37.8%). In India, the major cause of SCI is fall injury followed by motor vehicle accidents (Chacko, Joseph, Mohanty, & Jacob, 1986; Mathur et al., 2015; Singh et al., 2003). Though tremendous advances have improved the life expectancy of patients with SCI, it still remains lower than that of the general population, particularly during the first year postinjury, as well as for patients who sustain severe SCI (NSCISC, 2016).

The predominant risk factors for SCI include younger age, male gender, and alcohol and drug use (Bader et al., 2016). The frequency with which these risk factors are associated with SCI serves to emphasize the importance of primary prevention. The same interventions suggested earlier in this chapter for head injury prevention help decrease the incidence of SCI (see Chart 51-1). Life expectancy continues to increase for people with SCI because of improved health care but remains slightly lower than for those without SCI. The major causes of death are pneumonia, pulmonary embolism (PE), and sepsis (Hickey, 2014).

Paraplegia (paralysis of the lower body) and tetraplegia (paralysis of all four extremities; formerly called *quadriplegia*) can occur, with incomplete tetraplegia being the most frequently occurring injury, followed by complete paraplegia, complete tetraplegia, and incomplete paraplegia.

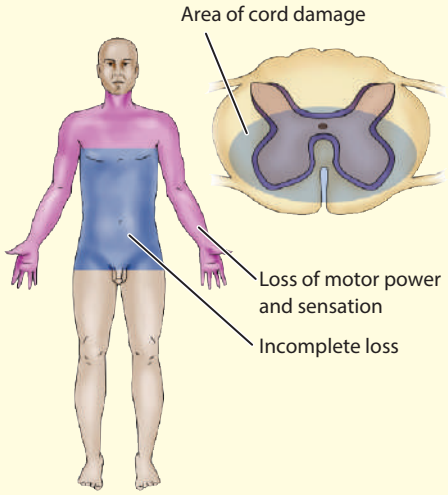
Pathophysiology

Damage in SCI ranges from transient concussion (from which the patient fully recovers) to contusion, laceration, and compression of the spinal cord tissue (either alone or in combination), to complete transection (severing) of the spinal cord (which renders the patient paralyzed below the level of the injury). The vertebrae most frequently involved are the 5th, 6th, and 7th cervical vertebrae (C5–C7), the 12th thoracic vertebra (T12), and the 1st lumbar vertebra (L1). These vertebrae are most susceptible because there is a greater range of mobility in the vertebral column in these areas (Hickey, 2014).

SCIs can be separated into two categories: primary injuries and secondary injuries. Primary injuries are the result of the initial insult or trauma and are usually permanent. Secondary injuries resulting from SCI include edema and hemorrhage (Bader et al., 2016); (Mohit, 2016). The secondary injury is a major concern for critical care nurses. Early treatment is essential to prevent partial damage from becoming total and permanent.

Clinical Manifestations

Manifestations of SCI depend on the type and level of injury (see Chart 51-7). The type of injury refers to the extent of injury to the spinal cord itself. A complete spinal cord lesion signifies loss of both sensory and voluntary motor communication from the brain to the periphery, resulting in paraplegia or tetraplegia (Bader et al., 2016). Incomplete spinal cord lesion denotes that the ability of the spinal cord to relay messages to and from the brain is not completely absent. Sensory and/or motor fibers are preserved below the lesion. Injuries are classified according to the area of spinal cord damage: central, lateral, anterior, or peripheral (see Chart 51-7).

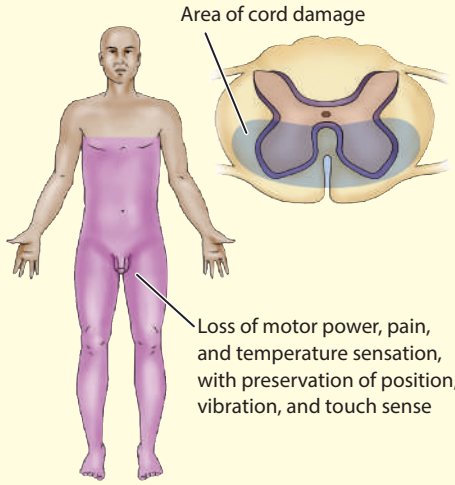


The American Spinal Injury Association (ASIA) provides classification of SCI according to the degree of sensory and motor function present after injury (see Fig. 51-5; (ASIA, 2016)).

Chart 51-7

Effects of Spinal Cord Injuries

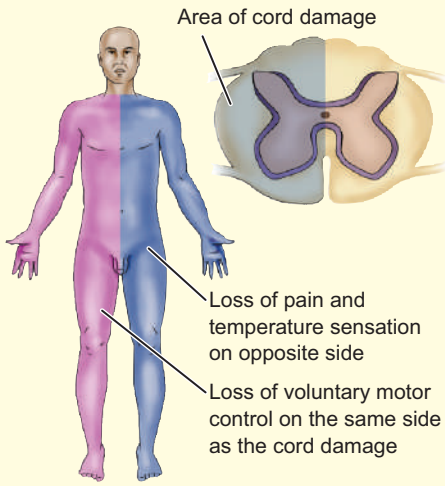
Central Cord Syndrome



- *Characteristics*: Motor deficits (in the upper extremities compared to the lower extremities; sensory loss varies but is more pronounced in the upper extremities); bowel/bladder dysfunction is variable, or function may be completely preserved.
- *Cause*: Injury or edema of the central cord, usually of the cervical area. May be caused by hyperextension injuries.

Central cord syndrome

Anterior Cord Syndrome



- *Characteristics*: Loss of pain and temperature sensation and motor function is noted below the level of the lesion; light touch, position, and vibration sensation remain intact.
- *Cause:* The syndrome may be caused by acute disc herniation or hyperflexion injuries associated with fracture/dislocation of vertebra. It also may occur as a result of injury to the anterior spinal artery, which supplies the anterior two thirds of the spinal cord.

Anterior cord syndrome

Lateral Cord Syndrome (Brown–Séquard Syndrome)

- *Characteristics*: Ipsilateral paralysis or paresis is noted, together with ipsilateral loss of touch, pressure, and vibration and contralateral loss of pain and temperature sensation.
- *Cause:* The lesion is caused by a transverse hemisection of the cord (half of the cord is transected from north to south), usually as a result of a knife or missile injury, fracture/dislocation of a unilateral articular process, or possibly an acute ruptured disc.

Brown–Séquard syndrome

Adapted from Hickey, J. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The neurologic level refers to the lowest level at which sensory and motor functions are intact. Below the neurologic level, there may be total or partial, sensory and/or motor paralysis (dependent upon affected tracts), loss of bladder and bowel control (usually with urinary retention and bladder distention), loss of sweating and vasomotor tone, and marked reduction of blood pressure from loss of peripheral vascular resistance.

If conscious, the patient usually complains of acute pain in the back or neck, which may radiate along the involved nerve. However, absence of pain does not rule out spinal injury, and a careful assessment of the spine should be conducted if there has been a significant force and mechanism of injury (i.e., concomitant head injury).

Respiratory dysfunction is related to the level of injury. The muscles contributing to respiration are the diaphragm (C4), intercostals (T1–T6), and abdominals (T6–T12). Injuries at C4 or above (causing paralysis of the diaphragm) often will require ventilator support, since acute respiratory failure is a leading

cause of death (Hickey, 2014). Injuries of T12 and above will have impact on respiratory function. Functional abilities by level of injury are described in Table 51-3.

Assessment and Diagnostic Findings

A detailed neurologic examination is performed. Diagnostic x-rays (lateral cervical spine x-rays) and CT scanning are usually performed initially. An MRI scan may be ordered as a further workup if a ligamentous injury is suspected, because significant spinal cord damage may exist even in the absence of bony injury (Hickey, 2014). If an MRI scan is contraindicated, a myelogram may be used to visualize the spinal axis. An assessment is made for other injuries, because spinal trauma often is accompanied by concomitant injuries, commonly to the head and chest. Continuous electrocardiographic monitoring may be indicated if an SCI is suspected, because bradycardia (slow heart rate) and asystole (cardiac standstill) are common in patients with acute spinal cord injuries.

Emergency Management

The immediate management at the scene of the injury is critical, because improper handling of the patient can cause further damage and loss of neurologic function. Any patient who is involved in a motor vehicle crash, a diving or contact sports injury, a fall, or any direct trauma to the head and neck must be considered to have SCI until such an injury is ruled out. Initial care must include a rapid assessment, immobilization, extrication, and stabilization or control of life-threatening injuries, and transportation to the most appropriate medical facility. Immediate transportation to a trauma center with the capacity to manage major neurologic trauma is then necessary (Hickey, 2014).

At the scene of the injury, the patient must be immobilized on a spinal (back) board, with the head and neck maintained in a neutral position, to prevent an incomplete injury from becoming complete. One member of the team must assume control of the patient's head to prevent flexion, rotation, or extension; this is done by placing the hands on both sides of the patient's head at about ear level to limit movement and maintain alignment while a spinal board and/or cervical immobilizing device is applied. If possible, at least four people should slide the patient carefully onto a board for transfer to the hospital. Head blocks should also be considered, as they will further limit any neck movement. Any twisting movement may irreversibly damage the spinal cord by causing bony fragment

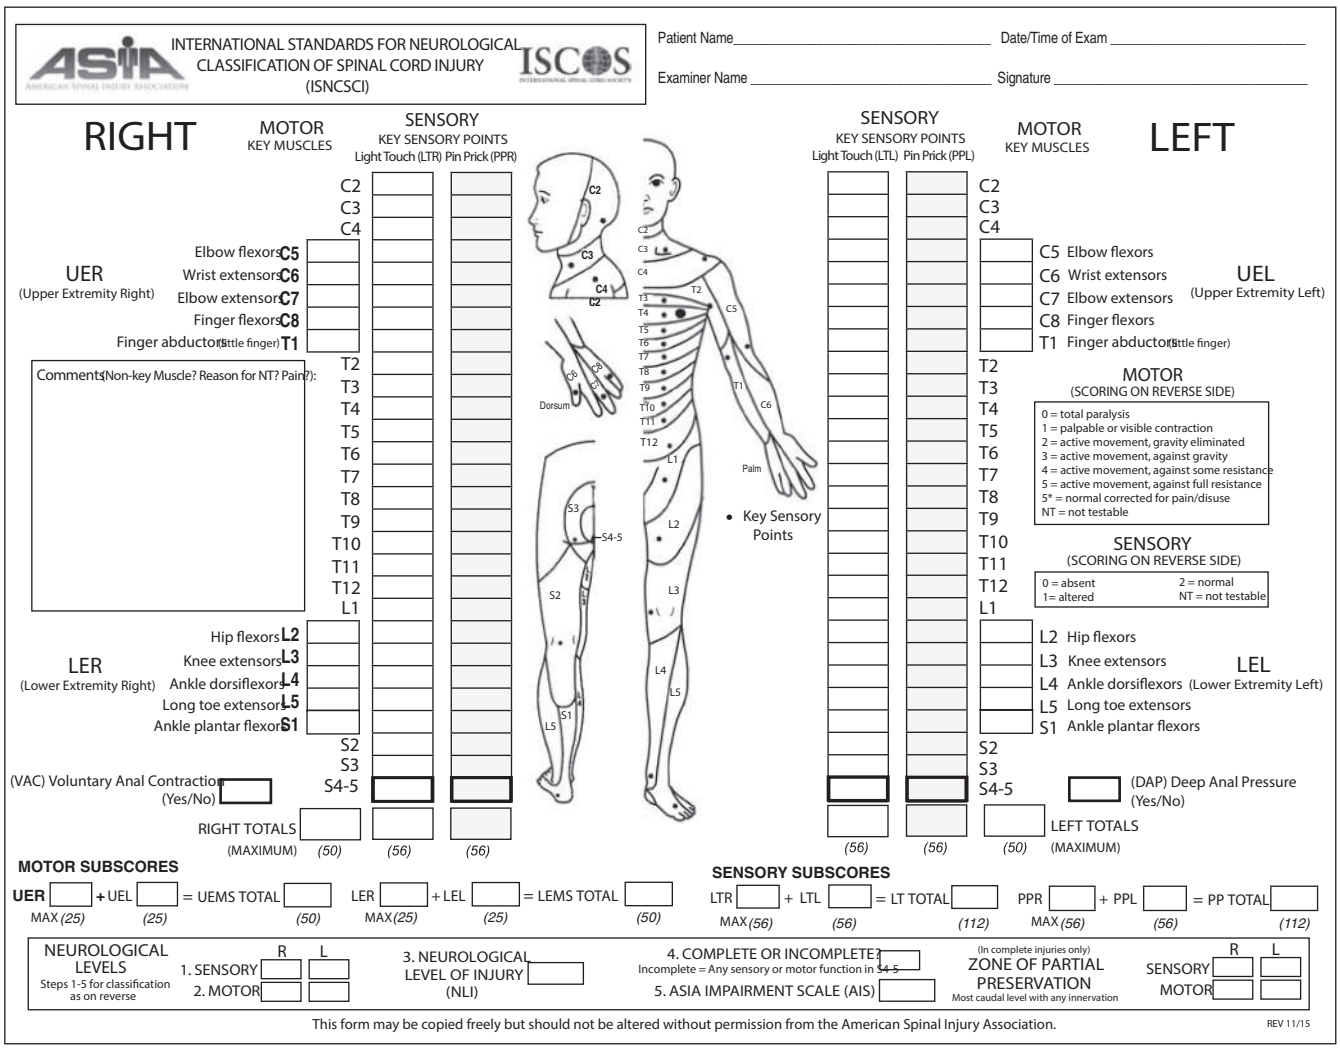


Figure 51-5 • Worksheet for the classification of SCI. Adapted from American Spinal Injury Association (ASIA). (2016). International standards for neurological classification of spinal cord injury. Retrieved on 2/23/17 at: www.asia-spinalinjury.org/wp-content/uploads/2016/02/International_Stds_Diagram_Worksheet.pdf. (*Continued*)

Muscle Function Grading

0 = total paralysis
1 = palpable or visible contraction
2 = active movement, full range of motion (ROM) with gravity eliminated
3 = active movement, full ROM against gravity
4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position
5 = (normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person
5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present
NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal ROM)

Sensory Grading

0 = Absent
1 = Altered, either decreased/impaired sensation or hypersensitivity
2 = Normal
NT = Not testable

When to Test Non-Key Muscles:

In a patient with an apparent AIS B classification, non-key muscle functions more than 3 levels below the motor level on each side should be tested to most accurately classify the injury (differentiate between AIS B and C).

Movement	Root level
Shoulder: Flexion, extension, abduction, adduction, internal and external rotation **Elbow:** Supination	C5
Elbow: Pronation **Wrist:** Flexion	C6
Finger: Flexion at proximal joint, extension. **Thumb:** Flexion, extension and abduction in plane of thumb	C7
Finger: Flexion at MCP joint **Thumb:** Opposition, adduction and abduction perpendicular to palm	C8
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	L3
Hip: Extension, abduction, internal rotation **Knee:** Flexion **Ankle:** Inversion and eversion **Toe:** MP and IP extension	L4
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments (S4-S5) by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body.
(This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

ASIA
AMERICAN SPINAL INJURY ASSOCIATION
INTERNATIONAL STANDARDS FOR NEUROLOGICAL CLASSIFICATION OF SPINAL CORD INJURY
ISCOS

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.
Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5).
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI)
This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively.
The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
*If voluntary anal contraction = **No** AND all S4-5 sensory scores = **0***
*AND deep anal pressure = **No,** then injury is **Complete.***
*Otherwise, injury is **Incomplete.***

5. Determine ASIA Impairment Scale (AIS) Grade:
Is injury Complete? **If YES, AIS=A** and can record ZPP (lowest dermatome or myotome on each side with some preservation)
NO ↓
Is injury Motor Complete? **If YES, AIS=B**
NO ↓ (No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?
NO ↓ **AIS=C** **YES** ↓ **AIS=D**

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

Figure 51-5 • (*Continued*) Worksheet for the classification of SCI. Adapted from American Spinal Injury Association (ASIA). (2016). International standards for neurological classification of spinal cord injury. Retrieved on 2/23/17 at: www.asia-spinalinjury.org/wp-content/uploads/2016/02/International_Stds_Diagram_Worksheet.pdf.

or disc movement or exacerbating ligamentous injury, causing further instability (Bader et al., 2016).

The patient is referred to a tertiary care providing spinal injury or trauma center because of the multidisciplinary personnel and support services required to counteract the destructive changes that occur in the first 24 hours after injury. During treatment in the emergency and x-ray departments, the patient is kept on the transfer board. The patient must always be maintained in an extended position. No part of the body should be twisted or turned, and the patient is not allowed to sit up. Once the extent of the injury has been determined, the patient may be placed on a rotating specialty bed or in a cervical collar (see Fig. 51-6). Later, if SCI and bone instability have been ruled out, the patient may be moved to a conventional bed or the collar may be removed without harm. If a specialty bed is needed but not available, the patient should be placed in a cervical collar and on a firm mattress.

Figure 51-6 • Cervical collar. Used with permission from Aspen Medical Products.

Medical Management (Acute Phase)

The goals of management are to prevent secondary injury, to observe for symptoms of progressive neurologic deficits, and to prevent complications. The patient is resuscitated as necessary, and oxygenation and cardiovascular stability are maintained.

TABLE 51-3 Functional Abilities by Level of Cord Injury

Injury Level	Segmental Sensorimotor Function	Dressing, Eating	Elimination	Mobility[a]
C1	Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation	Dependent	Dependent	Limited. Voice or sip-n-puff controlled electric wheelchair
C2–C3	Head and neck sensation; some neck control; independent of mechanical ventilation for short periods	Dependent	Dependent	Same as for C1
C4	Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement	Dependent; may be able to eat with adaptive sling	Dependent	Limited to voice, mouth, head, chin, or shoulder-controlled electric wheelchair
C5	Full head and neck control; shoulder strength; elbow flexion	Independent with assistance	Maximal assistance	Electric or modified manual wheelchair, needs transfer assistance
C6	Fully innervated shoulder; wrist extension or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair
C7–C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair
T1–T5	Full hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair
T6–T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair
T11–L5	Hip flexors, hip abductors (L1–L3); knee extension (L2–L4); knee flexion and ankle dorsiflexion (L4–L5)	Independent	Independent	Short distance to full ambulation with assistance
S1–S5	Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–S4)	Independent	Normal to impaired bowel and bladder function	Ambulate independently with or without assistance

[a]Assistance refers to adaptive equipment, setup, or physical assistance.

Adapted from Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

SCI is a devastating event; new treatment methods and medications are continually being investigated for the acute and chronic phases of care (Perez-Barcena et al., 2014); (Stocchetti & Maas, 2014).

Pharmacologic Therapy

Administration of high-dose IV corticosteroids (methylprednisolone sodium succinate [Solu-Medrol]) in the first 24 or 48 hours is controversial. The validity of studies has been questioned based on critical analysis of the original and additional data. As a result, there is now a consensus that corticosteroids may offer only a slight benefit. Corticosteroids are no longer considered the standard of care for acute SCI, although some centers continue to use corticosteroid protocols (Hickey, 2014).

Respiratory Therapy

Oxygen is given to maintain a high partial pressure of arterial oxygen (PaO_2), because hypoxemia can create or worsen a neurologic deficit of the spinal cord. If endotracheal intubation is necessary, extreme care is taken to avoid flexing or extending the patient's neck, which can result in extension of a cervical injury.

In high cervical spine injuries, spinal cord innervation to the phrenic nerve, which stimulates the diaphragm, is lost. Diaphragmatic pacing (electrical stimulation of the phrenic nerve) attempts to stimulate the diaphragm to help the patient breath. Intramuscular diaphragmatic pacing is currently in the clinical trial phase for the patient with a high cervical injury. This is implanted via laparoscopic surgery, usually after the acute phase.

Skeletal Fracture Reduction and Traction

Management of SCI requires immobilization and reduction of dislocations (restoration of preinjury position) and stabilization of the vertebral column. This can be accomplished by surgical and/or nonsurgical interventions; both aim to prevent new or worsening neurologic damage.

Cervical fractures can be reduced, and the cervical spine aligned with some form of skeletal traction, such as with skeletal tongs or with the use of the halo device (Bader et al., 2016). Traction is applied to the skeletal traction device by weights (ensuring the weights are unencumbered); the amount depends on the size of the patient and the degree of fracture displacement (see Fig. 51-7). The traction force is exerted along the longitudinal axis of the vertebral bodies, with the patient's neck in a neutral position. The traction is then gradually increased by adding more weights. As the amount of traction is increased, the spaces between the intervertebral discs widen and the vertebrae are given a chance to slip back into position. Reduction usually occurs after correct alignment has been restored. Once reduction is achieved, as verified by cervical spine x-rays and neurologic examination, the weights are gradually removed until the amount of weight needed to maintain the alignment is identified. Traction is sometimes supplemented with manual manipulation of the neck by a surgeon, to help achieve realignment of the vertebral bodies.

A halo device may be used initially with traction or may be applied after removal of the tongs. It consists of a titanium or stainless steel halo ring that is fixed to the skull by four pins,

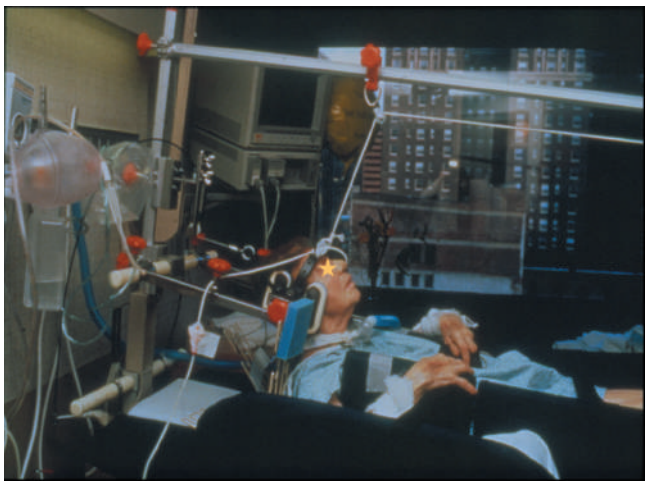

Figure 51-7 • Patient in skeletal traction in a rotating specialty bed. Adapted from Schwartz, E. D., Adam, E., & Flander, S. (2007). Spinal trauma: Imaging, diagnosis, and management. Philadelphia, PA: Lippincott Williams & Wilkins.

which are inserted into the outer table of the skull. The ring is attached to a removable halo vest, a device that suspends the weight of the unit circumferentially around the chest. A frame connects the ring to the chest. Halo devices provide immobilization of the cervical spine while allowing early ambulation (see Fig. 51-8) for patients with adequate function.

Figure 51-8 • Halo and vest for cervical and thoracic injuries. Adapted from Schwartz, E. D., Adam, E., & Flander, S. (2007). Spinal trauma: Imaging, diagnosis, and management. Philadelphia, PA: Lippincott Williams & Wilkins.

Thoracic and lumbar injuries are usually treated with surgical intervention, followed by immobilization with a fitted brace. Traction is often not indicated either before or after surgery, due to the relative stability of the spine in these regions.

Nursing Alert: The patient's vital organ functions and body defenses must be supported and maintained until spinal and neurogenic shock abates and the neurologic system have recovered from the traumatic insult; this can take up to 4 months.

Surgical Management

Surgery is indicated in any of the following situations:

- Compression of the cord is evident.
- The injury results in a fragmented or unstable vertebral body.
- The injury involves a wound that penetrates the cord.
- Bony fragments are in the spinal canal.
- The patient's neurologic status is deteriorating.

Early surgical stabilization may improve the clinical outcome of patients compared to surgery performed later during the clinical course. The goals of surgical treatment are to preserve neurologic function by removing pressure from the spinal cord and to provide stability.

Management of Acute Complications of Spinal Cord Injury

Spinal and Neurogenic Shock

The spinal shock associated with SCI reflects a sudden depression of reflex activity in the spinal cord (areflexia) below the level of injury. The muscles innervated by the part of the spinal cord segment below the level of the lesion are without sensation, paralyzed, and flaccid, and the reflexes are absent. Blood pressure may be decreased and the patient may be bradycardic. Studies suggest that hypotension and shock can further damage the spinal cord and that the mean arterial pressure (MAP) should be maintained at 85 mm Hg or higher during the hyperacute phase (Jia, Kowalski, Sciubba, et al., 2013). The reflexes that initiate bladder and bowel function are affected. Bowel distention and paralytic ileus can be caused by depression of the reflexes and are treated with intestinal decompression by insertion of a nasogastric tube. A paralytic ileus most often occurs within the first 2 to 3 days after SCI and resolves within 3 to 7 days (Bader et al., 2016).

Neurogenic shock develops as a result of the loss of autonomic nervous system function below the level of the lesion. The vital organs are affected, causing decreases in blood pressure, heart rate, and cardiac output, as well as venous pooling in the extremities and peripheral vasodilation (Bader et al., 2016). In addition, the patient does not perspire in the paralyzed portions of the body, because sympathetic activity is blocked; therefore, close observation is required for early detection of an abrupt onset of fever. See Chapter 8 for further discussion of neurogenic shock.

With injuries to the cervical and upper thoracic spinal cord, innervation to the major accessory muscles of respiration is lost and respiratory problems develop. These include decreased vital capacity, retention of secretions, increased partial pressure of arterial carbon dioxide ($PaCO_2$) levels and decreased oxygen levels, respiratory failure, and pulmonary edema.

Venous Thromboembolism

The risk of venous thromboembolism (VTE) is a potential complication of immobility and occurs in patients with SCI

at the same rate as those having had other types of traumatic injuries (Bader et al., 2016). Patients who develop VTE are at high risk for both deep vein thrombosis (DVT) and PE due to immobility, flaccidity, and decreased vasomotor tone (Jia et al., 2013).

Manifestations of PE include pleuritic chest pain, anxiety, shortness of breath, and abnormal blood gas values (increased $PaCO_2$ and decreased PaO_2). A fatal PE has been reported in up to 2% of patients with SCI within the first 3 months postinjury (Hickey, 2014).

Low-dose anticoagulation therapy usually is initiated to prevent DVT and PE, along with the use of antiembolism stockings or sequential pneumatic compression devices (SCDs). In some cases, permanent indwelling filters (see Chapter 12) may be placed prophylactically in the vena cava to prevent emboli (dislodged clots) from migrating to the lungs and causing PE. Prevention continues into the rehabilitation and chronic phases of SCI care (Abrams & Wakasa, 2014); (Jia et al., 2013).

Nursing Alert: The calves or thighs of a patient who is immobile should never be massaged because of the danger of dislodging an undetected thromboembolus.

Other Complications

In addition to respiratory complications (respiratory failure, pneumonia) and autonomic dysreflexia, other complications that may occur include pressure ulcers and infection (urinary, respiratory, and local infection at the skeletal traction pin sites).

NURSING PROCESS

The Patient with Acute Spinal Cord Injury

Assessment

The patient's breathing pattern and the strength of the cough are assessed and the lungs are auscultated, because paralysis of the diaphragm, in addition to abdominal and respiratory muscles, diminishes coughing and makes clearing of bronchial and pharyngeal secretions difficult. Reduced excursion of the chest also results.

The patient is monitored closely for any changes in motor or sensory function and for symptoms of progressive neurologic damage. In the early stages of SCI, determining whether the cord has been severed may not be possible, because signs and symptoms of cord edema are indistinguishable from those of cord transection. Edema of the spinal cord may occur with any severe cord injury and may further compromise spinal cord function.

Motor and sensory functions are assessed through careful neurologic examination. These findings are recorded on a flow sheet so that changes in the baseline neurologic status can be monitored closely and accurately. The ASIA classification is commonly used to describe the level of function for patients with SCI (see Fig. 51-5). Chart 51-7 also gives examples of the effects of altered spinal cord function. At the minimum:

- Motor ability is tested by asking the patient to spread the fingers, squeeze the examiner's hand, and move the toes or turn the feet.
- Sensation is evaluated by gently pinching the skin or touching it lightly with an object such as a tongue blade, starting at shoulder level and working down both sides of the extremities. The patient should have both eyes closed so that the examination reveals true findings, not what the patient hopes to feel. The patient is asked where the sensation is felt.
- Any decrease in neurologic function is reported immediately.

The patient is also assessed for spinal shock, which is a complete loss of all reflex, motor, sensory, and autonomic activity below the level of the lesion that causes bladder paralysis and distention. The lower abdomen is palpated for signs of urinary retention and overdistention of the bladder. Further assessment is made for gastric dilation and paralytic ileus caused by an atonic bowel, a result of autonomic disruption.

Temperature is monitored because the patient may have periods of hyperthermia as a result of altered temperature control, which is due to the inability to perspire related to autonomic disruption. Body temperature becomes dependent on surroundings (poikilothermia).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Ineffective breathing patterns related to weakness or paralysis of diaphragm, abdominal, and intercostal muscles
- Ineffective airway clearance related to muscle weakness and inability to clear secretions
- Impaired bed and physical mobility related to motor and sensory impairments
- Risk for injury related to motor and sensory impairment
- Risk for impaired skin integrity related to immobility and sensory loss
- Impaired urinary elimination related to inability to void spontaneously
- Constipation related to presence of atonic bowel as a result of autonomic disruption
- Acute pain related to treatment and prolonged immobility
- Autonomic dysreflexia related to uninhibited sympathetic response of the nervous system following SCI

Collaborative Problems/Potential Complications

Potential complications may include the following:

- VTE
- Orthostatic hypotension

Planning and Goals

The goals for the patient may include improved breathing pattern and airway clearance, improved mobility, prevention of injury due to sensory impairment, maintenance of skin integrity, relief of urinary retention, improved bowel function, decreasing pain, early recognition of autonomic dysreflexia, and absence of complications.

Nursing Interventions

Promoting Adequate Breathing and Airway Clearance

Possible impending respiratory failure is detected by observing the patient, measuring vital capacity, monitoring oxygen saturation through pulse oximetry, and monitoring arterial blood gases. Early and vigorous attention to clearing bronchial and pharyngeal secretions can prevent retention of secretions and atelectasis. Suctioning may be indicated, but it should be used with caution to avoid stimulating the vagus nerve and producing bradycardia and cardiac arrest.

If the patient cannot cough effectively because of decreased inspiratory volume and inability to generate sufficient expiratory pressure, chest physiotherapy and assisted coughing may be indicated. Specific breathing exercises are supervised by the nurse to increase the strength and endurance of the inspiratory muscles, particularly the diaphragm. Assisted coughing promotes clearing of secretions from the upper respiratory tract and is similar to the use of abdominal thrusts to clear an airway. Assisted coughing can be more effective than traditional suctioning because traditional suctioning clears the right mainstem bronchus, whereas sites for atelectasis and pneumonia are most commonly in the left lower lung lobe (Jia et al., 2013). Proper humidification and hydration are important to prevent secretions from becoming thick and difficult to remove even with coughing. The patient is assessed for signs of respiratory infection (e.g., cough, fever, dyspnea). Ascending edema of the spinal cord in the acute phase may cause respiratory difficulty that requires immediate intervention. Therefore, the patient's respiratory status must be monitored closely.

Improving Mobility

Proper body alignment is maintained at all times. If not on a specialized rotating bed, the patient should not be turned until the primary provider has indicated that it is safe to do so. Once safe for movement, the patient is repositioned frequently and is assisted out of bed as soon as the spinal column is stabilized. The feet are prone to footdrop; therefore, various types of splints are used to prevent footdrop. When used, the splints are removed and reapplied every 2 hours. Trochanter rolls, applied from the crest of the ilium to the midthigh of both legs, help prevent external rotation of the hip joints. Patients with lesions above the midthoracic level have loss of sympathetic control of peripheral vasoconstrictor activity, leading to hypotension. These patients may tolerate changes in position poorly and require monitoring of blood pressure when positions are changed.

Contractures can develop rapidly with immobility and muscle paralysis. A joint that is immobilized too long becomes fixed as a result of contractures of the tendon and joint capsule. Atrophy of the extremities results from disuse. Contractures and other complications may be prevented by range-of-motion exercises that help preserve joint motion and stimulate circulation. Passive range-of-motion exercises should be implemented as soon as possible after injury. Toes, metatarsals, ankles, knees, and hips should be put through a full range of motion at least four, or ideally five, times daily.

For most patients who have a cervical fracture without neurologic deficit, reduction in traction followed by rigid immobilization for 6 to 8 weeks restores skeletal integrity. These patients are allowed to move gradually to an erect position. A neck brace or molded collar is applied when the patient is mobilized after traction is removed (see Fig. 51-6).

Preventing Injury Due to Sensory and Perceptual Alterations

The nurse assists the patient to compensate for sensory and perceptual alterations that occur with SCI. The intact senses above the level of the injury are stimulated through touch, aromas, flavorful food and beverages, conversation, and music. Additional strategies include the following:

- Providing glasses to enable the patient to see from the supine position
- Encouraging the use of hearing aids, if indicated, to enable the patient to hear conversations and environmental sounds
- Providing emotional support to the patient and family
- Educating the patient and family about strategies to compensate for, or cope with, sensory deficits

Maintaining Skin Integrity

Pressure ulcers are a significant complication of SCI. The most common sites are over the sacrum (39.0%), heels (13.0%), ischial tuberosity (8.0%), and the occiput (back of head) (6.1%) (Jia et al., 2013). Pressure ulcers may begin within hours of an acute SCI where pressure is continuous and where the peripheral circulation is inadequate as a result of spinal shock and a recumbent position. It is important to move the patient from the backboard as soon as possible and inspect the skin. In addition, patients who wear cervical collars for prolonged periods may develop breakdown from the pressure of the collar under the chin, on the shoulders, and at the occiput. Pressure ulcers can add substantially to the personal and economic costs of living with SCI. The prevalence of this complication ranges from 17% for people 2 months after injury to 33% for those living with SCI.

The most effective approach to addressing this costly complication of SCI is prevention. The patient's position is changed at least every 2 hours (Bader et al., 2016). Turning not only assists in the prevention of pressure ulcers but also prevents pooling of blood and edema in the dependent areas. Careful inspection of the skin is made each time the patient is turned. The skin over the pressure points is assessed for redness or breaks; the perineum is checked for soilage, and the catheter is observed for adequate drainage. The patient's general body alignment and comfort are assessed. Special attention should be given to pressure areas in contact with the transfer board.

In addition, the patient's skin should be kept clean by washing with a mild soap, rinsing well, and blotting dry. Pressure-sensitive areas should be kept well lubricated and soft with oil or emollient lotion. The patient is educated about the danger of pressure ulcers and is encouraged to take control and make decisions about appropriate skin care. Other aspects of the prevention of pressure ulcers are discussed later in the chapter.

Maintaining Urinary Elimination

Immediately after SCI, the urinary bladder becomes atonic and cannot contract by reflex activity. Urinary retention is the immediate result. During the initial acute phase, a Foley catheter is inserted; however, prompt discontinuation is advised due to high risk of catheter-associated UTI. Once discontinued, the patient has no sensation of bladder distention and overstretching of the bladder and detrusor muscle may occur, delaying the return of bladder function.

Intermittent catheterization is carried out to avoid overdistention of the bladder and high risk for UTI due to retention of urine. At an early stage, family members are shown how to carry out intermittent catheterization and are encouraged to participate in this facet of care, because they will be involved in long-term follow-up and must be able to recognize complications so that treatment can be instituted.

The patient is educated to record fluid intake, voiding pattern, amounts of residual urine after voiding, characteristics of urine, and any unusual sensations that may occur. For the management of a neurogenic bladder, training is essential. (See the following section for bladder training).

Improving Bowel Function

Immediately after SCI, a paralytic ileus usually develops as a result of neurogenic paralysis of the bowel; therefore, a nasogastric tube is often required to relieve distention and to prevent vomiting and aspiration (Rodriguez, 2016).

Bowel activity usually returns within the first week. With the intake of nutrition, it is important to establish a bowel program. A bowel program can help to control bowel movements by establishing a pattern of planned evacuation. The nurse administers prescribed combinations of stool softeners, stimulant laxatives, bulking laxatives, and rectal laxatives along with rectal stimulation, to counteract the effects of immobility and analgesic agents (Rodriguez, 2016).

Providing Comfort Measures: The Patient in Traction With Tongs or Halo Vest

A patient who has had pins, tongs, or calipers placed for cervical stabilization may have a headache or discomfort for several days after the pins are inserted. Patients initially may be bothered by the rather startling appearance of these devices, but usually they readily adapt to it because the device provides comfort for the unstable neck (see Fig. 51-8). The patient may complain of being caged in and of noise created by any object coming in contact with the frame of a halo device, but they can be reassured that adaptation will occur.

The areas around the four pin sites of a halo device are cleaned at least daily and observed for redness, drainage, and pain. The pins are observed for loosening, which may contribute to infection. If one of the pins becomes detached, the head is stabilized in a neutral position by one person, while another notifies the primary provider. A torque screwdriver should be readily available in case the screws on the frame need tightening.

The skin under the halo vest is inspected for excessive perspiration, redness, and skin blistering, especially on the bony prominences. The vest is opened at the sides to allow the torso to be washed. The liner of the vest should not become wet, because dampness causes skin excoriation. Powder is not used inside the vest, because it may contribute to the development of pressure ulcers. The liner should be changed periodically to promote hygiene and good skin care. If the patient is to be discharged with the vest, detailed instructions must be given to the family, with time allowed for them to demonstrate the necessary skills of halo vest care (see Chart 51-8).

Recognizing Autonomic Dysreflexia

Autonomic dysreflexia, also known as autonomic hyperreflexia, is an acute life-threatening emergency that occurs as a result of exaggerated autonomic responses to stimuli that are harmless in people without SCI. It occurs only after spinal shock has resolved. This syndrome is characterized by a severe, pounding headache with paroxysmal hypertension, profuse diaphoresis above the spinal level of the lesion (most often of the forehead), nausea, nasal congestion, and bradycardia. It occurs among patients with cord lesions above T6 (the sympathetic visceral outflow level) after spinal shock has subsided (Bader et al., 2016). The sudden increase in blood pressure may cause retinal hemorrhage, hemorrhagic stroke, myocardial infarction, or seizures (Hickey, 2014). A number of stimuli may trigger this reflex: distended bladder (the most common cause); distention or contraction of the visceral organs, especially the bowel (from constipation, impaction); or stimulation of the skin (tactile, pain, thermal stimuli, pressure ulcer). Because this is an emergency situation, the objectives are to remove the triggering stimulus and to avoid the possibility of serious complications (Wan & Krassioukov, 2014).

The following measures are carried out:

- The patient is placed immediately in a sitting position to lower blood pressure.
- Rapid assessment is performed to identify and alleviate the cause.
- The bladder is emptied immediately via a urinary catheter. If an indwelling catheter is not patent, it is irrigated or replaced with another catheter.
- The rectum is examined for a fecal mass. If one is present, a topical anesthetic agent is inserted 10 to 15 minutes before the mass is removed, because visceral distention or contraction can cause autonomic dysreflexia.
- The skin is examined for any areas of pressure, irritation, or broken skin.
- Any other stimulus that could be the triggering event, such as an object next to the skin or a draft of cold air, must be removed.
- If these measures do not relieve the hypertension and excruciating headache, antihypertensive medications may be prescribed and given slowly by the IV route.

Chart 51-8 HOME CARE CHECKLIST

The Patient with a Halo Vest

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Describe the rationale for the use of the halo vest.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., diet, ADLs, IADLs, activity) necessary for recovery and health maintenance, as applicable.
  - Demonstrate safe techniques to assist the patient with self-care, hygiene, and ambulation.
  - Demonstrate assessment of frame, traction, tongs, and pins.
  - Demonstrate pin care using correct technique.
  - Demonstrate care of skin, including assessment (e.g., reddened or irritated areas, breakdown).
  - Identify signs and symptoms of infection.
  - Explain the reasons for and the method for changing the vest liner.
  - Identify holistic measures of pain management.
- Identify signs and symptoms of complications (e.g., venous thromboembolism, respiratory impairment, urinary tract infection).
- Describe emergency measures if respiratory or other complications develop while the patient is in the halo vest or if the frame becomes dislodged.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, spinal cord injury support groups, caregiver support).
- Identify the need for health-promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, independent activities of daily living.

- The medical record is labeled with a clearly visible note about the risk of autonomic dysreflexia.
- The patient is instructed about prevention and management measures.
- Any patient with a lesion above the T6 segment is informed that such an episode is possible and may occur even many years after the initial injury (Bader et al., 2016).

Monitoring and Managing Potential Complications

Patients are at high risk for VTE after SCI. The patient must be assessed for symptoms of VTE including DVT and PE. Chest pain, shortness of breath, and changes in arterial blood gas values must be reported promptly to the primary provider. The circumferences of the thighs and calves are measured and recorded daily; further diagnostic studies are performed if a significant increase is noted. Patients remain at high risk for thrombophlebitis for several months after the initial injury. Patients with paraplegia or tetraplegia are at increased risk for the rest of their lives. Immobilization and the associated venous stasis, as well as varying degrees of autonomic disruption, contribute to the high risk and susceptibility for DVT.

Anticoagulation should be initiated within 72 hours of injury and continued for at least 3 months (Jia et al., 2013). The use of low–molecular-weight heparin or low-dose unfractionated heparin may be followed by long-term oral anticoagulation (i.e., warfarin [Coumadin]). Additional measures such as range-of-motion exercises, antiembolism stockings, and adequate hydration are important preventive measures. SCDs may also be used to reduce venous pooling and promote venous return. It is also important to avoid external pressure on the lower extremities that may result from flexion of the knees while the patient is in bed.

Orthostatic Hypotension. For the first 2 weeks after SCI, the blood pressure tends to be unstable and can be quite low. It gradually returns to preinjury levels, but periodic episodes of severe orthostatic hypotension frequently interfere with efforts to mobilize the patient. Interruption in the reflex arcs that normally produce vasoconstriction in the upright position, coupled with vasodilation and pooling in abdominal and lower extremity vessels, can result in hypotension. Orthostatic hypotension is a particularly common problem for patients with lesions above T7. In some patients with tetraplegia, even slight elevations of the head can result in blood pressure dysregulation.

A number of techniques can be used to reduce the frequency of hypotensive episodes. Close monitoring of vital signs before and during position changes is essential. Optimization of fluid status and vasopressor medication can be used to treat the profound vasodilation. Antiembolism stockings should be applied to improve venous return from the lower extremities. Abdominal binders may also be used to encourage venous return and provide diaphragmatic support when the patient is upright (Bader et al., 2016); (Mills, Fung, Travios, et al., 2015). Activity should be planned in advance, and adequate time should be allowed for a slow progression of position changes from recumbent to sitting and upright. Tilt tables frequently are helpful in assisting patients to make this transition.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. In most cases, patients with SCI (i.e., patients with tetraplegia or paraplegia) need long-term rehabilitation. The process begins during hospitalization as acute symptoms begin to subside or come under better control and the overall deficits and long-term effects of the injury become clear. The goals begin to shift from merely surviving the injury to learning strategies necessary to cope with the alterations that the injury imposes on activities of daily living (ADLs). The emphasis shifts from ensuring that the patient is stable and free of complications to specific assessment and planning designed to meet the patient's rehabilitation needs. Patient education may initially focus on the injury and its effects on mobility; dressing; and bowel, bladder, and sexual function. As the patient and family acknowledge the consequences of the injury and the resulting disability, the focus of education broadens to address issues necessary for carrying out the tasks of daily living and taking charge of their lives. Education must begin in the acute phase and continue throughout rehabilitation and the patient's entire life as changes occur, the patient ages, and problems arise (Bader et al., 2016).

Caring for the patient with SCI at home may at first seem a daunting task to the family. They will require dedicated nursing support to gradually assume full care of the patient. Although maintaining function and preventing complications will remain important, goals regarding self-care and preparation for discharge will assist in a smooth transition to rehabilitation and eventually to the community.

Continuing and Transitional Care. The goal of the rehabilitation process is independence. The nurse becomes a support to both the patient and the family, assisting them to assume responsibility for increasing aspects of patient care and management. Care for the patient with SCI involves members of all health care disciplines, which may include nursing, medicine, rehabilitation, respiratory therapy, physical and occupational therapy, case management, and social services. The nurse often serves as coordinator of the management team and as a liaison with rehabilitation centers and home care agencies. The patient and family often require assistance in dealing with the psychological impact of the injury and its consequences; referral to a psychiatric clinical nurse specialist or other mental health care professional often is helpful. Therapeutic horseback riding may help increase balance, muscle strength, and self-esteem (Asselin, Ward, Penning, et al., 2012).

The nurse should reassure female patients with SCI that pregnancy is not contraindicated and fertility is relatively unaffected, but that pregnant women with acute or chronic SCI pose unique management challenges. The normal physiologic changes of pregnancy may predispose women with SCI to many potentially life-threatening complications, including autonomic dysreflexia, pyelonephritis, respiratory insufficiency, thrombophlebitis, PE, and unattended delivery. Preconception assessment and counseling are strongly recommended to ensure that the woman is in optimal health and to increase the likelihood of an uneventful pregnancy and healthy outcomes (Pebdani, Johnson, & Amtmann, 2014).

As more patients survive acute SCI, they face the changes associated with aging with a disability. Three common secondary health problems experienced by persons living with SCI include chronic pain, spasticity, and depression (Abrams & Wakasa, 2014); (Saunders, Clarke, Tate, et al., 2015). Education in the home and community focuses on health promotion and addresses the need to minimize risk factors (e.g., smoking, alcohol and drug abuse, obesity). Routine health screening and preventive services are needed for the older adult with SCI for early detection of secondary health problems. Home care nurses and others who have contact with patients with SCI are

in a position to educate patients about healthy lifestyles, remind them of the need for health screenings, and make referrals as appropriate. Assisting patients to identify accessible health care providers, clinical facilities, and imaging centers may increase the likelihood that they will participate in health screening.

Evaluation

Expected patient outcomes may include:

1. Demonstrates improvement in gas exchange and clearance of secretions, as evidenced by normal breath sounds on auscultation
   a. Breathes easily without shortness of breath
   b. Performs hourly deep breathing exercises, coughs effectively, and clears pulmonary secretions
   c. Is free of respiratory infection (e.g., has temperature, respiratory rate, and pulse within normal limits; breath sounds clear to auscultation; absence of purulent sputum)
2. Moves within limits of the dysfunction and demonstrates completion of exercises within functional limitations
3. Avoids injury due to sensory, motor, and perceptual alterations
   a. Uses assistive devices (e.g., glasses, hearing aids, computers) as indicated
   b. Describes sensory, motor, and perceptual alterations as a consequence of injury
4. Demonstrates optimal skin integrity
   a. Exhibits normal skin turgor; skin is free of reddened areas or breaks
   b. Participates in skin care and monitoring procedures within functional limitations
5. Regains urinary bladder function
   a. Exhibits no signs of UTI (e.g., has temperature within normal limits; voids clear, dilute urine)
   b. Has adequate fluid intake
   c. Participates in bladder training program within functional limitations
6. Regains bowel function
   a. Reports regular pattern of bowel movement
   b. Consumes adequate dietary fiber and oral fluids
   c. Participates in bowel training program within functional limitations
7. Reports absence of pain and discomfort
8. Recognizes manifestations of autonomic dysreflexia if they occur (e.g., headache, diaphoresis, nasal congestion, bradycardia, or diaphoresis)
9. Is free of complications
   a. Demonstrates no signs of thrombophlebitis, DVT, or PE
   b. Maintains blood pressure within normal limits
   c. Reports no lightheadedness with position changes

Medical Management of Long-Term Complications of Spinal Cord Injury

The patient faces a lifetime of disability, requiring ongoing follow-up and care. The expertise of a number of health professionals, including physicians, rehabilitation nurses, occupational therapists, physical therapists, psychologists, social workers, rehabilitation engineers, and vocational counselors, is necessary at different times as the need arises.

The patient with an SCI has a shorter life expectancy compared to those who have not had an SCI (Abrams & Wakasa, 2014). As patients with SCI age, they have many of the same medical problems as others. In addition, they face the threat of complications associated with their disability (Hickey, 2014). Usually, patients are encouraged to follow-up at an outpatient spinal cord clinic when complications and other issues arise. Lifetime care includes assessment of the urinary tract at prescribed intervals, because there is the likelihood of continuing alteration in detrusor and sphincter function, and the patient is prone to UTI (Abrams & Wakasa, 2014).

Long-term problems and complications of SCI include disuse syndrome, autonomic dysreflexia (discussed earlier), bladder and kidney infections, spasticity, and depression (Abrams & Wakasa, 2014). Pressure ulcers with potential complications of sepsis, osteomyelitis, and fistulas occur in about 10% of patients. Spasticity may be particularly disabling. Heterotopic ossification (overgrowth of bone) in the hips, knees, shoulders, and elbows occurs in many patients after SCI. Spasticity and heterotopic ossification of these complications are painful and can produce a loss of range of motion (Abrams & Wakasa, 2014). Management includes observing for and addressing any alteration in physiologic status and psychological outlook, as well as the prevention and treatment of long-term complications. The nursing role involves emphasizing the need for vigilance in self-assessment and care.

NURSING PROCESS

The Patient with Tetraplegia or Paraplegia

Assessment

Assessment focuses on the patient's general condition, complications, and how the patient is managing at that particular point in time. A head-to-toe assessment and review of systems should be part of the database, with emphasis on the areas that are prone to problems in this population. A thorough inspection of all areas of the skin for redness or breakdown is critical. The nurse reviews the established bowel and bladder program with the patient, because the program must continue uninterrupted. Patients with tetraplegia or paraplegia have varying degrees of loss of motor power, deep and superficial sensation, vasomotor control, bladder and bowel control, and sexual function. They are faced with potential complications related to immobility, skin breakdown and pressure ulcers, recurring UTIs, and contractures. Knowledge about these particular issues can further guide the assessment in any setting. Nurses in all settings, including home care, must be aware of these potential complications in the lifetime management of these patients.

An understanding of the emotional and psychological responses to tetraplegia or paraplegia is achieved by observing the responses and behaviors of the patient and family and by listening to their concerns (Chuang, Yang, & Kuo, 2015). Documenting these assessments and reviewing the plan with the entire team on a regular basis provide insight into how both the patient and the family are coping with the changes in lifestyle and body functioning. Additional information frequently can be gathered from the social worker or psychiatric/mental health worker.

It takes time for the patient and family to comprehend the magnitude of the disability. They may go through stages of grief, including shock, disbelief, denial, anger, depression, and acceptance. During the acute phase of the injury, denial can be a protective mechanism to shield the patient from the

acute reality of what has happened. As the patient realizes the permanent nature of paraplegia or tetraplegia, the grieving process may be prolonged and all-encompassing because of the recognition that long-held plans and expectations are interrupted or permanently altered. A period of depression often follows as the patient experiences a loss of self-esteem in areas of self-identity, sexual functioning, and social and emotional roles. Exploration and assessment of these issues can assist in developing a meaningful plan of care.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired bed and physical mobility related to loss of motor function
- Risk for disuse syndrome
- Risk for impaired skin integrity related to permanent sensory loss and immobility
- Impaired urinary elimination related to level of injury
- Constipation related to effects of spinal cord disruption
- Sexual dysfunction related to neurologic dysfunction
- Ineffective coping related to impact of disability on daily living
- Deficient knowledge about requirements for long-term management

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Spasticity
- Infection and sepsis

Planning and Goals

The goals for the patient may include attainment of some form of mobility; maintenance of healthy, intact skin; achievement of bladder management without infection; achievement of bowel control; achievement of sexual expression; strengthening of coping mechanisms; knowledge of long-term management; and absence of complications.

Nursing Interventions

The patient requires extensive rehabilitation, which is less difficult if appropriate nursing management has been carried out during the acute phase of the injury or illness. Nursing care is one of the key factors determining the success of the rehabilitation program. The main objective is for the patient to live as independently as possible in the home and community.

Increasing Mobility

Exercise Programs. The unaffected parts of the body are built up to optimal strength to promote maximal self-care. The muscles of the hands, arms, shoulders, chest, spine, abdomen, and neck must be strengthened in the patient with paraplegia, because they must bear full weight on these muscles to ambulate. The triceps and the latissimus dorsi are important muscles used in crutch walking. The muscles of the abdomen and the back also are necessary for balance and for maintaining the upright position.

To strengthen these muscles, the patient can do push-ups when in a prone position and sit-ups when in a sitting position. Extending the arms while holding weights (traction weights can be used) also develops muscle strength. Squeezing rubber balls or crumbling newspaper promotes hand strength.

With encouragement from all members of the rehabilitation team, the patient with paraplegia can develop the increased exercise tolerance needed for gait training and ambulation activities. The importance of maintaining cardiovascular fitness is stressed to the patient. Alternative exercises to increase the heart rate to target levels must be designed within the patient's abilities.

Mobilization. After the spine is stable enough to allow the patient to assume an upright posture, mobilization activities are initiated. A brace or vest may be used, depending on the level of the lesion. The sooner muscles are used, the less chance there is of disuse atrophy. The earlier the patient is brought to a standing position, the less opportunity there is for osteoporotic changes to take place in the long bones. Weight bearing also reduces the possibility of renal calculi and enhances many other metabolic processes.

Braces and crutches enable some patients with paraplegia to ambulate for short distances. Ambulation using crutches requires a high expenditure of energy. Motorized wheelchairs and specially equipped vans can provide greater independence and mobility for patients with high-level SCI or other lesions. Every effort should be made to encourage the patient to be as mobile and active as possible.

Long-term risks include altered body composition, a decrease in lean body mass, decreased bone mineral density, and increased BMI. Patients are at high risk for obesity due to high fat intake combined with decreased physical activity (Lieberman, Goff, Hammond, et al., 2014). This puts patients at higher risk of developing comorbid conditions such as diabetes and cardiovascular disease. Patients benefit from nutrition counseling to prevent these secondary complications. For those who are overweight or who have obesity, weight-loss programs must be designed to accommodate the dietary and physical activity barriers that are unique to this population (Lieberman et al., 2014).

Preventing Disuse Syndrome

Patients are at high risk for development of contractures as a result of disuse syndrome due to the musculoskeletal system changes (atrophy) brought about by the loss of motor and sensory functions below the level of injury. Range-of-motion exercises must be provided at least four times a day, and care is taken to stretch the Achilles tendon with exercises, to prevent footdrop. The patient is repositioned frequently and is maintained in proper body alignment whether in bed or in a wheelchair.

Contractures can complicate day-to-day care, increasing the difficulty of positioning and decreasing mobility. A number of surgical procedures have been tried, with varying degrees of success. These techniques are used if more conservative approaches fail, but the best treatment is prevention.

Promoting Skin Integrity

Because these patients spend a great portion of their lives in wheelchairs, pressure ulcers are an ever-present threat. Contributing factors are permanent sensory loss over pressure areas; immobility, which makes relief of pressure difficult; trauma from bumps (against the wheelchair, toilet, furniture, and so forth) that cause unnoticed abrasions and wounds; loss of protective function of the skin from excoriation and maceration due to excessive perspiration and possible incontinence; and poor general health (anemia, diabetes), leading to poor tissue perfusion.

The person with tetraplegia or paraplegia must take responsibility for monitoring (or directing monitoring) of their skin status. This involves relieving pressure and not remaining in any position for longer than 2 hours, in addition to ensuring that the skin receives meticulous attention and cleansing (Bader et al., 2016). The patient is educated that ulcers develop over bony prominences that are exposed to unrelieved pressure in the sitting and lying positions. The most vulnerable areas are identified. The patient with paraplegia is instructed to use mirrors, if possible, to inspect these areas morning and night, observing for redness, slight edema, or any abrasions. While in bed, the patient should turn at 2-hour intervals and then inspect the skin again for redness that does not fade on pressure. The bottom sheet should be checked for wetness and for creases. The patient with tetraplegia or paraplegia, who cannot perform these activities, is encouraged to direct others to check these areas and prevent ulcers from developing.

The patient is educated to relieve pressure while in the wheelchair by doing push-ups, leaning from side to side to relieve ischial pressure, and tilting forward while leaning on a table. The caregiver for the patient with tetraplegia will need to perform these activities if the patient cannot do so independently. A wheelchair cushion is prescribed to meet individual needs, which may change in time with changes in posture, weight, and skin tolerance. A referral can be made to a rehabilitation engineer, who can measure pressure levels while the patient is sitting and then tailor the cushion and other necessary aids and assistive devices to the patient's needs.

The diet for the patient with tetraplegia or paraplegia should be high in protein, vitamins, and calories to ensure minimal wasting of muscle and the maintenance of healthy skin, and high in fluids to maintain well-functioning kidneys. Excessive weight gain and obesity should be avoided, because they further limit mobility.

Improving Bladder Management

The effect of the spinal cord lesion on the bladder depends on the level of injury, the degree of cord damage, and the length of time after injury. A patient with tetraplegia or paraplegia usually has either a reflex or a nonreflex bladder. Both bladder types increase the risk of UTI.

The nurse emphasizes the importance of maintaining an adequate flow of urine by encouraging a fluid intake of about 2.5 L daily. The patient should empty the bladder frequently so that there is minimal residual urine and should pay attention to personal hygiene, because infection of the bladder and kidneys almost always occurs by the ascending route. The perineum must be kept clean and dry, and attention must be given to the perianal skin after defecation. Underwear should be cotton (which is more absorbent) and should be changed at least once a day.

If an external catheter (condom catheter) is used, the sheath is removed nightly; the penis is cleansed to remove urine and is dried carefully, because warm urine on the periurethral skin promotes the growth of bacteria. Attention also is given to the collection bag. The nurse emphasizes the importance of monitoring for signs of UTI: cloudy, foul-smelling urine or hematuria (blood in the urine); fever; or chills.

The female patient who cannot achieve reflex bladder control or self-catheterization may need to wear pads or waterproof undergarments. Surgical intervention may be indicated in some patients to create a urinary diversion.

Establishing Bowel Control

The objective of a bowel training program is to establish bowel evacuation through reflex conditioning, (bowel training is discussed later in the chapter.)

If the SCI occurs above the sacral segments or nerve roots and there is reflex activity, the anal sphincter may be massaged (digital stimulation) to stimulate defecation. If the cord lesion involves the sacral segment or nerve roots, anal massage is not performed because the anus may be relaxed and lack tone. Massage is also contraindicated if there is spasticity of the anal sphincter. The anal sphincter is massaged by inserting a gloved finger (which has been adequately lubricated) 2.5 to 3.7 cm (1 to 1.5 inches) into the rectum and moving it in a circular motion or from side to side. It soon becomes apparent which area triggers the defecation response. This procedure should be performed at regular time intervals (usually every 48 hours), after a meal, and at a time that will be convenient for the patient at home (Rodriguez, 2016). The patient also is educated about the symptoms of impaction (frequent loose stools; constipation) and is cautioned to watch for hemorrhoids. A diet with sufficient fluids and fiber is essential to developing a successful bowel training program, avoiding constipation, and decreasing the risk of autonomic dysreflexia.

Counseling on Sexual Expression

Many patients with tetraplegia and paraplegia can have some form of meaningful sexual relationship, although modifications are necessary. The patient and partner benefit from counseling about the range of sexual expression possible, special techniques and positions, exploration of body sensations offering sensual feelings, and urinary and bowel hygiene as related to sexual activity. For men with erectile failure, penile prostheses enable them to have and sustain an erection, and impotence drugs may be helpful. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis), for example, are oral smooth muscle relaxants that cause blood to flow into the penis, resulting in an erection (see Chapter 46). Patients who are sexually active should undergo counseling in birth control methods, as some methods (e.g., oral contraceptives) may increase risks of complications such as VTE (Hickey, 2014).

Sexual education and counseling services are included in the rehabilitation services at spinal centers. Small group meetings in which patients can share their feelings, receive information, and discuss sexual concerns and practical aspects are helpful in producing effective attitudes and adjustments.

Enhancing Coping Mechanisms

The impact of the disability and loss becomes marked when the patient returns home. Each time something new enters the patient's life (e.g., a new relationship, going to work), the patient is reminded anew of their limitations. Grief reactions and depression are common.

To work through depression, the patient must have some hope for relief in the future. The nurse can encourage the patient to feel confident in their ability to achieve self-care and relative independence. The role of the nurse ranges from caretaker during the acute phase to educator, counselor, and facilitator as the patient gains mobility and independence.

The patient's disability affects not only the patient but also the entire family. In many cases, family therapy is helpful in working through issues as they arise. Adjustment to the disability leads to the development of realistic goals for the future, making the best of the abilities that are left intact, and reinvesting in other

activities and relationships. Rejection of the disability causes self-destructive neglect and nonadherence to the therapeutic program, which leads to more frustration and depression. Crises for which interventions may be sought include social, psychological, marital, sexual, and psychiatric problems. The family usually requires counseling, social services, and other support systems to help them cope with the changes in their lifestyle and socioeconomic status.

A major goal of nursing management is to help the patient overcome their sense of futility and to encourage the patient in the emotional adjustment that must be made before they are willing to venture into the outside world. However, an excessively sympathetic attitude on the part of the nurse may cause the patient to develop an overdependence that defeats the purpose of the entire rehabilitation program. The patient is educated and assisted when necessary, but the nurse should avoid performing activities that the patient can do independently with a little effort. This approach to care more than repays itself in the satisfaction of seeing a patient, who is completely demoralized and helpless, become independent and find meaning in a newly emerging lifestyle.

Monitoring and Managing Potential Complications

Spasticity. Muscle spasticity can be a problematic complication of tetraplegia and paraplegia. Flexor or extensor spasms occur below the level of the spinal cord lesion and can interfere with the rehabilitation process, ADLs, and quality of life (Abrams & Wakasa, 2014). Spasticity results from an imbalance between the facilitatory and inhibitory effects on neurons that exist normally. The area of the cord distal to the site of injury or lesion becomes disconnected from the higher inhibitory centers located in the brain, so facilitatory impulses, which originate from muscles, skin, and ligaments, predominate.

Spasticity is defined as a condition of increased muscle tone in a muscle that is weak. Initial resistance to stretching is quickly followed by sudden relaxation. The stimulus that precipitates spasm can be obvious, such as movement or a position change, or subtle, such as a slight jarring of the wheelchair. Most patients with tetraplegia or paraplegia have some degree of spasticity. Because it increases muscle tone, some degree of spasticity can be beneficial in patients who are weak (Abrams & Wakasa, 2014). With SCI, the onset of spasticity usually occurs from a few weeks to 6 months after the injury. The same muscles that are flaccid during the period of spinal shock develop spasticity during recovery. The intensity of spasticity tends to peak approximately 2 years after the injury, after which the spasms tend to regress.

Management of spasticity is based on the severity of symptoms and the degree of incapacitation. Botulinum toxin (Botox) injections, as well as the antispasmodic medication baclofen (Lioresal), available in an oral and an intrathecal form, may be indicated (Comerford et al., 2015). Oral medications such as diazepam (Valium), dantrolene (Dantrium), and tizanidine (Zanaflex) help control spasms by decreasing sympathetic outflow from the central nervous system. Other forms of adjunctive therapy include oral and transdermal forms of clonidine (Catapres) (Hickey, 2014). All of the antispasmodic medications cause drowsiness, weakness, and vertigo in some patients. Passive range-of-motion exercises and frequent turning and repositioning are helpful, because stiffness tends to increase spasticity. These activities also are essential in the prevention of contractures, pressure ulcers, and bowel and bladder dysfunction.

Infection and Sepsis. Patients with tetraplegia and paraplegia are at increased risk for infection and sepsis from a variety of sources: urinary tract, respiratory tract, and pressure ulcers. Sepsis remains a major cause of complications and death in these patients. Prevention of infection and sepsis is essential through maintenance of skin integrity, complete emptying of the bladder at regular intervals, and prevention of urinary and fecal incontinence. The risk of respiratory infection can be decreased by avoiding contact with people who have symptoms of respiratory infection, performing coughing and deep breathing exercises to prevent pooling of respiratory secretions, receiving yearly influenza vaccines, and giving up smoking. A high-protein diet is important in maintaining an adequate immune system, as is avoiding factors that may reduce immune system function, such as excessive stress, drug abuse, and excessive alcohol intake.

If infection occurs, the patient requires thorough assessment and prompt treatment. Antibiotic therapy and adequate hydration, in addition to local measures (depending on the site of infection), are initiated immediately.

UTIs are minimized or prevented by aseptic technique in catheter management, adequate hydration, a bladder training program, and prevention of overdistention of the bladder and urinary stasis.

Skin breakdown and infection are prevented by maintenance of a turning schedule; frequent back care; regular assessment of all skin areas; regular cleaning and lubrication of the skin; passive range-of-motion exercise to prevent contractures; pressure relief over broken skin areas, bony prominences, and heels; and wrinkle-free bed linen.

Pulmonary infections are managed and prevented by frequent coughing, turning, and deep breathing exercises and chest physiotherapy; aggressive respiratory care and suctioning of the airway if a tracheostomy is present; assisted coughing as needed; and adequate hydration.

Infections of any kind can be life threatening. Aggressive nursing interventions are key to prevention, detection, and early management.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Patients with tetraplegia or paraplegia are at risk for complications for the rest of their lives. Therefore, a major aspect of nursing care is educating the patient and family about these complications and about strategies to minimize risks. UTIs, contractures, infected pressure ulcers, and sepsis may necessitate hospitalization. Other late complications that may occur include lower extremity edema, joint contractures, respiratory dysfunction, and pain. To avoid these and other complications, the patient and family members are educated about skin care, catheter care, range-of-motion exercises, breathing exercises, and other care techniques. Education is initiated as soon as possible and extends into the rehabilitation or long-term care facility and home. In all aspects of care, it is important for the nurse and patient to set mutual goals and discuss the tasks the patient is capable of doing independently and which tasks the patient needs assistance to complete.

Continuing and Transitional Care. Referral for home care is often appropriate for assessment of the home setting, patient education, and evaluation of the patient's physical and emotional status. During visits by the nurse, education about strategies to

prevent or minimize potential complications is reinforced. The home environment is assessed for adequacy of care and for safety. Environmental modifications are made, and specialized equipment is obtained, ideally before the patient goes home.

The nurse also assesses the patient's and the family's adherence to recommendations and their use of coping strategies. The use of inappropriate coping strategies (e.g., drug and alcohol use) is assessed, and referrals to counseling are made for the patient and family. Appropriate and effective coping strategies are reinforced. The nurse reviews previous education and determines the need for further physical or psychological assistance. The patient's self-esteem and body image may be very poor at this time. Because people with high levels of social support often report feelings of well-being despite major physical disability, it is beneficial for the nurse to assess and promote further development of the support system and effective coping strategies for each patient. Caregivers and peer mentors play a critical role in helping patients feel less dependent, experience feelings of freedom, and reintegrate into the community (Beauchamp, Scarlett, Ruissen, et al., 2016).

The patient requires continuing, lifelong follow-up by the primary provider, physical therapist, and other rehabilitation team members, because the neurologic deficit is usually permanent and new deficits, complications, and secondary conditions can develop. These require prompt attention before they take their toll in additional physical impairment, time, morale, and financial costs. Research suggests that education and peer mentoring may decrease complications following SCI (Abrams & Wakasa, 2014); (Beauchamp et al., 2016). The nurse is in a good position to remind patients and family members of the need for continuing health promotion and screening practices. Referral to accessible health care providers and imaging centers is important in health promotion and health screening.

Evaluation

Expected patient outcomes may include:

1. Attains maximum form of mobility
2. Contractures do not develop
3. Maintains healthy, intact skin
4. Achieves bladder control, absence of UTI
5. Achieves bowel control
6. Reports sexual satisfaction
7. Shows improved adaptation to environment and others
8. Exhibits reduction in spasticity
    a. Reports understanding of the precipitating factors
    b. Uses measures to reduce spasticity
9. Describes long-term management required
10. Exhibits absence of complications

Rehabilitation of Patients with Neurotrauma and Other Neurological Conditions

Patients who sustain head injury or spinal injury need extensive rehabilitative workup to meet the self-care demands and to prevent pressure ulcer and meet the bowel and bladder elimination needs. Other neurological conditions also need extensive rehabilitation workup to have ADL independence and to improve the quality of life.

NURSING PROCESS

The Patient with Impaired Skin Integrity

Pressure ulcers are localized areas of necrotic soft tissue that occur when pressure applied to the skin over time is greater than normal capillary closure pressure, which is about 32 mm Hg. Critically ill patients have a lower capillary closure pressure and a greater risk of pressure ulcers. Patients who are prone to pressure ulcers include those confined to bed for long periods, those with motor or sensory dysfunction, and those who experience muscular atrophy and reduction of padding between the overlying skin and the underlying bone (Sullivan & Schoelles, 2013). The Centers for Medicare and Medicaid Services (CMS) has recently implemented an Inpatient Rehabilitation Facility quality reporting measure related to the percentage of residents with new or worsened pressure ulcers. Based on data from the 2011 International Pressure Ulcer Prevalence Survey, the facility prevalence of pressures ulcers was 11.2% among all facilities surveyed (Wang, Niewczyk, DiVita, et al., 2014). As well as significant pain and suffering, the consequences of developing a pressure ulcer include increased morbidity and mortality and higher medical costs and resource use, and lower odds of discharge to the community.

The American Nurses Association tracks hospital-acquired pressure ulcers (HAPU) quarterly as part of the National Database of Nursing Quality Indicators® (NDNQI®). Between the years 2004 and 2011, there was a decreasing trend in the HAPU rate overall, with more improvement beginning in 2008 (He, Staggs, Bergquist-Beringer, et al., 2013). This improvement corresponds to the year the Agency for Healthcare Research and Quality (AHRQ) included data on pressure ulcers as a patient safety indicator in the Healthcare Cost and Utilization Project (HCUP) hospital database. Despite this decrease in overall HAPU rates, development of a pressure ulcer still presents a significant patient safety risk, with increased rates of patient death and longer hospital lengths of stays and readmissions (He et al., 2013). The average length of stay for hospitalizations related to pressure ulcers is 13.4 days, with an average treatment cost of nearly $20,000 for each affected patient (He et al., 2013). All possible efforts to prevent skin breakdown must be made because the treatment of pressure ulcers is costly in terms of health care dollars and quality of life for patients at risk.

The initial sign of pressure is erythema (redness of the skin) caused by reactive hyperemia, which normally resolves in less than 1 hour. Unrelieved pressure results in tissue ischemia or anoxia. The cutaneous tissues become broken or destroyed, leading to progressive destruction and necrosis of underlying soft tissue, and the resulting pressure ulcer is painful and slow to heal.

Assessment

Nursing assessment involves identifying and evaluating risk for development of pressure ulcers as well as assessment of the skin.

Assessment of Risk Factors

Immobility, impaired sensory perception or cognition, decreased tissue perfusion, decreased nutritional status, friction and shear forces, increased moisture, and age-related skin changes all contribute to the development of pressure ulcers (DiVita, Granger, Goldstein, et al., 2015); (García-Fernández, Agreda, Verdú, et al., 2014). Chart 51-9 lists risk factors for pressure ulcers. Scales such as the Braden scale (see Table 51-4) or Norton scale (Norton, McLaren, & Exton-Smith, 1962) may be used to facilitate systematic assessment and quantification

Chart 51-9 RISK FACTORS

Pressure Ulcers

- Prolonged pressure on tissue
- Immobility, compromised mobility
- Loss of protective reflexes, sensory deficit/loss
- Poor skin perfusion, edema
- Malnutrition, hypoproteinemia, anemia, vitamin deficiency
- Friction, shearing forces, trauma
- Incontinence of urine or feces
- Altered skin moisture: excessively dry, excessively moist
- Advanced age, debilitation
- Equipment: casts, traction, restraints
- Skin problems on admission

Adapted from DiVita, M. A., Granger, C. V., Goldstein, R., et al. (2015). Risk factors for development of new or worsened pressure ulcers among patients in inpatient rehabilitation facilities in the United States: Data from the Uniform Data System for Medical Rehabilitation. Physical Medicine & Rehabilitation, 7(6), 599–612; Dunk, A. M., & Carville, K. (2015). The international clinical practice guideline for prevention and treatment of pressure ulcers/injuries. Journal of Advanced Nursing, n/a-n/a. doi: 10.1111/jan.12614; García-Fernández, F. P., Agreda, J., Verdú, J., et al. (2014). A new theoretical model for the development of pressure ulcers and other dependence-related lesions. Journal of Nursing Scholarship, 46(1), 28–38; Stifter, J., Yao, Y., Lodhi, M. K., et al. (2015). Nurse continuity and hospital-acquired pressure ulcers. Nursing Research, 64(5), 361–371.

of a patient's risk for pressure ulcer, although the nurse should recognize that the reliability of these scales is not well established for all patient populations.

Specific nursing actions related to assessing risk include:

- Evaluate level of mobility.
- Note safety and assistive devices (e.g., restraints, splints).
- Assess neurovascular status.
- Evaluate circulatory status (e.g., peripheral pulses, edema).
- Note present health problems.
- Evaluate nutritional and hydration status.
- Review the results of the patient's laboratory studies, including hematocrit, hemoglobin, electrolytes, albumin, prealbumin, transferrin, and creatinine.
- Determine presence of incontinence.
- Review current medications.

Nursing Alert: Pressure ulcers are associated with increased costs of treatment and length of hospital stay as well as diminished quality of life for patients. It is imperative that nurses perform a skin assessment on every patient admitted to a hospital, inpatient rehabilitation facility, or skilled nursing facility.

Immobility. When a person is immobile and inactive, pressure is exerted on the skin and subcutaneous tissue by objects on which the person rests, such as a mattress, chair seat, or cast. The development of pressure ulcers is directly related to the duration of immobility: If pressure continues long enough, small vessel thrombosis and tissue necrosis occur and a pressure ulcer results. Weight-bearing bony prominences are most susceptible to pressure ulcer development because they are covered only by skin and small amounts of subcutaneous tissue. Susceptible areas include the sacrum and coccygeal areas, ischial tuberosities (especially in people who sit for prolonged periods), greater trochanter, heel, knee, malleolus, medial condyle of the tibia, fibular head, scapula, and elbow (see Fig. 51-9).

Impaired Sensory Perception or Cognition. Patients with sensory loss, impaired level of consciousness, or paralysis may not be aware of the discomfort associated with prolonged pressure on the skin and therefore may not change their positions to relieve the pressure. This prolonged pressure impedes blood flow, reducing nourishment of the skin and underlying tissues. A pressure ulcer may develop in a short period of time.

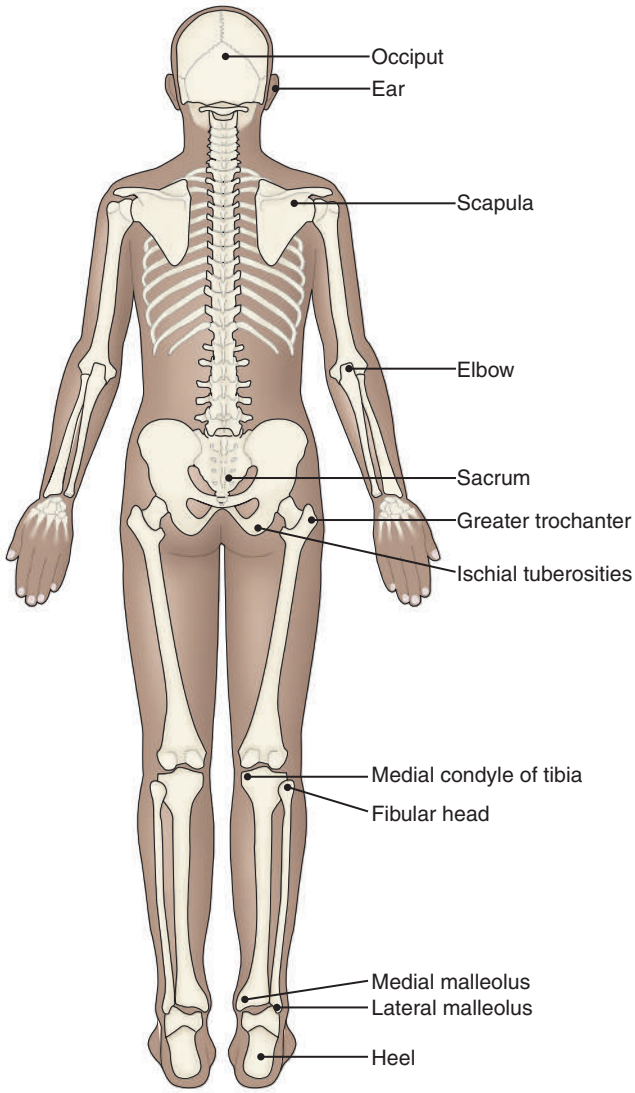

Figure 51-9 • Areas susceptible to pressure ulcers.

Decreased Tissue Perfusion. Any condition that reduces the circulation and nourishment of the skin and subcutaneous tissue (altered peripheral tissue perfusion) increases the risk of pressure ulcer development. Patients with diabetes have compromised microcirculation. Similarly, patients with edema have impaired circulation and poor nourishment of the skin tissue. Patients who are obese have large amounts of poorly vascularized adipose tissue, which is susceptible to breakdown.

Nutritional Status. Nutritional deficiencies, anemias, and metabolic disorders also contribute to the development of pressure ulcers. Anemia, regardless of its cause, decreases the blood's oxygen-carrying ability and predisposes the patient to pressure ulcers. Poor nutritional status can prolong the inflammatory phase of pressure ulcer healing and can reduce the quality and strength of wound healing (Thomas, 2015). Serum albumin and prealbumin levels are sensitive indicators of

TABLE 51-4 Braden Scale for Predicting Pressure Ulcer Risk

Patient's Name _____ Evaluator's Name _____ Date of Assessment _____								
Sensory Perception Ability to respond meaningfully to pressure-related discomfort	1. Completely Limited: Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation OR limited ability to feel pain over most of body.	2. Very Limited: Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness OR has a sensory impairment that limits the ability to feel pain or discomfort over half of body.	3. Slightly Limited: Responds to verbal commands, but cannot always communicate discomfort or the need to be turned. OR has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities.	4. No Impairment: Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain or discomfort.				
Moisture Degree to which skin is exposed to moisture	1. Constantly Moist: Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.	2. Very Moist: Skin is often, but not always, moist. Linen must be changed at least once a shift.	3. Occasionally Moist: Skin is occasionally moist, requiring an extra linen change approximately once a day.	4. Rarely Moist: Skin is usually dry, linen only requires changing at routine intervals.				
Activity Degree of physical activity	1. Bedfast: Confined to bed.	2. Chairfast: Ability to walk severely limited or nonexistent. Cannot bear own weight and/or must be assisted into chair or wheelchair.	3. Walks Occasionally: Walks occasionally during day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.	4. Walks Frequently: Walks outside room at least twice a day and inside room at least once every 2 hours during waking hours.				
Mobility Ability to change and control body position	1. Completely Immobile: Does not make even slight changes in body or extremity position without assistance.	2. Very Limited: Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.	3. Slightly Limited: Makes frequent though slight changes in body or extremity position independently.	4. No Limitation: Makes major and frequent changes in position without assistance.				
Nutrition Usual food intake pattern	1. Very Poor: Never eats a complete meal. Rarely eats more than a 1/3 of any food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement OR is NPO and/or maintained on clear liquids or IVs for more than 5 days.	2. Probably Inadequate: Rarely eats a complete meal and generally eats only about 1/2 of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement OR receives less than optimum amount of liquid diet or tube feeding.	3. Adequate: Eats half of most meals. Eats a total of 4 servings of protein (meat, dairy products) per day. Occasionally will refuse a meal, but will usually take a supplement when offered OR is on a tube feeding or TPN regimen, which probably meets most of nutritional needs.	4. Excellent: Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.				
Friction and Shear	1. Problem: Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.	2. Potential Problem: Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.	3. No Apparent Problem: Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair.

protein deficiency. Serum albumin levels of less than 3 g/dL are associated with hypoalbuminemic tissue edema and increased risk of pressure ulcers. Prealbumin levels are more sensitive indicators of protein status than albumin levels, but they are more costly to assess. The nurse should assess the patient's prealbumin and albumin values and electrolyte panel.

Friction and Shear. Mechanical forces also contribute to the development of pressure ulcers. Friction is the force of rubbing two surfaces against one another and is often caused by pulling a patient over a bed sheet (commonly known as sheet burn) or from a poorly fitted prosthetic device. Shear is the result of gravity pushing down on the patient's body and the resistance between the patient and the chair or bed (National Pressure Ulcer Advisory Panel, 2014). When shear occurs, tissue layers slide over one another, blood vessels stretch and twist, and the microcirculation of the skin and subcutaneous tissue is disrupted. Evidence of deep tissue damage may be slow to develop and may present through the development of a sinus tract, which is an area of destroyed tissue that extends from the edge of a wound. The sacrum and heels are most susceptible to the effects of shear. Pressure ulcers from friction and shear occur when the patient slides down in bed (see Fig. 51-10) or when the patient is positioned or moved improperly (e.g., dragged up in bed). Spastic muscles and paralysis increase the patient's vulnerability to pressure ulcers related to friction and shear.

Increased Moisture. Prolonged contact with moisture from perspiration, urine, feces, or drainage produces maceration (softening) of the skin. The skin reacts to caustic substances in the excreta or drainage and becomes irritated. Moist, irritated skin is more vulnerable to pressure breakdown. Once the skin breaks, the area is invaded by microorganisms (e.g., streptococci, staphylococci, *Pseudomonas aeruginosa, Escherichia coli*), and infection occurs. Foul-smelling infectious drainage is present. The lesion may enlarge and allow a continuous loss of serum, which may further deplete the body of essential protein needed for tissue repair and maintenance. The lesion may continue to enlarge and extend deep into the fascia, muscle, and bone, with multiple sinus tracts radiating from the pressure ulcer. With extensive pressure ulcers, life-threatening infections and sepsis may develop, frequently from gram-negative organisms.

Gerontologic Considerations. In older adults, the normal aging process leads to diminished epidermal thickness, dermal collagen, and tissue elasticity. The skin is drier as a result of diminished sebaceous and sweat gland activity. Cardiovascular changes result in decreased tissue perfusion. Muscles atrophy and bone structures become prominent. Diminished sensory perception and reduced ability to reposition oneself contribute to prolonged pressure on the skin. Therefore, older adults are more susceptible to pressure ulcers, which cause pain, suffering, and reduced quality of life.

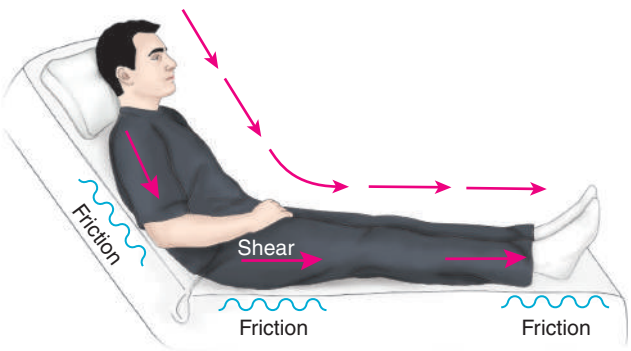

Figure 51-10 • Mechanical forces contribute to pressure ulcer development. As the person slides down or is improperly pulled up in bed, friction resists this movement. Shear occurs when one layer of tissue slides over another, disrupting microcirculation of skin and subcutaneous tissue.

Bariatric Considerations. In 2014, an international collaborative comprising members from the U.S. National Pressure Ulcer Advisory Panel (NPUAP), European Pressure Ulcer Advisory Panel (EPUAP), and the PanPacific Pressure Advisory Panel (PPPUAP) released the *Prevention and Treatment of Pressure Ulcers; Clinical Practice Guideline* (Dunk & Carville, 2015); (National Pressure Ulcer Advisory Panel, 2014). These updated guidelines include recommendations for adults who are obese with specific organization-level considerations, recommendations for the bariatric individual, as well as recommendations for bed and equipment selection and repositioning. Please see the NPUAP Web site link at the end of this chapter to review the quick reference guideline.

Assessment of Skin and Existing Ulcers

In addition to assessing risk, nursing actions to assess skin include:

- Assess total skin condition at least twice a day.
- Inspect each pressure site for erythema.
- Assess areas of erythema for blanching response.
- Palpate the skin for increased warmth.
- Inspect for dry skin, moist skin, and breaks in skin.
- Note drainage and odor.

If a pressure ulcer is seen, the nurse documents its size and location and uses a grading system to describe severity and provides a description of the site (see Chart 51-10). The appearance of purulent drainage or foul odor suggests an infection. With an extensive pressure ulcer, deep pockets of infection are often present. Drying and crusting of exudate may be present. Infection of a pressure ulcer may advance to osteomyelitis, pyarthrosis (pus formation within a joint cavity), sepsis, and septic shock.

Nursing Diagnosis

Based on the assessment data, nursing diagnoses may include the following:

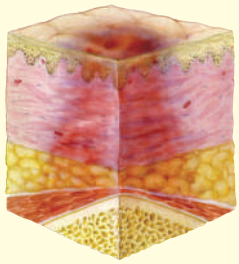
- Risk for impaired skin integrity
- Impaired skin integrity related to immobility, decreased sensory perception, decreased tissue perfusion, decreased nutritional status, friction and shear forces, excessive moisture, or advanced age

Planning and Goals

The major goals may include relief of pressure, improved mobility, improved sensory perception, improved tissue perfusion, improved nutritional status, minimized friction and shear forces, dry surfaces in contact with skin, and healing of pressure ulcer, if present.

Nursing Interventions

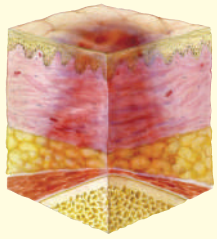
Relieving Pressure



Frequent changes of position are needed to relieve and redistribute the pressure on the patient's skin and to promote blood flow to the skin and subcutaneous tissues. This can be accomplished by instructing the patient to change position or by turning and repositioning the patient. The patient's family members should be educated about how to position and turn

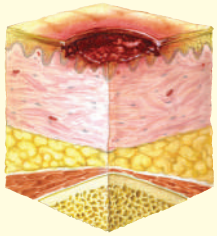
Chart 51-10

Stages in the Development of Pressure Ulcers



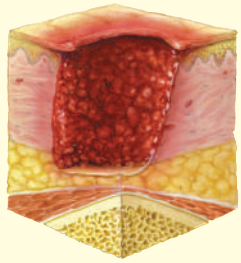
Suspected Deep Tissue Injury

- There may be a purple or maroon localized area of discolored intact skin or blood-filled blister.
- The area may be preceded in appearance by tissue that is painful, firm, mushy, boggy, and warmer or cooler as compared to adjacent tissue.
- Evolution may include a thin blister over a dark wound bed.
- The wound may further evolve and become covered by thin eschar.
- Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.



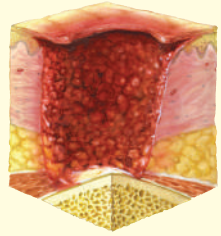
Stage I

- Intact skin
- Nonblanchable redness of a localized area, usually over a bony prominence
- Darkly pigmented skin may not have visible blanching.
- Color may differ from surrounding area.
- Area may be painful, firm, soft, and warmer or cooler as compared to adjacent tissue.



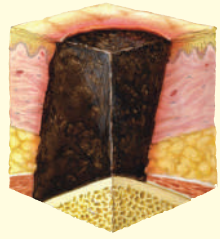
Stage II

- Partial thickness loss of dermis, presenting as a shallow open ulcer with red-pink wound bed without slough
- May present as an intact or open/ruptured serum-filled blister
- May present as a shiny or dry shallow ulcer without slough or bruising; bruising indicates suspected deep tissue injury
- Does not include skin tears, tape burns, perineal dermatitis, maceration, or excoriation



Stage III

- Full-thickness tissue loss
- Subcutaneous fat may be visible; however, bone, tendon, or muscle is not exposed.
- Slough may be present but does not obscure the depth of tissue loss.
- May include undermining and tunneling
- Depth of a stage III pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue; stage III ulcers can be shallow in these areas. Areas of significant adiposity can develop extremely deep stage III pressure ulcers.



Stage IV

- Ulcer presents with full-thickness tissue loss with exposed bone, tendon, or muscle.
- Slough or eschar may be present on some parts of the wound.
- Often includes undermining and tunneling
- Depth of a stage IV pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue; stage IV ulcers can be shallow in these areas. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule); osteomyelitis is possible. Exposed bone/tendon is visible or directly palpable.

Unstageable

- Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed
- Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined.
- Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as "the body's natural (biological) cover" and should not be removed.

the patient at home to prevent pressure ulcers. Shifting weight allows the blood to flow into the ischemic areas and helps tissues recover from the effects of pressure. Attention should be paid to patient migration (moving down in the bed) in those on bed rest, particularly when the head of the bed is elevated (Wiggermann, Kotowski, Davis, et al., 2015).

For patients who spend long periods in a wheelchair, pressure can be relieved by:

- *Push-ups*: The patient pushes down on armrests and raises buttocks off the seat of the chair (see Fig. 51-11).
- *One half push-up*: The patient repeats the push-up on the right side and then the left, pushing up on one side by pushing down on the armrest.
- *Moving side to side*: The patient moves from one side to the other while sitting in the chair.
- *Shifting*: The patient bends forward with the head down between the knees (if able) and constantly shifts in the chair.

Positioning the Patient

The degree of ability to move independently—the comfort, fatigue, loss of sensation, overall physical and mental status, and specific disorder—influences plans for changing position. Patients should be positioned laterally, prone, and dorsally in sequence unless a position is not tolerated or is contraindicated. Generally, those who experience discomfort after 30 to 60 minutes of lying prone need to be repositioned. The recumbent position is preferred to the semi-Fowler position because of increased supporting body surface area in this position.

Patients able to shift their weight every 15 to 20 minutes and move independently may change total position every 2 to 4 hours. Indications for routine repositioning every 2 hours or more frequently include loss of sensation, paralysis, coma, and edema.

Figure 51-11 • Wheelchair push-up to prevent ischial pressure ulcers. These push-ups should become an automatic routine (every 15 minutes) for the person with paraplegia. The person should stay up and out of contact with the seat for several seconds. The wheels are kept in the locked position during the exercise.

In addition to regular turning, small shifts of body weight, such as repositioning of an ankle, elbow, or shoulder, are necessary. The skin is inspected at each position change and assessed for temperature elevation. If redness or heat is noted or if the patient complains of discomfort, pressure on the area must be relieved.

Another way to relieve pressure over bony prominences is the bridging technique, accomplished through the correct positioning of pillows. Just as a bridge is supported on pillars to allow traffic to move underneath, the body can be supported by pillows to allow for space between bony prominences and the mattress. A pillow or commercial heel protector may be used to support the heels off the bed when the patient is supine. Placing pillows superior and inferior to the sacrum relieves sacral pressure. Supporting the patient in a 30-degree side-lying position avoids pressure on the trochanter. In older adult patients, frequent small shifts of body weight may be effective. Placing a small rolled towel or sheepskin under a shoulder or hip allows a return of blood flow to the skin in the area on which the patient is sitting or lying. The towel or sheepskin is moved around the patient's pressure points in a clockwise fashion. A turning schedule can help the family keep track of the patient's turns.

Using Pressure-Relieving Devices

At times, specialty beds or alternative bed surfaces may be indicated to help relieve the pressure on the skin (Stifter, Yao, Lodhi, et al., 2015). This is particularly important for patients who cannot get out of bed and who are at high risk for pressure ulcer development. These devices are designed to provide support for specific body areas or to distribute pressure evenly.

A patient who sits in a wheelchair for prolonged periods should have wheelchair cushions fitted and adjusted on an individualized basis, using pressure measurement techniques as a guide to selection and fitting. The aim is to redistribute pressure away from areas at risk for ulcers; however, no cushion can eliminate excessive pressure completely. The patient should be reminded to shift weight frequently and to rise for a few seconds every 15 minutes while sitting in a chair.

Static support devices (e.g., high-density foam, air, or liquid mattress overlays) distribute pressure evenly by bringing more of the patient's body surface into contact with the supporting surface. Gel-type flotation pads and air-fluidized beds reduce pressure. The weight of a body floating on a fluid system is evenly distributed over the entire supporting surface. Therefore, as the body sinks into the fluid, additional surface becomes available for weight bearing, body weight per unit area is decreased, and there is less pressure on the body parts.

Soft, moisture-absorbing padding is also useful because the softness and resilience of padding provide for more even distribution of pressure and the dissipation and absorption of moisture, along with freedom from wrinkles and friction. Bony prominences may be protected by gel pads, sheepskin padding, or soft foam rubber beneath the sacrum, the trochanters, heels, elbows, scapulae, and back of the head when there is pressure on these sites. One group of researchers found that sacral pressure was reduced using a liquid-based pad that covers only the sacral area and can be applied on any bed surface (Duetzmann, Forsey, Senft, et al., 2015).

Specialized beds are designed to prevent pressure on the skin. Air-fluidized beds allow the patient to float. Dynamic support surfaces, such as low air-loss pockets, alternately

inflate and deflate sections to change support pressure for very high risk patients who are critically ill and debilitated (i.e., impaired strength, weakened, injured, disabled) and cannot be repositioned to relieve pressure. Oscillating or kinetic beds change pressure by means of rocking movements of the bed that redistribute the patient's weight and stimulate circulation. These beds may be used with patients who have injuries attributed to multiple trauma. Specialized beds, which are more expensive than mattress overlays, are no more effective at preventing pressure ulcers than the overlays; there is insufficient evidence to support the choice of one specific bed surface over another (Qaseem, Humphrey, Forciea, et al., 2015).

Improving Mobility

The patient is encouraged to remain active and is ambulated whenever possible. When sitting, the patient is reminded to change positions frequently to redistribute weight. Active and passive exercises increase muscular, skin, and vascular tone. For patients at risk for pressure ulcers, turning and exercise schedules are essential, and repositioning must occur around the clock.

Improving Sensory Perception

The nurse helps the patient recognize and compensate for altered sensory perception. Depending on the origin of the alteration (e.g., decreased level of consciousness, spinal cord lesion), specific interventions are selected. Strategies to improve cognition and sensory perception may include stimulating the patient to increase awareness of self in the environment, encouraging the patient to participate in self-care, or supporting the patient's efforts toward active compensation for loss of sensation (e.g., a patient with paraplegia lifting up from the sitting position every 15 minutes). A patient with quadriplegia should be weight shifted every 30 minutes while sitting in a wheelchair. When decreased sensory perception exists, the patient and caregivers are taught to inspect potential pressure areas visually every morning and evening, using a mirror if necessary, for evidence of pressure ulcer development.

Improving Tissue Perfusion

Activity, exercise, and repositioning improve tissue perfusion. Massage of erythematous areas is avoided because damage to the capillaries and deep tissue may occur (National Pressure Ulcer Advisory Panel, 2014).

Nursing Alert: The nurse should avoid massaging reddened areas because this may increase the damage to already traumatized skin and tissue.

In patients who have evidence of compromised peripheral circulation (e.g., edema), positioning and elevation of the edematous body part to promote venous return and diminish congestion improve tissue perfusion. In addition, the nurse or family must be alert to environmental factors (e.g., wrinkles in sheets, pressure of tubes) that may contribute to pressure on the skin and diminished circulation and remove the source of pressure.

Improving Nutritional Status

The patient's nutritional status must be adequate, and a positive nitrogen balance must be maintained because pressure ulcers develop more quickly and are more resistant to treatment in patients with nutritional disorders. A high-protein diet with protein supplements may be helpful. Iron preparations may be necessary to raise the hemoglobin concentration so that tissue oxygen levels can be maintained within acceptable limits. Ascorbic acid (vitamin C) is necessary for tissue healing. Other nutrients associated with healthy skin include vitamin A, B vitamins, zinc, and sulfur. With adequate nutrition and hydration, the skin can remain healthy, and damaged tissues can be repaired (Posthauer, Banks, Dorner, et al., 2015); (Saha, Smith, Totten, et al., 2013).

To assess the patient's nutritional status in response to therapeutic strategies, the nurse monitors the patient's hemoglobin, pre-albumin level, and body weight weekly. Nutritional assessment is described in further detail in Chapter 3.

Reducing Friction and Shear

Raising the head of the bed by even a few centimeters increases the shearing force over the sacral area; therefore, the semi-reclining position is avoided in patients at risk. Proper positioning with adequate support is also important when the patient is sitting in a chair.

Nursing Alert: To avoid shearing forces when repositioning patients, the nurse must lift and avoid dragging patients across a surface. Lift devices should be used to prevent occupational injuries.

Minimizing Irritating Moisture

Continuous moisture on the skin must be prevented by meticulous hygiene measures. It is important to pay special attention to skin folds, including areas under the breasts, arms, and groin, and between the toes. Perspiration, urine, stool, and drainage must be removed from the skin promptly. The soiled skin should be washed immediately with mild soap and water and blotted dry with a soft towel. The skin may be lubricated with a bland lotion to keep it soft and pliable. Drying agents and powders are avoided. Topical barrier ointments (e.g., petroleum jelly) may be helpful in protecting the skin of patients who are incontinent.

Absorbent pads that wick moisture away from the body should be used to absorb drainage. Patients who are incontinent need to be checked regularly and have their wet incontinence pads and linens changed promptly. Their skin needs to be cleansed and dried promptly.

Promoting Pressure Ulcer Healing

Regardless of the stage of the pressure ulcer, the pressure on the area must be eliminated because the ulcer will not heal until all pressure is removed. The patient must not lie or sit on the pressure ulcer, even for a few minutes. Individualized positioning and turning schedules must be written in the plan of nursing care and followed meticulously.

In addition, inadequate nutritional status and fluid and electrolyte abnormalities must be corrected to promote healing. Wounds from which body fluids and protein drain place the patient in a catabolic state and predispose to hypoproteinemia and serious secondary infections. Protein deficiency must be corrected to promote the healing of the pressure ulcer. Carbohydrates are necessary to "spare" the protein and to provide an energy source. Vitamin C and trace elements, especially zinc, are necessary for collagen formation and wound healing. (Refer to Chart 51-10 for descriptions of stages of pressure ulcers.)

Deep Tissue Injury. These tissue injuries may evolve rapidly, and immediate pressure relief to the affected area is indicated.

Therefore, the nurse must be vigilant in assessing for these types of injuries (Dunk & Carville, 2015); (National Pressure Ulcer Advisory Panel, 2014).

Stage I Pressure Ulcers. To permit healing of stage I pressure ulcers, the pressure is removed to allow increased tissue perfusion, nutritional and fluid and electrolyte balance is maintained, friction and shear are reduced, and moisture to the skin is avoided (Dunk & Carville, 2015); (National Pressure Ulcer Advisory Panel, 2014).

Stage II Pressure Ulcers. In addition to measures listed for stage I pressure ulcers, a moist environment, in which migration of epidermal cells over the ulcer surface occurs more rapidly, should be provided to aid wound healing. The ulcer is gently cleansed with sterile saline solution. The use of a heat lamp to dry the open wound is avoided, as is the use of antiseptic solutions that damage healthy tissues and delay wound healing. Semipermeable occlusive dressings, hydrocolloid wafers, or wet saline dressings are helpful in providing a moist environment for healing and in minimizing the loss of fluids and proteins from the body (Dunk & Carville, 2015); (National Pressure Ulcer Advisory Panel, 2014).

Stage III Pressure Ulcers. Stage III pressure ulcers are characterized by extensive tissue damage, including slough (i.e., soft, moist avascular tissue), tunneling (i.e., formation of a sinus tract), and undermining (i.e., extensive tunneling under wound edge), to name a few. Given the extensive damage to tissue and necrosis that characterize stage III pressure ulcers, they must be cleaned (débrided) to create an area that will heal, in addition to the measures listed for stage I pressure ulcers. Necrotic, devitalized tissue favors bacterial growth, delays granulation, and inhibits healing. Wound cleaning and dressing are uncomfortable; therefore, the nurse must prepare the patient for the procedure by explaining what will occur and administering prescribed analgesia (Dunk & Carville, 2015); (National Pressure Ulcer Advisory Panel, 2014).

Stage IV Pressure Ulcers. Surgical interventions are required for these extensive pressure ulcers (National Pressure Ulcer Advisory Panel, 2014). (See the following Other Treatment Methods section.)

Other Treatment Methods

Débridement may be accomplished by wet-to-damp dressing changes, mechanical flushing of necrotic and infective exudate, application of prescribed enzyme preparations that dissolve necrotic tissue, or surgical dissection. If eschar (dry scab) covers the ulcer, it is removed surgically to ensure the wound is clean and vitalized. Exudate may be absorbed by dressings or special hydrophilic powders, beads, or gels. Cultures of infected pressure ulcers are obtained to guide the selection of antibiotic therapy.

After the pressure ulcer is clean, a topical treatment is prescribed to promote granulation. New granulation tissue must be protected from reinfection, drying, and damage, and care should be taken to prevent pressure and further trauma to the area. Dressings, solutions, and ointments applied to the ulcer should not disrupt the healing process. For chronic, noninfected ulcers that are healing by secondary intention (healing of an open wound from the base upward by laying down new tissue), vacuum-assisted closure (VAC) or hyperbaric oxygen treatment may be used. VAC involves the use of a negative-pressure sponge dressing in the wound to increase blood flow, increasing formation of granulation tissue and nutrient uptake and decreasing bacterial load. Hyperbaric oxygen therapy involves either the application of topical oxygen at increased pressure directly to the wound or placing the patient into a hyperbaric oxygen chamber. Both methods of hyperbaric oxygen therapy promote wound healing by stimulating new vascular growth and aiding in the preservation of damaged tissue (Dauwe, Pulikkottil, Lavery, et al., 2014). In a recent systematic review, Stoekenbroek, Santema, Legemate, et al. (2014) reported that hyperbaric oxygen therapy improves healing in patients with diabetic leg ulcers; however, more studies are needed prior to routinely introducing this therapy into clinical practice.

Multiple agents and protocols are used to treat pressure ulcers; however, consistency is an important key to success. Objective evaluation of the pressure ulcer (e.g., measurement of the size and depth of the pressure ulcer, inspection for granulation tissue) for response to the treatment protocol must be made every 4 to 6 days. Taking photographs at weekly intervals is a reliable strategy for monitoring the healing process, which may take weeks to months.

Surgical intervention is necessary when the ulcer is extensive, when complications (e.g., fistula) exist, and when the ulcer does not respond to treatment. Surgical procedures include débridement, incision and drainage, bone resection, and skin grafting. Osteomyelitis is a common complication of wounds of stage IV depth. (See Chapter 37 for more information on osteomyelitis.)

Preventing Recurrence

It may take more than a year for healing tissue to regain the strength of pre-injury skin; thus, care must be taken to prevent recurrence of pressure ulcers. However, recurrence of pressure ulcers should be anticipated; therefore, active, preventive intervention and frequent continuing assessments are essential. For example, pressure ulcers are the second most comorbid problem in patients with SCI with 85% of patients with SCI developing a pressure ulcer at least once in their lifetime (Scheel-Sailer, Wyss, Boldt, et al., 2013). The patient's tolerance for sitting or lying on the healed pressure area is increased gradually by increasing the time that pressure is allowed on the area in 5-to 15-minute increments. The patient is instructed to increase mobility and to follow a regimen of turning, weight shifting, and repositioning. The patient education plan includes strategies to reduce the risk of pressure ulcers and methods to detect, inspect, and minimize pressure areas. Early recognition and intervention are keys to long-term management of potential impaired skin integrity. Gould, Olney, Nichols, et al. (2014) suggest immobility and incontinence are among modifiable risk factors that contribute to recurrent pressure ulcer development, particularly in patients with SCI; they suggest the development of structured guidelines to prevent pressure ulcers rests on the identification of factors that differ in patients with SCI who have none, one, or more pressure ulcers. Identifying potentially modifiable risk factors or protective factors may then lead to evidence-based risk assessment tools and interventions customized to patient-specific risks.

Evaluation

Expected patient outcomes may include:

1. Maintains intact skin
   a. Exhibits no areas of nonblanchable erythema at bony prominences
   b. Avoids massage of bony prominences

   c. Exhibits no breaks in skin
2. Limits pressure on bony prominences
   a. Changes position every 1 to 2 hours
   b. Uses bridging techniques to reduce pressure
   c. Uses special equipment as appropriate
   d. Raises self from seat of wheelchair every 15 minutes
3. Increases mobility
   a. Performs range-of-motion exercises
   b. Adheres to turning schedule
   c. Advances sitting time as tolerated
4. Has improved sensory and cognitive ability
   a. Demonstrates improved level of consciousness
   b. Remembers to inspect potential pressure ulcer areas every morning and evening
5. Demonstrates improved tissue perfusion
   a. Exercises to increase circulation
   b. Elevates body parts susceptible to edema
6. Attains and maintains adequate nutritional status
   a. Verbalizes the importance of protein and vitamin C in diet
   b. Eats diet high in protein and vitamin C
   c. Exhibits acceptable levels of hemoglobin, electrolyte, prealbumin, transferrin, and creatinine
7. Avoids friction and shear
   a. Avoids semireclining position
   b. Uses heel protectors when appropriate
   c. Lifts body instead of sliding across surfaces
8. Maintains clean, dry skin
   a. Avoids prolonged contact with wet or soiled surfaces
   b. Keeps skin clean and dry
   c. Uses lotion to keep skin lubricated

NURSING PROCESS

The Patient With Altered Elimination Patterns

Urinary incontinence and bowel incontinence or constipation and impaction are problems that often occur in patients with disabilities. Incontinence curtails the person's independence, causing embarrassment and isolation. Based on structured oral interviews conducted to collect data on bothersome urinary or fecal incontinence in adults aged 50 and older, 20% of women and 6.4% of men reported urinary incontinence (less than once/month, a few times/month, a few times/week or every day/night) (Gorina, Schappert, Bercovitz, et al., 2014); (Roe, Flanagan, & Maden, 2015). Fecal incontinence (leakage of gas, mucus, liquid or solid stool at least monthly) was reported by 8.2% of women and 8.4% of men (Wu, Matthews, Vaughan, et al., 2015). Internationally, nearly 55% of nursing home residents will experience bowel and/or bladder incontinence at some point (Mandl, Halfens, & Lohrmann, 2015). For patients with disabilities who experience constipation, complete and predictable evacuation of the bowel is the goal. If a bowel routine is not established, the patient may experience abdominal distention; small, frequent oozing of stool; or impaction.

Assessment

Urinary incontinence may result from multiple causes, including urinary tract infection, detrusor instability, bladder outlet obstruction or incompetence, neurologic impairment, bladder spasm or contracture, and inability to reach the toilet in time. Urinary incontinence can be classified as urge, reflex, stress, functional, overflow, or total (Herdman & Kamitsuru, 2014):

- *Urge incontinence* occurs when involuntary elimination of urine is associated with a strong perceived need to void.
- *Reflex (neurogenic) incontinence* is associated with a spinal cord lesion that interrupts cerebral control, resulting in no sensory awareness of the need to void.
- *Stress incontinence* is associated with weakened perineal muscles that permit leakage of urine when intra-abdominal pressure is increased (e.g., with coughing or sneezing).
- *Functional incontinence* occurs in patients with intact urinary physiology who experience mobility impairment, environmental barriers, or cognitive problems and cannot reach and use the toilet before soiling themselves.
- *Overflow urinary incontinence* is described as the involuntary loss of urine associated with overdistention of the bladder. Reasons for overdistention and urine leakage vary, but may be related to improper emptying of the bladder, fecal impaction, urethral obstruction, or medication side effect.
- *Total urinary incontinence* occurs in patients who cannot control urine because of physiologic or psychological impairment. Management of the urine is an essential focus of nursing care.

Elimination Assessment

The health history is used to explore bladder and bowel function, symptoms associated with dysfunction, physiologic risk factors for elimination problems, perception of micturition (urination, or voiding), and functional toileting abilities. Previous and current fluid intake and voiding patterns may be helpful in designing the plan of nursing care. A record of times of voiding and amounts voided is kept for at least 48 hours. In addition, episodes of incontinence and associated activity (e.g., coughing, sneezing, lifting), fluid intake time and amount, and medications are recorded. This record is analyzed and used to determine patterns and relationships of incontinence to other activities and factors.

The ability to get to the bathroom, manipulate clothing, and use the toilet are important functional factors that may be related to incontinence. Related cognitive functioning (perception of need to void, verbalization of need to void, and ability to learn to control urination) must also be assessed. In addition, the nurse reviews the results of the diagnostic studies (e.g., urinalysis, urodynamic tests, post-voiding residual volumes).

Bowel incontinence and constipation may result from multiple causes, such as diminished or absent sphincter control, cognitive or perceptual impairment, neurogenic factors, diet, and immobility. The origin of the bowel problem must be determined. The nurse assesses the patient's normal bowel patterns, nutritional patterns, use of laxatives, gastrointestinal problems (e.g., colitis), bowel sounds, anal reflex and tone, and functional abilities. The character and frequency of bowel movements are recorded and analyzed.

Nursing Diagnosis

Based on the assessment data, major nursing diagnoses may include the following:

- Functional urinary incontinence
- Urge urinary incontinence

- Reflex urinary incontinence
- Stress urinary incontinence
- Impaired urinary elimination
- Overflow urinary incontinence
- Urinary retention
- Constipation
- Bowel incontinence

Planning and Goals

The major goals may include control of urinary incontinence or urinary retention, control of bowel incontinence, and regular elimination patterns.

Nursing Interventions

Promoting Urinary Continence

After the nature of the urinary incontinence has been identified, a plan of nursing care is developed based on an analysis of the assessment data. Various approaches to promote urinary continence have been developed (Roe, Flanagan, & Maden, 2015). Most approaches attempt to condition the body to control urination or to minimize the occurrence of unscheduled urination. Selection of the approach depends on the cause and type of the incontinence. For the program to be successful, participation by the patient and a desire to avoid incontinence episodes are crucial; an optimistic attitude with positive feedback for even slight gains is essential for success. Accurate recording of intake and output and of the patient's response to selected strategies is essential for evaluation.

At no time should the fluid intake be restricted to decrease the frequency of urination. Sufficient fluid intake (2,000 to 3,000 mL per day, according to patient needs) must be ensured. To optimize the likelihood of voiding as scheduled, measured amounts of fluids may be given about 30 minutes before voiding attempts. In addition, most of the fluids should be consumed before evening to minimize the need to void frequently during the night.

Nursing Alert: Carbonated soft drinks, milk shakes, alcohol, tomato juice, and citrus fruit juices are alkaline-producing drinks that promote bacterial growth in the urine. Patients should be encouraged to drink more acid-producing fluids (e.g., cranberry and cranapple juice) to reduce the chance of urinary tract infection. Water is a preferred fluid because it flushes the kidneys and bladder.

The goal of bladder training is to restore the bladder to normal function. Bladder training can be used with cognitively intact patients experiencing urge incontinence. A voiding and toileting schedule is developed based on an analysis of the assessment data. The schedule specifies times for the patient to try to empty the bladder using a bedpan, toilet, or commode. Privacy should be provided during voiding efforts. The interval between voiding times in the early phase of the bladder training period is short (90 to 120 minutes). The patient is encouraged not to void until the specified voiding time. Voiding success and episodes of incontinence are recorded. As the patient's bladder capacity and control increase, the interval is lengthened. Usually, there is a temporal relationship between drinking, eating, exercising, and voiding. Alert patients can participate in recording intake, activity, and voiding and can plan the schedule to achieve maximum continence. Barrier-free access to the toilet and modification of clothing can help patients with functional incontinence achieve self-care in toileting and continence.

Habit training is used to try to keep patients dry by strict adherence to a toileting schedule and may be successful with stress, urge, or functional incontinence. If the patient is confused, caregivers take the patient to the toilet according to the schedule before involuntary voiding occurs. Simple cuing and consistency promote success. Periods of continence and successful voiding are positively reinforced.

Biofeedback is a system through which patients learn to consciously contract urinary sphincters and control voiding cues. Cognitively intact patients who have stress or urge incontinence may gain bladder control through biofeedback.

Pelvic floor exercises (Kegel exercises) strengthen the pubococcygeus muscle. The patient is instructed to tighten the pelvic floor muscles for 4 seconds 10 times, and this is repeated 4 to 6 times a day. Stopping and starting the stream during urination is recommended to increase control. Daily practice is essential. These exercises are helpful for cognitively intact women who experience stress incontinence.

Suprapubic tapping or stroking of the inner thigh may produce voiding by stimulating the voiding reflex arc in patients with reflex incontinence. However, this method is not always effective, owing to a lack of detrusor sphincter muscle coordination. As the bladder reflexively contracts to expel urine, the bladder sphincter reflexively closes, producing a high residual urine volume and an increased incidence of urinary tract infection.

Intermittent self-catheterization is an appropriate alternative for managing reflex incontinence, urinary retention, and overflow incontinence attributed to an overdistended bladder. The nurse emphasizes regular emptying of the bladder rather than sterility. Patients with disabilities may reuse and clean catheters with bleach or hydrogen peroxide solutions or soap and water and may use a microwave oven to sterilize catheters. Aseptic intermittent catheterization technique is required in health care institutions because of the potential for bladder infection from resistant organisms. Intermittent self-catheterization may be difficult for patients with limited mobility, dexterity, or vision; however, family members can be taught the procedure.

Self-catheterization is also particularly pertinent for patients with SCI, because most of these patients do not have voluntary control of urination. Even those patients with spinal cord injuries who can voluntarily void should measure their residual urine (the amount of urine that remains in the bladder after voluntary or involuntary voiding) by self-catheterization.

Indwelling catheters are avoided if at all possible because of the high incidence of urinary tract infections associated with their use. Short-term use may be needed during treatment of severe skin breakdown due to continued incontinence. Patients with disabilities who cannot perform intermittent self-catheterization may elect to use suprapubic catheters for long-term bladder management. Suprapubic catheters are easier to maintain than indwelling catheters.

External catheters (condom catheters) and leg bags to collect spontaneous voidings are useful for male patients with reflex or total incontinence. The appropriate design and size must be chosen for maximal success, and the patient or caregiver must be taught how to apply the condom catheter and how to provide daily hygiene, including skin inspection. Instruction on emptying the leg bag must also be provided, and modifications can be made for patients with limited hand dexterity.

Incontinence pads (briefs) may be useful at times for patients with stress or total incontinence to protect clothing

but should be avoided whenever possible. Incontinence pads only manage, rather than solve, the incontinence problem. In addition, they have a negative psychological effect on patients, because many people think of the pads as diapers. Every effort should be made to reduce the incidence of incontinence episodes through the other methods that have been described. When incontinence pads are used, they should wick moisture away from the body to minimize contact of moisture and excreta with the skin. Wet incontinence pads must be changed promptly, the skin cleansed, and a moisture barrier applied to protect the skin. It is important for the patient's self-esteem to avoid use of the term *diapers*.

Promoting Bowel Continence

The goals of a bowel training program are to develop regular bowel habits and to prevent uninhibited bowel elimination. Regular, complete emptying of the lower bowel results in bowel continence. A bowel training program takes advantage of the patient's natural reflexes. Regularity, timing, nutrition and fluids, exercise, as well as correct positioning promote predictable defecation (Hotouras, Ribas, Allison, et al., 2014).

The nurse records defecation time, character of stool, nutritional intake, cognitive abilities, and functional self-care toileting abilities for 5 to 7 days. Analysis of this record is helpful when designing a bowel program for patients with fecal incontinence.

Consistency in implementing the plan is essential. A regular time for defecation is established, and attempts at evacuation should be made within 15 minutes of the designated time daily. Natural gastrocolic and duodenocolic reflexes occur about 30 minutes after a meal; therefore, after breakfast is one of the best times to plan for bowel evacuation. However, if the patient had a previously established habit pattern at a different time of day, it should be followed.

The anorectal reflex may be stimulated by a rectal suppository (e.g., glycerin) or by mechanical stimulation (e.g., digital stimulation with a lubricated gloved finger or anal dilator). Mechanical stimulation should be used only in patients with a disability who have no voluntary motor function and no sensation as a result of injuries above the sacral segments of the spinal cord, such as patients with quadriplegia, high paraplegia, or severe brain injuries. The technique is not effective in patients who do not have an intact sacral reflex arc (e.g., those with flaccid paralysis). Mechanical stimulation, suppository insertion, or both should be initiated about 30 minutes before the scheduled bowel elimination time, and the interval between stimulation and defecation is noted for subsequent modification of the bowel program. Once the bowel routine is well established, stimulation with a suppository may not be necessary.

The patient should assume the normal squatting position and be in a private bathroom for defecation if at all possible, although a padded commode chair or bedside toilet is an alternative. An elevated toilet seat is a simple modification that may make use of the toilet easier for the patient with a disability. Seating time is limited in patients who are at risk for skin breakdown. Bedpans should be avoided. A patient with a disability who cannot sit on a toilet should be positioned on the left side with legs flexed and the head of the bed elevated 30 to 45 degrees to increase intra-abdominal pressure. Protective padding is placed behind the buttocks. When possible, the patient is instructed to bear down and to contract the abdominal muscles. Massaging the abdomen from right to left facilitates movement of feces in the lower tract.

Preventing Constipation

The record of bowel elimination, character of stool, food and fluid intake, level of activity, bowel sounds, medications, and other assessment data are reviewed to develop the plan of care. Multiple approaches may be used to prevent constipation. The diet should include adequate intake of high-fiber foods (vegetables, fruits, bran) to prevent hard stools and to stimulate peristalsis. Daily fluid intake should be 2 to 3 L unless contraindicated. Drinking prune juice (120 mL) 30 minutes before a meal once daily is helpful in some cases when constipation is a problem. Physical activity and exercise are encouraged, as is self-care in toileting. Patients are encouraged to respond to the natural urge to defecate. Privacy during toileting is provided. Stool softeners, bulk-forming agents, mild stimulants, and suppositories may be prescribed to stimulate defecation and to prevent constipation.

Evaluation

Expected patient outcomes may include:

1. Demonstrates control of bowel and bladder function
   a. Experiences no episodes of incontinence
   b. Avoids constipation
   c. Achieves independence in toileting
   d. Expresses satisfaction with level of bowel and bladder control
2. Achieves urinary continence
   a. Uses therapeutic approach that is appropriate to type of incontinence
   b. Maintains adequate fluid intake
   c. Washes and dries skin after episodes of incontinence
3. Achieves bowel continence
   a. Participates in bowel program
   b. Verbalizes need for regular time for bowel evacuation
   c. Modifies diet to promote continence
   d. Uses bowel stimulants as prescribed and needed
4. Experiences relief of constipation
   a. Uses high-fiber diet, fluids, and exercise to promote defecation
   b. Responds to urge to defecate

Promoting Home, Community-Based, and Transitional Care

An important goal of rehabilitation is to assist the patient to return to the home environment after learning to manage the disability. A referral system maintains continuity of care when the patient is transferred to the home or to a long-term care facility. The plan for discharge is formulated when the patient is first admitted to the hospital, and discharge plans are made with the patient's functional potential in mind.

Educating Patients About Self-Care

Significant expenditures of time and resources are necessary to ensure that patients gain the skills and confidence to self-manage their health effectively after discharge from the hospital (Schmidt, 2013). Formal programs provide patients with effective strategies for interpreting and managing disease-specific issues and skills needed for problem solving, as well as building and maintaining self-awareness and self-efficacy. Self-care programs often use multifaceted approaches, including didactic teaching,

group sessions, individual learning plans, and Web-based resources. When planning the approach to self-care, the nurse must consider the individual patient's knowledge, experience, social and cultural background, level of formal education, and psychological status. The preparation for self-care must also be spread out over the course of the recovery period, and it must be monitored and updated regularly as the patient masters aspects of self-care. Preparation for self-care is also highly relevant for informal caregivers of patients in rehabilitation.

When a patient is discharged from acute care or a rehabilitation facility, informal caregivers, typically family members, often assume the care and support of the patient. Although the most obvious care tasks involve physical care (e.g., personal hygiene, dressing, meal preparation), other elements of the caregiving role include psychosocial support and a commitment to this supportive role. Thus, the nurse must assess the patient's support system (family, friends) well in advance of discharge. The positive attitudes of family and friends toward the patient, their disability, and the return home are important in making a successful transition to home. Not all families can carry out the arduous programs of exercise, physical therapy, and personal care that the patient may need. They may not have the resources or stability to care for family members with a severe disability. The physical, emotional, economic, and energy strains of a disabling condition may overwhelm even a stable family. Members of the rehabilitation team must not judge the family but rather should provide supportive interventions that help the family to attain its highest level of function.

The family members need to know as much as possible about the patient's condition and care so that they do not fear the patient's return home. The nurse develops methods to help the patient and family cope with problems that may arise. For example, the nurse may develop an ADL checklist individualized for the patient and family to ensure that the family is proficient in assisting the patient with certain tasks (see Chart 51-11).

Chart 51-11 HOME CARE CHECKLIST

Managing the Therapeutic Regimen at Home

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of disability on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies after discharge.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization:
  - Wheelchair—manual/power
  - Cushion
  - Grab bars
  - Sliding board
  - Mechanical lift
  - Raised padded commode seat
  - Padded commode wheelchair
  - Bedside commode
  - Crutches
  - Walker
  - Cane
  - Prosthesis
  - Orthosis
  - Shower chair
  - Specialty bed
- Demonstrate usage of adaptive equipment for activities of daily living:
  - Long-handled sponge
  - Reacher
  - Universal cuff
  - Plate mat and guard
  - Rocker-knife, spork, weighted utensils
  - Special closures for clothing
  - Other
- Demonstrate mobility skills:
  - Transfers: bed to chair; in and out of toilet and tub; in and out of car
  - Negotiate ramps, curbs, stairs
  - Assume sitting from supine position
  - Turn side to side in bed
  - Maneuver wheelchair; manage armrests and leg rests; lock brakes
  - Ambulate safely using assistive devices
  - Perform range-of-motion exercises
  - Perform muscle-strengthening exercises
- Demonstrate skin care:
  - Inspect bony prominences every morning and evening
  - Identify stage I pressure ulcer and actions to take if present
  - Change dressings for stage II to IV pressure ulcers
  - State dietary requirements to promote healing of pressure ulcers
  - Demonstrate pressure relief at prescribed intervals
  - State sitting schedule and demonstrate weight lifts in wheelchair
  - Demonstrate adherence to bed turning schedule, bed positioning, and the use of bridging techniques
  - Apply and wear protective boots at prescribed times
  - Demonstrate correct wheelchair sitting posture
  - Demonstrate techniques to avoid friction and shear in bed
  - Demonstrate proper hygiene to maintain skin integrity
- Demonstrate bladder care:
  - State schedule for voiding, toileting, and catheterization
  - Identify relationship of fluid intake to voiding and catheterization schedule
  - State how to perform pelvic floor exercises
  - Demonstrate clean self-intermittent catheterization and care of catheterization equipment
  - Demonstrate indwelling catheter care
  - Demonstrate application of external condom catheter
  - Demonstrate application, emptying, and cleaning of urinary drainage bag
  - Demonstrate application of incontinence pads and performance of perineal hygiene
  - State signs and symptoms of urinary tract infection
  - State signs and symptoms of urinary catheter blockage
- Demonstrate bowel care:
  - State optimum dietary intake to promote evacuation
  - Identify schedule for optimum bowel evacuation
  - Demonstrate techniques to increase intra-abdominal pressure: Valsalva maneuver; abdominal massage; leaning forward
  - Demonstrate techniques to stimulate bowel movements: ingesting warm liquids; digital stimulation; insertion of suppositories

(*Continued*)

(*Continued*)

- Demonstrate optimum position for bowel evacuation: on toilet with knees higher than hips; left side in bed with knees flexed and head of bed elevated 30 to 45 degrees
- Identify complications and corrective strategies for bowel retraining: constipation, impaction, diarrhea, hemorrhoids, rectal bleeding, anal tears

• Identify community resources for peer and caregiver/family support:
- Identify sources of support (e.g., friends, relatives, faith community)
- Identify phone numbers of support groups for people with disabilities and their caregivers/families
- State meeting locations and times

• Demonstrate how to access transportation:
- Identify locations of wheelchair accessibility for public buses or trains
- Identify phone numbers for private wheelchair van
- Contact Division of Motor Vehicles for handicapped parking permit
- Contact Division of Motor Vehicles for driving test when appropriate
- Identify resources for adapting private vehicle with hand controls or wheelchair lift

• Identify vocational rehabilitation resources:
- State name and phone number of vocational rehabilitation counselor
- Identify educational opportunities that may lead to future employment

• Identify community resources for recreation:
- State local recreation centers that offer programs for people with disabilities
- Identify leisure activities that can be pursued in the community
- State how to reach primary provider with questions or if complications arise
- State time and date of follow-up appointments
- Identify the need for health promotion, disease prevention, and screening activities

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

Continuing and Transitional Care

A home care or transitional care nurse may visit the patient prior to discharge, interview the patient and the family, and review the ADL sheet to learn which activities the patient can perform. This helps to ensure that continuity of care is provided and that the patient does not regress yet maintains the independence gained while in the hospital or rehabilitation setting. The family may need to purchase, borrow, or improvise needed equipment, such as safety rails, a raised toilet seat or commode, or a tub bench. Ramps may need to be built or doorways widened to allow full access.

Family members are taught how to use equipment and are given a copy of the equipment manufacturer's instruction booklet, the names of resource people, lists of equipment-related supplies, and locations where they may be obtained. A written summary of the care plan is included in family education. The patient and family members are reminded about the importance of routine health screening and other health promotion strategies.

A network of support services and communication systems may be required to enhance opportunities for independent living. The nurse uses collaborative, administrative skills to coordinate these activities and pull together the network of care. The nurse also provides skilled care, initiates additional referrals when indicated, and serves as a patient advocate and counselor when obstacles are encountered. The nurse continues to reinforce prior patient education and helps the patient to set and achieve attainable goals. The degree to which the patient adapts to the home and community environment depends on the confidence and self-esteem developed during the rehabilitation process and on the acceptance, support, and reactions of family members, employers, and community members.

There is a growing trend toward independent living by people with severe disabilities, either alone or in groups that share resources. Preparation for independent living should include training in managing a household and working with personal care attendants as well as training in mobility. The goal is integration into the community—living and working in the community with accessible housing, employment, public buildings, transportation, and recreation.

State rehabilitation administration agencies provide services to assist people with disabilities in obtaining the help they need to engage in gainful employment. These services include diagnostic, medical, and mental health services. Counseling, training, placement, and follow-up services are available to help people with disabilities select and obtain jobs.

If the patient is transferred to a long-term care facility, the transition is planned to promote continued progress. Independence gained continues to be supported, and progress is fostered. Adjustment to the facility is promoted through communication. Family members are encouraged to visit, to be involved, and to take the patient home on weekends and holidays if possible.

CRITICAL THINKING EXERCISES

1. An 18-year-old man is brought to the ED by his family, who report that he was "dinged" in a football game 1 week ago. The patient does not recall the event. His family states that he is sleeping more than usual and seems forgetful. What is the evidence base for conducting a comprehensive and focused evaluation for a patient with a sports concussion injury? What evidence-based recommendations may guide return to sports for this patient? Identify the criteria used to evaluate the strength of the evidence for these practices.
2. A 90-year-old patient on anticoagulant therapy is admitted to your unit with a chronic SDH. Identify the priorities, approach, and techniques you would use to provide care for this patient in the preoperative phase of care. How will your priorities, approach, and techniques differ in the postoperative phase of care?
3. A 68-year-old woman was involved in a motor vehicle crash 2 days ago and sustained a T6 fracture with SCI. As a result, she has paraplegia and is in a neurologic intensive care unit. Identify the priorities, approach, and techniques you would use to provide care for this patient during the acute phase of care. Identify how your priorities, approach, and techniques will differ once the patient reaches the rehabilitation phase of care.

CHAPTER 52

Management of Patients with Neurologic Infections, Autoimmune Disorders, and Neuropathies

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Differentiate among the infectious disorders of the nervous system according to causes, manifestations, medical care, and nursing management.
2. Describe the pathophysiology, clinical manifestations, and medical and nursing management of multiple sclerosis, myasthenia gravis, and Guillain–Barré syndrome.
3. Use the nursing process as a framework for care of patients with multiple sclerosis and Guillain–Barré syndrome.
4. Explain disorders of the cranial nerves, their manifestations, and indicated nursing interventions.
5. Apply the nursing process as a framework for care of the patient with a cranial nerve disorder.

GLOSSARY

ataxia: impaired coordination of movement during voluntary movement
diplopia: double vision, or the awareness of two images of the same object occurring in one or both eyes
dysphagia: difficulty swallowing
dysphonia: voice impairment or altered voice production
hemiparesis: weakness of one side of the body, or part of it, due to an injury in the motor area of the brain
hemiplegia: paralysis of one side of the body, or part of it, due to an injury in the motor area of the brain
neuropathy: general term indicating a disorder of the nervous system
paresthesia: numbness, tingling, or a "pins and needles" sensation
prion: a pathogen smaller than a virus that is resistant to standard sterilization procedures
ptosis: drooping of the eyelids
spasticity: muscular hypertonicity with increased resistance to stretch often associated with weakness, increased deep tendon reflexes, and diminished superficial reflexes

Introduction

The diverse group of neurologic disorders that make up infectious and autoimmune disorders and cranial and peripheral neuropathies presents unique challenges for nursing care. The nurse who cares for patients with these disorders must have a clear understanding of the pathophysiology, diagnostic testing, medical and nursing care, and rehabilitation processes. Some of the issues nurses must help patients and families confront include adaptation to the effects of the disease, potential changes in family dynamics, and end-of-life issues.

INFECTIOUS NEUROLOGIC DISORDERS

The infectious disorders of the nervous system include meningitis, brain abscesses, various types of encephalitis, Creutzfeldt–Jakob disease (CJD), and variant Creutzfeldt–Jakob disease (vCJD). The clinical manifestations, assessment, and diagnostic findings, as well as the medical and nursing management, are related to the specific infectious process.

Meningitis

Meningitis is inflammation of the meninges, which cover and protect the brain and spinal cord. The three major causes of meningitis are bacterial, viral, and fungal infections (Bader, Littlejohns, & Olson, 2016). Meningitis can be the main reason a patient is hospitalized, or it can develop during hospitalization; it is classified as septic or aseptic. Septic meningitis is caused by bacteria. The bacteria *Streptococcus pneumoniae* and *Neisseria meningitidis* are responsible for the majority of cases of bacterial meningitis in adults. In aseptic meningitis, the cause is viral or secondary to cancer or having a weakened immune system, such as in human immune deficiency virus (HIV). The most common causative agents are the enteroviruses. Aseptic meningitis occurs more frequently in the summer and early fall.

Outbreaks of *N. meningitidis* infection are most likely to occur in dense community groups, such as college campuses and military installations. Although infections occur year-round, epidemic period corresponds with the end of winter (November–March) and the beginning of summer (April–July) in India (Sinclair, Preziosi, John, et al., 2010). Factors that increase the risk of bacterial meningitis include tobacco use and viral upper respiratory infection, because they increase the amount of droplet production. Otitis media and mastoiditis increase the risk of bacterial meningitis, because the bacteria can cross the epithelial membrane and enter the subarachnoid space. People with immune system deficiencies are also at greater risk for development of bacterial meningitis (Bader et al., 2016).

Pathophysiology

Meningeal infections generally originate in one of two ways: through the bloodstream as a consequence of other infections or by direct spread, such as might occur after a traumatic injury to the facial bones or secondary to invasive procedures.

The *N. meningitidis* bacteria exists in the throats and nasal passages of approximately 10% of the general population and

Chart 52-1

Meningitis in Specific Populations

Meningitis can occur as a complication of other diseases and is an opportunistic infection seen with greater frequency in patients who are immunocompromised.

Meningitis in Patients with Acquired Immune Deficiency Syndrome (AIDS)

- Cryptococcal meningitis is the most common fungal infection of the central nervous system in patients with AIDS. Patients may experience headache, nausea, vomiting, seizures, confusion, and lethargy. Treatment consists of IV administration of amphotericin B followed by fluconazole. Maintenance therapy with fluconazole may be necessary to prevent relapse.
- Some patients who are immunosuppressed develop few if any symptoms because of blunted inflammatory responses; others develop atypical features.
- Onset of fever, headache, nausea, and malaise most often occur over a few weeks. Only 25% of patients present with stiff neck and photophobia.

Meningitis in Patients with Lyme Disease

- Lyme disease is a multisystem inflammatory process caused by the tick-transmitted spirochete *Borrelia burgdorferi*.
- Neurologic deficits are seen in later stages (stages 2 or 3). Stage 2 occurs with the start of a characteristic rash or 1–6 months after the rash has disappeared.
- Neurologic comorbidities include aseptic meningitis, chronic lymphocytic meningitis, and encephalitis.
- Cranial nerve inflammation, including Bell palsy and other peripheral neuropathies, is common.
- Stage 3 (the chronic form of the disease) begins years after the initial tick infection and is characterized by arthritis, skin lesions, and neurologic abnormalities.
- Most patients with stage 2 and 3 Lyme disease are treated with IV antibiotics, usually ceftriaxone or penicillin G.
- Meningeal and systemic symptoms begin to improve within days, although other symptoms, such as headache, may persist for weeks.

Adapted from Theroux, N., Phipps, M., Zimmerman, L., & Relf, M. V. (2013). Neurological complications associated with HIV and AIDS: Clinical implications for nursing. Journal of Neuroscience Nursing, 45(1), 5–13.

is transmitted by secretion or aerosol contamination (National Meningitis Association, 2016). Bacterial or meningococcal meningitis also occurs as an opportunistic infection in patients with acquired immune deficiency syndrome (AIDS) and as a complication of Lyme disease (see Chart 52-1).

Once the causative organism enters the bloodstream, it crosses the blood–brain barrier and proliferates in the cerebrospinal fluid (CSF). The host immune response stimulates the release of cell wall fragments and lipopolysaccharides, facilitating inflammation of the subarachnoid and pia mater. Because the cranial vault contains little room for expansion, the inflammation may cause increased intracranial pressure (ICP). CSF circulates through the subarachnoid space, where inflammatory cellular materials from the affected meningeal tissue enter and accumulate.

The prognosis for bacterial meningitis depends on the causative organism, the severity of the infection and illness, and the timeliness of treatment. Acute fulminant presentation may include adrenal damage, circulatory collapse, and widespread hemorrhages (Waterhouse–Friderichsen syndrome). This

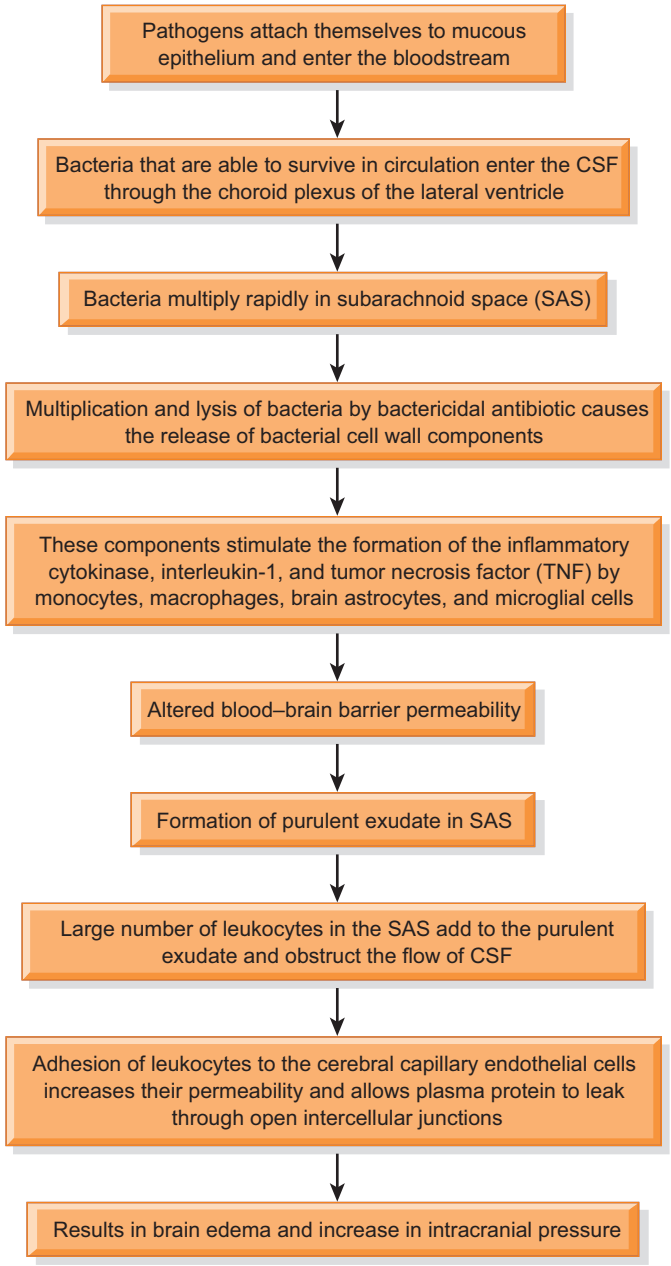

Figure 52-1 • Pathophysiology of meningitis. CSF, cerebrospinal fluid.

syndrome is the result of endothelial damage and vascular necrosis caused by the bacteria. Complications include visual impairment, deafness, seizures, paralysis, hydrocephalus, and septic shock. Pathophysiology of meningitis is presented in Figure 52-1.

Clinical Manifestations

Headache and fever are frequently the initial symptoms. Fever tends to remain high throughout the course of the illness. The headache is usually either steady or throbbing and very severe as a result of meningeal irritation (Weber & Kelley, 2014). Meningeal irritation results in a number of other well-recognized signs common to all types of meningitis:

- **Neck immobility:** A stiff and painful neck (nuchal rigidity) can be an early sign, and any attempts at flexion of the head are difficult because of spasms in the muscles of the neck.

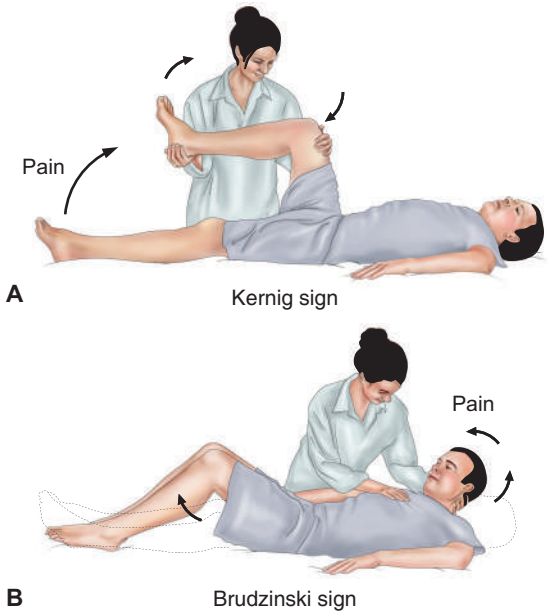

Figure 52-2 • Testing for meningeal irritation. **A**. Kernig sign. Flex the patient's leg at both the hip and knee and then straighten the knee. **B**. Brudzinski sign. As the neck is flexed, watch the hips and knees for a reaction.

Usually, the neck is supple, and the patient can easily bend the head and neck forward.

- **Positive Kernig sign:** When the patient is lying with the thigh flexed on the abdomen, the leg cannot be completely extended (see Fig. 52-2). When Kernig sign is bilateral, meningeal irritation is suspected (Weber & Kelley, 2014).
- **Positive Brudzinski sign:** When the patient's neck is flexed (after ruling out cervical trauma or injury), flexion of the knees and hips is produced; when the lower extremity of one side is passively flexed, a similar movement is seen in the opposite extremity (see Fig. 52-2). Brudzinski sign is a more sensitive indicator of meningeal irritation than Kernig sign.
- **Photophobia (extreme sensitivity to light):** This finding is common due to irritation of the meninges, especially around the diaphragm sellae (Digre & Brennan, 2012).
- A rash can be a striking feature of *N. meningitidis* infection, occurring in about half of patients with this type of meningitis. Skin lesions develop, ranging from a petechial rash with purpuric lesions to large areas of ecchymosis.

Disorientation and memory impairment are common early in the course of the illness. The changes depend on the severity of the infection as well as the individual response to the physiologic processes. Behavioral manifestations are also common. As the illness progresses, lethargy, unresponsiveness, and coma may develop.

Seizures can occur and are the result of areas of irritability in the brain. ICP increases secondary to diffuse brain swelling or hydrocephalus (Bader et al., 2016). The initial signs of increased ICP include decreased level of consciousness (LOC) and focal motor deficits. If ICP is not controlled, the uncus of the temporal lobe may herniate through the tentorium, causing pressure on the brainstem. Brainstem herniation is a life-threatening event that causes cranial nerve dysfunction and depresses the centers of vital functions, such as the medulla. See Chapter 49 for discussion of the patient with a change in LOC or increased ICP.

An acute fulminant infection occurs in about 10% of patients with meningococcal meningitis, producing signs of sepsis: an abrupt onset of high fever, extensive purpuric lesions (over the face and extremities), shock, and signs of disseminated intravascular coagulation (see Chapter 27). Death may occur within a few hours after onset of the infection.

Assessment and Diagnostic Findings

If the clinical presentation suggests meningitis, diagnostic testing is conducted to identify the causative organism. A computed tomography (CT) scan is used to detect a shift in brain contents (which may lead to herniation) prior to a lumbar puncture in patient with altered LOC, papilledema, neurologic deficits, new onset of seizure, immunocompromised state, or history of central nervous system (CNS) disease. Bacterial culture and Gram staining of CSF and blood are key diagnostic tests (Bader et al., 2016). An overview of CSF values and alterations in bacterial, viral, and fungal meningitis is presented in Table 52-1. Gram staining allows for rapid identification of the causative bacteria and initiation of appropriate antibiotic therapy.

Prevention

The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC, 2016) recommends that the meningococcal conjugated vaccine be given to youth at 11 to 12 years of age, with a booster dose at 16 years of age. First-year college students and members of the military who have not been vaccinated are at higher risk.

TABLE 52-1 Cerebrospinal Fluid Values Diagnostic for Meningitis

Parameter	Normal CSF	Bacterial Meningitis	Viral Meningitis	Fungal Meningitis
Opening pressure (mm H_2O)	100–180	200–500	≤250	>200
Leukocyte count (white blood cell/mm^3)	0–5	Increased 100–5000	Increased 50–1000	Increased >20
Neutrophils (%)	0	≥80	<40	
Protein (mg/dL)	18–45	Elevated 100–500	Elevated <200	Elevated >45
Glucose (mg/dL)	45–80; 0.6 times blood glucose level	<40; <0.4 times blood glucose level	>45	<40

CSF, cerebrospinal fluid.

People in close contact with patients with meningococcal meningitis should be treated with antimicrobial chemoprophylaxis using rifampin (Rifadin), ciprofloxacin hydrochloride (Cipro), or ceftriaxone sodium (Rocephin). Therapy should be started within 24 hours after exposure because a delay limits the effectiveness of the prophylaxis. Vaccination should also be considered as an adjunct to antibiotic chemoprophylaxis for anyone living with a person who develops meningococcal infection. Vaccination against *Haemophilus influenzae* and *S. pneumoniae* should be encouraged for children and adults who are at-risk (CDC, 2016).

Medical Management

Successful outcomes depend on the early administration of an antibiotic agent that crosses the blood–brain barrier into the subarachnoid space in sufficient concentration to halt the multiplication of bacteria. Penicillin G in combination with one of the cephalosporins (e.g., ceftriaxone sodium, cefotaxime sodium) is most often administered intravenously (IV), optimally within 30 minutes of hospital arrival (Bader et al., 2016).

Dexamethasone has been shown to be beneficial as adjunct therapy in the treatment of acute bacterial meningitis and in pneumococcal meningitis if it is given 15 to 20 minutes before the first dose of antibiotic and every 6 hours for the next 4 days. Research suggests that dexamethasone improves the outcome in adults and does not increase the risk of gastrointestinal bleeding (Bader et al., 2016).

Dehydration and shock are treated with fluid volume expanders. Seizures, which may occur early in the course of the disease, are treated with anticonvulsant medications. Increased ICP is treated as necessary (see Chapter 49).

Nursing Management

The patient with meningitis is critically ill; therefore, many of the nursing interventions are collaborative with the physician, respiratory therapist, and other members of the health care team. The patient's safety and well-being depend on sound nursing judgment. Most patients will need the following nursing interventions:

- Instituting infection control precautions until 24 hours after initiation of antibiotic therapy (oral and nasal discharge is considered infectious)
- Assisting with pain management due to overall body aches and neck pain
- Assisting with getting rest in a quiet, darkened room
- Implementing interventions to treat the elevated temperature, such as antipyretic agents and cooling blankets
- Encouraging the patient to stay hydrated either orally or peripherally
- Ensuring close neurologic monitoring (see Chapter 49)

Neurologic status and vital signs are continually assessed. Pulse oximetry and arterial blood gas values are used to quickly identify the need for respiratory support if increasing ICP compromises the brainstem. Insertion of a cuffed endotracheal tube (or tracheotomy) and mechanical ventilation may be necessary to maintain adequate tissue oxygenation.

Blood pressure (usually monitored using an arterial line) is assessed for early manifestations of shock, which precedes cardiac or respiratory failure. Rapid IV fluid replacement may be prescribed, but care is taken to prevent fluid overload. Fever also increases the workload of the heart and cerebral metabolism. ICP will increase in response to increased cerebral metabolic demands. Therefore, measures are taken to reduce body temperature as quickly as possible.

Other important components of nursing care include the following measures:

- Protecting the patient from injury secondary to seizure activity or altered LOC
- Monitoring daily body weight; serum electrolytes; and urine volume, specific gravity, and osmolality, especially if syndrome of inappropriate antidiuretic hormone (SIADH) is suspected
- Preventing complications associated with immobility, such as pressure ulcers and pneumonia

Any sudden, critical illness can be devastating to the family. Because the patient's condition is often critical and the prognosis guarded, the family needs to be informed about the patient's condition. Periodic family visits are essential to facilitate coping of the patient and family. An important aspect of the nurse's role is to support the family and assist them in identifying others who can be supportive to them during the crisis.

Promoting Home, Community-Based, and Transitional Care

After the patient has achieved physiologic homeostasis and has demonstrated achievement of major health care goals, rehabilitation continues either in a rehabilitation facility, skilled nursing facility or at home. Continued support and evaluation by the nurse are essential.

Because patients may have been critically ill and focused on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health-promotion and screening practices, such as regular physical examinations and appropriate diagnostic screening tests.

Brain Abscess

Brain abscesses account for approximately 8% of intracranial masses in developing countries and 1–2% in the western countries (Muzumdar, Jhawar, & Goel et al, 2011). Brain abscesses are rare in people who are immunocompetent; they are more frequently diagnosed in people who are immunosuppressed as a result of an underlying disease or the use of immunosuppressive medications.

Pathophysiology

A brain abscess is a collection of infectious material within the tissue of the brain. Bacteria are the most common causative organisms. The most common predisposing conditions for abscesses among adults who are immunocompetent are otitis media and rhinosinusitis. It is estimated that 40% of brain abscesses are otogenic in origin (Bader et al., 2016). An abscess can result from intracranial surgery, penetrating head injury, or tongue piercing. Organisms causing brain abscess may reach the brain by hematologic spread from the lungs, gums, tongue, or heart, or from a wound or intra-abdominal infection. Pathophysiology is presented in Figure 52-3.

Clinical Manifestations

The clinical manifestations of a brain abscess result from alterations in intracranial dynamics (edema, brain shift), infection, or the location of the abscess. Headache, usually worse in the morning, is the most prevalent symptom. Fever is

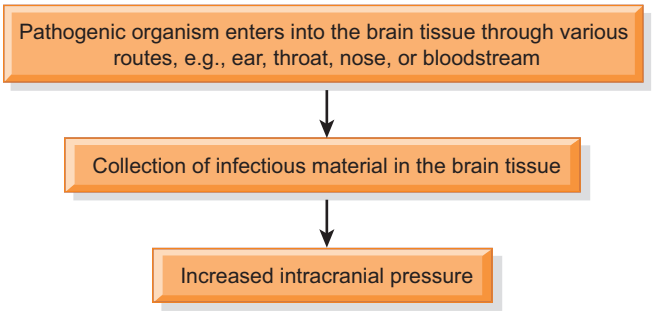

Figure 52-3 • Pathophysiology of brain abscess.

present 50% of the time (Slazinski, 2013). Vomiting and focal neurologic deficits occur as well. Focal deficits include weakness and decreasing vision reflect the area of brain that is involved. As the abscess expands, symptoms of increased ICP such as decreasing LOC and seizures occur.

Assessment and Diagnostic Findings

The baseline neurologic examination may reveal a variety of signs and symptoms based on the location of the abscess (see Chart 52-2). Neuroimaging with CT scanning with contrast is used most often to identify the size and location of the abscess. Cerebritis is a small infection in the brain that can progress to an abscess if not detected or treated. Aspiration of the abscess, guided by CT or MRI, is often used to culture and identify the infectious organism. MRI is the preferred study, because it is more sensitive to cerebritis and detecting smaller lesions (Slazinski, 2013). Blood cultures are obtained if the abscess is believed to arise from a distant source. Chest x-ray is performed to rule out predisposing lung infections, and electroencephalography (EEG) may help localize the lesion (Hickey, 2014).

Medical Management

Treatment is aimed at controlling increased ICP, draining the abscess, and providing antimicrobial therapy directed at the abscess and the main source of infection. Large IV doses of antibiotic agents are given to penetrate the blood–brain barrier and reach the abscess. The choice of the specific antibiotic medication is based on culture and sensitivity testing and directed at the causative organism. Antibiotics should be started as soon as possible and thus the initial antibiotic started typically is ceftriaxone, which will be adjusted based on the culture and sensitivity results. A stereotactic CT-guided aspiration may be used to drain the abscess and identify the causative organism. Surgical excision is the preferred method, but is not done as often as needle aspiration due to higher risk of neurologic complications (Slazinski, 2013). Corticosteroids may be prescribed to help reduce the inflammatory cerebral edema if the patient shows evidence of an increasing neurologic deficit. Anticonvulsant medications may be prescribed to prevent or treat seizures (see Chapter 49).

Chart 52-2 ASSESSMENT

Assessing for Brain Abscesses

Be alert to the following signs and symptoms of brain abscess:

Frontal Lobe

- Expressive aphasia (inability to express oneself)
- Frontal headache
- Hemiparesis (weakness on one side of the body)
- Seizures

Temporal Lobe

- Changes in vision
- Facial weakness
- Localized headache
- Receptive aphasia (inability to understand language)

Cerebellar Abscess

- Ataxia (inability to coordinate movements)
- Nystagmus (rhythmic, involuntary movements of the eye)
- Occipital headache

Nursing Management

Nursing care focuses on continuing to assess the neurologic status, administering medications, assessing the response to treatment, and providing supportive care.

Ongoing neurologic assessment alerts the nurse to changes in ICP, which may indicate a need for more aggressive intervention. The nurse also assesses and documents the responses to medications. Blood laboratory test results, specifically blood glucose and serum potassium levels, need to be closely monitored when corticosteroids are prescribed (Comerford, 2015). Administration of insulin or electrolyte replacement may be required to return these values to within normal limits.

Patient safety is another key nursing responsibility. Injury may result from decreased LOC or falls related to motor weakness or seizures.

The patient with a brain abscess is very ill, with neurologic deficits, such as hemiplegia (paralysis of one side of the body, or part of it), hemiparesis (weakness of one side of the body, or part of it), seizures, visual deficits, and cranial nerve palsies that may persist after treatment. The nurse must assess the family's ability to express distress at the patient's condition, cope with the patient's illness and deficits, and obtain support.

Herpes Simplex Encephalitis

Encephalitis is an acute inflammatory process of the brain tissue. The herpes simplex virus (HSV) is one of the most common cause of acute encephalitis, which is more common in the western world (Bader et al., 2016).

Pathophysiology

The pathology of encephalitis involves local necrotizing hemorrhage that becomes more generalized, followed by edema. There is also progressive deterioration of nerve cell bodies (Grossman & Porth, 2014).

Clinical Manifestations

The initial symptoms of herpes simplex encephalitis include fever, headache, confusion, and hallucinations. Focal neurologic symptoms reflect the areas of cerebral inflammation and necrosis and include fever, headache, behavioral changes, focal seizures, dysphasia, hemiparesis, and altered LOC (Grossman & Porth, 2014).

Assessment and Diagnostic Findings

Neuroimaging studies, such as EEG, and CSF examination are used to diagnose encephalitis. MRI is used to detect early changes caused by herpes simplex; scans usually show edema in the frontal and temporal lobes. The EEG shows diffuse slowing or focal changes in the temporal lobe in the majority of patients. Lumbar puncture often reveals a high opening pressure, glucose within normal limits, and high protein levels in CSF samples (see Table 52-1). Twenty percent of initial CSF studies have results within normal limits (Bader et al., 2016). Viral cultures are almost always negative. The polymerase chain reaction (PCR) is the standard test for early diagnosis of herpes simplex encephalitis. PCR identifies the deoxyribonucleic acid (DNA) bands of HSV-1 in the CSF. The validity of PCR is very high between the 3rd and 10th days after symptom onset.

Medical Management

Antiviral agents, either acyclovir (Zovirax) or ganciclovir (Cytovene), are the medications of choice in the treatment for HSV (Comerford, 2015). Early administration of antiviral agents (usually well tolerated) improves the prognosis associated with herpes simplex encephalitis. The mode of action is inhibition of viral DNA replication. To prevent relapse, treatment should continue for up to 3 weeks. Slow IV administration over 1 hour prevents crystallization of the medication in the urine. The usual dose of acyclovir is decreased if the patient has a history of renal insufficiency.

Nursing Management

Assessment of neurologic function is key to monitoring the progression of disease. Comfort measures to reduce headache include dimming the lights, limiting noise and visitors, grouping nursing interventions, and administering analgesic agents. Opioid analgesic medications may mask neurologic symptoms; therefore, they are used cautiously. Seizures and altered LOC require care directed at injury prevention and safety. Nursing care addressing patient and family anxieties is ongoing throughout the illness. Monitoring of blood chemistry test results and urinary output alert the nurse to the presence of renal complications related to antiviral therapy.

Arthropod-Borne Virus Encephalitis

Arthropod-borne viruses, or arboviruses, are maintained in nature through biologic transmission between susceptible vertebrate hosts by blood feeding arthropods (mosquitoes, psychodids, ceratopogonids, and ticks). Arthropod vectors transmit several types of viruses that cause encephalitis. The main vector is the mosquito. Arbovirus infection (transmitted by arthropod vectors) occurs in specific geographic areas during the summer and fall. (Bader et al., 2016).

Pathophysiology

Viral replication occurs at the site of the mosquito bite. The host immune response attempts to control viral replication. If the immune response is inadequate, viremia will ensue. The virus gains access to the CNS via the olfactory tract, resulting in encephalitis. It spreads from neuron to neuron, predominantly affecting the cortical gray matter, the brainstem, and the thalamus. Meningeal exudates compound the clinical presentation by irritating the meninges and increasing ICP (Fig. 52-4).

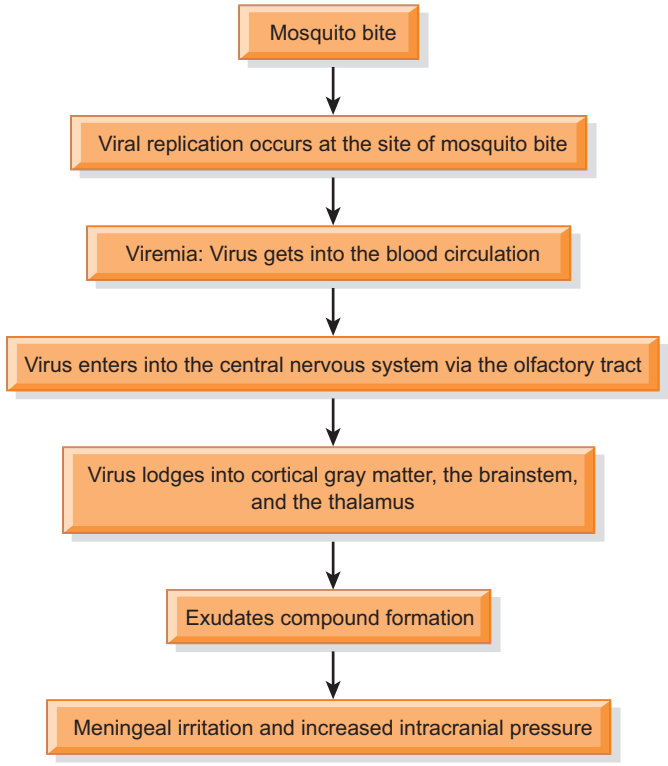

Figure 52-4 • Pathophysiology of arthropod-borne virus encephalitis.

Clinical Manifestations

St. Louis and West Nile virus encephalitis most commonly affect adults. An arboviral encephalitis occurs along a continuum with some cases having only flulike symptoms (i.e., headache and fever) but others progressing to specific neurologic manifestations that vary depending on the viral type (Bader et al., 2016). A unique clinical feature of St. Louis encephalitis is SIADH with hyponatremia. The incubation period in St. Louis encephalitis is from 4 to 12 days (Bader et al., 2016). Onset of symptoms is abrupt with fever, headache, dizziness, nausea, and malaise. If the disease spreads to the CNS, symptoms include stiff neck, confusion, dizziness, and tremors. Coma can occur in severe cases, and mortality increases with age. Eastern equine encephalitis has the highest mortality rate at 50% to 70% (Bader et al., 2016). Seizures, a poor prognostic indicator, are present in encephalitis and are more common in the St. Louis type.

One of the most common form of viral encephalitis in Asia is the Japanese encephalitis virus (JEV) caused by mosquito-borne flavivirus. The disease belongs to the same genus as dengue, yellow, and West Nile viruses. JEV primarily affects children as most adults tend to attain natural immunity from the disease (Tiwari, Singh, Tiwari, et al., 2012).

Assessment and Diagnostic Findings

Preliminary diagnosis is based on clinical presentation and location and dates of recent travel because certain viruses are endemic to certain geographic locales. Neuroimaging and CSF evaluation are useful in the diagnosis of encephalitis. The MRI scan demonstrates inflammation of the basal ganglia in cases of St. Louis encephalitis and inflammation in the periventricular area in cases of West Nile encephalitis. Immunoglobulin M antibodies to West Nile virus are observed in serum and CSF.

Serum cultures are not useful, because the viremia is brief. EEG can identify abnormal brain waves, which can help identify some viral infections.

Medical Management

No specific medication for arboviral encephalitis exists; therefore, symptom management is key. Controlling the seizures and the increased ICP are critical components of care in cases with neurologic manifestations. Interferon may be useful in treating St. Louis encephalitis, although no specific drug is indicated. Neuropsychiatric complications, such as emotional outbursts and other behavior changes, occur frequently.

Nursing Management

Many patients, particularly those with only fever and headache, are treated on an outpatient basis. If the patient is very ill, hospitalization may be required. The nurse carefully assesses neurologic status and identifies improvement or deterioration in the patient's condition. Injury prevention is key in light of the potential for falls or seizures. Any encephalitis that progresses may result in death or lifelong residual health issues such as neurologic deficits and seizures. The family will need support and education to cope with these outcomes.

Public education addressing the prevention of arboviral encephalitis is a key nursing role. Clothing that provides coverage and insect repellents containing 20% to 35% diethyltoluamide (DEET) should be used on exposed clothing and skin in high-risk areas to decrease mosquito and tick bites (Bader et al., 2016). Remaining indoors at dawn and dusk when mosquito activity is highest is recommended. Screens should be in good repair in the home, and standing water should be removed. All cases of arboviral encephalitis must be reported to the local health department.

Fungal Encephalitis

Fungal infections of the CNS occur rarely in people who are healthy. The presentation of fungal encephalitis is related to geographic area or to an immune system that is compromised due to disease or immunosuppressive medication. Causes of fungal infections include *Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum, Aspergillus fumigatus, Candida,* and *Coccidioides immitis* (Bader et al., 2016). It is a risk for coal miners, construction workers, and farmers. *C. neoformans* is associated with exposure to bird droppings and may be seen in bird handlers.

Pathophysiology

The fungal spores enter the body via inhalation. They initially infect the lungs, causing vague respiratory symptoms or pneumonitis. The fungi may enter the bloodstream, causing a fungemia. If the fungemia overwhelms the person's immune system, the fungus may spread to the CNS. The fungal invasion may cause meningitis, encephalitis, brain abscess, granuloma, or arterial thrombus (Fig. 52-5).

Clinical Manifestations

The common symptoms of fungal encephalitis include fever, malaise, headache, meningeal signs, and change in LOC or cranial nerve dysfunction. Symptoms of increased ICP related to hydrocephalus often occur. *C. neoformans* and *C. immitis* are associated with specific skin lesions. *H. capsulatum* is associated with seizures, and *A. fumigatus* may cause ischemic or hemorrhagic strokes.

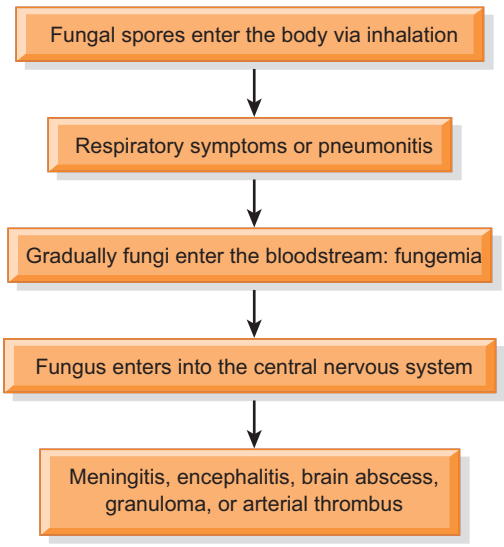

Figure 52-5 • Pathophysiology of fungal encephalitis.

Assessment and Diagnostic Findings

A history of immunosuppression associated with AIDS or the use of immunosuppressive medications may indicate fungal disease of the brain (Theroux, Phipps, Zimmerman, et al., 2013). Occupational and travel history may point to a fungal cause of CNS infection. Infections caused by *H. capsulatum* and *C. immitis* will demonstrate fungal antibodies in serologic tests. The CSF usually demonstrates elevated white cell and protein levels; glucose levels are decreased. *C. neoformans* is easily identified in CSF fungal cultures. *Candida* may be cultured from the blood or CSF. To identify *B. dermatitidis,* cisternal or ventricular cultures of CSF may need to be obtained. *A. fumigatus* is difficult to isolate in CSF and is diagnosed by lung biopsy. Neuroimaging is used to identify CNS changes related to fungal infection. MRI is the study of choice; it demonstrates areas of hemorrhage, abscess, or enhanced meninges indicating inflammation.

Medical Management

Medical management is directed at the causative fungus and the neurologic consequences of the infection. Seizures are controlled by standard anticonvulsant medications. Increased ICP is controlled by repeated lumbar punctures or shunting of CSF.

Antifungal agents are given for a specific period to cure the infection in patients with competent immune systems. Patients with compromised immune systems receive antifungal therapy until the infection is controlled, after which they receive a maintenance dose of the medication for an indefinite period. Amphotericin B is used for a progressive fungal infection that does not respond to conventional drug therapy. Dosing depends on the causative organism, and it is usually administered IV. Adverse reactions include fever, nausea and vomiting, anemia, uremia, and electrolyte abnormalities (especially potassium and magnesium). Toxicities may occur, and renal insufficiency is a serious reaction to amphotericin B that can occur (Comerford, 2015).

Fluconazole (Diflucan) or flucytosine (Ancobon) may be given orally in conjunction with amphotericin B as maintenance therapy. Potential side effects of fluconazole include nausea, vomiting, and a transient increase in liver enzymes. The most common adverse reaction to flucytosine is bone marrow depression (Comerford, 2015). Therefore, patients receiving flucytosine should have leukocyte and platelet counts monitored regularly.

Nursing Management

The ICP will increase if hydrocephalus develops and the inflammatory response progresses. Nursing assessment aimed at early identification of increased ICP is necessary to ensure early control and management. See Chapter 49 for management of the patient with increased ICP. Administering nonopioid analgesic agents, limiting environmental stimuli, and positioning may optimize patient comfort. Administering diphenhydramine (Benadryl) and acetaminophen/paracetamol (Tylenol) approximately 30 minutes before giving amphotericin B may prevent flulike side effects. If renal insufficiency develops, the dose may need to be reduced. Increasing levels of serum creatinine and blood urea nitrogen may alert the nurse to the development of renal insufficiency and the need to address the patient's renal status.

Providing support assists the patient and family to cope with the illness. Workup of the patient for immune deficiency diseases such as AIDS may put additional stress on the family. The nurse may need to mobilize community support systems for the patient and family, because the recovery may be long.

Neurocysticercosis

Neurocysticercosis is one of the common parasitic infections affecting the central nervous system. The larval form of pig tape worm (*Taeneia solium*) infests the central nerve system which is known as *neurocysticercosis*. Neurocysticercosis is the common cause of epilepsy in adults.

Epidemiology

It is highly endemic in countries where pig breeding is common and uncontrolled along with poor excreta hygiene and in countries where the immigration of people is high from Africa, Asia, and Latin America. An estimated 1 million cases are reported in India. In countries with low pork consumption, cysticercosis is uncommon (Jankovic, 2022).

Pathophysiology

Human beings are the definitive host of the pig tape worm. Pigs are the intermediate host. The *Taenia solium* gets itself hooked into the small intestine of the human being and passes hundreds of eggs along with excreta. When pigs eat the excreta containing the eggs, the eggs enter the pig gut and from there live larvae reach pork's blood and muscle tissues. When the pork flush infected with the live form of larvae called *cysticerci* is eaten in half cooked form the taenia cysticerci reach the various tissues of nervous system, eyes, and muscles. It may be a single cysticercus or multiple cysticerci growing together like a brain tumor. It may be calcified and remain quiet also. When it gets into meninges it may cause serious complications such as meningitis and encephalitis. The inflammatory reaction along with cysticerci may block the CSF circulation causing hydrocephalus.

It may affect the eyes leading to inflammation of the vitreous humor, uveitis, and endophthalmitis, progressive loss of visual acuity, and visual field loss.

In muscles, it may produce progressive weakness and enlargement of muscle (Del Brutto, 2012). The pathophysiology is depicted in Figure 52-6.

Clinical Manifestations

Symptom may start after 1–35 years of infestation. Atypical epilepsy is the most common manifestation. Other symptoms include the following:

- Headache
- Irritability
- Cognitive dysfunction
- Focal neurological deficit
- Rarely, signs of meningitis and hydrocephalus
- Occasionally, parkinsonian symptoms and psychiatric disturbances
- Loss of visual acuity and visual field loss
- Weakness and enlargement of involved muscles

Diagnosis

CT scan and MRI scan may show "hole-with-dot" appearance, diffuse brain edema, and cysticercus granuloma. Serological tests, e.g., enzyme-linked immunoblot test, will demonstrate antibody specific to *Taenia solium*.

Treatment

- Antihelminthic drugs such as albendazole, or praziquantel
- Anticonvulsant drugs

Control

- Hygienic disposal of human excreta
- Control of freely roaming pigs around human residential localities
- Hygienic slaughtering of pigs following veterinary standards

Creutzfeldt–Jakob and Variant Creutzfeldt–Jakob Diseases

CJD and vCJD belong to a group of degenerative, infectious neurologic disorders called *transmissible spongiform encephalopathies* (TSE). CJD is very rare and has no identifiable cause. vCJD, the human variation of bovine spongiform encephalopathy (BSE) (commonly known as mad cow disease), results from the ingestion by humans of prions in infected meat. TSEs are caused by prions, which are pathogens smaller than a virus that are resistant to standard methods of sterilization (National Institute of Neurological Disorders and Stroke [NINDS], 2016). Although CJD and vCJD have distinct clinical features, one characteristic they share is a lack of CNS inflammation. CJD may lie dormant for decades before causing neurologic degeneration. The incubation period of vCJD seems to be shorter (less than 10 years). In both diseases, the symptoms are progressive, there is no definitive treatment, and the outcome is fatal (Bader et al., 2016).

Almost all cases of vCJD have been reported in the United Kingdom, with a smaller number of cases being identified in 10 other countries worldwide. The risk of vCJD in the United States is thought to be low, because cattle are fed primarily with

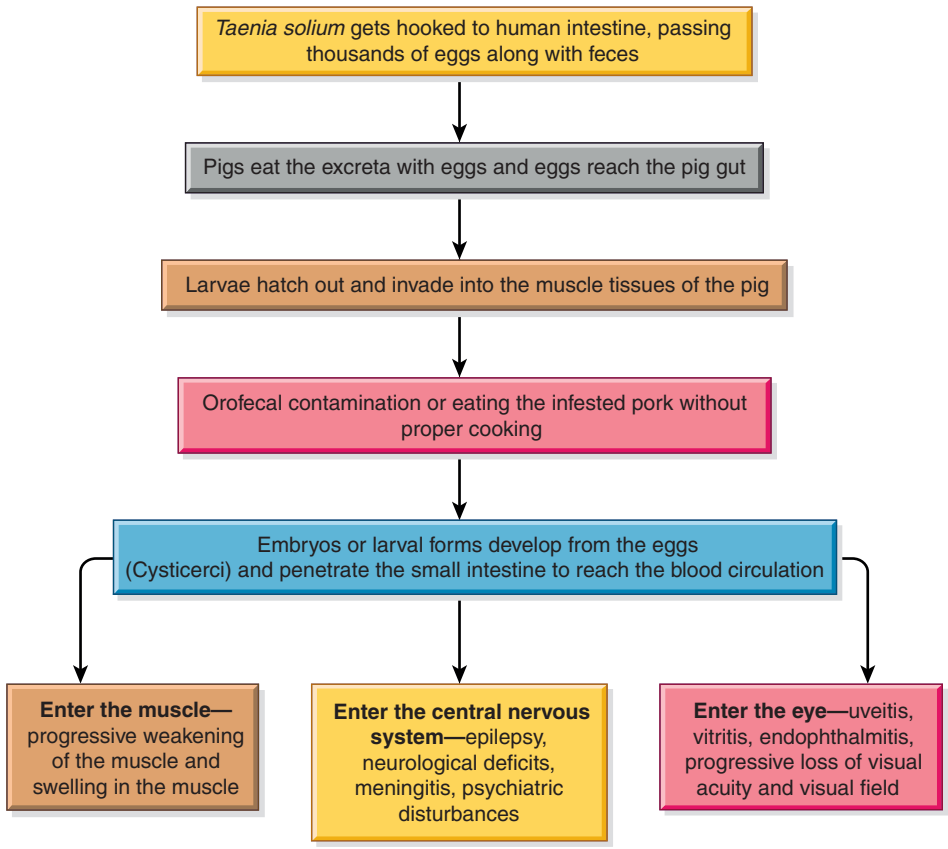

Figure 52-6 • Pathophysiology of neurocysticercosis.

soy-derived feed as opposed to feed containing animal parts (NINDS, 2016). CJD is not common in India and only 69 cases have been reported in NIMHANS during over 30 years period (Shankar & Chandra, 1997), 10 cases reported from Delhi, and 7 from Mumbai (Mehndiratta, Bajaj, Gupta, et al., 2001).

Pathophysiology

The prion is a unique pathogen because it lacks nucleic acid, which enables the organism to withstand conventional means of sterilization. It has not been isolated and it is believed to be a protein that takes on a different form (NINDS, 2016). In both CJD and vCJD, the prion crosses the blood–brain barrier and is deposited in brain tissue and causes degeneration of brain tissue. Cell death occurs, and spongiform changes (spongy vacuoles) are produced in the brain. The spongiform vacuoles are surrounded by amyloid plaque.

There are three major forms of CJD. Approximately 85% of cases of CJD appear sporadically; this form is called sporadic CJD. The incidence is one case per 1 million people. Sporadic CJD occurs spontaneously with no risk factors. The second form is familial or hereditary CJD, and this type accounts for 5% to 10% of cases (NINDS, 2016). The final type is acquired CJD. This form is transmitted by contaminated brain, tissue, or neurosurgical instruments and accounts for less than 1% of cases (Vacca, 2016).

The prion exists in lymphoid tissue and blood in both vCJD and CJD. Both prion diseases are believed to be blood-borne. No method is available to screen blood for infectivity. Pathophysiology of CJD/vCJD is presented in Figure 52-7.

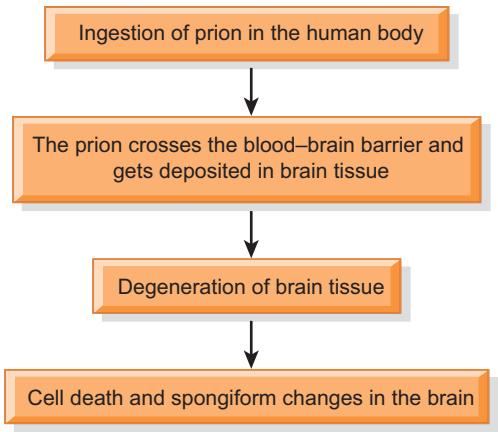

Figure 52-7 • Pathophysiology of Creutzfeldt–Jakob disease.

Clinical Manifestations

CJD and vCJD have several clinically distinct features. Psychiatric symptoms occur early in vCJD, whereas they are a late symptom in CJD. The mean age at onset of vCJD is 27 years, whereas the mean age for CJD onset is 65 years. The presenting symptoms of vCJD include affective symptoms (i.e., behavioral changes), sensory disturbance, and limb pain. Muscle spasms and rigidity, dysarthria, incoordination, cognitive impairment, and sleep disturbances follow. Patients with sporadic CJD present with mental deterioration, ataxia, and visual disturbance. Memory loss, involuntary movement, paralysis, and mutism occur as the disease progresses. After clinical presentation, people with

vCJD survive an average of 22 months; those with CJD survive for less than 1 year (Bader et al., 2016).

Assessment and Diagnostic Findings

Brain biopsy is not recommended to diagnose CJD. The three diagnostic tests currently used in suspicious clinical presentations to support the diagnosis of CJD are immunologic assessment, EEG, and MRI scanning. Immunologic assessment of CSF detects a protein kinase inhibitor referred to as 14–3–3. The presence of this inhibitor indicates neuronal cell death, which is not specific to CJD but does support the diagnosis. The EEG reveals a characteristic pattern over the duration of the disease. After initial slowing, the EEG shows periodic activity. Later in the course of the disease, the EEG shows burst suppressions characterized by periodic spikes alternating with slow periods. The MRI scan demonstrates symmetric or unilateral hyperintense signals arising from the basal ganglia (Bader et al., 2016).

Medical Management

After the onset of specific neurologic symptoms, progression of disease occurs quickly. There is no effective treatment for CJD or vCJD. The care of the patient is supportive and palliative. Goals of care include prevention of injury related to immobility and dementia, promotion of patient comfort, and provision of support and education for the family.

Nursing Management

The nursing care of patients is primarily supportive and palliative. Psychological and emotional support of the patient and family throughout the course of the illness is needed. Care extends to providing for a dignified death and supporting the family through the processes of grief and loss. Hospice services are appropriate either at home or at an inpatient facility. See Chapter 59 for an in-depth discussion of end-of-life issues.

Prevention of disease transmission is an important part of nursing care. Although patient isolation is not necessary, the use of standard precautions is important. Institutional protocols are followed for handling of brain, spinal cord, pituitary gland, and eye tissue; and for exposure and decontamination of equipment. In the operating room, it is recommended that disposable instruments be used and then incinerated, because conventional methods of sterilization do not destroy the prion (Bader et al., 2016). If disposable instruments cannot be used, stringent sterilization methods such as the use of bleach for cleaning and extended sterilization time for instruments should be used.

AUTOIMMUNE PROCESSES

Autoimmune nervous system disorders include multiple sclerosis (MS), myasthenia gravis, and Guillain–Barré syndrome (GBS).

Multiple Sclerosis

MS is an immune-mediated, progressive demyelinating disease of the CNS. Demyelination refers to the destruction of myelin—the fatty and protein material that surrounds certain nerve fibers in the brain and spinal cord; it results in impaired transmission of nerve impulses (see Fig. 52-8). MS may occur at any age,

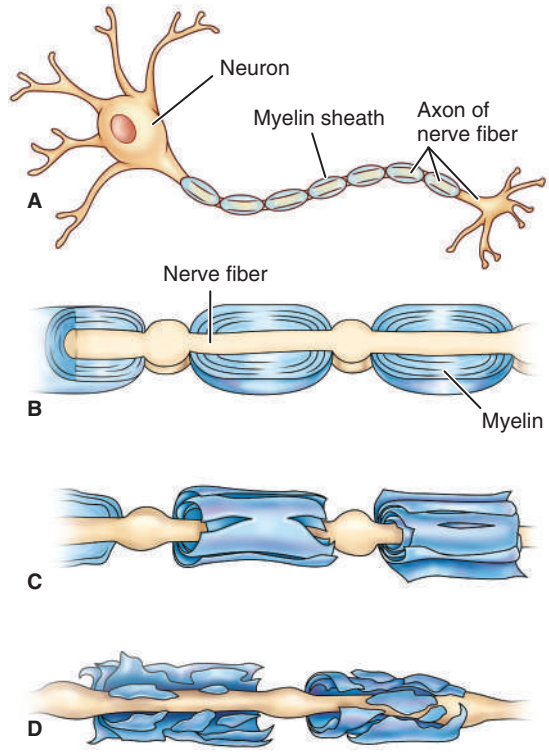

Figure 52-8 • The process of demyelination. **A**, **B**. A normal nerve cell and axon with myelin. **C**, **D**. The slow disintegration of myelin, resulting in a disruption in axon function.

but the age of peak onset is between 25 and 35 years; it affects women more frequently than men (Bader et al., 2016).

The cause of MS is an area of ongoing research. Autoimmune activity results in demyelination, but the sensitized antigen has not been identified. Multiple factors play a role in the initiation of the immune process. Geographic prevalence is highest in Europe, New Zealand, southern Australia, the northern United States, and southern Canada. MS is less prevalent in Asians. There is a North–South gradient, with greater frequency in temperate regions and latitudes away from the equator (Bader et al., 2016). The estimated prevalence rate of MS in India is 5 to 10 per 100,000 population; it may occur at any age but the peak onset is between 25–30 years and it affects women more frequently than men (Singhal, 2015).

MS is considered to have many risks, including genetic factors. However, it has not been found to be genetically transmitted (Bader et al., 2016). Genetic predisposition is indicated by the presence of a specific cluster (haplotype) of human leukocyte antigens on the cell wall. Its presence may increase susceptibility to factors, such as viruses, that trigger the autoimmune response activated in MS. A specific virus capable of initiating the autoimmune response has not been identified. It is believed that DNA on the virus mimics the amino acid sequence of myelin, resulting in an immune system cross-reaction in the presence of a defective immune system. Environmental risks include smoking, lack of vitamin D exposure, and exposure to the Epstein–Barr virus (Bader et al., 2016).

Pathophysiology

Sensitized T- and B lymphocytes cross the blood–brain barrier; their function is to check the CNS for antigens and then leave.

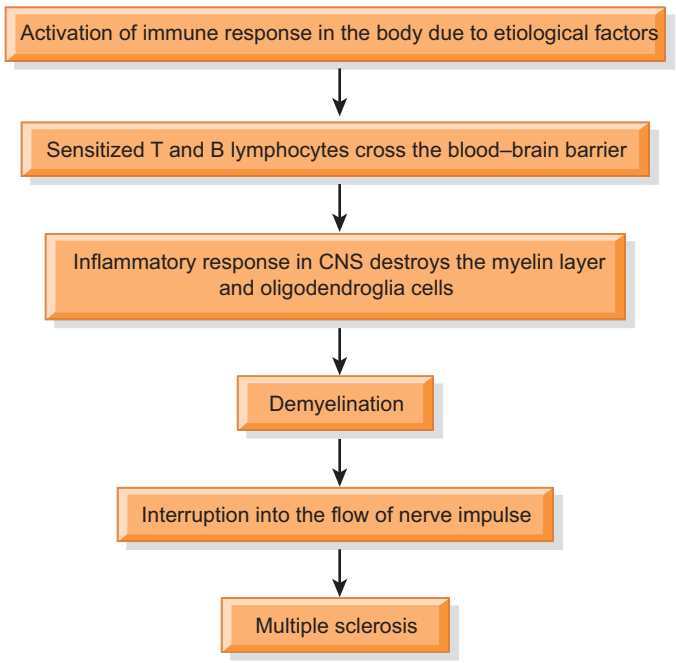

Figure 52-9 • Pathophysiology of multiple sclerosis.

In MS, sensitized T cells remain in the CNS and promote the infiltration of other agents that damage the immune system. The immune system attack leads to inflammation that destroys myelin (which insulates the axon and speeds the conduction of impulses along the axon) and the oligodendroglial cells that produce myelin in the CNS.

Demyelination interrupts the flow of nerve impulses and results in a variety of manifestations, depending on the nerves affected. Plaques appear on demyelinated axons, further interrupting the transmission of impulses. Demyelinated axons are scattered irregularly throughout the CNS. The areas most frequently affected are the optic nerves, chiasm, and tracts; the cerebrum; the brainstem and cerebellum; and the spinal cord. The axons themselves begin to degenerate, resulting in permanent and irreversible damage (Wu & Alvarez, 2016). Pathophysiology of MS is presented in Figure 52-9.

Clinical Manifestations

The course of MS may assume many different patterns (Lublin & Reingold, 1996) (see Fig. 52-10). In some patients, the disease follows a benign course, and symptoms are so mild that the patient does not seek health care or treatment. Approximately 85% of patients with MS have a *relapsing-remitting* (RR) course. With each relapse, recovery is usually complete; however, residual deficits may occur and accumulate over time, contributing to functional decline. Over time, most patients with the RR course of MS progress to a *secondary progressive* course, in which disease progression occurs with or without relapses. Approximately 15% of patients have a *primary progressive* course, in which disabling symptoms steadily increase, with rare plateaus and temporary minor improvement. Primary progressive MS may result in quadriparesis, cognitive dysfunction, visual loss, and brainstem syndromes. The least common presentation (about 5% of cases) is the *progressive-relapsing* course. It is characterized by relapses with continuous disabling progression between exacerbations (Hickey, 2014).

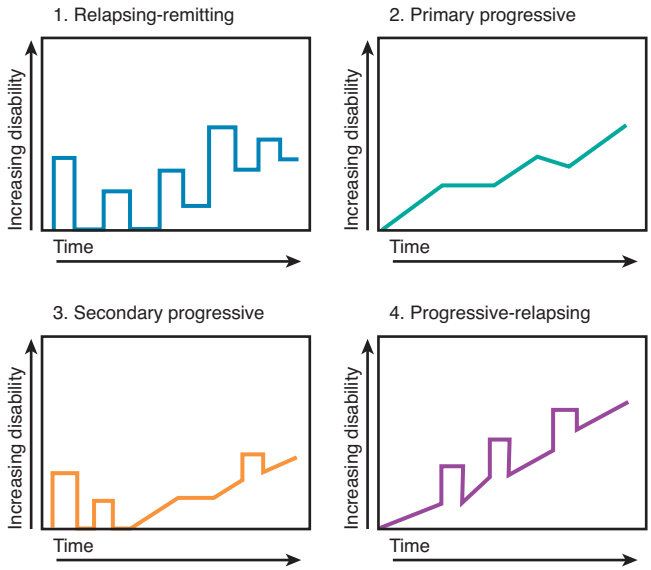

Figure 52-10 • Types and courses of multiple sclerosis (MS). **1**. Relapsing-remitting (RR) MS is characterized by clearly acute attacks with full recovery or with sequelae and residual deficit upon recovery. Periods between disease relapses are characterized by lack of disease progression. **2**. Primary progressive MS is characterized by disease showing progression of disability from onset, without plateaus and temporary minor improvements. **3**. Secondary progressive MS begins with an initial RR course, followed by progression of variable rate, which may also include occasional relapses and minor remissions. **4**. Progressive-relapsing MS shows progression from onset but with clear acute relapses with or without recovery. From Lublin, F. D., & Reingold, S. C. (1996). Defining the clinical course of multiple sclerosis: Results of an international survey. Neurology, 46(64), 907–911. Used with permission from Lippincott Williams & Wilkins.

The signs and symptoms of MS are varied and multiple, reflecting the location of the lesion (plaque) or combination of lesions. The main symptoms most commonly reported are fatigue, depression, weakness, numbness, difficulty in coordination, loss of balance, spasticity, and pain (Bader et al., 2016). Visual disturbances due to lesions in the optic nerves or their connections may include blurring of vision, diplopia (double vision), scotoma (patchy blindness), and total blindness.

Fatigue affects most people with MS and is often the most disabling symptom (Riley & Vargus, 2015); (Morrison & Stuifbergen, 2016). Heat, depression, anemia, deconditioning, and medication may contribute to fatigue. Avoiding hot temperatures, effective treatment of depression and anemia, a change in medication as well as occupational and physical therapies may help manage fatigue.

Pain is another common symptom of MS that can contribute to social isolation. Lesions on the sensory pathways cause pain. Additional sensory manifestations include paresthesias, dysesthesias, and proprioception loss. Many people with MS need daily analgesic medications. In some cases, pain is managed with opioids, anticonvulsant medications, or antidepressants. Rarely, surgery may be needed to interrupt pain pathways.

Among women who are perimenopausal, those with MS are more likely to have pain related to osteoporosis. In addition to estrogen loss, immobility and corticosteroid therapy play a role in the development of osteoporosis among women with MS. Bone mineral density testing is recommended for this high-risk group. See Chapter 37 for a discussion of the diagnosis of and treatment for osteoporosis.

Spasticity (muscle hypertonicity) occurs in 90% of patients with MS, most often in the lower extremities, and can include loss of the abdominal reflexes. Spasticity results from involvement of the main motor pathways (pyramidal tracts) of the spinal cord. Cognitive and psychosocial problems may reflect frontal or parietal lobe involvement. Some degree of cognitive change (e.g., memory loss, decreased concentration) occurs in about half of patients, but severe cognitive changes with dementia (progressive organic mental disorder) are rare.

Involvement of the cerebellum or basal ganglia can produce ataxia (impaired coordination of movements) and tremor. Loss of the control connections between the cortex and the basal ganglia may occur and cause emotional lability and euphoria. Bladder, bowel, and sexual dysfunctions are common.

Researchers reported that patients with MS have higher rates of depression, arthritis, diabetes, coronary artery disease, migraine headaches, and cancer compared to a normative population (Newland, Jensen, Budhathoki, et al., 2015). Additional complications include urinary tract infections, constipation, pressure ulcers, contracture deformities, dependent pedal edema, pneumonia, and osteoporosis. Emotional, social, marital, economic, and vocational problems may also occur.

Exacerbations and remissions are characteristic of MS. During exacerbations, new symptoms appear and existing ones worsen; during remissions, symptoms decrease or disappear. Relapses may be associated with emotional and physical stress.

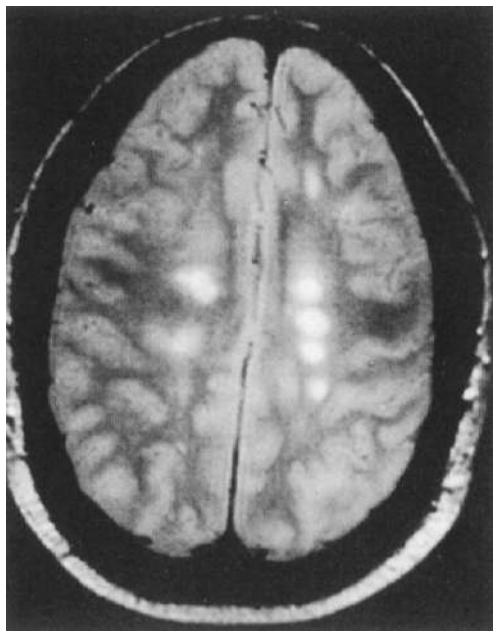

Figure 52-11 • Multiple sclerosis. Axial T-2 weighted image shows ovoid hyperintense lesions in both hemispheres. From Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Gerontologic Considerations

The life expectancy for patients with MS is 5 to 7 years shorter than patients without MS (Bader et al., 2016). Those diagnosed with secondary progressive disease live an average of 38 years after onset. Older adult patients with MS have specific physical and psychosocial challenges. They may have chronic health problems, for which they may be taking additional medications that could interact with medications prescribed for MS. The absorption, distribution, metabolism, and excretion of medications are altered in the older adult as a result of age-related changes in kidney and liver functions. Therefore, older adult patients must be monitored closely for adverse and toxic effects of MS medications and for osteoporosis (particularly if corticosteroids have been used frequently to treat exacerbations). The cost of medications may lead to poor adherence to the prescribed regimen in older adult patients on fixed incomes.

Older adult patients with MS are particularly concerned about increasing disability, family burden, marital concern, and the possible future need for nursing home care. Immobility resulting in fewer social opportunities contributes to loneliness and depression. Researchers found that 58% of older adults with MS reported frequent depressed feelings and more than 30% contemplated suicide (Buhse, 2015). In addition to functional loss, the physical challenges experienced by older adults with MS include spasticity, pain, bladder dysfunction, impaired sleep, and an increased need for assistance with self-care.

Assessment and Diagnostic Findings

The diagnosis of MS is based on the presence of multiple plaques in the CNS observed with MRI (Hickey, 2014) (see Fig. 52-11). Additional studies augment the diagnosis. Electrophoresis of CSF identifies the presence of oligoclonal banding (several bands of immunoglobulin G bonded together, indicating an immune system abnormality). Evoked potential studies can help define the extent of the disease process and monitor changes. Underlying bladder dysfunction is diagnosed by urodynamic studies. Neuropsychological testing may be indicated to assess cognitive impairment. A sexual history helps identify changes in sexual function.

Medical Management

No cure exists for MS. An individual treatment program is indicated to relieve the patient's symptoms and provide continuing support, particularly for patients with cognitive changes, who may need more structure and support. The goals of treatment are to delay the progression of the disease, manage chronic symptoms, and treat acute exacerbations. Common symptoms requiring intervention include ataxia, bladder dysfunction, depression, fatigue, and spasticity. Management includes pharmacologic and nonpharmacologic strategies.

Pharmacologic Therapy

Medications prescribed for MS include those for disease modification and those for symptom management. Disease-modifying therapies are available to treat some of the different forms of MS (Hickey, 2014). Many types of medications are used for symptom management in MS.

Disease-Modifying Therapies

The disease-modifying medications reduce the frequency of relapse, the duration of relapse, and the number and size of plaques observed on MRI in the RR form of MS, but are not effective in the primary progressive type of MS (Hickey, 2014).

Interferon beta-1a (Rebif) and interferon beta-1b (Betaseron) may be given subcutaneously every other day. Another preparation of interferon beta-1a (Avonex) may be given intramuscularly once a week. Side effects of all interferon-beta medications include flulike symptoms in approximately half of

patients taking these drugs that cause patients to discontinue therapy (Filipi, Beavin, Brillante, et al., 2014). For optimal control of disability, disease-modifying medications should be started early in the course of the disease (Comerford, 2015).

Glatiramer acetate (Copaxone) also reduces the rate of relapse in the RR course of MS. Copaxone is given subcutaneously daily (Hickey, 2014). Copaxone is an option for those with an RR course; however, it may take 6 months for evidence of an immune response to appear. There are oral disease-modifying agents that also reduce disease activity and disease progression. Teriflunomide (Aubagio), fingolimod (Gilenya), and dimethyl fumarate (Tecfidera) are oral alternatives that may be better tolerated by the patient who have difficulty with injection reactions (Hickey, 2014).

IV methylprednisolone, the key agent in treating acute relapse in the RR course, shortens the duration of relapse but has not been found to have long-term benefit (Bader et al., 2016). It exerts anti-inflammatory effects by acting on T cells and cytokines. The medication is given as 1 g IV daily for 3 to 5 days, followed by an oral taper of prednisone. Side effects include mood swings, weight gain, and electrolyte imbalances (Comerford, 2015).

The medication mitoxantrone (Novantrone) is given via IV infusion every 3 months. Mitoxantrone can reduce the frequency of clinical relapses in patients with secondary progressive or worsening RR MS. Patients must be very closely monitored for side effects (i.e., cardiac toxicity), and there is a maximum lifetime dose that can be given (Hickey, 2014).

Symptom Management

Medications are also prescribed for management of specific symptoms. Baclofen (Lioresal), a gamma-aminobutyric acid agonist, is the medication of choice for treating spasticity. It can be given orally or by intrathecal injection for severe spasticity. Benzodiazepines (e.g., diazepam [Valium]), tizanidine (Zanaflex), and dantrolene (Dantrium) may also be used to treat spasticity (Hickey, 2014). Patients with disabling spasms and contractures may require nerve blocks or surgical intervention. Fatigue that interferes with activities of daily living (ADLs) may be treated with amantadine (Symmetrel), pemoline (Cylert), or dalfampridine (Ampyra). Ataxia is a chronic problem most resistant to treatment. Medications used to treat ataxia include beta-adrenergic blockers (e.g., propranolol [Inderal]), the anticonvulsant agent gabapentin (Neurontin), and benzodiazepines (e.g., clonazepam [Klonopin]).

Bladder and bowel problems are often difficult for patients, and a variety of medications (anticholinergic agents, alpha-adrenergic blockers, antispasmodic agents) may be prescribed. Nonpharmacologic strategies also assist in establishing effective bowel and bladder elimination (see later discussion).

Urinary tract infection may be superimposed on the underlying neurologic dysfunction. Ascorbic acid (vitamin C) may be prescribed to acidify the urine, making bacterial growth less likely. Antibiotic agents are prescribed when appropriate.

NURSING PROCESS

The Patient with MS

Assessment

Nursing assessment addresses neurologic deficits, secondary complications, and the impact of the disease on the patient and family. The patient's mobility and balance are observed to determine whether there is risk of falling. Assessment of function is carried out both when the patient is well rested and when fatigued. The patient is assessed for weakness, spasticity, visual impairment, incontinence, and disorders of swallowing and speech. Additional areas of assessment include how MS has affected the patient's lifestyle, how the patient is coping, adherence to the prescribed medication regimen, and what the patient would like to improve.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired bed and physical mobility related to weakness, muscle paresis, spasticity, increased weight
- Risk for injury related to sensory and visual impairment
- Impaired urinary elimination (urgency, frequency, incontinence), constipation, and bowel incontinence related to nervous system dysfunction
- Impaired verbal communication and risk for aspiration related to cranial nerve involvement
- Chronic confusion related to cerebral dysfunction
- Ineffective coping related to uncertainty of course of MS
- Impaired home maintenance management related to physical, psychological, and social limits imposed by MS
- Ineffective sexuality pattern related to lesions or psychological reaction

Planning and Goals

The major goals for the patient may include promotion of physical mobility, avoidance of injury, achievement of bladder and bowel continence, promotion of speech and swallowing mechanisms, improvement of cognitive function, development of coping strengths, improved home maintenance management, and adaptation to sexual dysfunction.

Nursing Interventions

An individualized program of physical, occupational, and speech-language therapy, rehabilitation, and education is combined with emotional support. An educational plan of care is developed to enable the person with MS to deal with the physiologic, social, and psychological problems that accompany chronic disease. The presence of depression, pain, fatigue, and walking difficulty all decrease physical activity. Assisting patients with management of these symptoms may help increase the level of physical activity and overall sense of well-being.

Promoting Physical Mobility

Relaxation and coordination exercises promote muscle efficiency. Progressive resistive exercises are used to strengthen weak muscles, because diminishing muscle strength is often significant in MS.

Exercises. Walking improves the gait, particularly the problem of loss of position sense of the legs and feet. If certain muscle groups are irreversibly affected, other muscles can be trained to compensate. Instruction in the use of assistive devices may be needed to ensure their safe and correct use.

Minimizing Spasticity and Contractures. Muscle spasticity is common and, in its later stages, is characterized by severe adductor spasm of the hips with flexor spasm of the hips and knees. Without relief, fibrous contractures of these joints occur. Warm packs may be beneficial, but hot baths should be avoided because of risk of burn injury secondary to sensory loss and

increasing symptoms that may occur with elevation of the body temperature.

Daily exercises for muscle stretching are prescribed to minimize joint contractures. Special attention is given to the hamstrings, gastrocnemius muscles, hip adductors, biceps, and wrist and finger flexors. Muscle spasticity is common and interferes with usual function. Application of prescribed orthotics may help maintain a functional position and reduce contractures. A stretch–hold–relax routine is helpful for relaxing and treating muscle spasticity. Swimming and stationary bicycling are useful, and progressive weight bearing can relieve spasticity in the legs. The patient should not be hurried in any of these activities, because this often increases spasticity.

Activity and Rest. The patient is encouraged to work and exercise to a point just short of fatigue. Very strenuous physical exercise is not advisable, because it raises the body temperature and may aggravate symptoms. The patient is advised to take frequent short rest periods, preferably lying down. Extreme fatigue may contribute to the exacerbation of symptoms. One study reported that functional limitations and depressive symptoms were the strongest predictors of fatigue impact in patients with long-standing MS (see Chart 52-3) (Morrison & Stuifbergen, 2016).

Nutrition. Similar to the population at large, many patients with MS are overweight or have obesity. Contributing factors include the use of corticosteroids for exacerbations of symptoms and mobility impairments as a result of the disease. Interventions to promote healthy eating and weight reduction need to take into account that fatigue and mobility impairments are barriers to engagement in nutritional behaviors for people with MS. Nurses also need to be certain to include family members in interventions and nutrition education, because they are often the gatekeepers for food preparation and selection. Additional strategies include avoidance of alcohol and cigarette smoking (Bader et al., 2016).

Minimizing Effects of Immobility. Because of the decrease in physical activity that often occurs with MS, complications associated with immobility, including pressure ulcers, expiratory muscle weakness, and accumulation of bronchial secretions, need to be considered and steps taken to prevent them. Measures to prevent such complications include assessing and maintaining skin integrity and having the patient perform coughing and deep-breathing exercises.

Preventing Injury

If motor dysfunction causes problems of incoordination and clumsiness, or if ataxia is apparent, then the patient is at risk for falling. To overcome this disability, the patient is instructed to walk with feet apart to widen the base of support and to increase walking stability. If loss of position sense occurs, the patient is instructed to watch the feet while walking. Gait training may require assistive devices (walker, cane, braces, crutches, parallel bars) and instruction about their use by a physiotherapist. If the gait remains inefficient, a wheelchair or motorized scooter may be the solution. The occupational therapist is a valuable resource person in suggesting and securing aids to promote independence. If incoordination is a problem and tremor of the upper extremities occurs when voluntary movement is attempted (intention tremor), weighted bracelets or wrist cuffs are helpful. The patient is trained in transfer and ADLs.

Because sensory loss may occur in addition to motor loss, pressure ulcers are a continuing threat to skin integrity. The need to use a wheelchair continuously increases the risk. See Chapter 51 for a discussion of the prevention and treatment of pressure ulcers.

Enhancing Bladder and Bowel Control

In general, bladder symptoms fall into the following categories: (1) inability to store urine (hyperreflexic, uninhibited); (2) inability to empty the bladder (hyporeflexic, hypotonic); and (3) a mixture of both types. The patient with urinary frequency, urgency, or incontinence requires special support. The sensation of the need to void must be heeded immediately, so the bedpan or urinal should be readily available. A voiding time schedule is set up (every 1.5 to 2 hours initially, with gradual lengthening of the interval). The patient is instructed

Chart 52-3 NURSING RESEARCH PROFILE

Predictors of Fatigue in Patients with MS

Morrison, J. D., & Stuifbergen, A. K. (2016). Predictors of fatigue impact in persons with long-standing multiple sclerosis. Journal of Neuroscience Nursing, 48(3), 143–150.

Purpose

Fatigue is very common among those with MS and has a negative impact on many aspects of their lives. The underlying mechanisms are poorly understood and treatment is a challenge. The purpose of this study was to explain the physical, cognitive, and psychosocial dimensions of fatigue among those with long-standing MS.

Design

More than 300 people with long-standing MS (for 17 years or more) were surveyed to measure fatigue impact, MS related functional limitations, depressive symptoms, barriers to health promotion, personal resources, and health promoting behaviors. The relationships among fatigue impact, age, MS duration, MS related functional limitations, depressive symptoms, barriers to health promotion, personal resources, and health promoting behaviors were also explored.

Findings

Age and MS duration were not significantly related to fatigue impact. Moderate to strong positive, linear relationships were reported among fatigue impact measures and MS functional limitations (range: $r = 0.41–0.58$, $p < 0.01$), depressive symptoms (range: $r = 0.58–0.63$, $p < 0.01$), and barriers (range: $r = 0.55–0.63$, $p < 0.01$). Moderate inverse linear relationships were reported among fatigue impact measures and personal resources (range: $r = –0.40–0.50$, $p < 0.01$) and health-promoting behaviors (range: $r = –0.34–0.44$, $p < 0.01$). MS functional limitation was reported as the strongest predictor of physical and psychosocial fatigue impact, while depressive symptoms was the strongest predictor of total and cognitive fatigue impact.

Nursing Implications

Nurses working with patients with MS should know that functional limitations and depressive symptoms were strong predictors of fatigue impact in this study. This illustrates the importance of nurses assessing and monitoring depressive symptoms, functional status, and dimensions of fatigue at each encounter with patients, whether in the in-patient or out-patient setting.

to drink a measured amount of fluid every 2 hours and then attempt to void 30 minutes after drinking. The use of a timer or wristwatch with an alarm may be helpful for the patient who does not have enough sensation to signal the need to empty the bladder. The nurse encourages the patient to take the prescribed medications to treat bladder spasticity, because this allows greater independence. Intermittent self-catheterization (see Chapter 51) has been successful in maintaining bladder control in patients with MS. If a female patient has permanent urinary incontinence, urinary diversion procedures may be considered. The male patient may wear a condom appliance for urine collection.

Bowel problems include constipation, fecal impaction, and incontinence. Adequate fluids, dietary fiber, and a bowel training program are frequently effective in solving these problems. See Chapter 51 for a discussion of promoting bowel continence.

Enhancing Communication and Managing Swallowing Difficulties

If the cranial nerves that control the mechanisms of speech and swallowing are affected, dysarthrias (defects of articulation) marked by slurring, low volume of speech, and difficulties in phonation may occur. Dysphagia (difficulty swallowing) may also occur. A speech-language pathologist evaluates speech and swallowing and instructs the patient, family, and health team members about strategies to compensate for speech and swallowing problems. The nurse reinforces this instruction and encourages the patient and family to adhere to the plan.

Nursing Alert: Impaired swallowing increases the patient's risk of aspiration. To reduce that risk, the nurse implements strategies such as having suction apparatus available, ensuring careful feeding, confirming correct food and liquid consistency, and positioning properly for eating.

Improving Cognitive Function

Measures may be taken if visual defects or changes in cognitive status occur and result in chronic confusion.

Vision. The cranial nerves affecting vision may be affected by MS. An eye patch or a covered eyeglass lens may be used to block the visual impulses of one eye if the patient has diplopia. Prism glasses may be helpful for patients who are confined to bed and have difficulty reading in the supine position.

Cognition and Emotional Responses. Cognitive impairment and emotional lability occur early in MS in some patients and may impose numerous stresses on the patient and family. Some patients with MS are forgetful and easily distracted and may exhibit emotional lability.

Patients adapt to illness in a variety of ways, including denial, depression, withdrawal, and hostility. Emotional support assists patients and their families to adapt to the changes and uncertainties associated with MS and to cope with the disruption in their lives. The family should be made aware of the nature and degree of cognitive impairment. Patients with MS have identified that the support of family and friends is a major need. The patient is assisted to set meaningful and realistic goals, to remain as active as possible, and to maintain interests and activities. Hobbies may help the patient's morale and provide satisfying interests if the disease progresses to the stage in which formerly enjoyed activities can no longer be pursued. The environment is kept structured, distractions are reduced, and lists and other memory aids are used to help the patient with cognitive changes maintain a daily routine. The occupational therapist can be helpful in formulating a structured daily routine.

Strengthening Coping Mechanisms

The diagnosis of MS is always distressing to the patient and family. They need to know that no two patients with MS have identical symptoms or courses of illness. Although some patients do experience significant disability early, others have a near-normal lifespan with minimal disability. Some families, however, face acute frustrations and problems. MS affects people who are often in an early stage of life and concerned about career and family responsibilities. Family conflict, disintegration, separation, and divorce are not uncommon. Often, very young family members assume the responsibility of caring for a parent with MS. Nursing interventions in this area include assisting patients and families to manage or reduce stress and making appropriate referrals for counseling and support to minimize the adverse effects of dealing with chronic illness.

The nurse, mindful of these complex problems, initiates home care and coordinates a network of services, including social services, speech therapy, physical therapy, and homemaker services. To strengthen the patient's coping skills, as much information as possible is provided. Patients need an updated list of available assistive devices, services, and resources.

Coping through problem solving involves helping the patient define the problem and develop alternatives for its management. Planning carefully, maintaining flexibility, and preserving a hopeful attitude are useful for psychological and physical adaptation.

Improving Home Management

MS can affect every facet of daily living. Certain abilities are often impossible to regain after they are lost. Physical function may vary from day to day. Modifications that allow independence in home management should be implemented (e.g., assistive eating devices, raised toilet seat, bathing aids, telephone modifications, long-handled comb, tongs, modified clothing). Exposure to heat increases fatigue and muscle weakness, so air conditioning is recommended in at least one room. Exposure to extreme cold may increase spasticity.

Promoting Sexual Functioning

Patients with MS and their partners face problems that interfere with sexual activity, both as a direct consequence of nerve damage and also from psychological reactions to the disease. Easy fatigability, conflicts arising from dependency and depression, emotional lability, and loss of self-esteem compound the problem. Erectile and ejaculatory disorders in men and orgasmic dysfunction and adductor spasms of the thigh muscles in women can make sexual intercourse difficult or impossible. Bladder and bowel incontinence and urinary tract infections add to the difficulties.

Collaboration between the patient, family, and primary provider is essential for supporting intimacy. A sexual counselor can help bring into focus the patient's or partner's sexual resources and suggest relevant information and supportive therapy. Sharing and communicating feelings, planning for sexual activity (to minimize the effects of fatigue), and exploring alternative methods of sexual expression may open up a wide range of sexual enjoyment and experiences.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. As the disease progresses, the patient and family need to learn new strategies to maintain optimal independence. Educating about self-care techniques may be initiated in the hospital or clinic setting and reinforced in the home. Self-care education may address the use of assistive devices, self-catheterization, and administration of medications that affect the course of the disease or treat complications. An education plan that addresses intramuscular or subcutaneous administration of medications (including side effects) is developed for the patient and their family or caregiver. A panel of experts concluded that flulike symptoms resulting from injectable disease-modifying drugs can be mitigated by dose titration, use of analgesics, evening dosing, drug formulation, solution temperature, adequate hydration, and a nutritious diet (Filipi et al., 2014). The patient and family are educated about exercises that enable the patient to continue some form of activity or that maintain or improve swallowing, speech, or respiratory function (see Chart 52-4).

Continuing and Transitional Care. After discharge, the nurse often provides education and reinforcement of new interventions in the patient's home. Nurses in the home setting assess for changes in the patient's physical and emotional status; provide physical care to the patient if required; coordinate outpatient services and resources; and encourage health promotion, appropriate health screenings, and adaptation. If changes in the disease or its course are noted, the nurse encourages the patient to contact the primary provider, because treatment of an acute exacerbation or new problem may be indicated. Continuing health care and follow-up are recommended.

Evaluation

Expected patient outcomes may include:

1. Improves physical mobility
   a. Participates in gait training and rehabilitation program
   b. Establishes a balanced program of rest and exercise
   c. Uses assistive devices correctly and safely
2. Is free of injury
   a. Uses visual cues to compensate for decreased sense of touch or position
   b. Asks for assistance when necessary
3. Attains or maintains control of bladder and bowel patterns
   a. Monitors self for urine retention and employs intermittent self-catheterization technique, if indicated
   b. Identifies the signs and symptoms of urinary tract infection
   c. Maintains adequate fluid and fiber intake
   d. Identifies the foods that are constipating versus food that increase gastric motility
4. Participates in strategies to improve speech and swallowing
   a. Practices exercises recommended by speech therapist
   b. Maintains adequate nutritional intake without aspiration
5. Compensates for chronic confusion
   a. Uses lists and other aids to compensate for memory losses
   b. Discusses problems with trusted advisor or friend
   c. Substitutes new activities for those that are no longer possible
6. Demonstrates effective coping strategies
   a. Maintains sense of control
   b. Modifies lifestyle to fit goals and limitations
   c. Verbalizes desire to pursue goals and developmental tasks of adulthood
   d. Demonstrates healthy social interactions
   e. Participates in groups or community activities
7. Adheres to plan for home maintenance management
   a. Uses appropriate techniques to maintain independence
   b. Engages in health-promotion activities and health screenings as appropriate
8. Adapts to changes in sexual function
   a. Is able to discuss problem with partner and appropriate health professional
   b. Identifies alternative means of sexual expression

Chart 52-4 HOME CARE CHECKLIST

The Patient with MS

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of MS and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
  - Demonstrate correct techniques of administering injectable medications, if prescribed.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., exercise, activity) necessary to maintain health.
  - Demonstrate environmental modifications and adaptive techniques for accomplishing activities of daily living.
  - Identify strategies to manage symptoms (pain, cognitive responses, dysphagia, tremors, visual disturbances).
  - State how to prevent complications (e.g., pressure ulcers, pneumonia, depression).
  - Identify coping strategies.
  - Identify ways to minimize fatigue.
  - Explain how to prevent injury.
  - Identify optimal nutritional intake; consider weight reduction as indicated if patient is overweight or has obesity.
  - State ways to promote sexual function.
  - Discuss ways to manage bowel and bladder function.
  - Name benefits of exercise and physical activity.
  - Identify ways to minimize immobility and spasticity.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living; MS, multiple sclerosis.

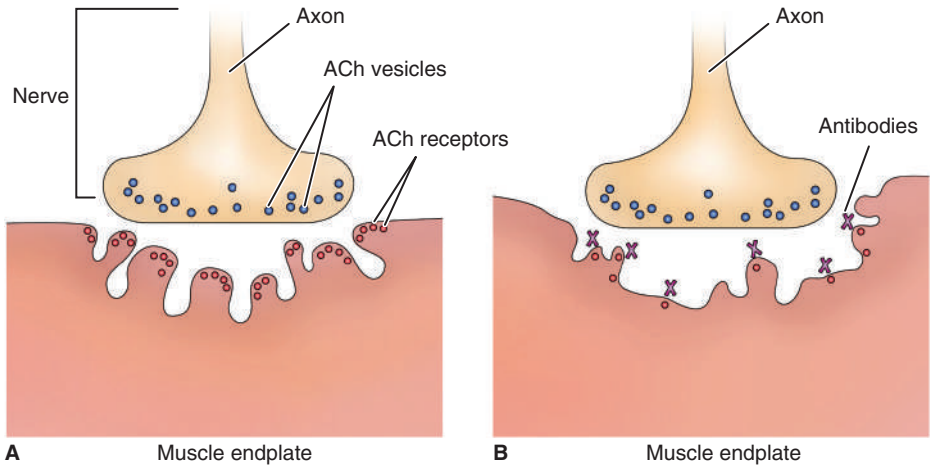

Figure 52-12 • Myasthenia gravis. **A.** Usual acetylcholine (ACh) receptor site. **B.** ACh receptor site in myasthenia gravis.

Myasthenia Gravis

Myasthenia gravis, an autoimmune disorder affecting the myoneural junction, is characterized by varying degrees of weakness of the voluntary muscles. More women than men are affected, commonly in the second and third decades of life; however, after age 50, the gender distribution is more equal (American Association of Neuroscience Nurses [AANN], 2013); (Bader et al., 2016).

Unlike in western countries, men are affected more than women in India (ratio is 2.70:1). Onset of this condition among men is common in the fifth to sixth decades, whereas women experience early onset of the condition, i.e., commonly in third decades of life (Singhal, Bhatia, & Umesh, 2008).

Pathophysiology

Normally, a chemical impulse precipitates the release of acetylcholine from vesicles on the nerve terminal at the myoneural junction. The acetylcholine attaches to receptor sites on the motor endplate and stimulates muscle contraction. Continuous binding of acetylcholine to the receptor site is required for muscular contraction to be sustained.

In myasthenia gravis, antibodies directed at the acetylcholine receptor sites impair transmission of impulses across the myoneural junction. Therefore, fewer receptors are available for stimulation, resulting in voluntary muscle weakness that escalates with continued activity (see Fig. 52-12). These antibodies are found in 80% to 90% of people with myasthenia gravis (Hickey, 2014). Of people with myasthenia gravis, 75% have either thymic hyperplasia or a thymic tumor, and the thymus gland is believed to be the site of antibody production (Bader et al., 2016). In patients who are antibody negative, researchers believe that the offending antibody is directed at a portion of the receptor site rather than the whole complex (AANN, 2013). Pathophysiology of myasthenia gravis is presented in Figure 52-13.

Clinical Manifestations

The initial manifestation of myasthenia gravis in 80% of patients involves the ocular muscles. Diplopia and ptosis (drooping of the eyelids) are common (Bader et al., 2016). Many patients also experience weakness of the muscles of the face and throat (bulbar symptoms) and generalized weakness. Weakness of the facial muscles results in a bland facial expression. Laryngeal involvement produces dysphonia (voice impairment) and dysphagia, which increases the risk of choking and aspiration. Generalized weakness affects all extremities and the intercostal muscles, resulting in decreasing vital capacity and respiratory failure (Mcilvoy, 2014). Myasthenia gravis is purely a motor disorder with no effect on sensation or coordination.

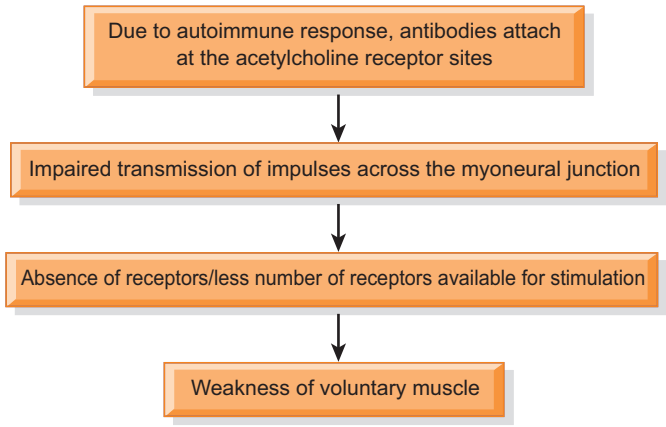

Figure 52-13 • Pathophysiology of myasthenia gravis.

Assessment and Diagnostic Findings

A common test used to diagnose myasthenia gravis is the acetylcholinesterase inhibitor test. It is performed by administering edrophonium chloride (Tensilon) IV; 30 seconds after injection, facial muscle weakness and ptosis should resolve for about 5 minutes (Hickey, 2014). Immediate improvement in muscle strength after administration of this agent represents a positive test and usually confirms the diagnosis. Atropine should be available to control potential side effects of this medication, which include bradycardia, asystole, bronchoconstriction, sweating, and cramping.

Another study, the ice test, is indicated in patients who have cardiac conditions or asthma. With this test, an ice pack is held over the patient's eyes for 1 minute; the ptosis should temporarily resolve in a patient with myasthenia gravis (Hickey, 2014).

Several blood tests for acetylcholine antibodies are also used to confirm the diagnosis (AANN, 2013). Repetitive nerve

stimulation (RNS) demonstrates a decrease in successive action potentials. A single-fiber electromyography (EMG) detects a delay or failure of neuromuscular transmission and is about 99% sensitive in confirming the diagnosis of myasthenia gravis (Hickey, 2014). This is an uncomfortable test for the patient.

The thymus gland, a site of acetylcholine receptor antibody production, may be enlarged in myasthenia gravis and may be identified by MRI scan.

Medical Management

Management of myasthenia gravis is directed at improving function and reducing and removing circulating antibodies. Therapeutic modalities include administration of anticholinesterase medications and immunosuppressive therapy, intravenous immune globulin (IVIG), therapeutic plasma exchange (TPE), and thymectomy. There is no cure for myasthenia gravis; treatments do not stop the production of the acetylcholine receptor antibodies.

Pharmacologic Therapy

Pyridostigmine bromide (Mestinon), an anticholinesterase medication, is the first line of therapy (Mcilvoy, 2014). It provides symptomatic relief by inhibiting the breakdown of acetylcholine and increasing the relative concentration of available acetylcholine at the neuromuscular junction. The dosage is gradually increased to a daily maximum and is given in divided doses (usually four times a day). Adverse effects of anticholinesterase medications include diarrhea, abdominal cramps, and/or excessive saliva (Comerford, 2015). Pyridostigmine tends to have fewer side effects than other anticholinesterase medications.

If pyridostigmine bromide does not improve muscle strength and control fatigue, the next agents used are the immunomodulating drugs. The goal of immunosuppressive therapy is to reduce production of the antibody. Corticosteroids suppress the patient's immune response, decreasing the amount of antibody production, and this correlates with clinical improvement. An initial dose of prednisone is given daily and maintained for 1 to 2 months; as symptoms improve, the medication is tapered (Bader et al., 2016). As the corticosteroid medications take effect, the dosage of anticholinesterase medication can usually be lowered. Cytotoxic medications are used to treat myasthenia gravis if there is inadequate response to steroids. Azathioprine (Imuran) inhibits T lymphocytes and B-cell proliferation and reduces acetylcholine receptor antibody levels. Therapeutic effects may not be evident for 3 to 12 months. Leukopenia and hepatotoxicity are serious adverse effects, so monthly evaluation of liver enzymes and white blood cell count is necessary.

Intravenous immune globulin (IVIG) can be used to treat exacerbations; however, in selected patients, it is used on a long-term adjunctive basis. IVIG treatment involves the administration of pooled human gamma-globulin and improvement occurs in a few days (Hickey, 2014). The effects of IVIG typically last only about 28 days after infusion, and complications include headache, migraine exacerbation, aseptic meningitis, and flulike symptoms (Cherin, Marie, Michallet, et al., 2016).

A number of medications are contraindicated for patients with myasthenia gravis because they exacerbate the symptoms. The primary provider and the patient should weigh risks and benefits before any new medications are prescribed. Procaine (Novocaine) should be avoided, and the patient's dentist is informed of the diagnosis of myasthenia gravis.

Therapeutic Plasma Exchange

A technique called TPE, formerly referred to as plasmapheresis, is used to treat exacerbations. The patient's plasma and plasma components are removed through a centrally placed large-bore double-lumen catheter. The blood cells and antibody-containing plasma are separated, after which the cells and a plasma substitute are reinfused. Temporary reduction in the level of circulating antibodies is provided with TPE. A typical course consists of daily or alternate-day treatment, and the number of treatments is determined by the patient's response. Symptoms improve in 75% of patients undergoing TPE; however, improvement lasts only a few weeks after treatment is completed (Hickey, 2014).

Surgical Management

Thymectomy (surgical removal of the thymus gland) can produce antigen-specific immunosuppression and result in clinical improvement. This surgery is frequently performed in patients younger than 65 years who have had myasthenia gravis diagnosed within the past 3 years. It is the only treatment that can result in complete remission, which occurs in approximately 35% of patients (Hickey, 2014). Improvements may take several months to several years after surgery to occur. A course of preoperative TPE decreases the time needed for postoperative mechanical ventilation.

The entire thymus gland must be removed for optimal clinical outcomes. There are three surgical approaches: transsternal, transcervical thymectomy, and video-assisted thoracoscopic surgery (AANN, 2013). After surgery, the patient is monitored in an intensive care unit, with special attention to respiratory function. The patient is weaned from mechanical ventilation after thorough respiratory assessment. After the thymus gland is removed, it may take up to 3 years for the patient to benefit from the procedure because of the long life of circulating T cells. The earlier the surgery in the disease process, the better the prognosis (Bader et al., 2016).

Complications

A myasthenic crisis is an exacerbation of the disease process characterized by severe generalized muscle weakness and respiratory and bulbar weakness that may result in respiratory failure. Crisis may result from disease exacerbation or a specific precipitating event. The most common precipitator is respiratory infection; others include medication change, surgery, pregnancy, and medications that exacerbate myasthenia. A cholinergic crisis caused by overmedication with cholinesterase inhibitors is rare (AANN, 2013).

Neuromuscular respiratory failure is the critical complication in myasthenic and cholinergic crises. Respiratory muscle and bulbar weakness combine to cause respiratory compromise. Weak respiratory muscles do not support inhalation. An inadequate cough and an impaired gag reflex, caused by bulbar weakness, result in poor airway clearance. A downward trend of two respiratory function tests, the negative inspiratory force and vital capacity, is the first clinical sign of respiratory compromise.

Endotracheal intubation and mechanical ventilation may be needed (see Chapter 11). Noninvasive positive-pressure ventilation uses an external device in the form of a vest that provides respiratory support without endotracheal intubation. Cholinesterase inhibitors are stopped when respiratory failure

occurs and gradually restarted after the patient demonstrates improvement with a course of TPE or IVIG. Nutritional support may be needed if the patient is intubated for a long period or swallowing ability is affected (see Chapter 15).

Nursing Management

Because myasthenia gravis is a chronic disease and most patients are seen on an outpatient basis, much of the nursing care focuses on patient and family education. Educational topics for outpatient self-care include medication management, energy conservation, strategies to help with ocular manifestations, and prevention and management of complications.

Medication management is a crucial component of ongoing care. Understanding the actions of the medications and taking them on schedule is emphasized, as are the consequences of delaying medication and the signs and symptoms of myasthenic and cholinergic crises. The patient can determine the best times for daily dosing by keeping a diary to determine fluctuation of symptoms and to learn when the medication is wearing off. The medication schedule can then be manipulated to maximize strength throughout the day.

Nursing Alert: Maintenance of stable blood levels of anticholinesterase medications is imperative to stabilize muscle strength. Therefore, the anticholinesterase medications must be given on time. Any delay in administration of medications may exacerbate muscle weakness and make it impossible for the patient to take medications orally.

Regular administration of IVIG or subcutaneous immunoglobulin (SCIG) may be prescribed. The patient and family are educated about managing immunoglobulin therapy.

The procedural guidelines for management of IVIG are discussed in the Procedural Guidelines 52-1.

The patient is also educated about strategies to conserve energy. To do this, the nurse helps the patient identify the optimal times for rest throughout the day. If the patient lives in a two-story home, the nurse can suggest that frequently used items (e.g., hygiene products, cleaning products, snacks) be kept on each floor to minimize travel between floors. Using consistent routines, scheduling periods of rest, monitoring for depression, maintaining good sleep patterns, and incorporating interventions to conserve energy are all strategies to reduce fatigue (Bader et al., 2016).

To minimize the risk of aspiration, mealtimes should coincide with the peak effects of anticholinesterase medication. In addition, rest before meals is encouraged to reduce muscle fatigue. The patient is advised to sit upright during meals, with the neck slightly flexed to facilitate swallowing. Soft foods in gravy or sauces can be swallowed more easily. Eating large meals in the morning and smaller meals in the evening is another good strategy (Bader et al., 2016). Supplemental feedings may be helpful to ensure adequate nutrition.

If choking occurs frequently, the patient should be evaluated by a speech-language pathologist for formal dietary and mechanical techniques to avoid aspiration. Suction should be available at home, with the patient and family instructed in its use.

Impaired vision results from ptosis of one or both eyelids, decreased eye movement, or double vision. To prevent corneal damage when the eyelids do not close completely, the patient is instructed to tape the eyes closed for short intervals and to regularly instill artificial tears. Patients who wear eyeglasses can have "crutches" attached to help lift the eyelids. Patching of one eye can help with double vision.

The patient is reminded of the importance of maintaining health-promotion practices and following health care screening recommendations. Factors that exacerbate symptoms and potentially cause crisis should be noted and avoided: emotional stress, infections (particularly respiratory infections), vigorous physical activity, some medications, and high environmental temperature. The Myasthenia Gravis Foundation of America provides support groups, services, and educational materials for patients, families, and health care providers (see the Resources section).

Myasthenic Crisis

Respiratory distress and varying degrees of dysphagia, dysarthria (difficulty speaking), eyelid ptosis, diplopia, and prominent muscle weakness are symptoms of myasthenic crisis. The patient is placed in an intensive care unit for constant monitoring because of associated intense and sudden fluctuations in clinical condition.

Providing ventilatory assistance takes precedence in the immediate management of the patient with myasthenic crisis. Ongoing assessment for respiratory failure is essential. The nurse assesses the respiratory rate, depth, and breath sounds and monitors pulmonary function parameters (vital capacity and negative inspiratory force) to detect pulmonary problems before respiratory dysfunction progresses. Blood is drawn for arterial blood gas analysis. Endotracheal intubation and mechanical ventilation may be needed (see Chapter 11).

If the abdominal, intercostal, and pharyngeal muscles are severely weak, the patient cannot cough, take deep breaths, or clear secretions. Chest physiotherapy, including postural drainage to mobilize secretions and suctioning to remove secretions, may have to be performed frequently. (Postural drainage should not be performed for 30 minutes after feeding.)

Assessment strategies and supportive measures include the following:

- Arterial blood gases, serum electrolytes, input and output, and daily weight are monitored.
- If the patient cannot swallow, enteral tube feedings may be prescribed (see Chapter 15).
- Sedative and tranquilizing agents are avoided, because they aggravate hypoxia and hypercapnia and can cause respiratory and cardiac depression.

Guillain–Barré Syndrome (GBS)

GBS, also known as acute idiopathic polyneuritis, is an autoimmune attack on the peripheral nerve myelin. The result is acute, rapid segmental demyelination of peripheral nerves and some cranial nerves, producing ascending weakness with dyskinesia (inability to execute voluntary movements), hyporeflexia, and paresthesias (a sensation of numbness, tingling, or a "pins and needles" sensation). An antecedent event (most often a viral infection) precipitates clinical presentation in approximately 60% to 70% of cases (Bader et al., 2016). *Campylobacter jejuni* (implicated in 24% to 50% of cases), cytomegalovirus, Epstein–Barr virus, *Mycoplasma pneumoniae, H. influenzae,* and HIV are the most common infectious agents that are associated with the development of GBS.

Procedural Guidelines 52-1

Managing Immunoglobulin Therapy

Immunoglobulin therapy is an important treatment for a variety of disease states that are characterized by deficient production of antibodies. Immunoglobulin can be administered for replacement therapy as an IV infusion or subcutaneous (SC) injection. It can safely be administered in outpatient as well as inpatient settings.

Equipment (as needed)

- Single-use tourniquet
- Single-use scissors or clippers for hair removal
- IVIG solution, tubing, connector, catheter, or syringe
- Chlorhexidine gluconate, povidone–iodine, or alcohol swabs
- Nonlatex gloves
- Transparent dressing, bandage, or sterile gauze
- Padded, appropriate-length arm board
- Tape
- Topical analgesics
- Preservative-free 0.9% NaCl flush solution
- Padded, appropriate-length arm board or finger splint
- Electronic infusion pump

Implementation

Nursing Actions	Rationale
1. Verify prescription for IVIG therapy and identify patient.	1. Serious errors can be avoided by careful checking. Immunoglobulin is supplied in a 5% solution or a lyophilized powder with a reconstituting diluent prepared from Cohn fraction II obtained from pools of 1,000–20,000 donors. Currently, a number of different IV preparations are approved for use and have been shown to be effective and safe by the U.S. Food and Drug Administration. Immunoglobulin can also be administered via SC injection.
2. Check for allergies (i.e., latex, iodine).	2. Checking for allergies reduces risk of allergic reaction.
3. Explain procedure to patient.	3. Knowledge increases patient comfort and cooperation.
4. Perform hand hygiene, and put on disposable nonlatex gloves.	4. Asepsis is essential to prevent infection. The use of nonlatex gloves prevents exposure of nurse to patient's blood and of patient and nurse to latex.
5. Obtain height and weight of patient before treatment.	5. Obtaining Ht. and Wt. helps verify accurate dosing.
6. Assess baseline vital signs before, during, and after treatment.	6. An elevated temperature at the beginning of treatment may be an indication to delay the therapy to avoid misinterpreting this as an adverse reaction.
7. Premedicate with acetaminophen/paracetamol (Tylenol) and diphenhydramine (Benadryl) as prescribed 30 minutes before the start of infusion therapy. Corticosteroids may be prescribed as well.	7. Premedicating may help avert adverse reactions. Corticosteroids may be used to prevent possible severe reactions in patients who are perceived to be at risk.
8. Verify the route and dose of IVIG therapy.	8. IVIG can be administered via the IV or SC routes. The optimal dose is determined by the patient's response. In most instances, an IV dose of 200–800 mg/kg of body weight is administered every 3–4 weeks to ensure adequate serum levels of immunoglobulin G (IgG).
9. Insert IV cannula or catheter according to Guidelines for Starting a Peripheral Intravenous Infusion, as needed.	9. Patient may need IV access, may have a port or long-term catheter for an IV infusion.
10. Administer the IV infusion at a slow rate, not to exceed 3 mL/min, usually at 100–200 mL/h.	10. Administer according to manufacturer's instructions. Beginning at a slow rate helps minimize adverse reactions.
11. Continually assess the patient for adverse reactions.	11. Be aware of complaints of a tickle or lump in the throat as the precursor to laryngospasm that precedes bronchoconstriction. Caution should be exercised when changing IVIG products, because they are not biologically equivalent. Understand that long-term tolerance of an older IVIG product does not necessarily imply tolerance to a newer product, even if it is technically superior.
12. Stop IV infusion at the first sign of reaction.	12. Initiate the institutional protocol to be followed in an emergent situation. Patients who have an IgA deficiency have IgE antibodies to IgA, which requires administration of plasma or immunoglobulin replacement from IgA-deficient patients. Because all IV immunoglobulin preparations contain some IgA, they may cause an anaphylactic reaction in patients with IgE anti-IgA antibodies.
13. Administer SC immunoglobulin as orders.	13. The pharmacokinetics of IgG differ when smaller doses are given more frequently, as is commonly done with SC regimens.

Adapted from Cherin, P., Marie, I., Michallet, M., et al. (2016). Management of adverse events in the treatment of patients with immunoglobulin therapy: A review of evidence. Autoimmunity Reviews, 15, 71–81.

There are several types of GBS. With the most well-known type, the patient experiences weakness in the lower extremities, which progresses upward and has the potential for respiratory failure. The second type is purely motor with no altered sensation. A third type, called descending GBS, is much more difficult to diagnose; it mostly affects the head and neck muscles. The rarest type, the Miller–Fisher variant, presents with ataxia, areflexia, and ophthalmoplegia (McNair, 2013).

The annual incidence of GBS is 1 to 2 cases per 100,000 people, and it is more frequent in males between 16 and 25 years of age and those older than 55 years (Bader et al., 2016). Death occurs in 5% to 10% of cases, resulting from respiratory failure, autonomic dysfunction, sepsis, or pulmonary embolism (PE) (Hickey, 2014). There is scanty data available about the incidence or prevalence of GBS in India. However, some of the studies from Europe and Asia have reported familial relationship in the occurrence of this disease. Same familial relations in the occurrence of GBS have been reported by a hospital-based study conducted in South India, where 150 GBS patients were studied for a period of 10 years (Naik, Saroja, & Patil, 2012); (Rastogi, 2016). Association of Zika virus and GBS has been reported by nine different countries during 2015 and 2016 (WHO, 2016).

Pathophysiology

Myelin is a complex substance that covers nerves, providing insulation and speeding the conduction of impulses from the cell body to the dendrites. The cell that produces myelin in the peripheral nervous system is the Schwann cell. In GBS, the Schwann cell can be spared, allowing for remyelination in the recovery phase of the disease. If damage has occurred to the axons, then regrowth is required and takes months or years and is often incomplete (Hickey, 2014).

GBS is the result of a cell-mediated and humoral immune attack on peripheral nerve myelin proteins that causes inflammatory demyelination. The best-accepted theory of cause is molecular mimicry, in which an infectious organism contains an amino acid that mimics the peripheral nerve myelin protein. The immune system cannot distinguish between the two proteins and attacks and destroys peripheral nerve myelin. The exact location of the immune attack within the peripheral nervous system is the ganglioside GM1b. With the autoimmune attack, there is an influx of macrophages and other immune-mediated agents that attack myelin and cause inflammation and destruction, interruption of nerve conduction, and axonal loss (Hickey, 2014). Pathophysiology of GBS is also presented in Figure 52-14.

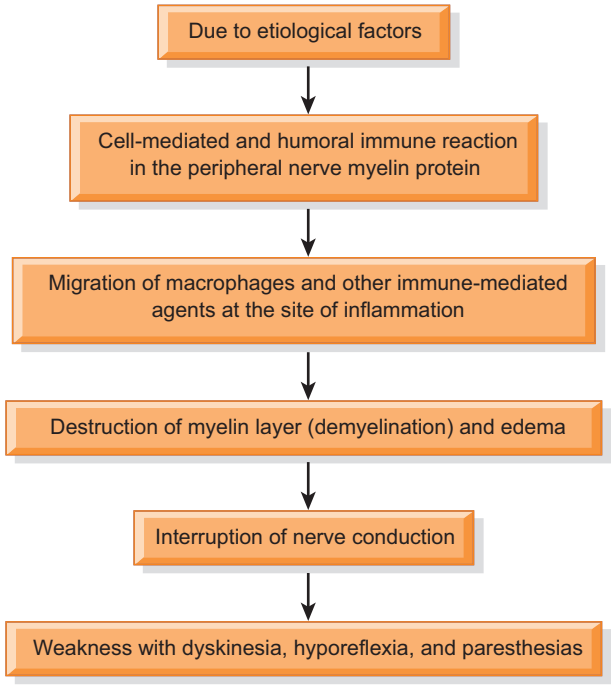

Figure 52-14 • Pathophysiology of Guillain–Barré syndrome.

Clinical Manifestations

GBS typically begins with muscle weakness and diminished reflexes of the lower extremities. Hyporeflexia and weakness may progress to tetraplegia. Demyelination of the nerves that innervate the diaphragm and intercostal muscles results in neuromuscular respiratory failure. Sensory symptoms include paresthesias of the hands and feet and pain related to the demyelination of sensory fibers.

The antecedent event usually occurs 1 to 3 weeks before symptoms begin. Weakness usually begins in the legs and may progresses upward. Maximum weakness (the plateau) varies in length but usually includes neuromuscular respiratory failure and bulbar weakness. GBS progresses to peak severity typically within 2 weeks and no longer than 4 weeks. If progression is longer, then the patient is classified as having chronic inflammatory demyelinating polyneuropathy (Hickey, 2014). Any residual symptoms are permanent and reflect axonal damage from demyelination.

Cranial nerve demyelination can result in a variety of clinical manifestations. Optic nerve demyelination may result in blindness. Bulbar muscle weakness related to demyelination of the glossopharyngeal and vagus nerves results in the inability to swallow or clear secretions. Vagus nerve demyelination results in autonomic dysfunction, manifested by instability of the cardiovascular system. The presentation is variable and may include tachycardia, bradycardia, hypertension, or orthostatic hypotension. The symptoms of autonomic dysfunction occur and resolve rapidly. GBS does not affect cognitive function or LOC.

Although the classic clinical features include areflexia and ascending weakness, variations in the clinical presentation occurs. There may be a sensory presentation, with progressive sensory symptoms; an atypical axonal destruction; or the Miller–Fisher variant, which includes paralysis of the ocular muscles, ataxia, and areflexia (McNair, 2013).

Assessment and Diagnostic Findings

The patient presents with symmetric weakness, diminished reflexes, and upward progression of motor weakness. A history of a viral illness in the previous few weeks suggests the diagnosis. Changes in vital capacity and negative inspiratory force are assessed to identify impending neuromuscular respiratory failure. Serum laboratory tests are not useful in the diagnosis. However, elevated protein levels are detected in CSF evaluation, without an increase in other cells. Evoked potential studies demonstrate a progressive loss of nerve conduction velocity.

Medical Management

Because of the possibility of rapid progression and neuromuscular respiratory failure, GBS is a medical emergency that may require management in an intensive care unit. After baseline values are identified, assessment of changes in muscle

strength and respiratory function alert the clinician to the physical and respiratory needs of the patient. Respiratory therapy or mechanical ventilation may be necessary to support pulmonary function and adequate oxygenation. Some clinicians recommend elective intubation before the onset of extreme respiratory muscle fatigue. Emergent intubation may result in autonomic dysfunction, and mechanical ventilation may be required for an extended period. The patient is weaned from mechanical ventilation after the respiratory muscles can again support spontaneous respiration and maintain adequate tissue oxygenation.

Other interventions are aimed at preventing the complications of immobility. These may include the use of anticoagulant agents and sequential compression boots to prevent venous thromboembolism (VTE), including deep vein thrombosis (DVT) and PE.

TPE and IVIG are used to directly affect the peripheral nerve myelin antibody level. Both therapies decrease circulating antibody levels and reduce the amount of time the patient is immobilized and dependent on mechanical ventilation. The cardiovascular risks posed by autonomic dysfunction require continuous electrocardiographic (ECG) monitoring. Tachycardia and hypertension are treated with short-acting medications such as alpha-adrenergic blocking agents. The use of short-acting agents is important, because autonomic dysfunction is very labile. Hypotension is managed by increasing the amount of IV fluid administered.

NURSING PROCESS

The Patient with GBS

Assessment

Ongoing assessment for disease progression is critical. The patient is monitored for life-threatening complications (respiratory failure, cardiac dysrhythmias, VTE [including DVT or PE]) so that appropriate interventions can be initiated. Because of the threat to the patient in this sudden, potentially life-threatening disease, the nurse must assess the patient's and family's ability to cope and their use of coping strategies.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Ineffective breathing pattern and impaired gas exchange related to rapidly progressive weakness and impending respiratory failure
- Impaired bed and physical mobility related to paralysis
- Imbalanced nutrition: less than body requirements related to inability to swallow
- Impaired verbal communication related to cranial nerve dysfunction
- Fear and anxiety related to loss of control and paralysis

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Respiratory failure
- Autonomic dysfunction

Planning and Goals

The major goals for the patient may include improved respiratory function, increased mobility, improved nutritional status, effective communication, decreased fear and anxiety, and absence of complications.

Nursing Interventions

Maintaining Respiratory Function

Respiratory function can be maximized with incentive spirometry and chest physiotherapy. Monitoring for changes in vital capacity and negative inspiratory force is key to early intervention for neuromuscular respiratory failure. Mechanical ventilation is required if the vital capacity falls, making spontaneous breathing impossible and tissue oxygenation inadequate.

The potential need for mechanical ventilation should be discussed with the patient and family on admission to provide time for psychological preparation and decision making. Intubation and mechanical ventilation result in less anxiety if they are initiated on a nonemergency basis to a patient who has been well informed. The patient may require mechanical ventilation for a long period. See Chapter 11 for the nursing management of the patient requiring mechanical ventilation.

Bulbar weakness that impairs the ability to swallow and clear secretions is another factor in the development of respiratory failure in the patient with GBS. Suctioning may be needed to maintain a clear airway.

The nurse assesses the blood pressure and heart rate frequently to identify autonomic dysfunction so that interventions can be initiated quickly if needed. Medications are given or a temporary pacemaker placed for clinically significant bradycardia.

Enhancing Physical Mobility

Nursing interventions to enhance physical mobility and prevent the complications of immobility are key to the function and survival of patients. The paralyzed extremities are supported in functional positions, and passive range-of-motion exercises are performed at least twice daily. DVT and PE are threats to the patient who is paralyzed. Nursing interventions are aimed at preventing VTE. Range-of-motion exercises, position changes, anticoagulation, the use of antiembolism stockings and sequential compression boots, and adequate hydration decrease the risk of VTE.

Padding may be placed over bony prominences, such as the elbows and heels, to reduce the risk of pressure ulcers. The need for frequent position changes cannot be overemphasized. The nurse evaluates laboratory test results that may indicate malnutrition or dehydration, both of which increase the risk of pressure ulcers and decrease mobility. The nurse collaborates with the primary provider and dietitian to develop a plan to meet the patient's nutritional and hydration needs.

Providing Adequate Nutrition

Paralytic ileus may result from insufficient parasympathetic activity. In this event, the nurse administers IV fluids and parenteral nutrition as a supplement and monitors for the return of bowel sounds. If the patient cannot swallow because of bulbar paralysis (immobility of muscles), a gastrostomy tube may be placed to administer nutrients. The nurse carefully assesses the return of the gag reflex and bowel sounds before resuming oral nutrition.

Improving Communication

Because of paralysis, the patient cannot talk, laugh, or cry and therefore has no method for communicating needs or expressing emotion. Although the patient may be unable to speak, cognition is completely intact. Establishing some form

of communication with picture cards or an eye blink system provides a means of communication. Collaboration with the speech therapist may be helpful in developing a communication mechanism that is most effective for a specific patient.

Decreasing Fear and Anxiety

The patient and family are faced with a sudden, potentially life-threatening disease; therefore, their levels of anxiety and fear may be high. The impact of disease on the family depends on the patient's role within the family. Referral to a support group may provide information and support to the patient and family.

The family may feel helpless in caring for the patient. Mechanical ventilation and monitoring devices may frighten and intimidate them. Family members often want to participate in physical care; with instruction and support by the nurse, they should be allowed and encouraged to do so.

In addition to fear, the patient may experience isolation, loneliness, and lack of control. Nursing interventions that increase the patient's sense of control include providing information about the condition, emphasizing a positive appraisal of coping resources, and providing instruction about relaxation exercises and distraction techniques. The positive attitude and atmosphere of the multidisciplinary team are important to promote a sense of well-being.

Diversional activities are encouraged to decrease loneliness and isolation. Encouraging visitors, engaging visitors or volunteers to read to the patient, listening to music or books on tape, and watching television are ways to alleviate the patient's sense of isolation.

Monitoring and Managing Potential Complications

Thorough assessment of respiratory function at regular and frequent intervals is essential, because respiratory insufficiency and subsequent failure due to weakness or paralysis of the intercostal muscles and diaphragm may develop quickly. Respiratory failure is the major cause of mortality. In addition to the respiratory rate and the quality of respirations, vital capacity is monitored frequently and at regular intervals so that respiratory insufficiency can be anticipated. Decreasing vital capacity with associated muscle weakness indicates impending respiratory failure. Signs and symptoms include breathlessness while speaking, shallow and irregular breathing, the use of accessory muscles, tachycardia, weak cough, and changes in respiratory pattern.

Other complications include cardiac dysrhythmias (which necessitate ECG monitoring), transient hypertension, orthostatic hypotension, DVT, PE, urinary retention, and other threats to any patient who is immobilized and paralyzed. These complications require monitoring and attention to prevent them and prompt treatment if indicated.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Patients with GBS and their families are usually frightened by the sudden onset of life-threatening symptoms and their severity. Therefore, educating the patient and family about the disorder and its generally favorable prognosis is important (see Chart 52-5).

During the acute phase of the illness, the patient and family are educated about strategies that can be implemented to minimize the effects of immobility and other complications. As function begins to return, family members and other home care providers are educated about care of the patient and their role in the rehabilitation process. Preparation for discharge is an interdisciplinary effort requiring family or caregiver education by all team members, including the nurse, physician, occupational and physiotherapists, speech therapist, and respiratory therapist.

Continuing and Transitional Care. Most patients with GBS experience complete recovery. Patients who have experienced total or prolonged paralysis require intensive rehabilitation; the extent depends on the patient's needs. Approaches include a comprehensive inpatient program if deficits are significant, an outpatient program if the patient can travel by car, or a home program of physical and occupational therapy. The recovery

Chart 52-5 HOME CARE CHECKLIST

The Patient with GBS

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of GBS and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State what types of environmental and safety changes or supports are needed for optimum functioning in the home.
  - State changes in lifestyle (e.g., nutrition, skin care, exercise, activity) necessary during recovery period and to maintain health as indicated.
  - Demonstrate environmental modifications and adaptive techniques for accomplishing ADLs (e.g., bathing, hygiene, grooming, dressing) and safely managing self-care.
  - Manage respiratory needs—tracheostomy care, suctioning.
  - Verbalize dietary adjustments and optimum nutrition during recovery.
  - Demonstrate proper body mechanics regarding lifting and transfers.
  - Practice gait training and strength endurance.
  - Perform range-of-motion exercises.
  - Discuss bowel and bladder management.
  - Operate and explain function of medical equipment and mobility aids—walkers, wheelchairs, bedside commodes, tub transfer benches, adaptive devices.
  - Describe coping mechanisms and diversional activities appropriately.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives).
- Identify the need for health promotion, disease prevention, and screening activities

See Chapters 38 and 51 for additional information on rehabilitation aspects.

ADL, activities of daily living; GBS, Guillain–Barré syndrome; IADL, independent activities of daily living.

phase may be long and requires patience as well as involvement on the part of the patient and family.

During acute care, the focus is on immediate issues and deficits. The nurse needs to remind or educate patients and family members of the need for continuing health-promotion and screening practices after this initial phase of care.

Evaluation

Expected patient outcomes may include the following:

1. Maintains effective respirations and airway clearance
   a. Has clear breath sounds on auscultation
   b. Demonstrates gradual improvement in respiratory function
   c. Breathes spontaneously
   d. Has vital capacity within normal range
   e. Exhibits arterial blood gases and pulse oximetry within normal limits
2. Shows increasing mobility
   a. Regains use of extremities
   b. Participates in rehabilitation program
   c. Demonstrates no contractures and minimal muscle atrophy
3. Receives adequate nutrition and hydration
   a. Consumes diet adequate to meet nutritional needs
   b. Swallows without aspiration
4. Demonstrates recovery of speech
   a. Communicates needs through alternative strategies
   b. Practices exercises recommended by the speech therapist
5. Shows lessening fear and anxiety
6. Has absence of complications
   a. Maintains intact skin integrity
   b. Does not develop VTE
   c. Voids without difficulty

CRANIAL NERVE DISORDERS

Because the brainstem and cranial nerves involve vital motor, sensory, and autonomic functions of the body, these nerves may be affected by conditions arising primarily within these structures or in secondary extension from adjacent disease processes. The cranial nerves are examined separately and in sequence (see Chapter 48). Some cranial nerve deficits can be detected by observing the patient's face, eye movements, speech, and swallowing. EMG is used to investigate motor and sensory dysfunction. An MRI scan is used to obtain images of the cranial nerves and brainstem. An overview of disorders that may affect each of the cranial nerves, including clinical manifestations and nursing interventions, is presented in Table 52-2. The following discussion centers on the most common disorders of the cranial nerves: trigeminal neuralgia, a condition affecting the fifth cranial nerve, and Bell palsy, caused by involvement of the seventh cranial nerve.

Trigeminal Neuralgia (Tic Douloureux)

Trigeminal neuralgia is a condition of the fifth cranial nerve that is characterized by paroxysms of sudden pain in the area innervated by any of the three branches of the nerve

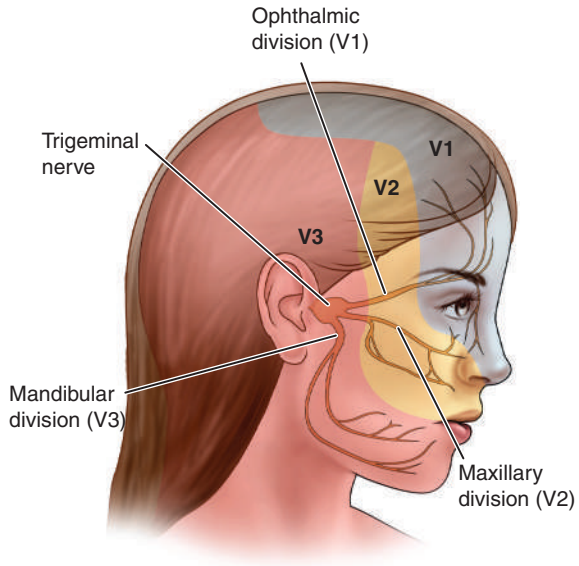

Figure 52-15 • Distribution of trigeminal nerve branches—the fifth cranial nerve.

(Bader et al., 2016) (see Fig. 52-15). The pain ends as abruptly as it starts and is described as a unilateral shooting and stabbing or burning sensation. The unilateral nature of the pain is an important feature. Associated involuntary contraction of the facial muscles can cause sudden closing of the eye or twitching of the mouth, hence the former name *tic douloureux* (painful twitch). Although the cause is not certain, it is thought to be demyelination of axons in the ganglion, root, and nerve (Grossman & Porth, 2014).

Trigeminal neuralgia occurs most often as people age, most commonly between the fifth and sixth decades of life. It is more common in men and in people from urban areas (Yadav, Mittal, Sachdeva, et al., 2015).

Trigeminal neuralgia occurs most often as people age, most commonly between the fifth and sixth decade of life. It is more common in women and in people with MS compared to the general population (Bader et al., 2016). Patients who develop trigeminal neuralgia before age 50 years should be evaluated for the coexistence of MS, because trigeminal neuralgia occurs in approximately 5% of patients with MS (Bader et al., 2016). Pain-free intervals may be measured in terms of minutes, hours, days, or longer. With advancing years, the painful episodes tend to become more frequent and agonizing. The patient lives in constant fear of attacks.

Paroxysms can occur with any stimulation of the terminals of the affected nerve branches, such as washing the face, shaving, brushing the teeth, eating, and drinking. A draft of cold air or direct pressure against the nerve trunk may also cause pain. Certain areas are called *trigger points* because the slightest touch immediately starts a paroxysm or episode. To avoid stimulating these areas, patients with trigeminal neuralgia try not to touch or wash their faces, shave, chew, or do anything else that might cause an attack. These behaviors are a clue to the diagnosis.

Medical Management

Pharmacologic Therapy

Anticonvulsant agents, such as carbamazepine (Tegretol), relieve pain in most patients with trigeminal neuralgia by reducing

TABLE 52-2 Disorders of Cranial Nerves

Disorder	Clinical Manifestations	Nursing Interventions
Olfactory Nerve—I		
Head trauma Intracranial tumor Intracranial surgery	Unilateral or bilateral anosmia (temporary or persistent) Diminished taste for food	Assess sense of smell. Assess for cerebrospinal fluid rhinorrhea if patient has sustained head trauma.
Optic Nerve—II		
Optic neuritis Increased intracranial pressure Pituitary tumor	Lesions of optic tract producing homonymous hemianopia	Assess visual acuity. Restructure environment to prevent injuries. Educate patient to accommodate for visual loss.
Oculomotor Nerve—III		Assess extraocular movement and for nonreactive pupil.
Trochlear Nerve—IV		Assess extraocular movement and for nonreactive pupil.
Abducens Nerve—VI		
Vascular Brainstem ischemia Hemorrhage and infarction Neoplasm Trauma Infection	Dilation of pupil with loss of light reflex on one side Impairment of ocular movement Diplopia Gaze palsies Ptosis of eyelid	Assess extraocular movement and for nonreactive pupil.
Trigeminal Nerve—V		
Trigeminal neuralgia Head trauma Cerebellopontine lesion Sinus tract tumor and metastatic disease Compression of trigeminal root by tumor	Pain in face Diminished or loss of corneal reflex Chewing dysfunction	Assess for pain and triggering mechanisms for pain. Assess for difficulty in chewing. Discuss trigger zones and pain precipitants with patient. Protect cornea from abrasion. Ensure good oral hygiene. Educate patient about medication regimen.
Facial Nerve—VII		
Bell palsy Facial nerve tumor Intracranial lesion Herpes zoster	Facial dysfunction; weakness and paralysis Hemifacial spasm Diminished or absent taste Pain	Recognize facial paralysis as emergency; refer for treatment as soon as possible. Discuss protective care for eyes. Select easily chewed foods; patient should eat and drink from unaffected side of mouth. Emphasize importance of oral hygiene. Provide emotional support for changed appearance of face.
Vestibulocochlear Nerve—VIII		
Tumors and acoustic neuroma Vascular compression of nerve Ménière syndrome	Tinnitus Vertigo Hearing difficulties	Assess pattern of vertigo. Provide for safety measures to prevent falls. Ensure that patient can maintain balance before ambulating. Caution patient to change positions slowly. Assist with ambulation. Encourage the use of assistive devices.
Glossopharyngeal Nerve—IX		
Glossopharyngeal neuralgia from neurovascular compression of cranial nerves IX and X Trauma Inflammatory conditions Tumor Vertebral artery aneurysms	Pain at base of tongue Difficulty in swallowing Loss of gag reflex Palatal, pharyngeal, and laryngeal paralysis	Assess for paroxysmal pain in throat, decreased or absent swallowing, and gag and cough reflexes. Monitor for dysphagia, aspiration, and nasal dysarthric speech. Position patient upright for eating or tube feeding.

(Continued)

(Continued)

Vagus Nerve—X		
Spastic palsy of larynx; bulbar paralysis; high vagal paralysis	Voice changes (temporary or permanent hoarseness)	Assess for airway obstruction/provide airway management.
Guillain–Barré syndrome	Vocal paralysis	Prevent aspiration.
Vagal body tumors	Dysphagia	Support patient having voice reconstruction procedures.
Nerve paralysis from malignancy, surgical trauma such as carotid endarterectomy		
Spinal Accessory Nerve—XI		
Spinal cord disorder	Drooping of affected shoulder with limited shoulder movement	Support patient undergoing diagnostic tests.
Amyotrophic lateral sclerosis	Weakness or paralysis of head rotation, flexion, extension; shoulder elevation	
Trauma		
Guillain–Barré syndrome		
Hypoglossal Nerve—XII		
Medullary lesions	Abnormal movements of tongue	Observe swallowing ability.
Amyotrophic lateral sclerosis	Weakness or paralysis of tongue muscles	Observe speech pattern.
Polio and motor system disease, which may destroy hypoglossal nuclei	Difficulty in talking, chewing, and swallowing	Be aware of swallowing or vocal difficulties.
Multiple sclerosis		Prepare for alternate feeding methods (tube feeding) to maintain nutrition.
Trauma		

Adapted from Bader, M., Littlejohns, L. R., & Olson, D. (2016). AANN core curriculum for neuroscience nursing (6th ed.). Chicago, IL: American Association of Neuroscience Nurses. Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

the transmission of impulses at certain nerve terminals. Carbamazepine is taken with meals. Serum levels must be monitored to avoid toxicity in patients who require high doses to control the pain. Side effects include nausea, dizziness, drowsiness, and aplastic anemia. Serious drug reactions occur more often in people of Asian ethnicity (Bader et al., 2016). The patient is monitored for bone marrow depression during long-term therapy. Gabapentin and baclofen are also used for pain control. If pain control is still not achieved, phenytoin may be used as adjunctive therapy.

Surgical Management

If pharmacologic management fails to relieve pain, a number of surgical options are available. Although these procedures may relieve facial pain for a few years, recurrence and complication rates are high (Hickey, 2014). The choice of procedure depends on the patient's preference and health status. The procedures are designed to either decompress the nerve and save nerve function or to damage the nerve and destroy nerve function to keep it from malfunctioning (Bader et al., 2016).

Microvascular Decompression of the Trigeminal Nerve

An intracranial approach is used to relieve the contact between the cerebral vessel and the trigeminal nerve root entry. With the aid of an operating microscope, the artery loop is lifted from the nerve to relieve the pressure, and a small prosthetic device is inserted to prevent recurrence of impingement on the nerve. The postoperative management is the same as for other intracranial surgeries (see Chapter 49).

Radiofrequency Thermal Coagulation

Percutaneous radiofrequency produces a thermal lesion on the trigeminal nerve. Although immediate pain relief is experienced, dysesthesia of the face and loss of the corneal reflex may occur. The use of stereotactic MRI for identification of the trigeminal nerve followed by gamma knife radiosurgery is being used at some medical centers. Gamma knife radiosurgery is a noninvasive method of delivering focused radiation to the trigeminal nerve; it requires 6 to 8 weeks of treatment for maximal effect to occur (Zakrzewska & Akram, 2011).

Percutaneous Balloon Microcompression

Percutaneous balloon microcompression disrupts large myelinated fibers in all three branches of the trigeminal nerve. After its placement, the balloon is filled with a contrast material for fluoroscopic identification. The balloon compresses the nerve root for 1 minute and provides microvascular decompression (Bader et al., 2016).

Nursing Management

Preventing Pain

Preoperative management of a patient with trigeminal neuralgia occurs mostly on an outpatient basis and includes recognizing factors that may aggravate excruciating facial pain, such as food that is too hot or too cold or jarring of the patient's bed or chair. Even washing the face, combing the hair, or brushing the teeth may produce acute pain. The nurse can assist the patient in preventing or reducing this pain by providing instructions about preventive strategies. Providing cotton pads and room temperature water for washing the face, instructing the patient to rinse with mouthwash after eating if toothbrushing causes pain, and performing personal hygiene during pain-free intervals are all effective strategies. The patient is instructed to take food and fluids at room temperature, to chew on the unaffected side, and to ingest soft foods. The nurse recognizes that anxiety, depression, and insomnia often accompany chronic painful conditions and uses appropriate interventions and referrals. See Chapter 9 for management of patients with chronic pain.

Providing Postoperative Care

Postoperative neurologic assessments are conducted to evaluate the patient for facial motor and sensory deficits in each of the

three branches of the trigeminal nerve. If the surgery results in sensory deficits to the affected side of the face, the patient is instructed not to rub the eye because the pain of a resulting injury will not be detected. The eye is assessed for irritation or redness. Artificial tears may be prescribed to prevent dryness in the affected eye. The patient is cautioned not to chew on the affected side until numbness has diminished. The patient is observed carefully for any difficulty in eating or swallowing foods of different consistencies.

Bell Palsy

Bell palsy (facial paralysis) is caused by unilateral inflammation of the seventh cranial nerve, which results in weakness or paralysis of the facial muscles on the affected side (see Fig. 52-16). Although the cause is unknown, theories include vascular ischemia, viral disease (herpes simplex, herpes zoster), autoimmune disease, or a combination of all of these factors. Most adults with Bell palsy are younger than 45 years (Hickey, 2014).

Bell palsy may be a type of pressure paralysis. The inflamed, edematous nerve becomes compressed to the point of damage, or its blood supply is occluded, producing ischemic necrosis of the nerve. The face is distorted from paralysis of the facial muscles; decreased lacrimation (tearing) occurs; and the patient experiences painful sensations in the face, behind the ear, and in the eye. The patient may also experience speech difficulties and may be unable to eat on the affected side because of weakness or paralysis of the facial muscles. The majority of patients recover completely and Bell palsy rarely recurs (Hickey, 2014).

Medical Management

The objectives of treatment are to maintain the muscle tone of the face and to prevent or minimize denervation. The patient should be reassured that no stroke has occurred and that spontaneous recovery occurs within 3 to 5 weeks in most patients.

Corticosteroid therapy (prednisone) may be prescribed to reduce inflammation and edema; this reduces vascular compression and permits restoration of blood circulation to the nerve. Early administration of corticosteroid therapy appears to diminish the severity of the disease, relieve the pain, and prevent or minimize denervation (Gagyor, Madhok, Daly, et al., 2016).

Facial pain is controlled with analgesic agents. Electrical stimulation may be applied to the face to prevent muscle atrophy. Although most patients recover with conservative treatment, surgical exploration of the facial nerve may be indicated if a tumor is suspected, for surgical decompression of the facial nerve, or for surgical treatment of a paralyzed face (Hickey, 2014).

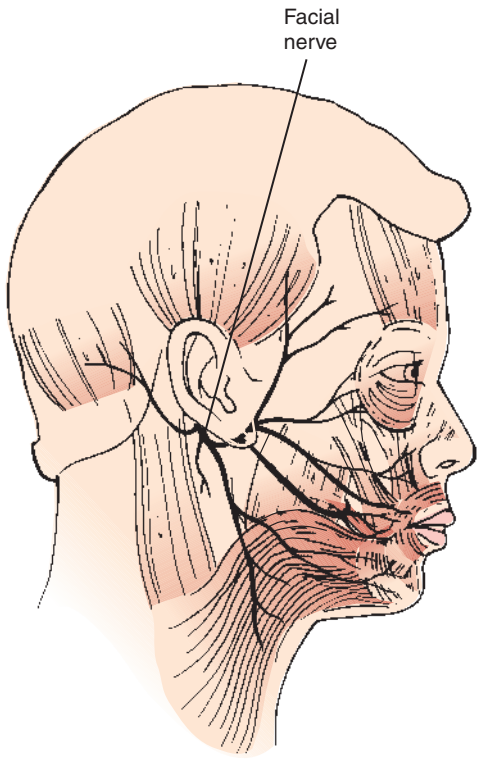

Figure 52-16 • Distribution of the facial nerve—the seventh cranial nerve.

Nursing Management

While the paralysis is present, nursing care involves protection of the eye from injury. Frequently, the eyelid does not close completely and the blink reflex is diminished, so the eye is vulnerable to injury from dust and foreign particles. Corneal irritation and ulceration may occur. Distortion of the lower lid alters the proper drainage of tears. To prevent injury, the eye should be covered with a protective shield at night. The eye patch may abrade the cornea, however, because there is some difficulty in keeping the partially paralyzed eyelids closed. Moisturizing eye drops during the day and eye ointment at bedtime may help prevent injury (Hickey, 2014). The patient can be educated to close the paralyzed eyelid manually before going to sleep. Wraparound sunglasses or goggles may be worn during the day to decrease evaporation from the eye.

After the sensitivity of the nerve to touch decreases and the patient can tolerate touching the face, the nurse can suggest massaging the face several times daily, using a gentle upward motion, to maintain muscle tone. Facial exercises, such as wrinkling the forehead, blowing out the cheeks, and whistling, may be performed with the aid of a mirror to prevent muscle atrophy. Exposure of the face to cold and drafts is avoided.

DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Peripheral Neuropathies

A peripheral neuropathy (disorder of the nervous system) is a disorder affecting the peripheral motor and sensory nerves. Peripheral nerves connect the spinal cord and brain to all other organs. They transmit motor impulses from the brain and relay sensory impulses to the brain. Peripheral neuropathies are characterized by bilateral and symmetric disturbance of function, usually beginning in the feet and hands. The most common cause of peripheral neuropathy is diabetes with poor glycemic control. The major symptoms of peripheral nerve disorders are loss of sensation, muscle atrophy, weakness, diminished reflexes, pain, and paresthesia of the extremities.

Peripheral nerve disorders are diagnosed by history, physical examination, and electrodiagnostic studies such as EEG. The diagnosis of peripheral neuropathy in the geriatric population is challenging because many symptoms, such as decreased reflexes, can be associated with the normal aging process (Eliopoulos, 2018).

No specific treatment exists for peripheral neuropathy. Elimination or control of the cause may slow progression. Patients

with peripheral neuropathy are at risk for falls, thermal injuries, and skin breakdown. The plan of care includes inspection of the lower extremities for skin breakdown. Assistive devices such as a walker or cane may decrease the risk of falls. Bathwater temperature is checked to avoid thermal injury. Footwear should be accurately sized. Driving may be limited or eliminated, thereby disrupting the patient's sense of independence.

Mononeuropathy

Mononeuropathy is limited to a single peripheral nerve and its branches. It arises when the trunk of the nerve is compressed or entrapped (as in carpal tunnel syndrome), traumatized (as when bruised by a blow), overstretched (as in joint dislocation), punctured by a needle used to inject a drug or damaged by the drugs thus injected, or inflamed because an adjacent infectious process extends to the nerve trunk. Mononeuropathy is frequently seen in patients with diabetes.

Pain is seldom a major symptom of mononeuropathy when the condition is due to trauma, but in patients with complicating inflammatory conditions such as arthritis, pain is prominent. Pain is increased with all body movements that tend to stretch, strain, or cause pressure on the injured nerve and sudden jarring of the body (e.g., from coughing or sneezing). The skin in the areas supplied by nerves that are injured or diseased may become reddened and glossy, the subcutaneous tissue may become edematous, and the nails and hair in this area are altered. Chemical injuries to a nerve trunk, such as those caused by drugs injected into or near it, are often permanent.

The objective of treatment of mononeuropathy is to remove the cause, if possible (e.g., freeing the compressed nerve). Local corticosteroid injections may reduce inflammation and the pressure on the nerve. Aspirin or codeine may be used to relieve pain. Chronic pain can be treated with neuropathic pain medications such as gabapentin (Bader et al., 2016).

Nursing care involves protection of the affected limb or area from injury, as well as appropriate patient education about mononeuropathy and its treatment.

CRITICAL THINKING EXERCISES

1. A 19-year-old patient is admitted with suspected meningitis. Describe the pathophysiology of meningitis. What are the signs of meningeal irritation the nurse should watch for and how are they tested? What is the priority nursing diagnosis in the patient with meningitis? What history and physical findings are common in the patient with meningitis?
2. Identify the priorities, approach, and techniques you would use to provide care to the patients in your assignment on an intermediate neuroscience unit. Two of the patients have a diagnosis of myasthenia gravis, one is intubated and on a ventilator, one patient has a diagnosis of GBS and the other has meningitis. What tasks can you delegate and to whom?
3. A 35-year-old woman is newly diagnosed with Bell palsy. Identify her treatment options. Describe the evidence base for the options that you have identified and the criteria used to evaluate the strength of the evidence for her various treatment options.

CHAPTER 53

Management of Patients with Oncologic or Degenerative Neurologic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe brain and spinal cord tumors: their classification, pathophysiology, clinical manifestations, diagnosis, and medical and nursing management.
2. Use the nursing process as a framework for care of patients with nervous system metastases or primary brain tumor.
3. Explain the pathophysiologic processes responsible for various neurodegenerative disorders.
4. Prepare a nursing care plan for a patient with Alzheimer disease.
5. Apply the nursing process as a framework for care of patients with Parkinson disease.
6. Identify resources for patients and families with oncologic and degenerative neurologic disorders.
7. Use the nursing process as a framework for care of patients following a cervical discectomy.

GLOSSARY

bradykinesia: abnormally slow voluntary movements and speech
chorea: rapid, jerky, involuntary, purposeless movements of the extremities or facial muscles, including facial grimacing
dementia: broad term for a syndrome characterized by a general decline in higher brain functioning, such as reasoning, with a pattern of eventual decline in ability to perform even basic activities of daily living, such as toileting and eating
dyskinesia: impaired ability to execute voluntary movements
dysphonia: voice impairment or altered voice production
neurodegenerative: a disease, process, or condition leading to deterioration of cells or function of the nervous system
papilledema: edema of the optic nerve usually due to increased intracranial pressure (ICP)
paresthesia: numbness, tingling, or a "pins and needles" sensation
sciatica: pain and tenderness that radiates along the sciatic nerve that runs through the thigh and leg
spondylosis: degenerative changes occurring in a disc and adjacent vertebral bodies; can occur in the cervical or lumbar vertebrae

Introduction

The occurrence of oncologic or degenerative disease processes in the neurologic system produces a unique set of nursing challenges. Thus nurses who care for patients with these disorders must have a clear understanding of the pathophysiology, diagnostic testing, medical and nursing care, and rehabilitation processes. Nurses care for patients with oncologic or degenerative disease processes in many inpatient and outpatient settings. Oncologic disorders include brain and spinal cord tumors. Degenerative neurologic disorders include Parkinson disease (PD), Huntington disease, amyotrophic lateral sclerosis (ALS), muscular dystrophies, and degenerative disc disease. Post-polio syndrome (PPS) is thought to be degenerative in nature and is included in this chapter.

ONCOLOGIC DISORDERS OF THE BRAIN AND SPINAL CORD

There are many types of brain and spinal cord tumors, each with its own biology, prognosis, and treatment options. Because of the unique anatomy and physiology, tumors of the central nervous system (CNS) are challenging to diagnose and treat.

Brain Tumors

A brain tumor occupies space within the skull, growing as a spherical mass or diffusely infiltrating tissue. The effects of brain tumors are caused by inflammation, compression, and infiltration of tissue. A variety of physiologic changes result, causing any or all of the following pathophysiologic events:

- Increased intracranial pressure (ICP) and cerebral edema
- Seizure activity and focal neurologic signs
- Hydrocephalus
- Altered pituitary function

Neoplastic lesions in the brain ultimately cause death by increasing ICP and impairing vital functions, such as respiration.

According to the American Brain Tumor Association (ABTA, 2014), there are over 100 types of brain tumors with an estimated annual occurrence of 78,000 new cases. These include 25,000 malignant and 53,000 nonmalignant brain tumors (ABTA, 2014). Brain tumors are classified as primary or secondary. Primary brain tumors originate from cells within the brain. In adults, most primary brain tumors originate from glial cells (cells that make up the structure and support system of the brain and spinal cord) and are supratentorial (located above the covering of the cerebellum). Primary tumors progress locally and rarely metastasize outside the CNS.

Developed countries have a higher incidence of primary brain tumors, with rates of 5.1 per 100,000 compared to 3.0 per 100,000 in less developed countries. This is most likely due to more frequent diagnosis with improved imaging modalities. Although many risk factors have been investigated, exposure to ionizing radiation is the only known modifiable risk factor (American Association of Neuroscience Nurses [AANN], 2014a). Many genetic factors and genetic syndromes (such

as neurofibromatosis) are associated with brain tumor risk in families (AANN, 2014a).

Secondary, or metastatic, brain tumors develop from structures outside the brain and are twice as common as primary brain tumors (AANN, 2014a). Metastatic lesions to the brain can occur from the lung, breast, lower gastrointestinal tract, pancreas, kidney, and skin (melanomas) neoplasms. Single or multiple metastases may occur, and brain metastases may be found at any time during the disease course, even at initial diagnosis of the primary disease. Patient survival rates from primary brains cancers are improving, however, the incidence of brain metastases are increasing (AANN, 2014a); (Lovely, Stewart-Amidei, Page, et al., 2013).

The highest incidence of brain tumors in adults occurs in the fifth through seventh decades of life. There is a slight male predominance in the incidence of malignant brain tumors.

In India, prevalence of CNS tumor ranges from 5–10 per 100,000 population which accounts for 2% of malignancy (Nair, Varghese, & Swaminathan, 2015; Yeole, 2008).

It has been observed from the recent past that there is an increasing incidence rate of CNS tumor (Sarkar, Sharma, Deb, et al., 2005). Data of the year 2006 from Tata Memorial Hospital, Mumbai, have shown astrocytomas (38.7%) were the most common primary tumors with the majority being high-grade gliomas (59.5%) and rest were low-grade gliomas, 79 (33.1%) cases, where highest incidence was reported among adults in the age group of 19–40 years (Jalali & Datta, 2008).

Types of Primary Brain Tumors

Brain tumors may be classified into several groups: those arising from the coverings of the brain (e.g., dural meningioma), those developing in or on the cranial nerves (e.g., acoustic neuroma), those originating within brain tissue (e.g., glioma), and metastatic lesions originating elsewhere in the body. Tumors of the pituitary and pineal glands and of cerebral blood vessels are also types of brain tumors. Relevant clinical considerations include the location and the histologic character of the tumor. Tumors may be benign or malignant. A benign tumor, such as a colloid cyst, can occur in a vital area and can grow large enough to have serious effects (Hickey, 2014). See Chart 53-1 for the classification of brain tumors.

Chart 53-1

Classification of Brain Tumors in Adults

I. Intracerebral Tumors
   A. Gliomas—infiltrate any portion of the brain; most common type of brain tumor
      1. Astrocytomas (grades I and II)
      2. Glioblastoma (astrocytoma grades III and IV)
      3. Oligodendroglioma (low and high grades)
      4. Ependymoma (grades I to IV)
      5. Medulloblastoma
II. Tumors Arising From Supporting Structures
   A. Meningiomas
   B. Neuromas (acoustic neuroma, schwannoma)
   C. Pituitary adenomas
III. Developmental Tumors
   A. Angiomas
   B. Dermoid, epidermoid, teratoma, craniopharyngioma
IV. Metastatic Lesions

Gliomas

In adults, gliomas (principally astrocytoma) account for approximately 30% of symptomatic primary brain tumors. Glial tumors, the most common type of intracerebral brain neoplasm, are divided into many categories (Ostrom, Gittleman, Fulop, et al., 2015). Astrocytomas, arising from astrocytic cells, are the most common type of glioma and are graded from I to IV, indicating the degree of malignancy (ABTA, 2014). The grade is based on cellular density, cell mitosis, and degree of differentiation from the original cell type. Grades III and IV tumors are known as glioblastomas and have little resemblance to the original cell type. Astrocytomas infiltrate into the surrounding neural connective tissue and therefore cannot be totally removed without causing considerable damage to vital structures.

Oligodendroglial tumors, arising from oligodendroglial cells (about 4% of primary brain tumors) represent about 10% to 15% of the gliomas. Most oligodendrogliomas occur in adults ages 50 to 60, are found in men more often than in women, and are categorized as low or high grade (anaplastic) (ABTA, 2014). The histologic distinction between astrocytomas and oligodendrogliomas is difficult to make but is important, because oligodendrogliomas are more sensitive than astrocytomas to chemotherapy. Tumors originating from ependymal cells, another type of glial cell, are known as ependymomas and are more common in children than adults. Glial tumors may be treated with a combination of surgery, radiation therapy, and chemotherapy, depending on specific cell and patient characteristics.

Based on Indian Council for Medical Research hospital registry from 2004–2006, glioma incidence in Indian major cities revealed 3.5% in Chennai, 6.7% in Bangalore, 5.6% Dibrugarh, 5.8% in Mumbai, and 28.2% in Trivandrum among males and 5.6% in Bangalore, 7.5% in Chennai, 0% in Dibrugarh, 6.3% in Mumbai, and 21.8% in Trivandrum among females (Nandakumar & Ramnath, 2009).

Meningiomas

Meningiomas are common benign encapsulated tumors of arachnoid cells on the meninges (Ostrom et al., 2015). They are slow growing, occur most often in middle-aged adults, and are more common in women. Meningiomas most often occur in areas proximal to the venous sinuses. Manifestations depend on the area involved and are often the result of compression rather than invasion of brain tissue. Preferred treatment for symptomatic lesions is surgery with complete removal or partial dissection, although radiation therapy may be useful for some patients.

A Mumbai-based study reported that meningiomas account for 2.89% of brain tumors among all the patients diagnosed with brain tumors (Jalali & Datta, 2008).

Acoustic Neuromas

An acoustic neuroma is a tumor of the eighth cranial nerve—the cranial nerve most responsible for hearing and balance. It usually arises just within the internal auditory meatus, where it frequently expands before filling the cerebellopontine recess. An acoustic neuroma may grow slowly and attain considerable size before it is diagnosed. The patient usually experiences loss of hearing, tinnitus, and episodes of vertigo and staggering gait. As the tumor becomes larger, painful sensations of the face may occur on the same side as a result of the tumor's compression of

the fifth cranial nerve (ABTA, 2014). Many acoustic neuromas are benign and can be managed conservatively. Many that continue to grow can be surgically removed and have a good prognosis (see Chapter 41). Some acoustic neuromas may be suitable for stereotactic radiotherapy rather than open craniotomy. Stereotactic radiotherapy is discussed later in this chapter.

Pituitary Adenomas

Pituitary tumors account for about 16% of all primary brain tumors (ABTA, 2014). They can occur at any age, but they are more common in older adults. Women are affected more often than men, particularly during the childbearing years. Pituitary tumors are rarely malignant but cause symptoms as a result of pressure on adjacent structures or hormonal changes (ABTA, 2014).

However, Indian literature documented that pituitary adenoma accounts for 8.38% of all brain tumors. It is more common in 41–60 years of age group and men are affected more than women (Jalali & Datta, 2008).

Pressure Effects of Pituitary Adenomas

Pressure from a pituitary adenoma may be exerted on the optic nerves, optic chiasm, or optic tracts or on the hypothalamus or the third ventricle if the tumor invades the cavernous sinuses or expands into the sphenoid bone. These pressure effects produce headache, visual dysfunction, hypothalamic disorders (disorders of sleep, appetite, temperature, and emotions), increased ICP, and enlargement and erosion of the sella turcica.

Hormonal Effects of Pituitary Adenomas

Functioning pituitary tumors can produce one or more hormones normally produced by the anterior pituitary. Hormonal hypersecretion is caused only by pituitary adenomas. Most adenomas (65% to 70%) secrete an excess amount of hormone including prolactin (prolactinomas), growth hormone (GH) producing acromegaly in adults, adrenocorticotropic hormone (ACTH) resulting in Cushing syndrome, or thyroid-stimulating hormone (TSH) (Melmed, 2016). Adenomas that secrete TSH or follicle-stimulating hormone and luteinizing hormone occur infrequently, whereas adenomas that produce both GH and prolactin are relatively common.

The female patient whose pituitary gland is secreting excessive quantities of prolactin presents with amenorrhea or galactorrhea (excessive or spontaneous flow of milk). Male patients with prolactinomas may present with impotence and hypogonadism. Acromegaly, caused by excess GH, produces enlargement of the hands and feet, distortion of the facial features, and pressure on peripheral nerves (entrapment syndromes). The clinical features of Cushing syndrome, a condition associated with prolonged overproduction of cortisol, occur with excessive production of ACTH. Manifestations include a form of obesity with redistribution of fat to the facial, supraclavicular, and abdominal areas; hypertension; purple striae and ecchymoses; osteoporosis; elevated blood glucose levels; and emotional disorders. See Chapter 32 for a discussion of endocrine disorders resulting from these tumors.

Gerontologic Considerations

The most frequent tumor types in the older adult are anaplastic astrocytoma, glioblastoma, and cerebral metastases from other sites (Perkins & Liu, 2016). The incidence of all brain tumors increases with age. Intracranial tumors can produce personality changes, confusion, speech dysfunction, or disturbances of gait. In older adult patients, early signs and symptoms of intracranial tumors can be easily overlooked or incorrectly attributed to cognitive and neurologic changes associated with normal aging (Eliopoulos, 2018). Neurologic signs and symptoms in the older adult must be carefully evaluated, because brain metastases occur in patients with a history of prior cancer. Regardless of the age of the patient or the decision to proceed or not with treatment, the nurse provides supportive care. Researchers are investigating patterns of care and clinical outcomes of older adult patients with primary brain tumors (Gallego Perez-Larraya & Delattre, 2014).

Clinical Manifestations

Brain tumors can produce both focal or generalized neurologic signs and symptoms. Generalized symptoms reflect increased ICP, and the most common focal or specific signs and symptoms result from tumors that interfere with functions in specific brain regions. Figure 53-1 indicates common brain tumor sites.

Increased Intracranial Pressure

As discussed in Chapter 49, the skull is a rigid compartment containing essential noncompressible contents: brain matter, intravascular blood, and cerebrospinal fluid (CSF). The Monro-Kellie hypothesis or doctrine explains the dynamic equilibrium of the cranial contents. According to this hypothesis, if any one of these skull components increases in volume, ICP increases unless one of the other components decreases in volume. Consequently, any change in volume occupied by the brain (as occurs with disorders such as brain tumor or cerebral edema) produces signs and symptoms of increased ICP (Hickey, 2014).

The enlarging tumor and its associating edema disrupts the equilibrium between the brain, blood, and CSF. As the tumor grows, compensatory adjustments may occur through compression of intracranial veins, reduction of CSF volume (by increased absorption or decreased production), a modest decrease in cerebral blood flow, or reduction of intra- and extracellular brain tissue mass. When these compensatory mechanisms fail, the patient develops signs and symptoms of increased ICP, most often including headache, nausea with or without vomiting, and papilledema (swelling of the optic nerve) (Hickey, 2014). Personality changes and a variety of focal deficits, including motor, sensory, and cranial nerve dysfunction, are common.

Headache

Headache, although not always present, is most common in the early morning and is made worse by coughing, straining, or sudden movement. It is thought to be caused by the tumor invading, compressing, or distorting the pain-sensitive structures or by edema that accompanies the tumor. Headaches are usually described as deep, expanding, dull, but unrelenting. Frontal tumors usually produce a bilateral frontal headache; pituitary gland tumors produce pain radiating between the two temples (bitemporal); in cerebellar tumors, the headache may be located in the suboccipital region at the back of the head.

Vomiting

Vomiting, seldom related to food intake, is usually the result of irritation of the vagal centers in the medulla. Forceful vomiting is described as projectile vomiting. Headache may be relieved by vomiting.

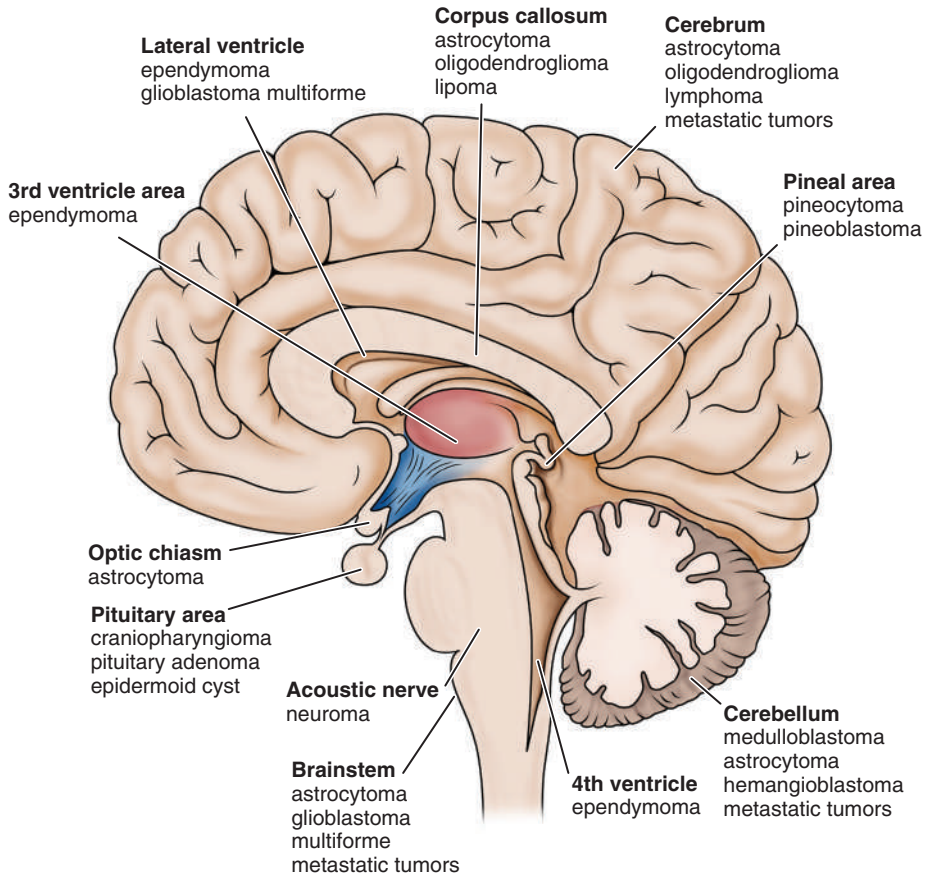

Figure 53-1 • Common brain tumor sites.

Visual Disturbances

The tumor itself or the surrounding edema can compress the third cranial nerve, causing optic disc swelling or papilledema. This limits the visual acuity along the visual pathway, mildly or profoundly, as diplopia (double vision), hemianopsia (visual field deficits), or varying levels of blindness (Rigi, Almarzbuqi, Morgan, et al., 2015).

Seizures

Seizures are common, occurring in 60% of patients with brain tumors either initially or throughout their disease process (AANN, 2014a). Seizures may be focal or generalized. Tumors of the frontal, parietal, and temporal lobes carry the greatest risk of seizures; seizures are unusual with brainstem or cerebellar tumors. See Chapter 49 for discussion about seizures and related management.

If not the initial presentation, seizures can be a result of metabolic factors (electrolyte imbalances, liver failure or kidney disease, radiation or chemotherapy side effects), structural causes (parenchymal metastases, leptomeningeal disease, dural metastases) or a new hemorrhage, thrombosis, or development of meningitis (Hickey, 2014). If the patient presents with a seizure, then anticonvulsant drugs are prescribed. Medications with the best evidence for controlling seizure activity include levetiracetam (Keppra), carbamazepine (Tegretol), phenytoin (Dilantin), and zonisamide (Zonegran) (Vecht, Kerkhof, & Duran-Pena, 2014).

Localized Symptoms

When specific regions of the brain are affected, local signs and symptoms occur, such as sensory or motor abnormalities, visual alterations, alterations in cognition, or language disturbances (e.g., aphasia). Identifying the signs and symptoms is important, because it can help identify tumor location. Some tumors are not easily localized because they lie in so-called silent areas of the brain (i.e., areas in which functions are not well defined). Many tumors can be localized by correlating the signs and symptoms to specific areas in the brain, as follows:

- A tumor in the motor cortex of the frontal lobe produces hemiparesis and partial seizures on the opposite side of the body or generalized seizures. A frontal lobe tumor may also produce changes in emotional state and behavior, as well as an apathetic mental attitude. The patient often becomes impulsive, inappropriate in speech, gestures, and behavior.
- A parietal lobe tumor may cause decreased sensation on the opposite side of the body or generalized seizures.
- A temporal lobe tumor may cause seizures as well as psychological disorders.
- An occipital lobe tumor produces visual manifestations: contralateral homonymous hemianopsia (visual loss in half of the visual field on the opposite side of the tumor) and visual hallucinations.
- A cerebellar tumor causes dizziness; an ataxic or staggering gait with a tendency to fall toward the side of the lesion; marked muscle incoordination; and nystagmus (involuntary rhythmic eye movements), usually in the horizontal direction.
- A cerebellopontine angle tumor usually originates in the sheath of the acoustic nerve and gives rise to a characteristic sequence of symptoms. Tinnitus and vertigo appear first,

soon followed by progressive nerve deafness (eighth cranial nerve dysfunction). Numbness and tingling of the face and tongue occur (due to involvement of the fifth cranial nerve). Later, weakness or paralysis of the face develops (seventh cranial nerve involvement). Finally, because the enlarging tumor presses on the cerebellum, abnormalities in motor function may be present.

- Brainstem tumors may be associated with cranial nerve deficits along with complex motor and sensory function impairments (Hickey, 2014).

Assessment and Diagnostic Findings

The history of the illness, the manner, and the time frame in which the symptoms evolved are key components in the diagnosis of brain tumors. A neurologic examination indicates the involved areas of the CNS. To assist in the precise localization of the lesion, a battery of tests is performed. Computed tomography (CT) scans, enhanced by a contrast agent, can give specific information concerning the number, size, and density of the lesions, and the extent of secondary cerebral edema. CT can provide information about the ventricular system. A magnetic resonance imaging (MRI) scan is the most helpful diagnostic tool for detecting brain tumors, particularly smaller lesions, and tumors in the brainstem and pituitary regions, where bone is thick (see Fig. 53-2). MRI is also useful in monitoring response to treatment.

Computer-assisted stereotactic (three-dimensional) biopsy is used to diagnose deep-seated brain tumors and to provide a basis for treatment and prognosis. Stereotactic approaches involve the use of a three-dimensional frame that allows very precise localization of the tumor; a stereotactic frame and multiple imaging studies (x-rays, CT scans, or MRIs) are used to localize the tumor and verify its position (see Fig. 53-3). Brain-mapping technology helps determine the proximity of diseased areas of the brain to structures essential for normal brain function.

Positron emission tomography (PET) is used to supplement MRI scanning in centers where it is available. On PET scans, low-grade tumors are associated with hypometabolism, and high-grade tumors show hypermetabolism. This information can be useful in making treatment decisions (AANN, 2014a). An electroencephalogram can detect abnormal brain waves in regions occupied by or adjacent to tumor; it is used to evaluate temporal lobe seizures and to assist in ruling out other disorders. Cytologic studies of the CSF may be performed to detect malignant cells as CNS tumors can shed cells into the CSF resulting in metastasis.

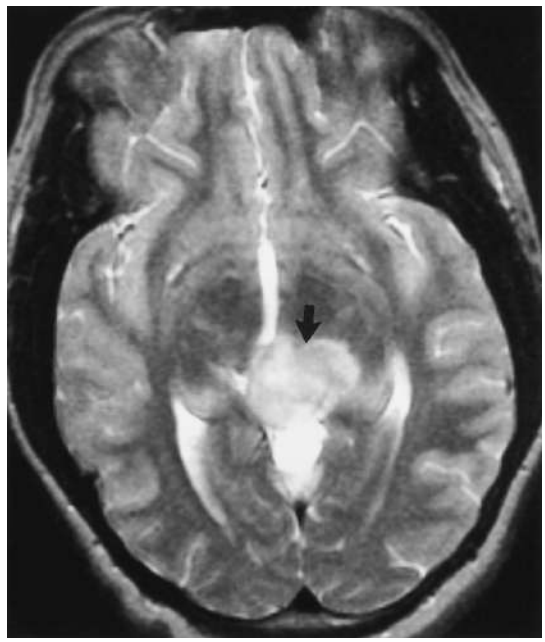

Figure 53-2 • Magnetic resonance image of the brain shows an exophytic tectal glioma (*arrow*) in this patient with neurofibromatosis type 1. From Brant, W. E., & Helms, C. A. (2006). Fundamentals of diagnostic radiology (3rd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

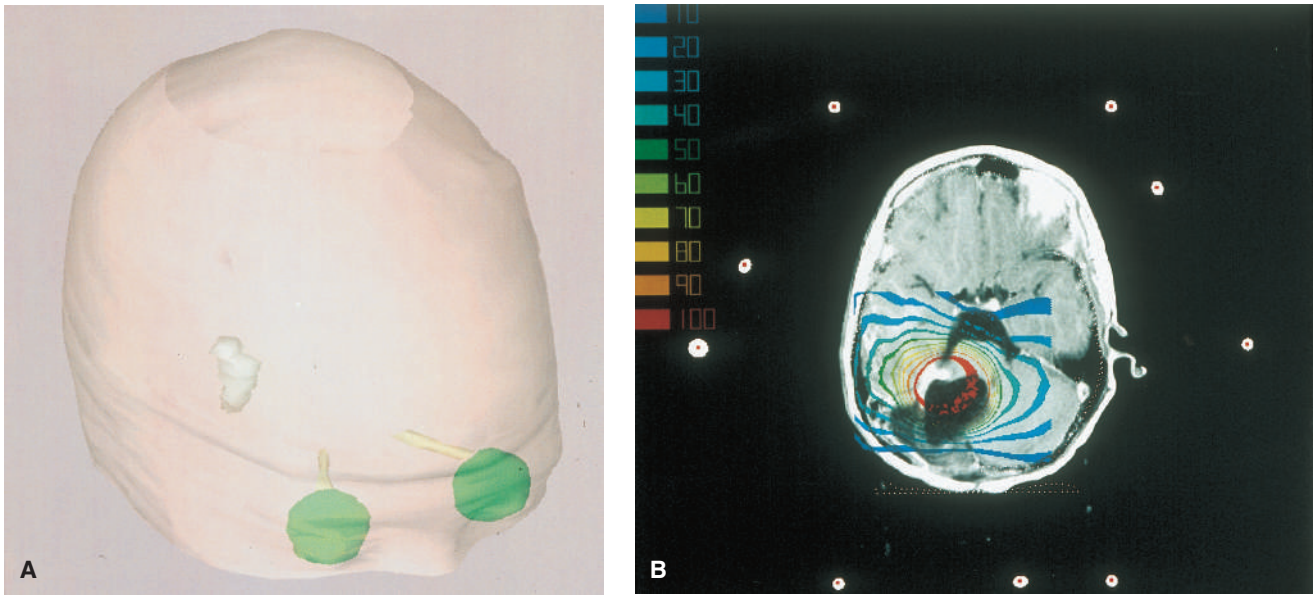

Figure 53-3 • **A.** Using stereotactic or "brain-mapping" guided approach, a three-dimensional computer image fuses the computed tomography image and magnetic resonance image to pinpoint the exact location of the brain tumor. This low-grade astrocytoma is localized adjacent to the brainstem, is inoperable, and is treated with radiation. Note the optic chasm and optic nerves. **B.** Computerized image of the prescribed radiation dose.

Medical Management

A variety of medical management approaches, including surgery, chemotherapy, and external-beam radiation therapy, are used alone or in combination (AANN, 2014a).

Secreting tumors may be treated with medications that suppress hormones. Nonfunctioning tumors may have no effect on pituitary function or may suppress hormone production and release. Hormone replacement may be necessary for these patients to restore normal endocrine function.

Surgical Management

The objective of surgical management is to remove as much tumor as possible without increasing the neurologic deficit (paralysis, blindness), or to relieve symptoms by partial removal (decompression). Surgery also provides tissue to establish a definitive diagnosis. A variety of surgical approaches may be used; the specific approach depends on the type of tumor, its location, and its accessibility. Conventional surgical approaches require a craniotomy (incision into the skull). See Chapter 49 for a discussion of care of the patient who has undergone a craniotomy. This approach is used in patients with meningiomas, acoustic neuromas, cystic astrocytomas of the cerebellum, colloid cysts of the third ventricle, congenital tumors such as dermoid cyst, and some of the granulomas. With improved imaging techniques and the availability of the operating microscope and microsurgical instrumentation, even large tumors can be removed through a relatively small craniotomy. For patients with malignant glioma, complete removal of the tumor and cure are not possible, but the rationale for resection includes relief of ICP, removal of any necrotic tissue, and reduction in the bulk of the tumor, which theoretically leaves behind fewer cells to become resistant to radiation or chemotherapy. Most pituitary adenomas are treated by transsphenoidal microsurgical removal (see Chapter 49), and the remainder of tumors that cannot be removed completely are treated by radiation (Hickey, 2014).

Radiation Therapy

Radiation therapy—the cornerstone of treatment for many brain tumors—decreases the incidence of recurrence of incompletely resected tumors (AANN, 2014a). Gamma radiation is delivered via an external beam to the tumor in multiple fractions. Brachytherapy (the surgical implantation of radiation sources to deliver high doses at a short distance) is an option for some types of tumors depending on their location. It is usually used as an adjunct to conventional radiation therapy or as a rescue measure for recurrent disease. Radioisotopes such as iodine 131 (^{131}I) are used to minimize effects on surrounding brain tissue.

Stereotactic procedures may be performed using a linear accelerator or gamma knife to perform radiosurgery (Hickey, 2014). These procedures allow treatment of deep, inaccessible tumors, often in a single session. Precise localization of the tumor is accomplished by the stereotactic approach and by minute measurements and precise positioning of the patient. Multiple narrow beams then deliver a very high dose of radiation. An advantage of this method is that no surgical incision is needed. Disadvantages include the lag time between treatment and the desired result as well as the potential for developing radiation necrosis (AANS, 2014a).

Chemotherapy

Chemotherapy may be used in conjunction with radiation therapy, or as the sole therapy, with the goal of increasing survival time. The greatest challenge in chemotherapy of brain tumors is that the blood–brain barrier prevents drugs from getting to the tumor in effective doses without causing systemic toxicity (AANN, 2014a).

Malignant glioma is usually treated with 6 weeks of oral temozolomide (Temodar) during radiation therapy, followed by 6 to 12 months of oral temozolomide. Low-grade gliomas may be treated with 6 months of oral temozolomide alone. Temozolomide is the first oral chemotherapy that crosses the blood–brain barrier (Hickey, 2014). Several other chemotherapy agents are used alone or in combination depending on the type of tumor (see Chapter 58)

Autologous bone marrow transplantation is used in some patients who will receive chemotherapy or radiation therapy, because it can "rescue" the patient from the bone marrow toxicity associated with high doses of chemotherapy and radiation. A fraction of the patient's bone marrow is aspirated, usually from the iliac crest, and stored. The patient receives large doses of chemotherapy or radiation therapy to destroy large numbers of malignant cells. The marrow is then reinfused intravenously after treatment is completed. See Chapter 28 for discussion of bone marrow transplant.

Pharmacologic Therapy

Corticosteroids are useful in relieving headache and alterations in level of consciousness. Corticosteroids such as dexamethasone (Decadron) are thought to reduce inflammation and edema around tumors (AANN, 2014a). Other medications used include osmotic diuretics (e.g., mannitol [Osmitrol] and hypertonic saline) to decrease the fluid content of the brain, which leads to a decrease in ICP. Anticonvulsant medications are used to treat and control seizures (Vecht et al., 2014). Venous thromboembolic events, such as deep vein thrombosis and pulmonary embolism, occur in about 15% of patients and are associated with significant morbidity. Patients receiving anticoagulant agents must be closely monitored because of the risk of CNS hemorrhage (Farge, 2013).

Nursing Management

Headache characteristics should be assessed. Upright positioning and pain medications may be useful in managing pain; nurses should evaluate effectiveness of pain management interventions. Even if seizure history is absent, the patient and family should be educated about the possibility of seizure and the need to adhere to prophylactic anticonvulsant medications, if prescribed. The patient with a brain tumor may be at increased risk for aspiration as a result of cranial nerve dysfunction. Medications to alleviate nausea and prevent vomiting should be considered. Preoperatively, the gag reflex and ability to swallow are evaluated. In patients with diminished gag response, care includes educating the patient to direct food and fluids toward the unaffected side, having the patient sit upright to eat, offering a semisoft diet, and having suction readily available. The effects of increased ICP caused by the tumor mass are reviewed in Chapter 49. The nurse performs neurologic checks; monitors vital signs; maintains a neurologic observation record (see Fig. 49-8 in Chapter 49); spaces nursing interventions to prevent rapid increase in ICP; and reorients the patient when necessary to person, time, and place. The use of corticosteroids to control headache and neurologic symptoms requires astute nursing assessment and intervention because many adverse effects can occur, including hyperglycemia,

electrolyte abnormalities, and muscle weakness (see Table 32-5 in Chapter 32). Patients with changes in cognition caused by their lesion require frequent reorientation and the use of orienting devices (e.g., personal possessions, photographs, lists, a clock), supervision of and assistance with self-care, and ongoing monitoring and intervention for prevention of injury. Patients with seizures are carefully monitored and protected from injury. Motor function is checked at intervals because specific motor deficits may occur, depending on the tumor's location. When muscle weakness is present, a multidisciplinary approach, including the nurse and physical and occupational therapists, can be used to preserve muscle strength, promote range of motion, and facilitate independence in self-care. Sensory disturbances are assessed and any area of numbness should be protected from injury. Speech is evaluated, and patients with speech deficits can be educated to use alternative forms of communication. Eye movement and pupillary size and reaction may be affected by cranial nerve involvement. Fatigue is common during therapy; efforts should be made to conserve energy and promote rest.

The psychosocial effects on family caregivers of a family member who has a primary malignant brain tumor may be significant (Dhandapani, Gupta, Dhandapani, et al., 2015). Caregiving family members should be included in the plan of care.

The nursing process for patients undergoing neurosurgery is discussed in Chapter 49. The patient's functional abilities should be reassessed postoperatively, because changes can occur.

Cerebral Metastases

A significant number of patients with cancer experience neurologic deficits caused by metastasis to the nervous system, which can include the brain, CSF, and meninges. Metastatic lesions to the brain are twice as common as primary brain tumors (Ostrom et al., 2015). This high rate of occurrence is clinically important, as more patients with all forms of cancer live longer because of improved therapies. Neurologic signs and symptoms include headache, gait disturbances, visual impairment, personality changes, altered mentation (memory loss and confusion), focal weakness, paralysis, aphasia, and seizures. These signs and symptoms can be devastating to both patient and family. Metastases to the CSF and meninges, known as leptomeningeal metastases, can produce symptoms of headache and isolated cranial nerve deficits.

Medical Management

The treatment of metastatic nervous system cancer is palliative and involves eliminating or reducing serious symptoms. Even when palliation is the goal, distressing signs and symptoms can be relieved, thereby improving the quality of life for both patient and family. Patients with intracerebral metastases who are not treated have a steady downhill course with a limited survival time. The therapeutic options include whole brain radiation therapy (the foundation of treatment) for multiple metastases or stereotactic radiosurgery for up to three sites of metastases. Surgery may be considered for a single symptomatic metastasis. Systemic chemotherapy directed at the primary cancer may be ineffective in crossing the blood–brain barrier, but chemotherapy that crosses this barrier may be added. Intrathecal chemotherapy, with direct injection of chemotherapy agents into the CSF of the brain or spinal canal, may be useful in persons with leptomeningeal metastases (Lukas, Buerke, & Mrugula, 2016). Some combination of these treatments is usually the optimal method.

Pain can be a significant problem and is managed by means of a stepped progression in the doses and type of analgesic agents needed for relief. If the patient has severe pain, morphine can be infused into the epidural or subarachnoid space through a spinal needle and a catheter placed as near as possible to the spinal segment where the pain is projected. Small doses of morphine are given at prescribed intervals (see Chapter 9).

NURSING PROCESS

The Patient with Nervous System Metastases or Primary Brain Tumor

Assessment

The nursing assessment includes a baseline neurologic examination and focuses on how the patient is functioning, moving, and walking; adapting to weakness or paralysis and to loss of vision and speech; and dealing with seizures. Assessment addresses symptoms that cause distress to the patient and affect the quality of life, including pain, respiratory problems, bowel and bladder disorders, and sleep disturbances, as well as impairment of skin integrity, fluid balance, and temperature regulation (Hickey, 2014). Nutritional status is assessed, because cachexia and cancer-related anorexia-cachexia syndrome are common (see Chapter 58).

The nurse takes a dietary history to assess food intake, intolerance, and preferences. Calculation of body mass index can confirm the loss of subcutaneous fat and lean body mass (see Chapter 3). Biochemical measurements are reviewed to assess the degree of malnutrition, impaired cellular immunity, and electrolyte balance (normal laboratory values are found in Appendix A). A dietitian assists in determining the caloric needs of the patient.

The nurse works with other members of the health care team to assess the impact of the illness on the family in terms of home care, altered relationships, financial problems, time pressures, and family problems. This information is important in helping family members cope with the diagnosis and the changes associated with it.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Self-care deficit (feeding, bathing, and toileting) related to loss or impairment of motor and sensory functions and decreased cognitive abilities
- Imbalanced nutrition: less than body requirements related to cachexia due to treatment and tumor effects, decreased nutritional intake, and malabsorption
- Imbalanced nutrition: more than body requirements related to increased nutritional intake and impaired metabolism
- Anxiety related to fear of dying, uncertainty, change in appearance, or altered lifestyle
- Interrupted family processes related to anticipatory grief and the burdens imposed by the care of the person with a terminal illness

Other nursing diagnoses of the patient with nervous system metastases may include acute pain related to tumor compression; impaired gas exchange related to dyspnea; constipation related to decreased fluid and dietary intake and medications; impaired urinary elimination related to reduced fluid intake, vomiting, and side effects of medications; sleep pattern disturbances related to discomfort and fear of dying; impairment of skin integrity related to cachexia, poor tissue perfusion, and decreased mobility; deficient fluid volume related to fever, vomiting, and low fluid intake; and ineffective thermoregulation related to hypothalamic involvement, fever, and chills. See Chapter 58 for assessment and nursing interventions for the patient with cancer.

Planning and Goals

The goals for the patient include compensating for self-care deficits, improving nutrition, reducing anxiety, enhancing family coping skills, and absence of complications.

Nursing Interventions

Compensating for Self-Care Deficits

The patient may have difficulty participating in goal setting as the tumor metastasizes and affects cognitive function. The nurse should encourage the family to keep the patient as independent as possible for as long as possible (AANN, 2014a). Increasing assistance with self-care activities is to be expected. Because the patient with nervous system metastasis and the family live with uncertainty, they are encouraged to plan for each day and to make the most of each day. The tasks and challenges are to assist the patient to find useful coping mechanisms, adaptations, and compensations for solving problems that arise. This helps patients maintain some sense of control. An individualized exercise program helps maintain strength, endurance, and range of motion. Eventually, referral for home or hospice care may be necessary (see Chapter 59).

Improving Nutrition

Patients with nausea, vomiting, diarrhea, breathlessness, and pain are rarely interested in eating. These symptoms are managed or controlled through assessment, planning, and care. The nurse educates the family about how to position the patient for comfort and safety during meals. A dietician may help with alternative food choices that are easily tolerated. Meals are planned for times when the patient is rested and in less distress from pain or the effects of treatment.

The patient needs to be clean, comfortable, and free of pain for meals, in an environment that is as attractive as possible. Oral hygiene before meals helps to improve appetite. Offensive sights, sounds, and odors are eliminated. Creative strategies may be required to make food more palatable, provide enough fluids, and increase opportunities for socialization during meals. The family may be asked to keep a log of daily weights and to record the quantity of food eaten to determine the daily calorie count. Dietary supplements, if acceptable to the patient, can be provided to meet increased caloric needs. If the patient is not interested in most usual foods, those foods preferred by the patient should be offered. When the patient shows marked deterioration as a result of tumor growth and effects, some other form of nutritional support (e.g., tube feeding, parenteral nutrition) may be indicated if consistent with the patient's end-of-life preferences (AANN, 2014a). Nursing interventions include assessing the patency of the central and intravenous lines or feeding tube, monitoring the insertion site for infection, checking the infusion rate, monitoring intake and output, and changing the intravenous tubing and dressing. Family members are instructed in these techniques if they will be providing care at home. Parenteral nutrition can be provided at home if indicated. The patient's quality of life may guide the selection, initiation, maintenance, and discontinuation of nutritional support. The nurse and family should not place too much emphasis on eating or on discussions about food, because the patient may not desire aggressive nutritional intervention. The subsequent course of action must be congruent with the wishes and choices of the patient and family.

Increased appetite may occur in patients receiving steroids and may result in weight gain as well as hyperglycemia. Patients and family members should be instructed to monitor weight and blood glucose (if appropriate), as well as maintain a healthy diet with caloric intake appropriate to patient needs.

Relieving Anxiety

Patients may be restless, with changing moods that may include intense depression, euphoria, paranoia, and severe anxiety. The response of patients to terminal illness reflects their pattern of reaction to other crisis situations. Serious illness imposes additional strains that often bring other unresolved problems to light. The patient's own coping strategies can help deal with anxious and depressed feelings. Health care providers need to be sensitive to the patient's concerns and fears.

Patients need the opportunity to exercise some control over their situation. A sense of mastery can be gained as they learn to understand the disease and its treatment and how to deal with their feelings. The presence of family, friends, a spiritual advisor, and health professionals may be supportive. Brain tumor support groups may provide a feeling of support and strength (see the Resources section).

Spending time with patients allows them time to talk and to communicate their fears and concerns. Open communication and acknowledgment of fears are often therapeutic. Touch is also a form of communication. These patients need reassurance that continuing care will be provided and that they will not be abandoned. The situation becomes more endurable when others share in the experience of dying. If a patient's emotional reactions are very intense or prolonged, additional help from a spiritual advisor, social worker, or mental health professional may be indicated.

Enhancing Family Processes

The family needs to be reassured that their loved one is receiving optimal care and that attention will be paid to the patient's changing symptoms and concerns. When the patient can no longer carry out self-care, the family and additional support systems (social worker, home health aide, home care nurse, hospice nurse) may be needed. Educating family members on how to care for their loved one with additional physical, cognitive, and maybe behavioral impairments is necessary, acute, and challenging. Investigating what supportive and financial resources are available may decrease the burden on the caregivers. These efforts improve quality of life for the patient and family (Dhandapani et al., 2015).

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The patient and family often have major responsibility for care at home. Caregivers

Chart 53-2 HOME CARE CHECKLIST

The Patient with Nervous System Metastases

At the completion of education, the patient and/or caregiver will be able to:

- State effects of the tumor according to its type and location in the brain or spinal cord.
- State the impact of the tumor and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
  - Describe goals and side effects of treatment and suggested management approaches.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - When indicated, use nonpharmacologic pain management techniques in addition to prescribed pharmacologic methods.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., nutritional needs, ADL assistance) necessary to maintain health.
- Identify coping strategies, such as:
  - Taking control, setting daily goals, and staying positive.
  - Rehabilitation to improve self-care.
  - Relaxation techniques.
  - Family support.
  - Support groups.
- Identify community resources, including palliative care, home health service, hospice, as appropriate.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider.
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.

Resources

See Chapter 58, Chart 58-10 Home Care Checklist: The Client Undergoing Care for an Oncologic Disorder.

ADL, activities of daily living; IADL, independent activities of daily living.

may struggle with a new "normal" while their support systems fluctuate as their relationship with the patient they are caring for is strengthened, maintained, or strained (Ownsworth, Goadby, & Chambers, 2015). In addition to the psychological aspect, education includes pain management strategies, prevention of complications related to treatment strategies, and methods to ensure adequate fluid and food intake (see Chart 53-2). Educational needs of the patient and family regarding care priorities are likely to change as the disease progresses. The nurse should assess the changing needs of the patient and the family and inform them about resources and services early and frequently to assist them in dealing with changes in the patient's condition (see the Resources section).

Continuing and Transitional Care. Home care nursing and hospice services are valuable resources that should be made available to the patient and the family early in the course of a terminal illness. Anticipating needs before they occur can assist in smooth initiation of services. Home care needs and interventions focus on four major areas: palliation of symptoms and pain control, assistance in self-care, control of treatment complications, and administration of specific forms of treatment (e.g., parenteral nutrition). The nurse assesses pain management, respiratory status, complications of the disorder and its treatment, and the patient's cognitive and emotional status. In addition, the nurse assesses the family's ability to perform necessary care and notifies the primary provider about changing needs or complications, if indicated.

The patient and family who elect to care for the patient at home as the disease progresses can benefit from the care and support provided through hospice and palliative care services (Ownsworth et al., 2015). Steps to initiate hospice care, including discussion of hospice care as an option, should not be postponed until death is imminent. Exploration of hospice care as an option should be initiated at a time when hospice services can provide support and care to the patient and family consistent with their end-of-life decisions and can assist in allowing death with dignity. See Chapter 59 for in-depth discussion of end-of-life care.

Evaluation

Expected patient outcomes may include:

1. Engages in self-care activities as long as possible
   a. Uses assistive devices or accepts assistance as needed
   b. Schedules periodic rest periods to permit maximal participation in self-care
2. Maintains as optimal a nutritional status as possible
   a. Eats and accepts food within limits of condition and preferences
   b. Accepts alternative methods of providing nutrition if indicated
3. Reports being less anxious
   a. Is less restless and is sleeping better
   b. Verbalizes concerns and fears about death
   c. Participates in activities of personal importance as long as feasible
4. Family members seek help as needed
   a. Demonstrate ability to bathe, feed, and care for the patient and participate in pain management and prevention of complications
   b. Express feelings and concerns to appropriate health professionals
   c. Discuss and seek hospice care as an option

Spinal Cord Tumors

Tumors within the spinal canal are classified according to their anatomic relation to the spinal cord (Bader, Littlejohns, Olson, et al., 2016). They include intramedullary lesions (within the spinal cord), extramedullary-intradural lesions (within or under the spinal dura), and extramedullary-extradural lesions (outside the dural membrane). Primary tumors are usually intramedullary, consisting of astrocytoma or ependymoma; meningiomas can occur as extramedullary-intradural lesions. Secondary tumors are far more common and are usually extramedullary-extradural lesions. Tumors that occur within the spinal canal or exert pressure on it cause symptoms ranging

from localized or shooting pains, weakness and loss of reflexes below the tumor level to progressive loss of motor function and paralysis. Usually, sharp pain occurs in the area innervated by the spinal roots that arise from the cord in the region of the tumor. In addition, increasing sensory deficits develop below the level of the lesion. Loss of bowel and bladder function is common.

Bhat et al. (2016) reported that the incidence rate of spinal cord and bone primary and metastatic tumors in Jammu and Kashmir, India, was about 0.24 per 100,000 population per year for all ages. Among children (≤18 years) it was 0.014 per 100,000 persons per year. Furthermore, it was reported that the occurrence of spinal cord tumor was more among males than females and these were mostly found in fourth and fifth decades whereas intradural intramedullary tumors were seen in third and fourth decades and mostly in males.

Assessment and Diagnostic Findings

Neurologic examination and diagnostic studies are used to make the diagnosis. Neurologic examination focuses on assessing pain and identifying loss of reflexes, sensation, or motor function. Helpful diagnostic studies include CT scans, MRI scans, and biopsy. The MRI scan is the most commonly used and the most sensitive diagnostic tool (Hickey, 2014) and it is particularly helpful in detecting epidural spinal cord compression and metastases.

Medical Management

Treatment of specific intraspinal tumors depends on the type and location of the tumor and the presenting symptoms and physical status of the patient. Surgical intervention is the primary treatment for most spinal cord tumors followed by chemotherapy and radiation therapy. Research is ongoing with direct, localized drug delivery and nanomedicine treatment (Tobin, Geraghty, Engelhard, et al., 2015).

Extramedullary-extradural spinal cord compression occurs in 5% to 7% of patients who die of cancer and is considered a neurologic emergency. For the patient with spinal cord compression resulting from metastatic cancer (most commonly from breast, prostate, or lung), high-dose dexamethasone (Decadron) combined with radiation therapy is effective in relieving pain (see Chapter 51 for a discussion of care of the patient with spinal cord compression). Palliative care may be an option for the medical management of some patients. Chemotherapy specific to the tumor type may be considered (Perkins & Liu, 2016).

Surgical Management

Tumor removal is desirable but not always possible. The goal is to remove as much tumor as possible while sparing uninvolved portions of the spinal cord. Sudden decrease or loss of motor, sensory, and bowel and bladder function indicates the need for emergent surgery to reestablish function and protect the cord from further damage (Hickey, 2014). Microsurgical techniques have improved the prognosis for patients with intramedullary tumors. Extramedullary-intradural tumors may be completely resected. Prognosis is related to the degree of neurologic impairment at the time of surgery, the speed with which symptoms occurred, and the origin of the tumor. Patients with extensive neurologic deficits before surgery are less likely to regain full functional recovery after successful tumor removal.

Nursing Management

Providing Preoperative Care

The objectives of preoperative care include recognition of neurologic changes through ongoing assessments, pain control, and management of altered activities of daily living (ADLs) resulting from sensory and motor deficits and bowel and bladder dysfunction. The nurse assesses for weakness, muscle wasting, spasticity, sensory changes, bowel and bladder dysfunction, and potential respiratory problems, especially if a cervical tumor is present. The patient is also evaluated for coagulation deficiencies. A history of anticoagulation medication use is obtained and reported, because the use of these may impede hemostasis postoperatively. The patient is educated about breathing exercises, and they are demonstrated preoperatively. Postoperative pain management strategies are discussed with the patient before surgery.

Assessing the Patient After Surgery

The patient is monitored for deterioration in neurologic status. A sudden onset of neurologic deficit is an ominous sign and may be due to spinal cord ischemia or infarction. Frequent neurologic checks are carried out, with emphasis on movement, strength, and sensation of the upper and lower extremities. Assessment of sensory function involves pinching the skin of the arms, legs, and trunk to determine if there is loss of feeling and, if so, at what level. Vital signs are monitored at regular intervals.

Managing Pain

The prescribed pain medication should be given in adequate amounts and at appropriate intervals to relieve pain and prevent its recurrence. Pain is the hallmark of spinal metastasis. Patients with sensory root involvement may suffer excruciating pain, which requires effective pain management.

The bed is usually kept flat initially. The nurse turns the patient as a unit, keeping shoulders and hips aligned and the back straight (also referred to as logrolling) (see Fig. 53-12). The side-lying position is usually the most comfortable, because this position imposes the least pressure on the surgical site. Placement of a pillow between the knees of the patient in a side-lying position helps to prevent extreme knee flexion.

Monitoring and Managing Potential Complications

If the tumor was in the cervical area, respiratory compromise due to postoperative edema may occur (Marchetti, 2014). The nurse monitors the patient for asymmetric chest movement, abdominal breathing, and abnormal breath sounds. For a high cervical lesion, the endotracheal tube remains in place until adequate respiratory function is ensured. The patient is encouraged to perform deep-breathing and coughing exercises.

The area over the bladder is palpated or a bladder scan performed to assess for urinary retention. The nurse also monitors for incontinence, because urinary dysfunction usually implies significant decompensation of spinal cord function. An intake and output record is maintained. In addition, the abdomen is auscultated for bowel sounds.

Staining of the dressing may indicate leakage of CSF from the surgical site, which may lead to serious infection or to an inflammatory reaction in the surrounding tissues that can cause severe pain in the postoperative period. Bulging at the incision may indicate contained CSF leak. The site should be monitored for increasing bulging, known as pseudomeningocele, which may require surgical repair (Hickey, 2014).

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

In preparation for discharge, the patient is assessed for the ability to function independently in the home and for the availability of resources such as family members to assist in caregiving. Patients with residual sensory involvement are cautioned about the dangers of extremes in temperature. They should be educated about the dangers of heating devices (e.g., hot water bottles, heating pads, space heaters) as their sensory integration may be impaired, causing them to lose the ability to detect dangerous stimulations and to react appropriately. The patient is educated to check skin integrity daily. Patients with impaired motor function related to motor weakness or paralysis may require training in ADLs and safe use of assistive devices, such as a cane, walker, or wheelchair (see Chapter 38). The patient and family members are educated about pain management strategies, bowel and bladder management, and assessment for signs and symptoms that should be reported promptly (see Chart 53-2).

Continuing and Transitional Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities. A consultation for home, community-based or transitional care may be indicated and provides the nurse with the opportunity to assess the patient's physical and psychological status and the patient's and family's ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The patient's respiratory status and nutritional status are assessed. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief. The need for hospice services or placement in an extended care facility is discussed with the patient and family if warranted, and the patient is asked about preferences for end-of-life care. In addition, social workers may be consulted to assist the patient and family members in identifying support groups and agencies that can provide help in coping with the disease process (Hickey, 2014).

DEGENERATIVE DISORDERS

Disorders of the central and peripheral nervous system that are neurodegenerative (leading to deterioration of normal cells or function of the nervous system) are characterized by the slow onset of signs and symptoms. Patients are managed at home for as long as possible and are admitted to the acute care setting for exacerbations, treatments, and surgical interventions as needed.

Alzheimer Disease

AD, the sixth leading cause of death for older adults, is a progressive, irreversible, degenerative neurologic disease that begins insidiously and is characterized by gradual losses of cognitive function and disturbances in behavior and affect. AD can occur in people as young as 40 years of age but is uncommon before 65 years of age. Although the prevalence of AD increases dramatically with increasing age, affecting as many as half of those 85 years and older, AD is not a normal part of aging. Without a cure or any preventive measures, it is estimated that 13.4 million Americans will have this disease by 2050 (Kochanek, Murphy, Xu, et al., 2014); (Weuve, Hebert, Scherr, et al., 2014).

There are numerous theories about the cause of age-related cognitive decline. Although the greatest risk factor for AD is increasing age, many environmental, dietary, and inflammatory factors also may determine whether a person suffers from this cognitive disease. AD is a complex brain disorder caused by a combination of various factors that may include genetics, neurotransmitter changes, vascular abnormalities, stress hormones, circadian changes, head trauma, and the presence of seizure disorders.

AD can be classified into two types: familial or early-onset AD and sporadic or late-onset AD. Familial AD is rare, accounting for less than 1% of all cases, and is frequently associated with genetic mutations (Sherva & Kowall, 2015). It can occur in middle-aged adults. If family members have at least one other relative with AD, then there is a familial component, which may include both environmental triggers and genetic determinants.

Pathophysiology

The pathogenesis of AD is uncertain but the disease includes specific neuropathologic and biochemical changes that interfere with neurotransmission. These changes consist of neurofibrillary tangles (tangled masses of nonfunctioning neurons) and senile or neuritic plaques (deposits of amyloid protein, part of a larger protein called *amyloid precursor protein* in the brain) (see Fig. 53-4). The neuronal damage occurs primarily in the cerebral cortex and results in decreased brain size. Similar changes are found in the normal brain tissue of nonsymptomatic older adults, although to a lesser extent. Cells that use the neurotransmitter acetylcholine are principally affected by AD. At the biochemical level, the enzyme active in producing acetylcholine, which is specifically involved in memory processing, is decreased.

Scientists have been studying complex neurodegenerative diseases such as AD and have focused on two key issues: whether a gene might influence a person's overall risk of developing the disease, and whether a gene might influence some particular aspect of a person's risk, such as the age at which the disease begins (age at onset). There are genetic differences in early- and late-onset forms of AD (Sherva & Kowall, 2015). Researchers are investigating what predisposes people to develop the plaques and neurofibrillary tangles that can be seen at autopsy in the brains of patients with AD. Understanding the complex ways in which aging as well as genetic and nongenetic factors affect brain cells over time, eventually leading to AD, continues to increase.

Clinical Manifestations

In the early stages of AD, forgetfulness and subtle memory loss occur. Patients may experience small difficulties in work or social activities but have adequate cognitive function to compensate for the loss and continue to function independently. With further progression of AD, the deficits can no longer be concealed. Forgetfulness is manifested in many daily actions; patients may lose their ability to recognize familiar faces, places, and objects and they may become lost in a familiar environment. They may repeat the same stories or ask the same question repeatedly. Trying to reason with people with AD and using reality orientation only increase their anxiety without increasing function. Conversation becomes difficult, and word-finding difficulties occur. The ability to formulate concepts and

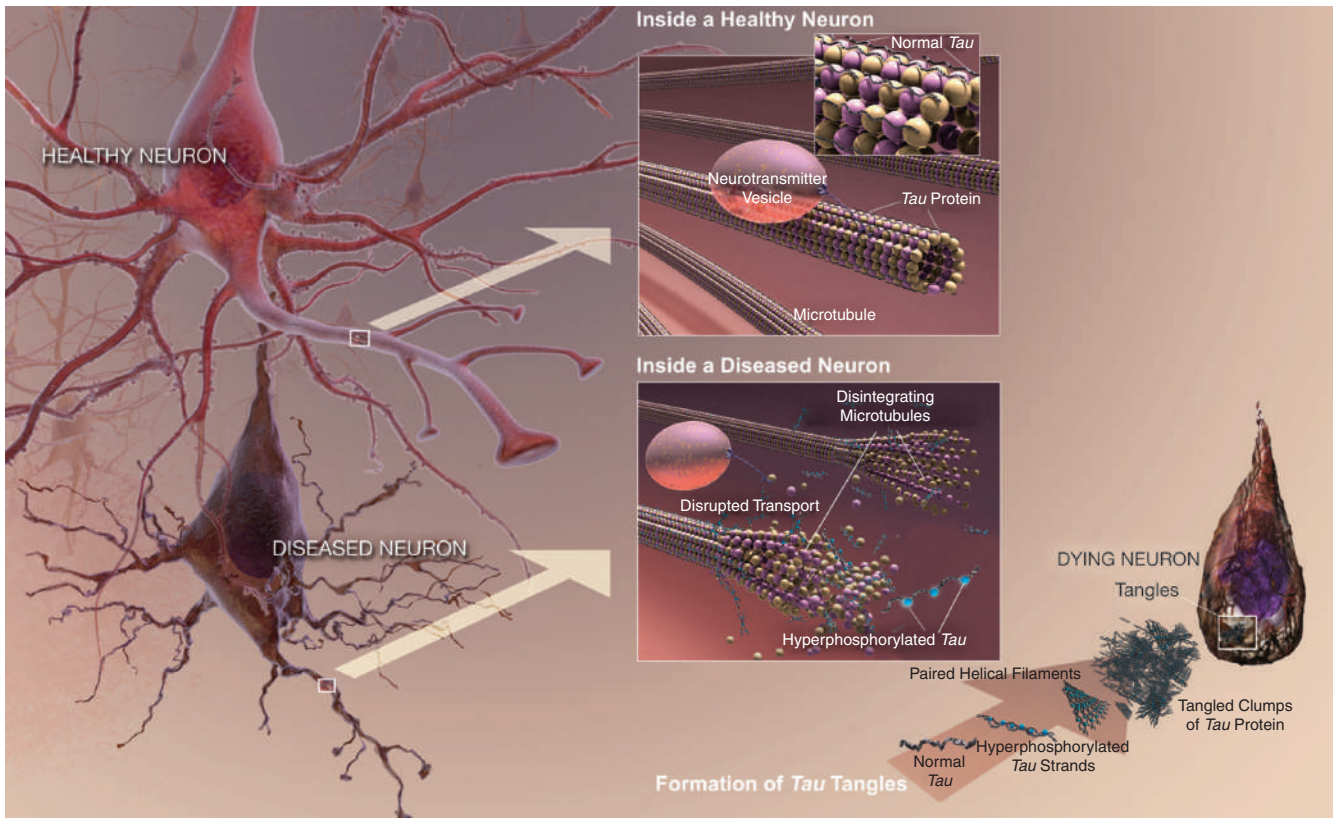

Figure 53-4 • Healthy and diseased neurons and formation of tau tangles. From National Institute on Aging, National Institutes of Health, Alzheimer's Disease Education and Referral Center. Retrieved at: www.nia.nih.gov/alzheimers/scientific-images.

think abstractly disappears—for example, a patient can interpret a proverb only in concrete terms. Patients are often unable to recognize the consequences of their actions and, therefore, exhibit impulsive behavior—for example, on a hot day a patient may decide to wade in the city fountain fully clothed. Patients have difficulty with everyday activities, such as operating simple appliances and handling money.

Personality changes are also usually evident. Patients may become depressed, suspicious, paranoid, hostile, and even combative. Progression of the disease intensifies the symptoms: Speaking skills deteriorate to nonsense syllables, agitation and physical activity increase, and patients may wander at night. Eventually, assistance is needed for most ADLs, including eating and toileting, because dysphagia and incontinence develop. The terminal stage, in which patients are usually immobile and require total care, may last months or years. Occasionally, patients may recognize family members or caregivers. Death occurs as a result of complications such as pneumonia, malnutrition, or dehydration.

Assessment and Diagnostic Findings

A definitive diagnosis of AD can be made only at autopsy; however, an accurate clinical diagnosis can be made in the majority of cases. The most important goal is to rule out other causes of dementia that are reversible, such as depression, delirium, alcohol or drug abuse, or inappropriate drug dosage or drug toxicity. AD is a diagnosis of exclusion; a diagnosis of probable AD is made when the medical history, physical examination, and laboratory tests have excluded all known causes of other dementias.

The health history—including medical history, family history, social and cultural history, and medication history—and the physical examination, including functional and mental health status, are essential to the diagnosis of probable AD. Diagnostic tests, including complete blood count, chemistry profile, and vitamin B_{12} and thyroid hormone levels, as well as screening with electroencephalography, computed tomography (CT), magnetic resonance imaging (MRI), and examination of the cerebrospinal fluid, may all refute or support a diagnosis of probable AD.

Depression can closely mimic early-stage AD and coexists in many patients. Therefore, assessing the patient for underlying depression is important. The GDS is a useful tool to assess for depression (see chapter 62, Chart 62-6). Tools such as the MMSE (see Chart 62-3) are useful for assessing cognitive status and screening for AD. Both CT and MRI of the brain are useful for excluding hematoma, brain tumor, stroke, normal-pressure hydrocephalus, and atrophy but are not reliable in making a definitive diagnosis of AD. Infections and physiologic disturbances, such as hypothyroidism, Parkinson disease, and vitamin B_{12} deficiency, can cause cognitive impairment that may be misdiagnosed as AD. Biochemical abnormalities can be excluded through examination of the blood and cerebrospinal fluid.

Medical Management

In AD, the primary goal is to manage the cognitive and behavioral symptoms. Although there is no cure, several medications slow the progression of the disease. Cholinesterase inhibitors donepezil hydrochloride (Aricept) and rivastigmine tartrate (Exelon), for example, enhance acetylcholine uptake

in the brain, thus maintaining memory skills for a period of time. Cognitive ability may improve within 6 to 12 months of therapy. Rivastigmine (Exelon Patch) is indicated for severe AD; It is recommended that treatment continue as long as possible (Comerford, 2015).

Behavioral problems such as agitation and psychosis can be managed by behavioral and psychosocial therapies. Associated depression and behavioral problems can also be treated pharmacologically if other interventions fail. Because symptoms change over time, all patients with AD should be reevaluated routinely, and the nurse should document and report both positive and negative responses to medications (Miller, 2015).

Nursing Management

Nurses play an important role in the recognition of dementia, particularly in hospitalized older adults, by assessing for signs (e.g., repeating or asking the same thing over and over). Nursing interventions for dementia are aimed at promoting patient function and independence for as long as possible. Other important goals include promoting the patient's physical safety, promoting independence in self-care activities, reducing anxiety and agitation, improving communication, providing for socialization and intimacy, promoting adequate nutrition, promoting balanced activity and rest, and supporting and educating family caregivers. These nursing interventions apply to all patients with dementia, regardless of cause.

Supporting Cognitive Function

Because dementia of any type is degenerative and progressive, patients display a decline in cognitive function over time. In the early phase of dementia, minimal cuing and guidance may be all that are needed for the patient to function fairly independently for a number of years. However, as the patient's cognitive ability declines, family members must provide more and more assistance and supervision. A calm, predictable environment helps people with dementia interpret their surroundings and activities. Environmental stimuli are limited, and a regular routine is established. A quiet, pleasant manner of speaking, clear and simple explanations, and the use of memory aids and cues help minimize confusion and disorientation and give patients a sense of security. Prominently displayed clocks and calendars may enhance orientation to time. Color-coding the doorway may help patients who have difficulty locating their room. Active participation may help patients maintain cognitive, functional, and social interaction abilities for a longer period. Physical activity and communication have also been demonstrated to slow some of the cognitive decline of AD.

Promoting Physical Safety

A safe home and hospital environment allows the patient to move about as freely as possible and relieves the family of constant worry about safety. For the patient residing at home, in order to prevent falls and other injuries, all obvious hazards are removed and hand rails are installed. A hazard-free environment allows the patient maximum independence and a sense of autonomy. Adequate lighting, especially in halls, stairs, and bathrooms, is necessary. Nightlights are helpful, particularly if the patient has increased confusion at night, sometimes referred to as sundowning. Driving is prohibited, and smoking is allowed only with supervision. The patient may have a short attention span and be forgetful; therefore, the nurse and the family must be patient, repeat instructions as needed, and use reminders (i.e., post-it notes, electronic reminders) for daily activities. Doors leading from the house must be secured. Outside the home, all activities must be supervised to protect the patient, and the patient should wear some type of identification in case of separation from the caregiver.

If the patient is hospitalized, additional precautionary measures should be taken. Wandering behavior, which may be worse in the hospital due to unfamiliar surroundings, can often be reduced by gentle persuasion, distraction, or by placing the patient close to the nursing station. Restraints should be avoided because they can increase agitation and lead to injury.

Promoting Independence in Self-Care Activities

Pathophysiologic changes in the brain make it difficult for people with AD to maintain physical independence. Patients should be assisted to remain functionally independent for as long as possible. One way to do this is to simplify daily activities by organizing them into short, achievable steps so that the patient experiences a sense of accomplishment. Frequently, occupational therapists can suggest ways to simplify tasks or recommend adaptive equipment. Direct patient supervision is sometimes necessary; however, maintaining personal dignity and autonomy is important for people with AD, who should be encouraged to make choices when appropriate and to participate in self-care activities as much as possible.

Reducing Anxiety and Agitation

Despite profound cognitive losses, patients are sometimes aware of their diminishing abilities. Patients need constant emotional support that reinforces a positive self-image. When loss of skills occurs, goals are adjusted to fit the patient's declining ability.

The environment should be kept familiar and noise free. Excitement and confusion can be upsetting and may precipitate a combative, agitated state known as a catastrophic reaction (overreaction to excessive stimulation). The patient may respond by screaming, crying, or becoming abusive (physically or verbally); this may be the patient's only way of expressing an inability to cope with the environment. When this occurs, it is important to remain calm and unhurried. Forcing the patient to proceed with the activity only increases the agitation. It is better to postpone the activity until later, even to another day. Frequently, the patient quickly forgets what triggered the reaction. Measures such as moving to a familiar environment, listening to music, stroking, rocking, or distraction may quiet the patient. Research suggests that the use of activities and music therapy, both individualized and in groups, help decrease agitation (Chang, Chu, Yang, et al., 2015); (Livingston, Kelly, Lewis-Holmes, et al., 2014). Becoming familiar with a particular patient's usual responses to certain stressors helps caregivers avoid stressful situations.

Patients with dementia who have progressed to the late stages of the disease often reside in nursing homes and are predominantly cared for by unlicensed assistive personnel. One systematic review found that training all staff in communication, person-centered care skills, or dementia care mapping are clinically important interventions that decreased agitation by 30% in long-term care (Livingston et al., 2014). Another study of nursing home residents with dementia suggested that adequately treating pain could reduce both physical and verbal aggression (Ahn, Garvan, & Lyon, 2015). Education for family members and caregivers is essential to minimize patient agitation and can be effectively taught by geriatric advanced nurse practitioners (Gies et al., 2014).

Improving Communication

To promote the patient's interpretation of messages, the nurse should remain unhurried and reduce noises and distractions. Use of clear, easy-to-understand sentences to convey messages is essential because patients frequently forget the meaning of words or have difficulty organizing and expressing thoughts. In the earlier stages of dementia, lists and simple written instructions that serve as reminders may be helpful. In later stages, the patient may be able to point to an object or use nonverbal language to communicate. Tactile stimuli, such as hugs or hand pats, are usually interpreted as signs of affection, concern, and security.

Providing for Socialization and Intimacy Needs

Because socialization with friends can be comforting, visits, letters, and phone calls are encouraged. Recreation is important, and people with dementia are encouraged to participate in simple activities. Realistic goals for activities that provide satisfaction are appropriate. Hobbies and activities such as walking, exercising, and socializing can improve quality of life. The nonjudgmental friendliness of a pet may provide stimulation, comfort, and contentment. Care of plants or a pet can also be satisfying and an outlet for energy.

AD does not eliminate the need for intimacy. Patients and their spouses may continue to enjoy sexual activity. Spouses should be encouraged to talk about any sexual concerns, and sexual counseling may be necessary. Simple expressions of love, such as touching and holding, are often meaningful.

Promoting Adequate Nutrition

Mealtime can be a pleasant social occasion or a time of upset and distress, and it should be kept simple and calm, without confrontations. Patients prefer familiar foods that look appetizing and taste good. Cueing may be necessary to encourage adequate nutrition and hydration. Food is cut into small pieces to prevent choking. Liquids may be easier to swallow if they are thickened. Hot food and beverages are served warm, and the temperature of the foods should be checked to prevent burns.

When lack of coordination interferes with self-feeding, adaptive equipment is helpful (see Fig. 53-5A). Some patients may do well eating with a spoon or with their fingers. If this is the case, an apron or a smock, rather than a bib, is used to protect clothing. As deficits progress, it may become necessary to feed the patient. Forgetfulness, disinterest, dental problems, lack of coordination, overstimulation, and choking all serve as barriers to good nutrition and hydration.

Promoting Balanced Activity and Rest

Many patients with dementia exhibit sleep disturbances, wandering, and behaviors that may be considered inappropriate. These behaviors are most likely to occur when there are unmet underlying physical or psychological needs. Caregivers must identify the needs of patients who are exhibiting these behaviors because further health decline may occur if the source of the problem is not corrected. Adequate sleep and physical exercise are essential. If sleep is interrupted or the patient cannot fall asleep, music, warm milk, or a back rub may help the patient relax. During the day, patients should be encouraged to participate in exercise because a regular pattern of activity and rest enhances nighttime sleep. Long periods of daytime sleeping are discouraged.

Home, Community and Transitional Care

The emotional burden on the families of patients with all types of dementia is enormous. The physical health of the patient is often very stable and the decline gradual. Family members may cling to the hope that the diagnosis is incorrect and that their relative will improve with greater effort. Family members provide at least 80% of the home care that is required by patients with AD (Gies et al., 2014). They are faced with numerous difficult decisions (e.g., when the patient should stop driving, when to assume responsibility for the patient's financial affairs). Aggression and hostility exhibited by the patient are often misunderstood by caregivers, who may feel unappreciated, frustrated, and angry. Feelings of guilt, nervousness, and worry contribute to caregiver fatigue, depression, and family dysfunction. Researchers have identified that a Web-based caregiver assessment can be an effective and efficient method of identifying care needs and planning interventions that promote balance and congruence in the lives of caregivers (Gies et al., 2014).

Neglect or abuse of the patient can occur, and this has been documented in home situations as well as in institutions. If neglect or abuse of any kind—including physical, emotional, sexual, neglect, or financial abuse—is suspected, the local adult

Figure 53-5 • A. Assistive feeding devices make it easy for patients to grasp and get food on utensils. **B.** Assistive feeding devices may be required for patients who are weak, fatigued, or paralyzed or have neuromuscular impairment.

protective services agency must be notified. The responsibility of the nurse is to report the suspected abuse, not to prove it.

The Alzheimer's Association is a coalition of family members and professionals who share the goals of family support and service, education, research, and advocacy. Family support groups, respite (relief) care, and adult day care may be available through different community resources, in which concerned volunteers are trained to provide structure to caregiver support groups. Respite care is a commonly provided service in which caregivers can get away from the home for short periods while someone else tends to the needs of the patient.

Parkinson Disease

PD is a slowly progressing neurologic movement disorder that eventually leads to disability. It affects about 1 million patients who are hospitalized in the United States each year (Moore, Smith, & Cho, 2017). The disease affects men more often than women. Symptoms usually first appear in the fifth decade of life; however, cases have been diagnosed as early as 30 years of age. The degenerative or idiopathic form of PD is the most common; there is also a secondary form with a known or suspected cause. Although the cause of most cases is unknown, research suggests a multifactorial combination of age, environment, and heredity (Moore et al., 2017).

It is more prevalent among Parsis who immigrated to India centuries ago from Persia than in Indians. (Muthane, Jain, & Gururaj, 2001). Highest incidence of PD has been reported in Mumbai city among Parsi community. It affects about 328 out of every 100,000 people despite living in a country, India, with one of the world's lowest incidence of PD (70 out of 100,000).

In Kolkata, average annual incidence rate was 5.71/100,000 per year and age-adjusted prevalence rate was 52.85/100,000 in 2010 and the adjusted average annual mortality rate was 2.89/100,000 per year (Das, Misra, Ray, et al., 2010).

Manganese-induced Parkinsonism is common in the manganese mine workers in India. These patients typically walk on their toes and fall frequently as they have severely impaired postural reflexes (Muthane, 2008).

Pathophysiology

PD is associated with decreased levels of dopamine resulting from degeneration of dopamine storage cells in the substantia nigra in the basal ganglia region of the brain (see Fig. 53-6). Fibers or neuronal pathways project from the substantia nigra to the corpus striatum, where neurotransmitters are vital to the control of complex body movements. Through the neurotransmitters acetylcholine (excitatory) and dopamine (inhibitory), striatal neurons relay messages to the higher motor centers that control and refine motor movements. The loss of dopamine stores in this area of the brain results in more excitatory neurotransmitters than inhibitory neurotransmitters, leading to an imbalance that affects voluntary movement (Hickey, 2014).

Clinical symptoms do not appear until 60% of the pigmented neurons are lost and the striatal dopamine level is decreased by 80%. Cellular degeneration impairs the extrapyramidal tracts that control semiautomatic functions and coordinated movements; motor cells of the motor cortex and the pyramidal tracts are not affected. Researchers are working on uncovering the exact mechanism of neurodegeneration. Current theories suggest a combined and complicated interweaving of both environmental and genetic factors that affect numerous fundamental cellular processes. Fifteen percent of early PD cases are associated with multiple genetic mutations (Gopalakrishna & Alexander, 2015). Ongoing research includes recognition of biomarkers and development of individualized treatment options (Kalia & Lang, 2015).

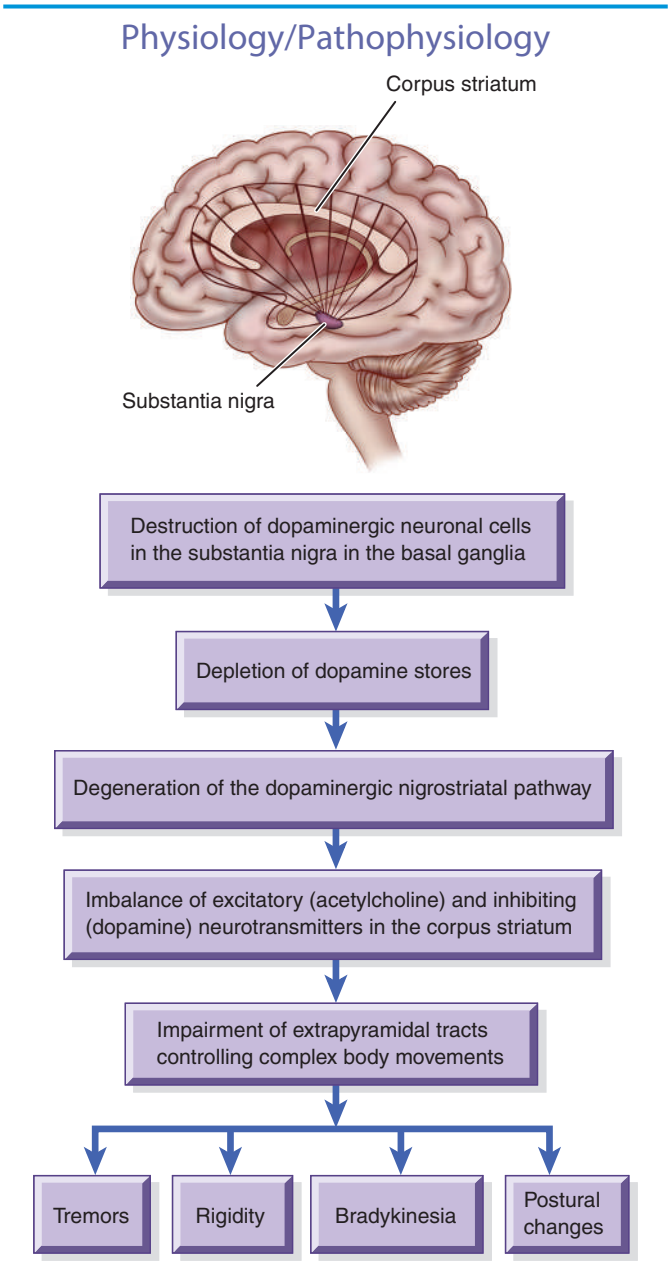

Figure 53-6 • Pathophysiology of Parkinson disease. The nuclei in the substantia nigra project fibers to the corpus striatum. The nerve fibers carry dopamine to the corpus striatum. The loss of dopamine nerve cells from the brain's substantia nigra is thought to be responsible for the symptoms of parkinsonism.

Clinical Manifestations

PD has a gradual onset, and symptoms progress slowly over a chronic, prolonged course. The cardinal signs are tremor, rigidity, bradykinesia/akinesia, and postural instability (Hickey, 2014). Two major subtypes of PD are evolving: tremor dominant (most other symptoms are absent) and nontremor dominant (akinetic-rigid and postural instability) (Kalia & Lang, 2015).

Tremor

Although symptoms are variable, a slow, unilateral resting tremor is present in the majority of patients at the time of diagnosis. Resting tremor characteristically disappears with purposeful movement and during sleep but is evident when the extremities are motionless or at rest. The tremor may manifest as a rhythmic, slow turning motion (pronation–supination) of the forearm and the hand and a motion of the thumb against the fingers as if rolling a pill between the fingers.

Rigidity

Resistance to passive limb movement characterizes muscle rigidity. Passive movement of an extremity may cause the limb to move in jerky increments, referred to as lead-pipe or cogwheel movements. Involuntary stiffness of the passive extremity increases when another extremity is engaged in voluntary active movement. Stiffness of the arms, legs, face, and posture are common. Early in the disease, the patient may complain of shoulder pain due to rigidity (Hickey, 2014).

Bradykinesia

One of the most common features of PD is bradykinesia, which refers to the overall slowing of active movement (Gopalakrishna & Alexander, 2015). Patients may also take longer to complete activities and have difficulty initiating movement, such as rising from a sitting position or turning in bed.

Postural Instability

The patient commonly develops postural and gait problems. Due to a loss of postural reflexes, the patient stands with the head bent forward and walks with a propulsive gait. The posture is caused by the forward flexion of the neck, hips, knees, and elbows. The patient may walk faster and faster, trying to move the feet forward under the body's center of gravity (shuffling gait). Difficulty in pivoting causes loss of balance, either forward (propulsion) or backward (retropulsion). Gait impairment and postural instability place the patient at increased risk for falls (Hickey, 2014). Approximately 80% of patients with a 17 years history of symptoms report gait impairment and falls (Kalia & Lang, 2015).

Other Manifestations

The effect of PD on the basal ganglia often produces autonomic symptoms that include excessive and uncontrolled sweating, drooling, paroxysmal flushing, orthostatic hypotension, gastric and urinary retention, constipation, and sexual dysfunction. Dysphagia remains a substantial problem as more than 50% of patients report choking as well as vision and olfactory changes (Hickey, 2014); (Kalia & Lang, 2015). Psychiatric changes include depression, anxiety, dementia (progressive mental deterioration), delirium, and hallucinations. Depression and anxiety are common; whether these are reactions to the disorder or related to a biochemical abnormality is uncertain (Moore et al., 2017). Stress, medications, and depression contribute to the cognitive changes of diminished executive functions, attention difficulties, decreased thinking, and word-finding challenges. More than 80% of patients with a 20-year disease duration of PD experience dementia (Kalia & Lang, 2015). In addition, auditory and visual hallucinations have been reported in up to 40% of people with PD and may be associated with depression, dementia, lack of sleep, or adverse effects of medications.

Hypokinesia (abnormally diminished movement) is also common and may appear after the tremor. The freezing phenomenon refers to a transient inability to perform active movement and is thought to be an extreme form of bradykinesia. The patient tends to shuffle and exhibits a decreased arm swing as well. As dexterity declines, micrographia (small handwriting) develops. The face becomes increasingly masklike and expressionless, and the frequency of blinking decreases. Dysphonia (voice impairment or altered voice production) may occur as a result of weakness and incoordination of the muscles responsible for speech. In many cases, the patient develops dysphagia, begins to drool, and is at risk for choking and aspiration (Hickey, 2014).

Complications associated with PD are common and are typically related to disorders of movement. As the disease progresses, patients are at risk for respiratory and urinary tract infection, skin breakdown, and injury from falls. The adverse effects of medications used to treat the symptoms are associated with numerous complications such as dyskinesia (impaired ability to execute voluntary movements) or orthostatic hypotension.

Assessment and Diagnostic Findings

Although laboratory tests and imaging studies are not helpful to the clinician in diagnosing PD ongoing research with PET and single-photon emission computed tomography scanning has been helpful in understanding the disease and advancing treatment. Currently, the disease is diagnosed clinically from the patient's history and the presence of two of the four cardinal manifestations: tremor, rigidity, bradykinesia, and postural changes.

Early diagnosis can be challenging because patients rarely are able to pinpoint when the symptoms started. Often, a family member notices a change such as stooped posture; a stiff arm; a slight limp; tremor; or slow, small handwriting. The medical history, presenting symptoms, neurologic examination, and response to pharmacologic management are carefully evaluated when making the diagnosis. Diagnosis is often confirmed by a positive response to a levodopa (Larodopa) trial (Hickey, 2014).

Medical Management

Treatment is directed toward controlling symptoms and maintaining functional independence, because no medical or surgical approaches in current use prevent disease progression. Care is individualized for each patient based on presenting symptoms and social, occupational, and emotional needs. Pharmacologic management is the mainstay of treatment, although advances in research have led to increased surgical options. Patients are usually cared for at home and are admitted to the hospital only for complications or to initiate new treatments.

Pharmacologic Therapy

Antiparkinsonian medications act by (1) increasing striatal dopaminergic activity; (2) reducing the excessive influence of excitatory cholinergic neurons on the extrapyramidal tract, thereby restoring a balance between dopaminergic and cholinergic activities; or (3) acting on neurotransmitter pathways other than the dopaminergic pathway. PD research efforts are focused on the development of disease-modifying drugs that slow or stop this neurodegenerative process (Kalia & Lang, 2015).

Levodopa is the most effective agent and the mainstay of treatment. Levodopa is converted to dopamine in the basal ganglia, producing symptom relief. Carbidopa is often added to levodopa to avoid metabolism of levodopa before it can reach the brain. The beneficial effects of levodopa therapy are

most pronounced in the first year or two of treatment. Benefits begin to wane and adverse effects become more severe over time (Hickey, 2014). Within 5 to 10 years, most patients develop a response to the medication characterized by dyskinesia including facial grimacing, rhythmic jerking movements of the hands, head bobbing, chewing and smacking movements, and involuntary movements of the trunk and extremities. The patient may experience an on–off syndrome in which sudden periods of near immobility ("off effect") are followed by a sudden return of effectiveness of the medication ("on effect"). Changing the drug dosing regimen or switching to other drugs may be helpful in minimizing the on–off syndrome. Other potential adverse effects include nausea, vomiting, appetite loss, decreased BP, dystonia, dyskinesia, and confusion (Moore et al., 2017). To minimize adverse effects of levodopa over time, current practice includes delaying use of levodopa-containing drugs as long as possible, with the use of other drugs for symptom control in the interim.

Nursing Alert: Nurses caring for patients with PD need a clear understanding of medications that are prescribed. Table 53-1 provides a summary of selected medications used in PD.

Surgical Management

The limitations of levodopa therapy, improvements in surgical techniques, and new approaches in transplantation have renewed interest in the surgical treatment of PD. In patients with disabling tremor, rigidity, or severe levodopa-induced dyskinesia, surgery may be considered. Although surgery provides symptom relief in selected patients, it has not been shown to alter the course of the disease or to produce permanent improvement.

Stereotactic Procedures

Thalamotomy and pallidotomy are ablative procedures that were formerly used to relieve symptoms of PD. However, these procedures permanently destroy brain tissue and are rarely used today. Deep brain stimulation (DBS) has largely replaced ablative procedures in the surgical treatment of PD (Kalia & Lang, 2015). DBS involves surgical implantation of an electrode into the brain in either the globus pallidus or subthalamic nucleus. Stimulation of these areas may increase dopamine release or block anticholinergic release, thereby improving tremor and rigidity. Levodopa medication dose may be able to be reduced, thus improving dyskinesias.

Patients eligible for DBS are those who have responded to levodopa but are impaired by dyskinesias, have had the disease for at least 5 years, and are disabled by tremor. Patients with dementia and atypical PD are usually not considered for surgical procedures. PD rating scales and specific neurologic tests are used to identify patients who are eligible. Surgical treatment typically occurs 10 to 13 years after diagnosis. Research is ongoing on the relationship between placing a DBS and patient quality of life (Kalia & Lang, 2015).

TABLE 53-1 Selected Medications Used to Treat Parkinson Disease

Medications	Indications and Therapeutic Effects	Common Side Effects
Anticholinergic Agents		
Trihexyphenidyl hydrochloride (Apo-Trihex)	Control of tremor in patients with early-onset disease	Blurred vision, flushing, rash, constipation, urinary retention, and acute confusional states
Benztropine mesylate (Cogentin)	Counteract the action of acetylcholine	Contraindicated in patients with narrow-angle glaucoma
Antiviral Agent		
Amantadine hydrochloride (Symmetrel)	Reduce rigidity, tremor, bradykinesia, and postural changes in early Parkinson disease (PD)	Psychiatric disturbances (mood changes, confusion, depression, hallucinations), lower extremity edema, nausea, epigastric distress, urinary retention, headache, and visual impairment
Dopamine Agonists		
Bromocriptine mesylate (Parlodel)	Early PD as well as secondary drug therapy after carbidopa or levodopa loses effectiveness	Nausea, vomiting, diarrhea, lightheadedness, hypotension, impotence, and psychiatric effects
Pergolide (Permax)		
Nonergot Derivatives		
Ropinirole hydrochloride (Requip)	Early stages of PD	May cause drowsiness or dizziness
Pramipexole (Mirapex)		
Monoamine Oxidase-Inhibitors		
Selegiline (Emsam)	Inhibit dopamine breakdown	Agitation, dizziness, nausea, headache, rhinitis, back pain, stomatitis, postural hypotension, insomnia
Rasagiline (Azilect)		
Catechol-O-Methyltransferase Inhibitors		
Entacapone (Comtan)	Increase the duration of action of carbidopa or levodopa	Abdominal pain, back pain, constipation, nausea, diarrhea, blood in urine
Tolcapone (Tasmar)	Reduce motor fluctuations in patients with advanced PD	

Adapted from Moore, D. J., Smith, B. M., & Cho, M. H. (2017). Managing meditations for hospital patients with Parkinson disease. American Nurse Today, 12(1), 9–12.

Figure 53-7 • A stereotactic frame is applied to a patient's head in preparation for deep brain stimulation. The frame provides external points of reference.

A CT or MRI scan is used to localize the appropriate surgical site in the brain. Then, the patient's head is positioned in a stereotactic frame (see Fig. 53-7). After the surgeon makes an incision in the skin and a burr hole, an electrode is passed through to the target area to the subthalamic nuclei or globus pallidus. The desired response of the patient to the electrical stimulation (i.e., a decrease in rigidity) is used to confirm electrode placement. Electrode placement is completed on one side of the brain at a time; bilateral electrodes are usually placed (AANN, 2014b). Electrodes are then connected to a pulse generator that is implanted in a subcutaneous subclavicular or abdominal pouch (see Fig. 53-8). The battery-powered pulse generator sends high-frequency electrical impulses through a wire placed under the skin to a lead anchored to the skull (see Fig. 53-8). These devices are not without complications that can result from both the surgical procedure needed for implantation (e.g., weakness, paresthesias, confusion, hemorrhage) and the device itself (e.g., infection, lead leakage) (Hickey, 2014).

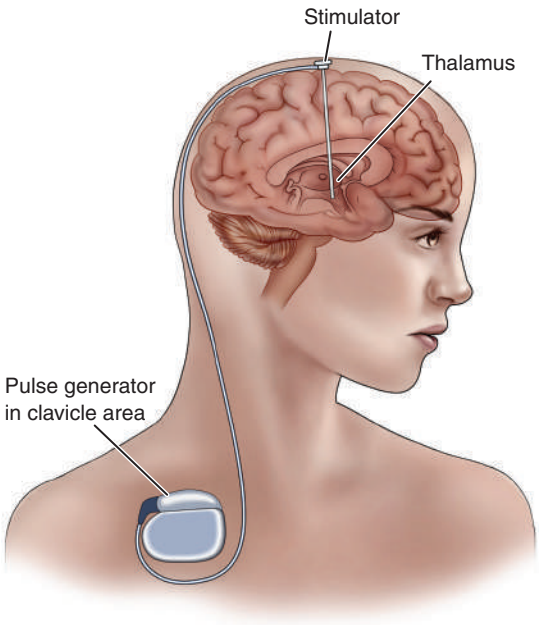

Figure 53-8 • Deep brain stimulation is provided by a pulse generator surgically implanted in a pouch beneath the clavicle. The generator sends high-frequency electrical impulses to the thalamus, thereby blocking the nerve pathways associated with tremors in Parkinson disease.

Neural Transplantation

Ongoing research is exploring transplantation of porcine neuronal cells, human fetal cells, and stem cells to replace degenerated striatal cells (Kim, Lee, & Kim, 2013). Legal, ethical, and political concerns surrounding the use of fetal brain cells and stem cells have limited the exploration of these procedures.

NURSING PROCESS

The Patient with Parkinson Disease

Assessment

Assessment focuses on how the disease has affected the patient's ADLs and functional abilities. The patient is observed for degree of disability and functional changes that occur throughout the day, such as responses to medication. Almost every patient with a movement disorder has some functional alteration and may have some type of behavioral dysfunction. The following questions may be useful to assess alterations:

- Do you have leg or arm stiffness?
- Have you experienced any irregular jerking of your arms or legs?
- Have you ever been "frozen" or rooted to the spot and unable to move?
- Does your mouth water excessively? Have you (or others) noticed yourself grimacing or making faces or chewing movements?
- What specific activities do you have difficulty doing?
- Have you had any recent falls?

During this assessment, the nurse observes the patient for quality of speech, loss of facial expression, swallowing deficits (drooling, poor head control, coughing), tremors, slowness of movement, weakness, forward posture, rigidity, evidence of mental slowness, and confusion. PD symptoms, as well as side effects of medications, put these patients at high risk for falls; therefore, a fall risk assessment should be conducted (Hickey, 2014); (Shin & Habermann, 2016a).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired physical mobility related to muscle rigidity and postural impairment
- Self-care deficits (feeding, dressing, bathing, and toileting) related to tremor and muscle rigidity
- Constipation related to medication and reduced activity
- Imbalanced nutrition: less than body requirements related to tremor, slowness in eating, difficulty in chewing and swallowing
- Impaired verbal communication related to decreased speech volume, slowness of speech, inability to move facial muscles
- Ineffective coping related to depression and dysfunction due to disease progression

Other nursing diagnoses may include sleep pattern disturbances, deficient knowledge, risk for injury, risk for activity intolerance, disturbed thought processes, and compromised family coping.

Planning and Goals

The goals for the patient may include improving functional mobility, maintaining independence in ADLs, achieving adequate bowel elimination, attaining and maintaining acceptable nutritional status, achieving effective communication, and developing positive coping mechanisms.

Nursing Interventions

Improving Mobility

A progressive program of daily exercise will increase muscle strength, improve coordination and dexterity, reduce muscular rigidity, and prevent contractures that occur when muscles are not used (Hickey, 2014). Walking, riding a stationary bicycle, swimming, and gardening are all exercises that help maintain joint mobility. Stretching (stretch–hold–relax) and range-of-motion exercises promote joint flexibility. Postural exercises are important to counter the tendency of the head and neck to be drawn forward and down. A physiotherapist may be helpful in developing an individualized exercise program and can provide instruction to the patient and caregiver on exercising safely. Faithful adherence to an exercise and walking program helps delay the progress of the disease. Warm baths and massage, in addition to passive and active exercises, help relax muscles and relieve painful muscle spasms that accompany rigidity.

Balance may be adversely affected because of the rigidity of the arms (arm swinging is necessary in normal walking). Special walking techniques must be learned to offset the shuffling gait and the tendency to lean forward. The patient is educated to concentrate on walking erect, to watch the horizon, and to use a wide-based gait (i.e., walking with the feet separated). A conscious effort must be made to swing the arms, raise the feet while walking, and use a heel–toe placement of the feet with long strides. The patient is advised to practice walking to marching music or to the sound of a ticking metronome, because this provides sensory reinforcement. Performing breathing exercises while walking provides additional movement of the ribcage and aerates larger parts of the lungs. Frequent rest periods aid in preventing frustration and fatigue.

Enhancing Self-Care Activities

Encouraging, educating, and supporting the patient during ADLs promote self-care (Hickey, 2014). See Chapters 38 and 51 for rehabilitation techniques.

Environmental modifications are necessary to compensate for functional disabilities. Patients may have severe mobility problems that make normal activities impossible. Adaptive or assistive devices may be useful. A hospital bed at home with bedside rails, an over-bed frame with a trapeze, or a rope tied to the foot of the bed can provide assistance in pulling up without help. An occupational therapist can evaluate the patient's needs in the home, make recommendations regarding adaptive devices, and educate the patient and caregiver how to improvise.

Improving Bowel Elimination

The patient may have severe problems with constipation. Among the factors causing constipation are weakness of the muscles used in defecation, lack of exercise, inadequate fluid intake, and decreased autonomic nervous system activity. The medications used for the treatment of the disease also inhibit normal intestinal secretions. A regular bowel routine may be established by encouraging the patient to follow a regular time pattern, consciously increase fluid intake, and eat foods with moderate fiber content. Laxatives should be avoided. Psyllium (Metamucil), for example, decreases constipation but carries the risk of bowel obstruction (Moore et al., 2017). A raised toilet seat is useful because the patient has difficulty in moving from a standing to a sitting position.

Improving Nutrition

Patients may have difficulty maintaining their weight. Eating becomes a very slow process, requiring concentration due to a dry mouth from medications and difficulty chewing and swallowing. These patients are at risk for aspiration because of impaired swallowing and the accumulation of saliva. They may be unaware that they are aspirating; subsequently, bronchopneumonia may develop.

Monitoring weight on a weekly basis indicates whether caloric intake is adequate. Supplemental feedings increase caloric intake. As the disease progresses, a nasogastric or percutaneous endoscopic gastrostomy (PEG) tube may be necessary to maintain adequate nutrition. A dietitian can be consulted regarding nutritional needs.

Enhancing Swallowing

Swallowing difficulties and choking are common in PD (Hickey, 2014). These can lead to problems with poor head control, tongue tremor, hesitancy in initiating swallowing, difficulty shaping food into a bolus, and disturbances in pharyngeal motility. To offset these problems, the patient should sit in an upright position during mealtime. A semisolid diet with thick liquids is easier to swallow than solids; thin liquids should be avoided. Thinking through the swallowing sequence is helpful. The patient is instructed to place the food on the tongue, close the lips and teeth, lift the tongue up and then back, and swallow. The patient is encouraged to chew first on one side of the mouth and then on the other. To control the buildup of saliva, the patient is reminded to hold the head upright and make a conscious effort to swallow. Massaging the facial and neck muscles before meals may be beneficial.

Encouraging the Use of Assistive Devices

An electric warming tray keeps food hot and allows the patient to rest during the prolonged time that it may take to eat. Special utensils also assist at mealtime. A plate that is stabilized, a nonspill cup, and eating utensils with built-up handles are useful self-help devices. The occupational therapist can assist in identifying appropriate adaptive devices. Individualized, innovative rehabilitative therapies can increase function in the patient with PD (Abbruzzese, Marchese, Avanzino, et al., 2016).

Improving Communication

Speech disorders are present in most patients with PD. The low-pitched, monotonous, soft speech of patients requires that they make a conscious effort to speak slowly, with deliberate attention to what they are saying. The patient is reminded to face the listener, exaggerate the pronunciation of words, speak in short sentences, and take a few deep breaths before speaking. A speech therapist may be helpful in designing speech improvement exercises and assisting the family and health care personnel to develop and use a method of communication that meets the patient's needs. A small electronic amplifier is helpful if the patient has difficulty being heard.

Supporting Coping Abilities

Support can be given by encouraging the patient and pointing out that activities will be maintained through active participation. A combination of physiotherapy, psychotherapy, medication therapy, and support group participation may help

reduce the depression that often occurs (Hickey, 2014). Patients with PD can become socially and emotionally withdrawn. It is best if patients are active participants in their therapeutic program, including social and recreational events. A planned program of activity throughout the day prevents too much daytime sleeping as well as disinterest and apathy.

Patients often feel embarrassed, apathetic, inadequate, bored, and lonely. In part, these feelings may result from physical slowness and the great effort that even small tasks require. The patient is assisted and encouraged to set achievable goals (e.g., improvement of mobility). Every effort should be made to encourage patients to carry out the tasks involved in meeting their own daily needs and to remain independent. Doing things for the patient merely to save time undermines the basic goal of improving coping abilities and promoting a positive self-concept.

Promoting Home, Community-Based, or Transitional Care

Educating Patients about Self-Care. Patient and family education is important in the management of PD. The needs depend on the severity of symptoms and the stage of the disease. Care must be taken not to overwhelm the patient and family with too much information early in the disease process. Ongoing assessment, intervention, and evaluation of the patient and family's adaptations and education requirements are necessary with every encounter. The strategies to promote health include a clear explanation of the disease and the goal of assisting the patient to remain functionally independent as long as possible (see Chart 53-3). The patient and family must be educated about the effects and side effects of medications and about the importance of reporting side effects to the primary provider. Nurses in the home help patients and their families enhance self-management and quality of life (Shin & Habermann, 2016 b).

Continuing and Transitional Care. Family members and partners often serve as caregivers, with home, community-based or transitional services available to assist in meeting health care needs as the disease progresses. The caregiver may be under considerable stress from living with and caring for a person with a significant disability. Providing information about treatment and care helps anticipate future needs. The caregiver is included in the plan and may be advised to learn stress reduction techniques, to include others in the caregiving process, to obtain periodic relief from responsibilities, and to have a yearly health assessment. Allowing family members and partners to express feelings of frustration, anger, and guilt is often helpful to them (Martin, 2015) (see Chart 53-4).

The patient should be evaluated in the home for adaptation and safety needs and compliance with the plan of care. In the advanced stages, patients usually enter long-term care facilities. Periodically, admission to an acute care facility may be necessary for changes in medical management or treatment of complications. Nurses provide support, education, and monitoring of patients over the course of the illness (Shin & Habermann, 2016b).

The nurse involved in home and continuing care educates the patient and family members about the importance of addressing health promotion needs such as screening for hypertension and stroke risk assessments in this predominantly older adult population. Patients are referred to appropriate health care providers. Information is available from both the Parkinson Disease Foundation and the American Parkinson's Disease Association (see the Resources section).

Evaluation

Expected patient outcomes may include:

1. Strives toward improved mobility
   a. Participates in exercise program daily
   b. Walks with wide base of support; exaggerates arm swinging when walking
   c. Takes medications as prescribed
2. Progresses toward self-care
   a. Allows time for self-care activities
   b. Uses self-help devices
3. Maintains bowel function
   a. Consumes adequate fluid
   b. Increases dietary intake of fiber
   c. Reports regular pattern of bowel function
4. Attains improved nutritional status
   a. Swallows without aspiration
   b. Takes time while eating
5. Achieves a method of communication

Chart 53-3 HEALTH PROMOTION

Strategies for the Patient with PD

To promote optimal health, the nurse works closely with the patient and family to ensure that they understand:

- How PD and its treatment impact physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality
- The importance of adhering to the prescribed medication regimen; including knowing the purpose, dose, route, schedule, side effects, and precautions for all medications
- How and when to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendors)
- Specific types of environmental and safety changes or support that will allow optimum functioning in the home
- The risk of falls/injury and how to implement fall prevention and adaptive measures in the home

In addition, the nurse advises the patient and family about lifestyle changes that are necessary to maintain health and promote self-care and independence. These include:

- Ensuring nutritional needs, including adhering to dietary restrictions, managing dysphagia, and preventing aspiration
- Promoting speech and communication skills: speech exercises, communication techniques, breathing exercises
- Managing constipation: fluid intake, bowel routine
- Managing urinary problems: functional incontinence, retention (indwelling urinary catheter care, suprapubic catheter care)
- Avoiding the effects of immobility and promoting the advantages of preventive care: skin breakdown (frequent turning, pressure release, skin care), pneumonia (deep breathing, movement), contractures (range-of-motion exercises)
- Promoting the benefits of a daily exercise program
- Ensuring safe walking and balancing
- Using appropriate coping mechanisms and diversional activities

PD, Parkinson disease; ADL, activities of daily living; IADL, independent activities of daily living.

Chart 53-4 NURSING RESEARCH PROFILE

When a Partner Has Parkinson Disease

Martin, S. C. (2015). Psychosocial challenges experienced by partners of people with Parkinson disease. Journal of Neuroscience Nursing, 47(4), 211–222.

Purpose

Persons with PD may experience devastating effects that impact those individuals who are close to them as well as the person experiencing the disease. The purpose of this study was to investigate the psychosocial experience of partners of people with PD.

Design

This qualitative descriptive study used in-depth interviews to investigate the psychosocial experience of partners of people with PD. A semistructured interview guide was used with 23 participants (15 women, 8 men) who identified that they were in a committed, romantic relationship with a person with PD.

Findings

Data analysis revealed a multitude of challenges for partners of people with PD. Some challenges included having the person with PD withdraw from communication, being unable to "rescue" the person from their disease (PD), and being the recipient of the person with PD's frustration. Additional challenges included becoming impatient with the person with PD, shouldering increased responsibilities, being confronted with the prospect of losing the person with PD, losing valued activities, being unable to predict the person with PD's daily well-being, and experiencing uncertainty about future caregiving and disease progression.

Nursing Implications

Partners of persons with PD face significant psychosocial challenges related to both caregiving and noncaregiving issues. Nurses should be prepared to provide reassurance to partners of persons with PD that their feelings are normal, as well as offer direction on how to enlist the support of family and friends and access additional support services.

   a. Communicates needs
   b. Practices speech exercises
6. Copes with effects of PD
   a. Sets realistic goals
   b. Demonstrates persistence in meaningful activities
   c. Verbalizes feelings to appropriate person

Huntington Disease

Huntington disease is a chronic, progressive, hereditary disease of the nervous system that results in progressive involuntary choreiform movement and dementia. The disease affects approximately 1 in 10,000 men or women of all races at midlife. Every person has the gene that causes Huntington disease; however, only those who inherit the expansion of the gene will develop the disease and pass it onto their children. Because it is transmitted by an autosomal dominant gene, each child of a parent with Huntington disease has a 50% risk of inheriting the disorder (Bader et al., 2016).

The prevalence of Huntington disease in Asia is much lower (0.40 per 100,000 population) than European countries (5.70 per 100,000 population) (Xu & Wu, 2015). Among the emerging countries, India appears after the 15th position in reference to incidence of HD (Barboza & Ghisi, 2018).

A genetic mutation in Huntington disease, the presence of a repeat in the Huntington gene (*HTT*), has been identified. Genetic testing can identify people who will develop this disease but cannot predict timing of disease onset. Although the gene was mapped in 1983, patients may choose not to be tested because of concerns about employment and health care discrimination. People of childbearing age with a family history of Huntington disease often seek information about their risk of disease transmission. Genetic counseling is crucial, and patients and their families may require long-term psychological counseling and emotional, financial, and legal support.

Pathophysiology

The basic pathology involves premature death of cells in the striatum (caudate and putamen) of the basal ganglia, the region deep within the brain that is involved in the control of movement. Cells also are lost in the cortex, the region of the brain associated with thinking, memory, perception, judgment, and behavior, and in the cerebellum, the area that coordinates voluntary muscle activity. Why the protein destroys only certain brain cells is unknown, but several theories have been proposed to explain the phenomenon. One possible theory is that glutamine, a building block for protein, abnormally collects in the cell nucleus, causing cell death (Ferrer, 2016). A brief pathophysiological mechanism of Huntington disease is presented in Figure 53-9.

Clinical Manifestations

This condition is characterized by a triad of symptoms: (1) motor dysfunction (the most prominent is chorea, or rapid, jerky, involuntary, purposeless movements); (2) cognitive impairment (problems with attention and emotion recognition); and (3) behavioral features, such as apathy and blunted affect (Bader et al., 2016). As the disease progresses, constant writhing, twisting, and uncontrollable movements may involve the entire body. These motions are devoid of purpose or rhythm, although patients may try to turn them into purposeful movement. All of the body musculature is involved. Facial movements produce tics and grimaces. Speech becomes slurred, hesitant, often explosive, and eventually unintelligible. Chewing and swallowing are difficult, and there is a constant danger of choking and aspiration. Choreiform movements persist during sleep but are diminished (Wilson, Pollock, & Aubeeluck, 2014).

As with speech, the gait becomes disorganized to the point that ambulation eventually is impossible. Although independent ambulation should be encouraged for as long as possible, a wheelchair usually becomes necessary. Eventually, the patient is confined to bed when the chorea interferes with walking, sitting, and all other activities. Bladder and bowel control is lost.

Cognitive impairment, such as problems with attention or emotion recognition, occurs early on while in later stages, marked dementia is present. Initially, the patient is aware that the disease is responsible for the myriad dysfunctions that are occurring.

The behavioral changes may be more devastating to the patient and family than the abnormal movements. Personality changes may result in nervous, irritable, or impatient behaviors. In the early stages, patients are particularly subject to uncontrollable fits of anger, profound and often suicidal depression, apathy, anxiety, psychosis, or euphoria. Judgment and memory are

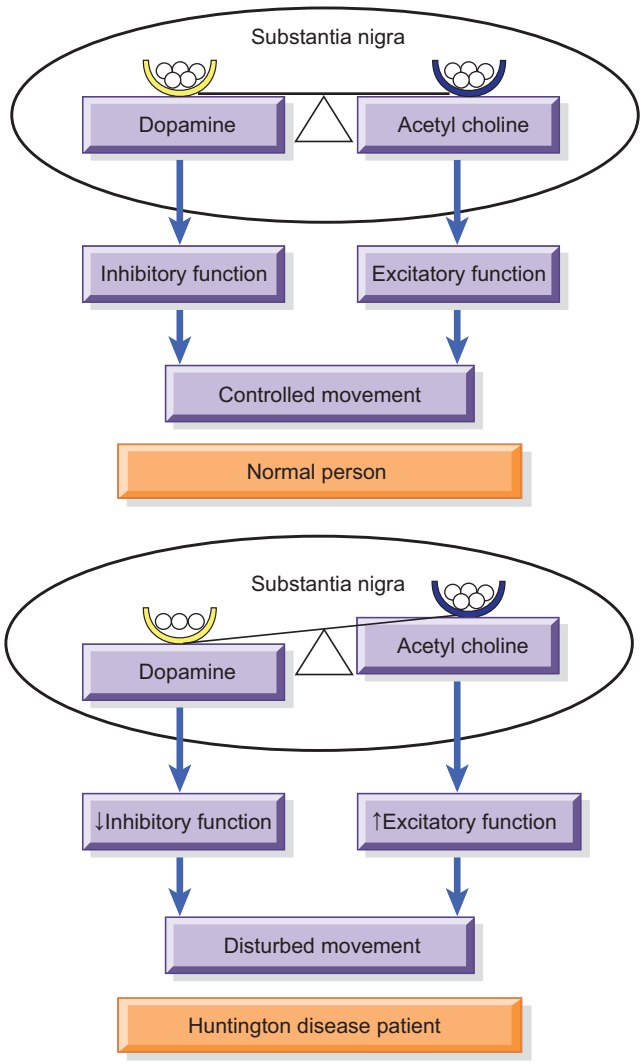

Figure 53-9 • Pathophysiological mechanism of Huntington disease.

impaired, and dementia eventually ensues (Ross, Aylward, Wild, et al., 2014). Hallucinations, delusions, and paranoid thinking may precede the appearance of disjointed movements. Emotional and cognitive symptoms often become less acute as the disease progresses (Wilson et al., 2014).

Onset usually occurs between 35 and 45 years of age, although about 10% of patients are children. The disease progresses slowly. Despite a ravenous appetite, patients usually become emaciated and exhausted. Patients succumb in 10 to 20 years to heart failure, pneumonia, or infection, or as a result of a fall or choking.

Assessment and Diagnostic Findings

The diagnosis is made based on the clinical presentation of characteristic symptoms, a positive family history, and the known presence of the genetic marker CAG repeats in *HTT* (Bader et al., 2016). CT or MRI scans show symmetrical striatal atrophy before motor symptoms appear (Ross et al., 2014).

Medical Management

No treatment halts or reverses the underlying process; therefore, the focus is on optimizing quality of life with available medication and supportive treatment. Patients experience the most benefit when they have integrated expertise of a Huntington disease multidisciplinary team (Smith, D'Cruz, Gray, et al., 2015). The only medication that is approved by the Food and Drug Administration to treat the symptom of chorea is tetrabenazine (Xenazine) (Kumar, Singh, Kumar, et al., 2015).

Benzodiazepines and neuroleptic drugs have also been reported to control chorea. Motor signs must be assessed and evaluated on an ongoing basis so that optimal therapeutic drug levels can be reached. Akathisia (motor restlessness) in the patient who is overmedicated is dangerous because it may be mistaken for the restless fidgeting of the illness and consequently may be overlooked. In certain types of the disease, hypokinetic motor impairment resembles PD. In patients who present with rigidity, some temporary benefit may be obtained from antiparkinson medications, such as levodopa.

Selective serotonin reuptake inhibitors and tricyclic antidepressants have been recommended for control of psychiatric symptoms. The threat of suicide is present particularly early in the course of the disease. Psychotic symptoms usually respond to antipsychotic medications. Psychotherapy aimed at allaying anxiety and reducing stress may be beneficial. Nurses must look beyond the disease to focus on the patient's needs and capabilities (see Chart 53-5).

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

The needs of the patient and family for education depend on the nature and severity of the physical, cognitive, and psychological changes experienced by the patient. The patient and family members are educated about the medications prescribed and about signs indicating a need for change in medication or dosage. The educational plan addresses strategies to manage symptoms such as chorea, swallowing problems, limitations in ambulation, memory loss, irritability, depression, and loss of bowel and bladder function. Consultation with a speech therapist may be indicated to assist in identifying alternative communication strategies if speech is affected. A PEG tube may be considered for nutritional support later in the disease (Wilson et al., 2014).

Continuing and Transitional Care

A program combining medical, nursing, psychological, social, occupational, speech, and physical rehabilitation services and palliative care is needed to help the patient and family cope with this severely disabling illness. Huntington disease exacts enormous emotional, physical, social, and financial tolls on every member of the family. The family needs supportive care as they adjust to the impact of the illness. Regular follow-up visits help allay the fear of abandonment.

Home care assistance, day care centers, respite care, and eventually skilled long-term care can assist the patient and family in coping with the constant strain of the illness. Although the relentless progression of the disease cannot be halted, families can benefit from supportive care. Planning for end-of-life care should occur early in the disease when possible (see Chapter 59).

Voluntary organizations can be major aids to families and have been largely responsible for bringing the illness to national attention.

Amyotrophic Lateral Sclerosis

ALS is a disease of unknown cause in which there is a loss of motor neurons (nerve cells controlling muscles) in the anterior

Chart 53-5

Care of the Patient with Huntington Disease

Nursing Diagnosis: Risk for injury from falls and possible skin breakdown (pressure ulcers, abrasions), resulting from constant movement

Nursing Interventions

Pad the sides and head of the bed; ensure that the patient can see over the sides of bed.
Use padded heel and elbow protectors.
Keep the skin meticulously clean.
Apply emollient cleansing agent and skin lotion as needed.
Use soft sheets and bedding.
Have patient wear football padding or other forms of padding.
Encourage ambulation with assistance to maintain muscle tone.
Secure the patient (only if necessary) in bed or chair with padded protective devices, making sure that they are loosened frequently.

Nursing Diagnosis: Imbalanced nutrition: less than body requirements due to inadequate intake and dehydration resulting from swallowing or chewing disorders and danger of choking or aspirating food

Nursing Interventions

Administer phenothiazines (chlorpromazine) as prescribed before meals (calms some patients).
Talk to the patient before mealtime to promote relaxation; use mealtime for social interaction. Provide undivided attention and help the patient enjoy the mealtime experience.
Use a warming tray to keep food warm.
Learn the position that is best for *this* patient. Keep patient as close to upright as possible while feeding. Stabilize patient's head gently with one hand while feeding.
Show the food, explain what the foods are, and temperature (e.g., whether hot or cold).
Encircle the patient with one arm and get as close as possible to provide stability and support while feeding. Use pillows and wedges for additional support.
Do not interpret stiffness, turning away, or sudden turning of the head as rejection; these are uncontrollable choreiform movements.
For feeding, use a long-handled spoon (iced tea spoon). Place spoon on middle of tongue and exert slight pressure.
Place bite-sized food between patient's teeth. Serve stews, casseroles, and thick liquids.
Disregard messiness, and treat the person with dignity.
Wait for the patient to chew and swallow before introducing another spoonful. Make sure that bite-sized food is small.
Give between-meal feedings. Constant movement expends more calories. Patients often have voracious appetites, particularly for sweets.
Use blenderized meals if patient cannot chew; do not repeatedly give the same strained baby foods. Gradually introduce increased textures and consistencies to the diet.
For swallowing difficulties:
- Apply gentle deep pressure around the patient's mouth.
- Rub fingers in circles on the patient's cheeks and then down each side of the patient's throat.
- Develop skill in the abdominal thrust (to be used in the event of choking).

Nursing Diagnosis: Impaired communication from excessive grimacing and unintelligible speech

Nursing Interventions

Read to the patient.
Employ biofeedback and relaxation therapy to reduce stress.
Consult with speech therapist to help maintain and prolong communication abilities.
Try to devise a communication system, perhaps using cards with words or pictures of familiar objects, before verbal communication becomes too difficult. Patients can indicate correct card by hitting it with hand, grunting, or blinking the eyes.
Learn how this particular patient expresses needs and wants—particularly nonverbal messages (widening of eyes, responses).
Patients can understand even if unable to speak. Do not isolate patients by ceasing to communicate with them.

Nursing Diagnosis: Confusion and impaired social interaction

Nursing Interventions

Reorient the patient after awakening.
Have clock, calendar, and wall posters in view to assist in orientation.
Use every opportunity for one-to-one contact.
Use music for relaxation.
Have the patient wear a medical identification bracelet.
Keep the patient in the social mainstream.
Recruit and train volunteers for social interaction. Role-model appropriate and creative interactions.
Do not abandon a patient because the disease is terminal. Patients are *living* until the end.

horns of the spinal cord and the motor nuclei of the lower brainstem. It is often referred to as Lou Gehrig disease, after the famous baseball player who suffered from the disease. As motor neuron cells die, the muscle fibers that they supply undergo atrophic changes. Neuronal degeneration may occur in both the upper and lower motor neuron systems (see Chapter 48). The leading theory held by researchers is that overexcitation of nerve cells by the neurotransmitter glutamate results in cell injury and neuronal degeneration. Risk factors that have been identified include smoking, viral infections, autoimmune disease, and environmental exposures to toxins. For example, veterans who deployed during the 1991 Gulf War had an increased number of cases of ALS compared to those who did not serve in that region. However, the exact cause is still unknown and requires further exploration (Bellomo & Cichminski, 2015).

ALS most commonly occurs between 40 and 60 years of age and affects all social, racial, and ethnic backgrounds, with men being affected at slightly higher rates than women. The majority of cases of ALS arise sporadically, but 5% to 10% of cases are familial ALS resulting from an autosomal dominant trait carried by one parent. Familial ALS occurs 10 years earlier than the ALS average, and those afflicted tend to have a shorter life span (Bellomo & Cichminski, 2015). About 30% of patients with ALS live for 5 years after diagnosis, with 10% to 20% surviving for up to 10 years and 5% surviving greater than 20 years postdiagnosis.

The prevalence of ALS in India is 6 per 100,000 persons and higher among people above 50 years of age. It is more common in male than female (2:1) (Praveen, 2015). Risk factors such as cigarette smoking, ingestion of non-protein amino acids, intense physical activity, and viral infections play a role in causation of ALS (Bastos, Orsini, Machado, et al., 2011) (Cone et al, Nazemi, & Cone, 2002) (Ferraiuolo, De Bono, Heath, et al., 2009).

Clinical Manifestations

Clinical manifestations depend on the location of the affected motor neurons, because specific neurons activate specific muscle fibers. The chief symptoms are fatigue, progressive muscle weakness, cramps, fasciculations (twitching), and lack of coordination. Loss of motor neurons in the anterior horns of the spinal cord results in progressive weakness and atrophy of the muscles of the arms, trunk, or legs. Spasticity usually is present, and the deep tendon stretch reflexes become brisk and overactive. Usually, the function of the anal and bladder sphincters remains intact, because the spinal nerves that control muscles of the rectum and urinary bladder are not affected.

In about 25% of patients, weakness starts in the muscles supplied by the cranial nerves, and difficulty in talking, swallowing, and ultimately breathing occurs. When the patient ingests liquids, soft palate and upper esophageal weakness cause the liquid to be regurgitated through the nose. Weakness of the posterior tongue and palate impairs the ability to laugh, cough, or even blow the nose. If bulbar muscles are impaired, speaking and swallowing are progressively difficult, and aspiration becomes a risk. The voice assumes a nasal sound, and articulation becomes so disrupted that speech is unintelligible. Some emotional lability may be present. It was traditionally believed that ALS spared cognitive function, but it is now recognized that some patients experience cognitive impairment.

The prognosis generally is based on the area of CNS involvement and the speed with which the disease progresses. Eventually, respiratory function is compromised. Death usually occurs as a result of infection, respiratory insufficiency, or aspiration.

Assessment and Diagnostic Findings

ALS is diagnosed on the basis of the signs and symptoms, because no clinical or laboratory tests are specific to this disease. Electromyography and muscle biopsy studies of the affected muscles indicate reduction in the number of functioning motor units. An MRI scan may show high signal intensity in the corticospinal tracts; this differentiates ALS from a multifocal motor neuropathy. Neuropsychological testing can assist in assessment and diagnosis (Hickey, 2014).

Management

No cure exists for ALS. The main focus of medical and nursing management is on interventions to maintain or improve function, well-being, and quality of life. Because ALS is a progressive disease, the therapeutic needs are different than those of patients with acute processes (Majmuder, Wu, & Pagnoni, 2014).

Riluzole (Rilutek), a glutamate antagonist, has been shown to prolong survival for persons with ALS for 3 to 6 months (Hickey, 2014). The action of riluzole is not clear, but its pharmacologic properties suggest that it may have a neuroprotective effect in the early stages of ALS. Symptomatic treatment and rehabilitative measures are used to support the patient and improve the quality of life. Baclofen (Lioresal), dantrolene sodium (Dantrium), or diazepam (Valium) may be useful for patients troubled by spasticity, which causes pain and interferes with self-care. Modafinil (Provigil) may be used for fatigue, and additional medications may be added to manage the pain, depression, drooling, and constipation that often accompany the disease. Research suggests that greater functional impairment is associated with greater depressive symptoms; consequently, managing depression helps to maintain a better quality of life (Rosengren, Gustafusson, & Jarnevi, 2015). Ongoing research for treatment options include neural transplantation (Carletti, Rispoli, DiChirico, et al., 2016).

Most patients with ALS are managed at home and in the community, with hospitalization for acute problems. The most common reasons for hospitalization are dehydration and malnutrition, pneumonia, and respiratory failure; recognizing these problems at an early stage in the illness allows for the development of preventive strategies. End-of-life issues include pain, dyspnea, and delirium (Hickey, 2014).

Mechanical ventilation (using negative-pressure ventilators) is an option if alveolar hypoventilation develops. Noninvasive positive-pressure ventilation is also an option. The use of noninvasive positive-pressure ventilation is particularly helpful at night and postpones the decision about whether to undergo a tracheotomy for long-term mechanical ventilation (Rabinstein, 2016). A patient experiencing aspiration and swallowing difficulties may require enteral feeding. A PEG tube is inserted before the forced vital capacity drops below 50% of the predicted value. The tube can be safely placed in patients who are using noninvasive positive-pressure ventilation for ventilatory support (Hickey, 2014); (ProGas Study Group, 2015).

Decisions about life support measures are made by the patient and family and should be based on a thorough understanding of the disease, the prognosis, and the implications of initiating such therapy. Patients are encouraged to complete an advance directive ("living will") to preserve their autonomy in decision making. See Chapter 59 for additional discussion of end-of-life care.

The ALS Association has broad programs of research funding, patient and clinical services, patient information and support, and medical and public information (see the Resources section). The *ALS Association Newsletter* is a source of practical information.

Muscular Dystrophies

The muscular dystrophies are a group of incurable muscle disorders characterized by progressive weakening and wasting of the skeletal or voluntary muscles with 30 different types to date. Most of these diseases are inherited. Duchenne muscular dystrophy, the most common and severe type, occurs in 1 of every 3500 male births (Bader et al., 2016).

The prevalence of muscular dystrophies in India is about 29 per 100,000 population (Duraiswamy, 2009).

The pathologic features include degeneration and loss of muscle fibers, variation in muscle fiber size, phagocytosis and regeneration, and replacement of muscle tissue by connective tissue. The common characteristics of these diseases include varying degrees of muscle wasting and weakness and abnormal elevation in serum levels of muscle enzymes. Differences among these diseases center on the genetic pattern of inheritance, the muscles involved, the age at onset, and the rate of disease progression. The symptoms can be diverse and may include muscle stiffness or weakness, dysphagia, mental deficits, vision, or infertility. Prognosis depends on the type of muscular dystrophy. Regardless of age of onset, this disease varies in progression (Dalton & Sampson, 2015). The unique needs of these patients, who in the past did not live to adulthood, must be addressed, considering they live longer because of better supportive care.

Medical Management

Treatment of the muscular dystrophies focuses on supportive care and prevention of complications in the absence of a cure or specific

pharmacologic interventions (Kang, Morrison, Iannaccone, et al., 2015). The goal of supportive management is to keep the patient active and functioning as normally as possible and to minimize functional deterioration. An individualized therapeutic exercise program is prescribed to prevent muscle tightness, contractures, and disuse atrophy. Night splints and stretching exercises are used to delay contractures of the joints, especially the ankles, knees, and hips. Braces may compensate for muscle weakness.

Spinal deformity is a severe problem. Weakness of trunk muscles and spinal collapse occur almost routinely in patients with severe neuromuscular disease. To help prevent spinal deformity, the patient is fitted with an orthotic jacket to improve sitting stability and reduce trunk deformity. This measure also supports cardiovascular status. In time, spinal fusion is performed to maintain spinal stability. Other procedures may be carried out to correct deformities.

Compromised pulmonary function may result either from progression of the disease or from deformity of the thorax secondary to severe scoliosis. Upper respiratory infections and fractures from falls must be vigorously treated in a way that minimizes immobilization because joint contractures become worse when the patient's activities are more restricted than usual.

Other difficulties may manifest in relation to the underlying disease. Weakness of the facial muscles makes it difficult to attend to dental hygiene and to speak clearly, and impairs the ability to swallow safely (LaDonna, Koopman, Ray, et al., 2016). Gastrointestinal tract problems may include gastric dilation, rectal prolapse, and fecal impaction. Finally, cardiomyopathy appears to be a common complication in all forms of muscular dystrophy.

Ongoing research is improving the clinical course and survival opportunities. Some research targets specific gene mutations, while other studies deal with the effects of muscle degeneration (Mercuri & Muntoni, 2013). Genetic counseling is advised for parents and siblings of the patient because of the genetic nature of this disease.

Nursing Management

The goals of the patient and the nurse are to maintain function at optimal levels and to enhance the quality of life. Therefore, the patient's physical requirements, which are considerable, are addressed without losing sight of emotional and developmental needs. The patient and family are actively involved in decision making, including end-of-life decisions (see Chapter 59).

During hospitalization for treatment of complications, the knowledge and expertise of the patient and family members responsible for caregiving in the home are assessed. Because the patient and family caregivers often have developed caregiving strategies that work effectively for them, these strategies need to be acknowledged and accepted, and provisions must be made to ensure that they are maintained during hospitalization (Piredda, Matarese, & Mastroianni, 2015).

Families of adolescents and young adults with muscular dystrophy need assistance to shift the focus of care from pediatric to adult care and to understand the usual disease course. Nursing goals include assisting the adolescent to make the transition to adult values and expectations while providing age-appropriate ongoing care. The nurse may need to help build the confidence of an older adolescent or adult patient by encouraging him or her to pursue job training to become economically independent. Other nursing interventions might include guidance in accessing adult health care and finding appropriate programs in sex education.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

Management goals are addressed in special rehabilitation programs or in the patient's home and community. Therefore, the patient and family require information and instruction about the disorder, its anticipated course, and care and management strategies that will optimize the patient's growth and development and physical and psychological status. Members of a variety of health-related disciplines are involved in patient and family education; recommendations are communicated to all members of the health care team so that they may work toward common goals.

Continuing and Transitional Care

Both the neuromuscular disease and the associated deformities may progress in adolescence and adulthood. Self-help and assistive devices can aid in maintaining maximum independence. These devices, recommended by physical and occupational therapists, often become necessary as more muscle groups are affected.

The family is instructed to monitor the patient for respiratory problems, because respiratory infection and cardiac failure are the most common causes of death. As respiratory difficulties develop, patients and their families need information regarding respiratory support. Options currently exist that can provide ventilatory support (e.g., negative-pressure devices, positive-pressure ventilators) while allowing mobility (Dalton & Sampson, 2015); (Rabinstein, 2016). Patients can remain relatively independent in a wheelchair, for example, while being maintained on a ventilator at home for many years.

The patient is encouraged to continue with range-of-motion exercises to prevent contractures, which are particularly disabling. Practical adaptations must be made, however, to cope with the effects of chronic neuromuscular disability. The patient at various stages of the disease may require a manual or an electric wheelchair, gait aids, upper and lower extremity and spinal orthotics, seating systems, bathroom equipment, lifts, ramps, and additional assistive devices, all of which require a team approach. The nurse assesses how the patient and family are managing, makes referrals, and coordinates the activities of the physical therapist, occupational therapist, and social services.

The patient is greatly concerned about issues surrounding the threat of increasing disability and dependence on others, accompanied by a significant deterioration in health-related quality of life. The patient is faced with a progressive loss of function, leading eventually to death. Feelings of helplessness and powerlessness are common. Each functional loss is accompanied by grief and mourning. The patient and family are assessed for depression, anger, or denial. The patient and family are assisted and encouraged to address decisions about end-of-life options before their need arises (see Chapter 59).

A psychiatric nurse clinician or other mental health professional may assist the patient to cope and adapt to the disease. By understanding and addressing clinical concerns that are important for patients and their families, while at the same time assessing caregiver knowledge and burden during every encounter, the nurse provides a hopeful, supportive, and nurturing environment (LaDonna et al., 2016). One study reported that adult patients' illness perceptions are directly connected to their quality of life in muscular dystrophy, and these perceptions influence their overall mood (Graham, Weinman, Sadjadi, et al., 2014).

Degenerative Disc Disease

Low back pain is the second most common neurologic disorder in the United States, with one quarter of all adults reporting recent (within 3 months) back pain (Hickey, 2014). It is frequently associated with depression and anxiety, and it is the most common reason for missed work and decreased productivity while at work. An estimated 500,000 spinal surgeries for herniated discs, stenosis, and degenerative changes were performed in 2010 in the United States. Low back pain results in significant economic costs to patients, their families, and society. Acute pain lasts less than 3 months (see Chart 37-2 in Chapter 37), whereas chronic pain has a duration of 3 months or longer. Most back problems are related to disc disease (Bader et al., 2016).

Different individual studies reported a wide variation in the prevalence of low back pain among Indians; prevalence in selected population was as high as 50% in National Capital Region (Bihari, Kesavachandran, Pangtey, et al., 2011), to 34.2% in Pune (Banerjee, Jadhav, & Bhawalkar, et al., 2012), 17.3% in Western India (Chopra, Patil, Billempelly, et al., 2001), and 6.2% in Jodhpur (Haldiya, Mathur, Mathur, et al., 2009).

Pathophysiology

The intervertebral disc is a cartilaginous plate that forms a cushion between the vertebral bodies (see Fig. 53-10A). This tough, fibrous material is incorporated in a capsule. A ball-like cushion in the center of the disc is called the *nucleus pulposus.* In herniation of the intervertebral disc (ruptured disc), the nucleus of the disc protrudes into the annulus (the fibrous ring around the disc), with subsequent nerve compression (Hickey, 2014). Protrusion or rupture of the nucleus pulposus usually is preceded by degenerative changes that occur with aging. Loss of protein polysaccharides in the disc decreases the water content of the nucleus pulposus. The development of radiating cracks in the annulus weakens resistance to nucleus herniation. After trauma (falls and repeated minor stresses such as lifting incorrectly), the cartilage may be injured. A brief pathophysiology of degenerative disc disease is presented in Figure 53-11.

For most patients, the immediate symptoms of trauma are short-lived, and those resulting from injury to the disc do not appear for months or years. Disc degeneration pushes the capsule back into the spinal canal. It could also rupture and allow the nucleus pulposus to be pushed back against the dural sac or against a spinal nerve as it emerges from the spinal column (see Fig. 53-10B). This disease of the spinal root, produces pain and extreme sensitivity to touch due to radiculopathy (pressure in the area of distribution of the involved nerve endings). Continued pressure may produce degenerative changes in the involved nerve, such as changes in sensation and deep tendon reflexes.

Clinical Manifestations

A herniated disc with accompanying pain may occur in any portion of the spine: cervical, thoracic (rare), or lumbar. The clinical manifestations depend on the location, the rate of development (acute or chronic), and the effect on the surrounding structures.

Assessment and Diagnostic Findings

A thorough health history and physical examination are important to rule out potentially serious conditions that may manifest as low back pain, including fracture, tumor, infection, or cauda equina syndrome (Hickey, 2014).

The MRI scan has become the diagnostic tool of choice for localizing even small disc protrusions, particularly for lumbar spine disease. If the clinical symptoms are not consistent with the pathology seen on MRI, CT scanning and myelography are performed. A neurologic examination is carried out to determine whether reflex, sensory, or motor impairment from root compression is present and to provide a baseline for future assessment. Electromyography may be used to localize the specific spinal nerve roots involved.

Medical Management

Herniations of the cervical and the lumbar discs occur most commonly and are usually managed conservatively with medication and physical therapy or exercise (Hickey, 2014). Surgery is sometimes necessary.

Surgical Management

Surgical excision of a herniated disc is performed if there is evidence of a progressing neurologic deficit (muscle weakness and atrophy, loss of sensory and motor function, loss of sphincter control) and radicular pain (pain that follows the

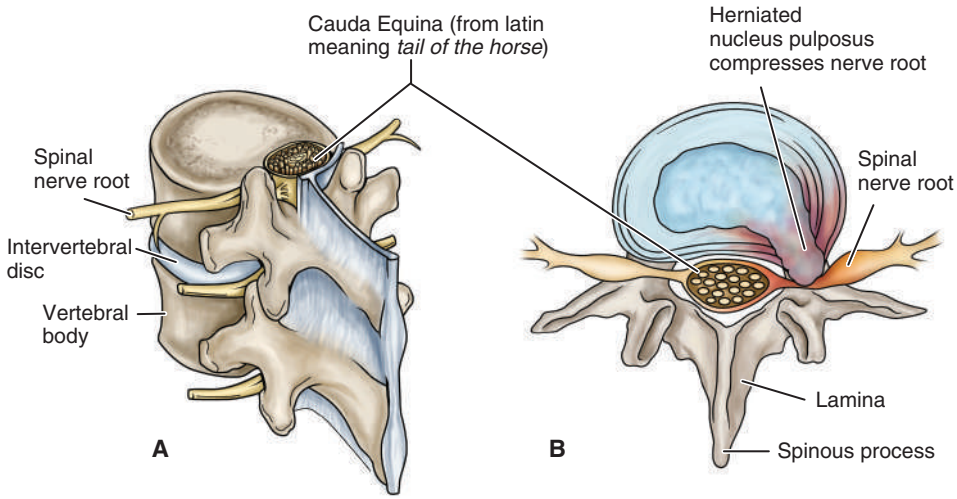

Figure 53-10 • A. Normal lumbar spine vertebrae, intervertebral discs, and spinal nerve root. **B.** Ruptured vertebral disc.

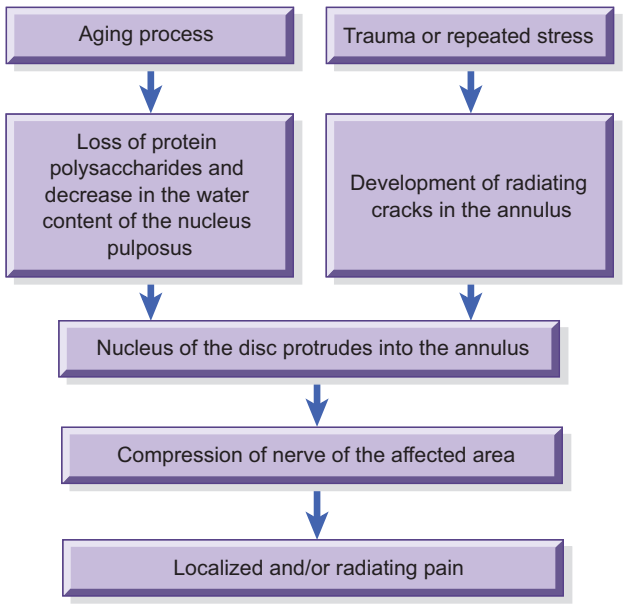

Figure 53-11 • Pathophysiology of degenerative disc disease.

dermatomal distribution [see Fig. 48-9 in Chapter 48] of the compressed nerve) that are unresponsive to conservative management. The goal of surgical treatment is to reduce the pressure on the nerve root to relieve pain and reverse neurologic deficits. Microsurgical techniques make it possible to remove only the amount of tissue that is necessary, which preserves the integrity of normal tissue better and imposes less trauma on the body. During these procedures, spinal cord function can be monitored electrophysiologically.

Some of the surgical techniques available include:

- *Microdiscectomy*: Removal of herniated or extruded fragments of intervertebral disc material
- *Laminectomy*: Removal of the bone between the spinal process and facet pedicle junction to expose the neural elements in the spinal canal (Hickey, 2014); this allows the surgeon to inspect the spinal canal, identify and remove pathologic tissue, and relieve compression of the cord and roots
- *Hemilaminectomy*: Removal of part of the lamina and part of the posterior arch of the vertebra
- *Partial laminectomy or laminotomy*: Creation of a hole in the lamina of a vertebra
- *Discectomy with fusion*: Fusion of the vertebral spinous process with a bone graft (from iliac crest or bone bank), with the object of spinal fusion being to bridge over the defective disc to stabilize the spine and reduce the rate of recurrence
- *Foraminotomy*: Removal of the intervertebral foramen to increase the space for exit of a spinal nerve, resulting in reduced pain, compression, and edema

Herniation of a Cervical Intervertebral Disc

The cervical spine is subjected to stresses that result from disc degeneration (due to aging, occupational stresses) and spondylosis (degenerative changes occurring in a disc and adjacent vertebral bodies). Cervical disc degeneration may lead to lesions that can cause damage to the spinal cord and its roots (Bader et al., 2016).

Clinical Manifestations

A cervical disc herniation usually occurs at the C5–C6 or C6–C7 interspaces and compresses a unilateral nerve root (Bader et al., 2016). Pain and stiffness may occur in the neck, the top of the shoulders, and the region of the scapulae. Patients sometimes interpret these signs as symptoms of heart trouble or bursitis. Pain may also occur in the arm and hand, accompanied by paresthesia (numbness, tingling, or a "pins and needles" sensation) of the upper extremity. Cervical MRI usually confirms the diagnosis. Occasionally, the disc herniates centrally onto the spinal cord, causing Lhermitte syndrome, an electriclike shock sensation in the extremities or spine with neck flexion or straining, and bilateral arm and leg weakness (myelopathy).

Medical Management

The goals of treatment are to rest and immobilize the cervical spine to give the soft tissues time to heal and to reduce inflammation in the supporting tissues and the affected nerve roots in the cervical spine (Hickey, 2014). It also reduces inflammation and edema in soft tissues around the disc, relieving pressure on the nerve roots. Proper positioning on a firm mattress may bring dramatic relief from pain.

The cervical spine may be rested and immobilized by a cervical collar, cervical traction, or a brace. A collar allows maximal opening of the intervertebral foramina and holds the head in a neutral or slightly flexed position. The patient may have to wear the collar 24 hours a day during the acute phase. The skin under the collar is inspected for irritation. After the patient is free of pain, cervical isometric exercises are started to strengthen the neck muscles.

Pharmacologic Therapy

Analgesic agents (nonsteroidal anti-inflammatory agents [NSAIDs], acetaminophen (paracetamol)/oxycodone [Tylox], or acetaminophen (paracetamol)/hydrocodone [Vicodin]) are prescribed during the acute phase to relieve pain, and sedative agents may be given to control the anxiety that is often associated with cervical disc disease. Muscle relaxants (cyclobenzaprine [Flexeril], methocarbamol [Robaxin], metaxalone [Skelaxin]) are given to interrupt muscle spasm and to promote comfort. NSAIDs (aspirin, ibuprofen [Motrin, Advil], naproxen [Naprosyn, Anaprox]) or corticosteroids are prescribed to treat the inflammation and swelling that usually occurs in the affected nerve roots and supporting tissues. Occasionally, a corticosteroid is injected into the epidural space for relief of radicular (spinal nerve root) pain. NSAIDs are given with food to prevent gastrointestinal irritation (Comerford, 2015). Hot, moist compresses (for 10 to 20 minutes) applied to the back of the neck several times daily increase blood flow to the muscles and help relax the patient and reduce muscle spasm. Nonpharmacologic interventions such as guided imagery, biofeedback, and relaxation provide relief as well (Abdulla, Adams, Bone, et al., 2013).

Surgical Management

Surgical excision of the herniated disc may be necessary if there is a significant neurologic deficit, progression of the deficit, evidence of cord compression, or pain that either worsens or fails to improve. A cervical discectomy, with or without fusion, may be performed to alleviate symptoms. An anterior surgical approach may be used through a transverse incision to remove disc material that has herniated into the spinal canal and foramina, or a posterior approach may be

used at the appropriate level of the cervical spine. Potential complications with the anterior approach include carotid or vertebral artery injury, recurrent laryngeal nerve dysfunction, esophageal perforation, and airway obstruction (Hickey, 2014). Complications of the posterior approach include damage to the nerve root or the spinal cord due to retraction or contusion of either of these structures, resulting in weakness of muscles supplied by the nerve root or cord.

Microsurgery, such as endoscopic microdiscectomy, may be performed in selected patients through a small incision, using magnification techniques. This usually results in less tissue trauma and pain, and patients consequently have a shorter length of hospital stay compared with those who have conventional surgery (Hickey, 2014).

NURSING PROCESS

The Patient Undergoing a Cervical Discectomy

Assessment

The patient is asked about past injuries to the neck (whiplash), because unresolved trauma can cause persistent discomfort, pain and tenderness, and symptoms of arthritis in the injured joint of the cervical spine. Assessment includes determining the onset, location, and radiation of pain and assessing for paresthesias, limited movement, and diminished function of the neck, shoulders, and upper extremities. It is important to determine whether the symptoms are bilateral; with large herniations, bilateral symptoms may be caused by cord compression. The area around the cervical spine is palpated to assess muscle tone and tenderness. Range of motion in the neck and shoulders is evaluated.

The patient is asked about any health issues that may influence the postoperative course and quality of life. It is also important to assess mood and stress levels. The nurse determines the patient's need for information about the surgical procedure and reinforces what the primary provider has explained. Strategies for pain management are discussed with the patient (Hickey, 2014).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Acute pain related to the surgical procedure
- Impaired physical mobility related to the postoperative surgical regimen
- Deficient knowledge about the postoperative course and home care management

Other nursing diagnoses may include preoperative anxiety, postoperative constipation, urinary retention related to the surgical procedure, self-care deficits related to use of a neck orthosis, and sleep pattern disturbance related to disruption in lifestyle.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hematoma at the surgical site, resulting in cord compression and neurologic deficit
- Recurrent or persistent pain after surgery

Planning and Goals

The goals for the patient may include relief of pain, improved mobility, increased knowledge and self-care ability, and prevention of complications.

Nursing Interventions

Relieving Pain

Incisional pain is expected. Radicular pain improves over time as the nerve recovers. If the patient has had a bone fusion with bone removed from the iliac crest, considerable pain may be experienced at the donor site. Interventions consist of monitoring the donor site for hematoma formation, administering the prescribed postoperative analgesic agent, positioning for comfort, and reassuring the patient that the pain can be relieved. If the patient experiences a sudden increase in pain, extrusion of the graft may have occurred, requiring reoperation. A sudden increase in pain should be promptly reported to the surgeon (Hickey, 2014).

The patient may experience a sore throat, hoarseness, and dysphagia due to temporary edema. These symptoms are relieved by throat lozenges, voice rest, and humidification. A pureed diet may be given if the patient has dysphagia.

Improving Mobility

Postoperatively, a cervical collar (neck orthosis) may be worn, which contributes to limited neck motion and altered mobility. The patient is instructed to turn the body instead of the neck when looking from side to side. The neck should be kept in a neutral (midline) position. The patient is assisted during position changes to make sure that the head, shoulders, and thorax are kept aligned. When assisting the patient to a sitting position, the nurse supports the patient's neck and shoulders. To increase stability, the patient should wear shoes when ambulating. The patient is encouraged not to lift more than 4.5 kg.

Monitoring and Managing Potential Complications

The patient is evaluated for bleeding and hematoma formation by assessing for swelling, excessive pressure in the neck, or severe pain in the incision area. The dressing is inspected for serosanguineous drainage, which suggests a dural leak. If this occurs, meningitis is a threat. A complaint of headache requires careful evaluation. Neurologic checks are made for swallowing deficits and upper and lower extremity weakness, because cord compression may produce rapid or delayed onset of paralysis (Hickey, 2014). The patient who has had an anterior cervical discectomy is also assessed for a sudden return of radicular (spinal nerve root) pain, which may indicate instability of the spine (AANN, 2014c).

Throughout the postoperative course, the patient is monitored frequently to detect any signs of respiratory difficulty, because retractors used during surgery may injure the recurrent laryngeal nerve, resulting in hoarseness and the inability to cough effectively and clear pulmonary secretions. In addition, the blood pressure and pulse are monitored to evaluate cardiovascular status and optimal circulation to the surgical site.

Bleeding at the surgical site and subsequent hematoma formation may occur. Severe localized pain not relieved by analgesic agents should be reported. A change in neurologic status (motor or sensory function) should be reported promptly, because it suggests hematoma formation that may necessitate surgery to prevent irreversible motor and sensory deficits (Hickey, 2014).

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The patient's length of hospital stay is likely to be short; therefore, the patient and family should understand the care that is important for a smooth recovery. A cervical collar, if prescribed, is usually worn for about 6 weeks. The patient is educated in the use and care of the cervical collar. The patient will need to alternate tasks that

involve minimal body movement (e.g., reading) with tasks that require greater body movement.

The patient is educated about strategies to manage the incision and to manage pain, and about signs and symptoms that may indicate complications that should be reported to the primary provider. The nurse assesses the patient's understanding of these management strategies, limitations, and recommendations. In addition, the nurse assists the patient in identifying strategies to cope with ADLs (e.g., self-care, child care) and minimize risks to the surgical site (see Chart 53-6). A discharge educational plan is developed collaboratively by members of the health care team to decrease the risk of recurrent disc herniation. Topics include those previously discussed as well as proper body mechanics, maintenance of optimal weight, proper exercise techniques, and modifications in activity.

Continuing and Transitional Care. The patient is instructed to see the primary provider at prescribed intervals so that the provider can document the disappearance of old symptoms and assess the range of motion of the neck. Recurrent or persistent pain may occur despite removal of the offending disc or disc fragments. Patients who undergo discectomy usually have consented to surgery after prolonged pain; they have often undergone repeated courses of ineffective conservative management and previous surgeries to relieve the pain. Therefore, the recurrence or persistence of symptoms postoperatively, including pain and sensory deficits, is often discouraging for the patient and family. The patient who experiences recurrence of symptoms requires emotional support and understanding. In addition, the patient is assisted in modifying activities and in considering options for subsequent treatment. The nurse educates the patient and family members about the need to participate in health-promotion and health-screening practices.

Evaluation

Expected patient outcomes may include:

1. Reports decreasing frequency and severity of pain
2. Demonstrates improved mobility
   a. Demonstrates progressive participation in self-care activities
   b. Identifies prescribed activity limitations and restrictions
   c. Demonstrates proper body mechanics
3. Is knowledgeable about postoperative course, medications, and home care management
   a. Lists the signs and symptoms to be reported postoperatively
   b. Identifies dose, action, and potential side effects of medications
   c. Identifies appropriate home care management activities and any restrictions
4. Has absence of complications
   a. Reports no increase in incision pain or sensory symptoms
   b. Demonstrates normal findings on neurologic assessment

Chart 53-6 HOME CARE CHECKLIST

The Patient with Cervical Discectomy and Cervical Collar

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in adapting to any permanent changes in structure or function to promote safety and optimum functioning.
  - Use adequate mattress and chair support.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Describe nonpharmacologic interventions for pain relief used in conjunction to prescribed pain relief preparations.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, and durable medical equipment and supply vendor).
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., exercises) and to limit or avoid (e.g., lifting, stair climbing, driving a car) during rehabilitation.
- Describe care for the surgical incision site.
  - Keep staples or sutures clean and dry and cover with dry dressing.
- Demonstrate proper body mechanics and prescribed exercise techniques.
  - Describe how to modify activity for optimum functioning.
  - Avoid sitting or standing for more than 30 minutes.
  - Avoid twisting, flexing, extending, or rotating the neck.
  - Avoid sleeping in a prone position or the use of pillows to minimize neck flexion in bed; keep head in a neutral position.
  - Wear low-heeled shoes.
  - Place a wrinkle-free silk scarf under the collar to increase comfort.
  - **For men**: Shave without twisting or moving the neck. This may be done with help while lying flat or sitting. Remove only the front part of the collar for shaving.
- Practice stress reduction and relaxation techniques.
- Care of the cervical collar:
  - Wear the collar at all times until directed otherwise by the primary provider.
  - Wash the neck under the collar twice a day with mild soap.
  - Keep the neck still while the collar is open.
  - With the assistance of a helper, wash the neck in steps.
  - Lie flat and supine.
  - Open the Velcro tabs on each side of the collar and remove its front portion.
  - Gently wash and dry the neck.
  - Replace the front part of the collar and refasten the tabs.
  - Turn to one side with a thin pillow under the head.
  - Open one tab.
  - Gently wash and dry the back of the neck. Refasten the tab.
  - Turn to the other side and wash and dry this side. Refasten the tab.
- Notify primary provider if any signs or symptoms of infection occur, such as fever, redness or irritation, drainage, increased pain.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, faith community, support groups, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

Herniation of a Lumbar Disc

Most lumbar disc herniations occur at the L5–S1 region (AANN, 2014d). A herniated lumbar disc produces low back pain accompanied by varying degrees of sensory and motor impairment.

Clinical Manifestations

The patient complains of low back pain with muscle spasm and sciatica (pain and tenderness that radiates along the sciatic nerve that runs through the thigh and leg). Pain is aggravated by actions that increase intraspinal fluid pressure, such as bending, lifting, or straining (as in sneezing or coughing), and usually is relieved by bed rest. There is often some type of postural deformity, because pain causes an alteration of the normal spinal mechanics. If the patient lies on the back and attempts to raise a leg in a straight position, pain radiates into the leg; this maneuver, called the *straight-leg raising test,* stretches the sciatic nerve. Additional signs include muscle weakness, alterations in tendon reflexes, and sensory loss.

Assessment and Diagnostic Findings

The diagnosis of lumbar disc disease is based on the history and physical findings, specifically the location, quality, severity of pain, and the use of imaging techniques such as MRI and CT scans as well as myelography.

Medical Management

The objectives of treatment are to relieve pain, slow disease progression, and increase the patient's functional ability (AANN, 2014d). Bed rest is discouraged because it may weaken muscles, but activities that exacerbate pain should be avoided.

Because muscle spasm is prominent during the acute phase, muscle relaxants are used. NSAIDs and systemic corticosteroids may be given to counter the inflammation and swelling that usually occurs in the supporting tissues and the affected nerve roots. Moist heat and massage help relax muscles. Strategies for increasing the patient's functional ability include weight reduction, physical therapy, and biofeedback. Exercises, prescribed by physical therapists, can help strengthen back muscles and decrease pain (Hickey, 2014). See Chapter 9 for descriptions of nursing interventions for the patient with pain.

Surgical Management

In the lumbar region, surgical treatment includes lumbar disc excision through a posterolateral laminotomy and the techniques of microdiscectomy and percutaneous discectomy. In microdiscectomy, an operating microscope is used to visualize the offending disc and compressed nerve roots; it permits a small incision (2.5 cm [1 inch]) and minimal blood loss and takes about 30 minutes of operating time. In general, the length of hospital stay is short, and the patient makes a rapid recovery. Several minimally invasive techniques in spinal surgery have led to improved patient outcomes and lower hospital costs, and research on these techniques is ongoing. Fusion is considered when vertebral instability is present and contributes to pain. Fusion procedures are longer and cause more postoperative pain. Research suggests that intraoperative wound infiltration with bupivacaine hydrochloride solution decreases pain and the need for opioids postoperatively. Some studies suggest that gel substances for disc replacement may decrease pain and improve spinal function.

A patient undergoing a disc procedure at one level of the vertebral column may have a degenerative process at other levels. A herniation relapse may occur at the same level or elsewhere, so the patient may become a candidate for another disc procedure. Arachnoiditis (inflammation of the arachnoid membrane) may occur after surgery (and after myelography); it involves an insidious onset of diffuse, frequently burning pain in the lower back, radiating into the buttocks. Disc excision can leave adhesions and scarring around the spinal nerves and dura, which then produce inflammatory changes that create chronic neuritis and neurofibrosis. Disc surgery may relieve pressure on the spinal nerves, but it does not reverse the effects of neural injury and scarring and the pain that results. Failed disc syndrome (recurrence of sciatica after lumbar discectomy) remains a cause of disability (Hickey, 2014).

Nursing Management

Providing Preoperative Care

Most patients fear surgery on any part of the spine and therefore need explanations about the surgery and reassurance that it will not weaken the back. When data are being collected for the health history, any reports of pain, paresthesia, or muscle spasm are recorded to provide a baseline for comparison after surgery. Health issues that may influence the postoperative course and quality of life (e.g., fatigue, mood, stress, patient expectations, smoking) are important to assess. Preoperative assessment also includes an evaluation of movement of the extremities as well as bladder and bowel function (Hickey, 2014). To facilitate the postoperative turning procedure, the patient is instructed to turn as a unit (called logrolling) as part of the preoperative preparation (see Fig. 53-12). Before surgery, the patient is also encouraged to take deep breaths, cough, and perform muscle setting exercises to maintain muscle tone.

Figure 53-12 • Before the patient undergoes laminectomy surgery, the logrolling technique that will be used for turning the patient should be demonstrated. The patient's arms will be crossed and the spine aligned. To avoid twisting the spine, the head, shoulders, knees, and hips are turned at the same time so that the patient rolls over like a log. When in a side-lying position, the patient's back, buttocks, and legs are supported with pillows.

Assessing the Patient after Surgery

After lumbar disc excision, vital signs are checked frequently and the wound is inspected for hemorrhage, because vascular injury is a complication of disc surgery. Because postoperative neurologic deficits may occur from nerve root injury, the sensation and motor strength of the lower extremities are evaluated at specified intervals, along with the color and temperature of the legs and sensation of the toes. It is important to assess for urinary retention, which is another sign of neurologic deterioration (AANN, 2014d). In discectomy with fusion, the patient has an additional surgical incision if bone fragments were taken from the iliac crest or fibula to serve as wedges in the spine. The recovery period is longer than for those patients who underwent discectomy with spinal fusion, because bony union must take place.

Positioning the Patient

To position the patient, a pillow is placed under the head, and the knee rest is elevated slightly to relax the back muscles. When the patient is lying on one side, however, extreme knee flexion must be avoided. The patient is encouraged to move from side to side to relieve pressure and is reassured that no injury will result from moving. When the patient is ready to turn, the bed is placed in a flat position and a pillow is placed between the patient's legs. The patient turns as a unit (logrolls) without twisting the back.

To get out of bed, the patient lies on one side while pushing up to a sitting position. At the same time, the nurse or family member eases the patient's legs over the side of the bed. Coming to a sitting or standing posture is accomplished in one long, smooth motion. Most patients walk to the bathroom on the same day as the surgery. Sitting is discouraged except for defecation.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

The patient is instructed to increase activity gradually, as tolerated, because it takes up to 6 weeks for the ligaments to heal. Excessive activity may result in spasm of the paraspinal muscles (Hickey, 2014).

Activities that produce flexion strain on the spine (e.g., driving a car) should be avoided until healing has taken place. Heat may be applied to the back to relax muscle spasms. Scheduled rest periods are important, and the patient is advised to avoid heavy work for 2 to 3 months after surgery. Exercises are prescribed to strengthen the abdominal and erector spinal muscles. A back brace or corset may be necessary if back pain persists.

Continuing and Transitional Care

Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities after medical or surgical treatment for herniation of a lumbar disc. A home care referral may be indicated and provides the nurse with the opportunity to assess the patient's physical and psychological status, as well as their ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief.

Lower back pain can be debilitating and costly. The use of electronic medical records may help physicians identify this earlier so they can develop plans to manage patients differently based on the number of times they seek health care.

Post-Polio Syndrome

Polio has mostly been eradicated globally due to concerted efforts on vaccination. However, people who survived the polio epidemic of the 1950s, many of whom are now older adults, are developing new symptoms of weakness, fatigue, and musculoskeletal pain identified as PPS. This phenomenon, which occurs 30 to 40 years after the polio exposure, affects 25% to 40% of all survivors of polio who were either immediately disabled or who recovered with few or no symptoms (Groce, Banks, & Stein, 2014). Men and women appear to be equally at risk for this condition.

Pathophysiology

The exact cause of PPS is not known, but researchers suspect that with aging or muscle overuse, the neurons not destroyed by the poliovirus continue generating axon sprouts (Woodward, 2014). These new terminal axon sprouts reinnervate the affected muscles after the initial insult but may become more vulnerable as the body ages.

Assessment and Diagnostic Findings

No specific diagnostic test exists for PPS. Clinical diagnosis is made on the basis of the history and physical examination and exclusion of other medical conditions that could be causing the new symptoms. Patients report a history of paralytic poliomyelitis followed by partial or complete recovery of function, with a plateau of function and then the recurrence of symptoms. Signs and symptoms may occur decades after the original onset of poliomyelitis (Woodward, 2014).

Management

No specific medical or surgical treatment is available for this syndrome, and therefore nurses play a pivotal role in the team approach to assisting patients and families in dealing with the symptoms of progressive loss of muscle strength and significant fatigue (McNalley, Yorkston, Jensen, et al., 2015). Pain and weakness may be improved with infusion of intravenous immunoglobulin (Woodward, 2014).

The procedural guideline for managing immunoglobulin therapy is discussed in Procedural Guidelines 53-1.

Other health care professionals who may assist in patient care include physical, occupational, speech, respiratory therapists, social workers, and nurses. Nursing interventions are aimed at maintaining the patient's strength as well as physical, psychological, and social well-being.

The patient needs to plan and coordinate activities to conserve energy and reduce fatigue. Rest periods should be planned and assistive devices used to reduce weakness and fatigue. Important activities should be planned for the morning, because fatigue often increases in the afternoon and evening.

Pain in muscles and joints may be a problem. Nonpharmacologic techniques such as the application of heat and cold are most appropriate, because older patients may not tolerate or may have strong reactions to medications.

Maintaining a balance between adequate nutritional intake and avoiding excess calories that can lead to obesity is a challenge in this group of patients who are sedentary. Pulmonary hygiene and adequate fluid intake can help with airway management. Several interventions can improve sleep, including limiting caffeine intake before bedtime and assessing for nocturia. The patient

Procedural Guidelines 53-1

Managing Immunoglobulin Therapy

Immunoglobulin therapy is an important treatment for a variety of disease states that are characterized by deficient production of antibodies. Immunoglobulin can be administered for replacement therapy as an IV infusion or subcutaneous (SQ) injection. It can safely be administered in outpatient as well as inpatient settings.

Equipment (as Needed)

- Single-use tourniquet
- Single-use scissors or clippers for hair removal
- IVIG solution, tubing, connector, catheter, or syringe
- Chlorhexidine gluconate, povidone–iodine, or alcohol swabs
- Nonlatex gloves
- Transparent dressing, bandage, or sterile gauze
- Padded, appropriate-length arm board
- Tape
- Topical analgesics
- Preservative-free 0.9% NaCl flush solution
- Padded, appropriate-length arm board or finger splint
- Electronic infusion pump

Implementation

Nursing Actions	Rationale
1. Verify prescription for IVIG therapy and identify patient.	1. Serious errors can be avoided by careful checking. Immunoglobulin is supplied in a 5% solution or a lyophilized powder with a reconstituting diluent prepared from Cohn fraction II obtained from pools of 1,000–20,000 donors. Currently, a number of different IV preparations are approved for use and have been shown to be effective and safe by the U.S. Food and Drug Administration. Immunoglobulin can also be administered via SQ injection.
2. Check for allergies (i.e., latex, iodine).	2. Checking for allergies reduces risk of allergic reaction.
3. Explain procedure to patient.	3. Knowledge increases patient comfort and cooperation.
4. Perform hand hygiene, and put on disposable nonlatex gloves.	4. Asepsis is essential to prevent infection. The use of nonlatex gloves prevents exposure of nurse to patient's blood and of patient and nurse to latex.
5. Obtain Ht. and Wt. of patient before treatment.	5. Obtaining Ht. and Wt. helps verify accurate dosing.
6. Assess baseline vital signs before, during, and after treatment.	6. An elevated temperature at the beginning of treatment may be an indication to delay the therapy to avoid misinterpreting this as an adverse reaction.
7. Premedicate with acetaminophen / paracetamol (Tylenol) and diphenhydramine (Benadryl) as prescribed 30 minutes before the start of infusion therapy. Corticosteroids may be prescribed as well.	7. Premedicating may help avert adverse reactions. Corticosteroids may be used to prevent possible severe reactions in patients who are perceived to be at risk.
8. Verify the route and dose of IVIG therapy.	8. IVIG can be administered via the IV or SQ routes. The optimal dose is determined by the patient's response. In most instances, an IV dose of 200–800 mg/kg of body weight is administered every 3–4 weeks to ensure adequate serum levels of immunoglobulin G (IgG).
9. Insert IV cannula or catheter according to Guidelines for Starting a Peripheral Intravenous Infusion, as needed.	9. Patient may need IV access, may have a port or long-term catheter for an IV infusion.
10. Administer the IV infusion at a slow rate, not to exceed 3 mL/min, usually at 100–200 mL/h.	10. Administer according to manufacturer's instructions. Beginning at a slow rate helps minimize adverse reactions.
11. Continually assess the patient for adverse reactions.	11. Be aware of complaints of a tickle or lump in the throat as the precursor to laryngospasm that precedes bronchoconstriction. Caution should be exercised when changing IVIG products, because they are not biologically equivalent. Understand that long-term tolerance of an older IVIG product does not necessarily imply tolerance to a newer product, even if it is technically superior.
12. Stop IV infusion at the first sign of reaction.	12. Initiate the institutional protocol to be followed in an emergent situation. Patients who have an IgA deficiency have IgE antibodies to IgA, which requires administration of plasma or immunoglobulin replacement from IgA-deficient patients. Because all IV immunoglobulin preparations contain some IgA, they may cause an anaphylactic reaction in patients with IgE anti-IgA antibodies.
13. Administer SQ immunoglobulin as orders.	13. The pharmacokinetics of IgG differ when smaller doses are given more frequently, as is commonly done with SQ regimens.

Ht., height; Wt., weight.

Adapted from Cherin, P., Marie, I., Michallet, M., et al. (2016). Management of adverse events in the treatment of patients with immunoglobulin therapy: A review of evidence. Autoimmunity Reviews, 15, 71–81.

may need to be evaluated for obstructive sleep apnea. Supportive ventilation may be appropriate, with continuous positive airway pressure if sleep apnea is a problem (see Chapter 40).

Bone density testing in patients with PPS has revealed low bone mass and osteoporosis. Therefore, the importance of identifying risks, preventing falls, and treating osteoporosis must be discussed with patients and families. Families also need to be made aware of the possibility of changes in individual and family relationships due to the many symptoms of PPS. The nurse also needs to remind patients and family members of the need for health-promotion activities and health screening (Woodward, 2014).

CRITICAL THINKING EXERCISES

1. A 34-year-old woman, working, married, with three children has been newly diagnosed with a spinal cord tumor. Assess and prioritize the patient's physiologic and psychosocial needs. What nursing interventions and actions would you suggest to assist in managing the treatment of and coping with a spinal cord tumor? How would this be different if the patient lives alone?
2. A 65-year-old man is newly diagnosed with ALS. Identify the evidence-based practices for the management of ALS. Describe the evidence base for the practices that you have identified and the criteria used to evaluate the strength of that evidence. Identify the health-promotion activities you would recommend to this patient and the rationale for your recommendations.
3. A 72-year-old woman is admitted for low back pain that radiates down her leg. What are your priorities for providing care for this patient? Give your rationale. What further diagnostic testing is needed? How will your priorities change if the patient is scheduled for back surgery?

CHAPTER

Assessment of Immune Function

54

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the body's general immune responses.
2. Discuss the stages of the immune response.
3. Differentiate between cellular and humoral immune responses.
4. Specify the effects of selected variables on function of the immune system.
5. Use assessment parameters for determining the status of patients' immune function.

GLOSSARY

agglutination: clumping effect occurring when an antibody acts as a cross-link between two antigens
antibody: a protein substance developed by the body in response to and interacting with a specific antigen
antigen: substance that induces the production of antibodies
antigenic determinant: the specific area of an antigen that binds with an antibody combining site and determines the specificity of the antigen–antibody reaction
apoptosis: programmed cell death that results from the digestion of deoxyribonucleic acid by end nucleases
B cells: cells that are important for producing a humoral immune response
cellular immune response: the immune system's third line of defense, involving the attack of pathogens by T cells
complement: series of enzymatic proteins in the serum that, when activated, destroy bacteria and other cells
cytokines: generic term for nonantibody proteins that act as intercellular mediators, as in the generation of immune response
cytotoxic T cells: lymphocytes that lyse cells infected with virus; also play a role in graft rejection
epitope: any component of an antigen molecule that functions as an antigenetic determinant by permitting the attachment of certain antibodies
genetic engineering: emerging technology designed to enable replacement of missing or defective genes
helper T cells: lymphocytes that attack foreign invaders (antigens) directly
humoral immune response: the immune system's second line of defense; often termed the *antibody response*
immune response: the coordinated response of the components of the immune system to a foreign agent or organism
immune system: the collection of organs, cells, tissues, and molecules that mediate the immune response
immunity: the body's specific protective response to a foreign agent or organism; resistance to disease, specifically infectious diseases
immunopathology: study of diseases resulting in dysfunctions within the immune system
immunoregulation: complex system of checks and balances that regulates or controls immune responses
immunosenescence: the gradual deterioration of the immune system brought on by the aging process
interferons: proteins formed when cells are exposed to viral or foreign agents; capable of activating other components of the immune system
lymphokines: substances released by sensitized lymphocytes when they come in contact with specific antigens
memory cells: cells that are responsible for recognizing antigens from previous exposure and mounting an immune response
natural killer (NK) cells: lymphocytes that defend against microorganisms and malignant cells
null lymphocytes: lymphocytes that destroy antigens already coated with the antibody
opsonization: the coating of antigen–antibody molecules with a sticky substance to facilitate phagocytosis
phagocytic cells: cells that engulf, ingest, and destroy foreign bodies or toxins
phagocytic immune response: the immune system's first line of defense, involving white blood cells that have the ability to ingest foreign particles
stem cells: precursors of all blood cells; reside primarily in bone marrow
suppressor T cells: lymphocytes that decrease B-cell activity to a level at which the immune system is compatible with life
T cells: cells that are important for producing a cellular immune response

Introduction

Immunity is the body's specific protective response to a foreign agent or organism. The immune system functions as the body's defense mechanism against invasion and allows a rapid response to foreign substances in a specific manner. Genetic and cellular responses result. Any qualitative or quantitative change in the components of the immune system can produce profound effects on the integrity of the human organism. Immune function is affected by a variety of factors, such as central nervous system integrity; general physical and emotional status; medications; dietary patterns; and the stress of illness, trauma, or surgery. Dysfunctions involving the immune system occur across the lifespan. Many are genetically based; others are acquired. Immune memory is a property of the immune system that provides protection against harmful microbial agents despite the timing of re-exposure to the agent. Tolerance is the mechanism by which the immune system is programmed to eliminate foreign substances such as microbes, toxins, and cellular mutations but maintains the ability to accept self-antigens. Some credence is given to the concept of surveillance, in which the immune system is in a perpetual state of vigilance, screening and rejecting any invader that is

TABLE 54-1 Immune System Disorders

Disorder	Description
Autoimmunity	Normal protective immune response paradoxically turns against or attacks the body, leading to tissue damage
Hypersensitivity	Body produces inappropriate or exaggerated responses to specific antigens
Gammopathies	Overproduction of immunoglobulins
Immune deficiencies	
Primary	Deficiency results from improper development of immune cells or tissues; usually congenital or inherited
Secondary	Deficiency results from some interference with an already developed immune system; usually acquired later in life

recognized as foreign to the host. The term immunopathology refers to the study of diseases that result from dysfunctions within the immune system. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the function of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens (see Table 54-1).

Growing numbers of patients with primary immune deficiencies live to adulthood, and many others acquire immune disorders during their adult years. Thus, nurses in many practice settings need to understand how the immune system functions as well as immunopathologic processes. In addition, knowledge about assessment and care of people with immunologic disorders enables nurses to make appropriate management decisions.

Anatomic and Physiologic Overview

Anatomy of the Immune System

The immune system is composed of an integrated collection of various cell types, each with a designated function in defending against infection and invasion by other organisms. Supporting this system are molecules that are responsible for the interactions, modulations, and regulation of the system. These molecules and cells participate in specific interactions with immunogenic **epitopes** (antigenic determinants) present on foreign materials, initiating a series of actions in a host, including the inflammatory response, the lysis of microbial agents, and the disposal of foreign toxins. The major components of the immune system include central and peripheral organs, tissues, and cells (see Fig. 54-1).

Bone Marrow

The white blood cells (WBCs) involved in immunity are produced in the bone marrow (see Fig. 54-2). Like other blood cells, lymphocytes are generated from stem cells (undifferentiated cells). There are two types of lymphocytes—B lymphocytes (B cells) and T lymphocytes (T cells) (see Fig. 54-3).

Lymphoid Tissues

The spleen, composed of red and white pulp, acts somewhat like a filter. The red pulp is the site where old and injured red blood cells (RBCs) are destroyed. The white pulp contains concentrations of lymphocytes. The lymph nodes, which are

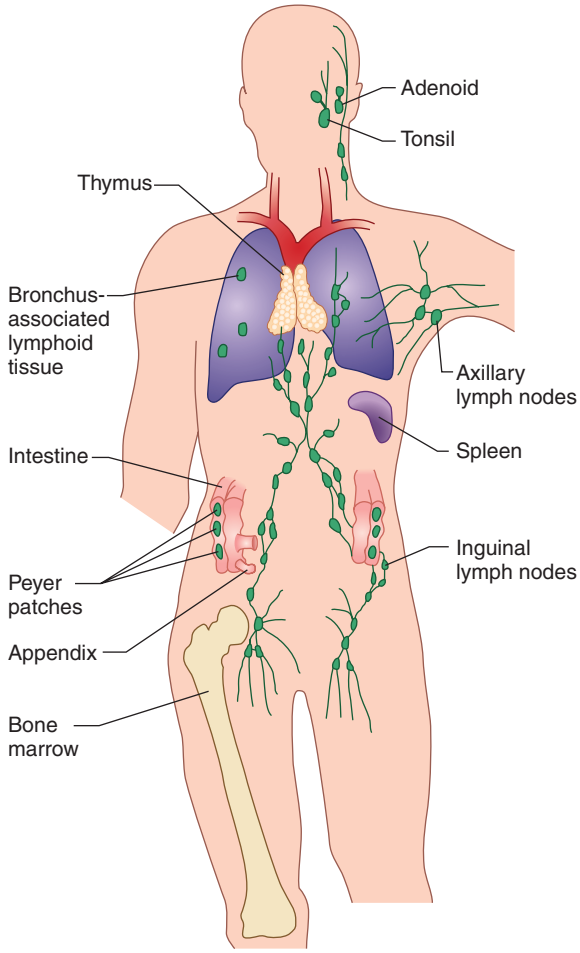

Figure 54-1 • Central and peripheral lymphoid organs, tissues, and cells. Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Physiology/Pathophysiology

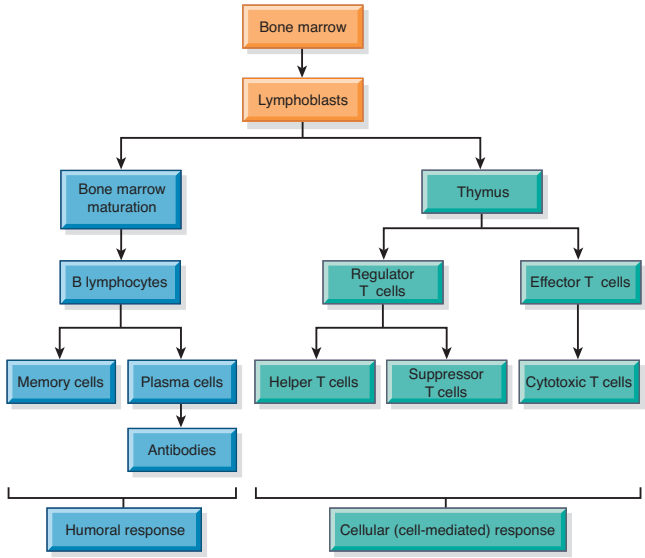

Figure 54-2 • Development of cells of the immune system.

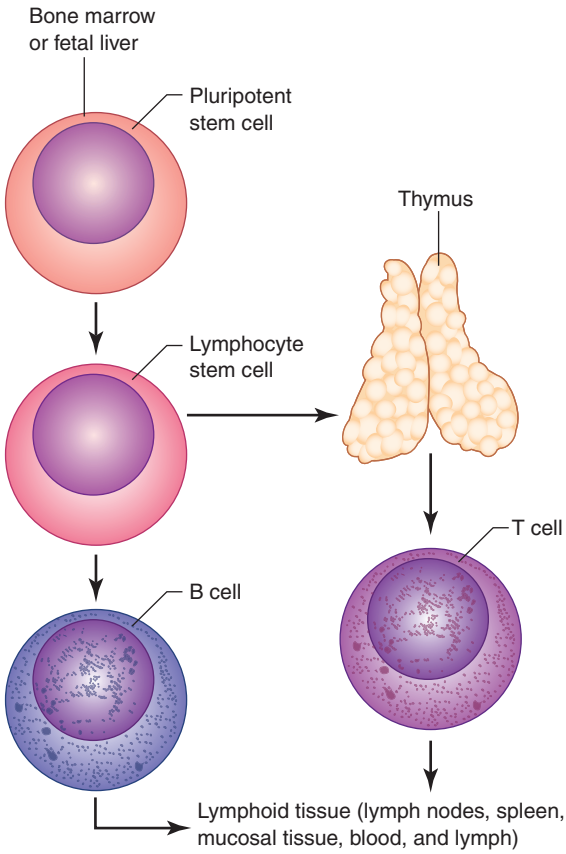

Figure 54-3 • Lymphocytes originate from stem cells in the bone marrow. B lymphocytes mature in the bone marrow before entering the bloodstream, whereas T lymphocytes mature in the thymus, where they also differentiate into cells with various functions. Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

connected by lymph channels and capillaries, are distributed throughout the body. They remove foreign material from the lymph system before it enters the bloodstream. The lymph nodes also serve as centers for immune cell proliferation. The remaining lymphoid tissues contain immune cells that defend the body's mucosal surfaces against microorganisms (McComb, Thiriot, Krishnan, et al., 2013).

Function of the Immune System

The basic function of the immune system is to remove foreign antigens such as viruses and bacteria to maintain homeostasis. There are two general types of immunity: natural (innate) and acquired (adaptive). Natural immunity or nonspecific immunity is present at birth. Acquired or specific immunity develops after birth. Each type of immunity has a distinct role in defending the body against harmful invaders, but the various components are usually interdependent (Levinson, 2014).

Natural Immunity

Natural immunity, which is nonspecific, provides a broad spectrum of defense against and resistance to infection. It is considered the first line of host defense following antigen exposure, because it protects the host without remembering prior contact with an infectious agent (Levinson, 2014). Responses to a foreign invader are very similar from one encounter to the next, regardless of the number of times the invader is encountered. Natural (innate) immunity co-coordinates the initial response to pathogens through the production of cytokines and other effector molecules, which either activate cells for control of the pathogen (by elimination) or promote the development of the acquired immune response. The cells involved in this response are monocytes, macrophages, dendritic cells, natural killer (NK) cells, basophils, eosinophils, and granulocytes. The early events in this process are critical in determining the nature of the adaptive immune response. Natural immune mechanisms can be divided into two stages: immediate (generally occurring within minutes) and delayed (occurring within several days after exposure) (Levinson, 2014).

White Blood Cell Action

The cellular response is the key to the effective initiation of the immune response. WBCs, or leukocytes, participate in both the natural and the acquired immune responses. Granular leukocytes, or granulocytes (so called because of granules in their cytoplasm), fight invasion by foreign bodies or toxins by releasing cell mediators, such as histamine, bradykinin, and prostaglandins, and by engulfing the foreign bodies or toxins. Granulocytes include neutrophils, eosinophils, and basophils.

Neutrophils (polymorphonuclear leukocytes) are the first cells to arrive at the site where inflammation occurs. Eosinophils and basophils, other types of granulocytes, increase in number during allergic reactions and stress responses. Nongranular leukocytes include monocytes or macrophages (referred to as histiocytes when they enter tissue spaces) and lymphocytes. Monocytes are the first to arrive on the scene and function as phagocytic cells, engulfing, ingesting, and destroying greater numbers and quantities of foreign bodies or toxins than granulocytes do. Lymphocytes, consisting of B cells and T cells, play major roles in humoral and cell-mediated immune responses. About 70% to 80% of lymphocytes in the blood are T cells, and about 10% to 15% are B cells (Haynes, Soderberg, & Fauci, 2015).

Inflammatory Response

The inflammatory response is a major function of the natural immune system that is elicited in response to tissue injury or invading organisms. Chemical mediators assist this response by minimizing blood loss, walling off the invading organism, activating phagocytes, and promoting formation of fibrous scar tissue and regeneration of injured tissue. The inflammatory response is facilitated by physical and chemical barriers that are part of the human organism.

Physical and Chemical Barriers

Activation of the natural immunity response is enhanced by processes inherent in physical and chemical barriers. Physical surface barriers include intact skin, mucous membranes, and cilia of the respiratory tract, which prevent pathogens from gaining access to the body. The cilia of the respiratory tract, along with coughing and sneezing responses, filter and clear pathogens from the upper respiratory tract before they can invade the body further. Chemical barriers, such as mucus, acidic gastric secretions, enzymes in tears and saliva, and substances in sebaceous and sweat secretions, act in a nonspecific way to destroy invading bacteria and fungi. Viruses are countered by other means, such as interferon (see discussion later in chapter).

Immune Regulation

Regulation of the immune response involves balance and counterbalance. Dysfunction of the natural immune system can occur when the immune components are inactivated or when they remain active long after their effects are beneficial. A successful immune response eliminates the responsible antigen. If an immune response fails to develop and clear an antigen sufficiently, the host is considered to be immunocompromised or immunodeficient. If the response is overly robust or misdirected, allergies, asthma, or autoimmune disease results. The immune system's recognition of one's own cells or tissues as "foreign" rather than as self is the basis of many autoimmune disorders (Grossman & Porth, 2014). Despite the fact that the immune response is critical to the prevention of disease, it must be well controlled to curtail immunopathology. Most microbial infections induce an inflammatory response mediated by T cells and cytokines, which, in excess, can cause tissue damage (Haynes et al., 2015). Therefore, regulatory mechanisms must be in place to suppress or halt the immune response. This is mainly achieved by the production of cytokines and transformation of growth factor that inhibit macrophage activation. In some cases, T-cell activation is so acute that these mechanisms fail, and pathology develops. Ongoing research on immunoregulation holds the promise of preventing graft rejection and aiding the body in eliminating cancerous or infected cells (Kannan, Madden, & Andrews, 2013); (Lo, Lee, & Powell, 2014).

Although natural immunity can often effectively combat infections, many pathogenic microbes have evolved that resist natural immunity. Acquired immunity is necessary to defend against these resistant agents.

Acquired Immunity

Acquired (adaptive) immunity usually develops as a result of prior exposure to an antigen through immunization (vaccination) or by contracting a disease, both of which generate a protective immune response. Weeks or months after exposure to the disease or vaccine, the body produces an immune response that is sufficient to defend against the disease on re-exposure. In contrast to the rapid but nonspecific natural immune response, this form of immunity relies on the recognition of specific foreign antigens. The acquired immune response is broadly divided into two mechanisms: (1) the cell-mediated response, involving T-cell activation, and (2) effector mechanisms, involving B-cell maturation and production of antibodies (Haynes et al., 2015).

The two types of acquired immunity are known as active and passive and are interrelated. Active acquired immunity refers to immunologic defenses developed by the person's own body. This immunity typically lasts many years or even a lifetime. Passive acquired immunity is temporary immunity transmitted from a source outside the body that has developed immunity through previous disease or immunization. Examples include immunity resulting from the transfer of antibodies from the mother to an infant in utero or through breast-feeding or receiving injections of immune globulin. Active and passive acquired immunity involve humoral and cellular (cell-mediated) immunologic responses (described later).

Response to Invasion

When the body is invaded or attacked by bacteria, viruses, or other pathogens, it has three means of defense:

- The phagocytic immune response
- The humoral or antibody immune response
- The cellular immune response

The first line of defense, the phagocytic immune response, primarily involves the WBCs (granulocytes and macrophages), which have the ability to ingest foreign particles and destroy the invading agent; eosinophils are only weakly phagocytic. Phagocytes also remove the body's own dying or dead cells. Cells in necrotic tissue that are dying release substances that trigger an inflammatory response. Apoptosis, or programmed cell death, is the body's way of destroying worn-out cells such as blood or skin cells or cells that need to be renewed (Grossman & Porth, 2014).

A second protective response, the humoral immune response (sometimes called the ***antibody response***), begins with the B lymphocytes, which can transform themselves into plasma cells that manufacture antibodies. These antibodies are highly specific proteins that are transported in the bloodstream and attempt to disable invaders. The third mechanism of defense, the cellular immune response, also involves the T lymphocytes, which can turn into special cytotoxic (or killer) T cells that can attack the pathogens.

The structural part of the invading or attacking organism that is responsible for stimulating antibody production is called an antigen (or an immunogen). For example, an antigen can be a small patch of proteins on the outer surface of a microorganism. Not all antigens are naturally immunogenic; some must be coupled to other molecules to stimulate the immune response. A single bacterium or large molecule, such as a diphtheria or tetanus toxin, may have several antigens, or markers, on its surface, thus inducing the body to produce a number of different antibodies. Once produced, an antibody is released into the bloodstream and carried to the attacking organism. There, it combines with the antigen, binding with it like an interlocking piece of a jigsaw puzzle (see Fig. 54-4). There are

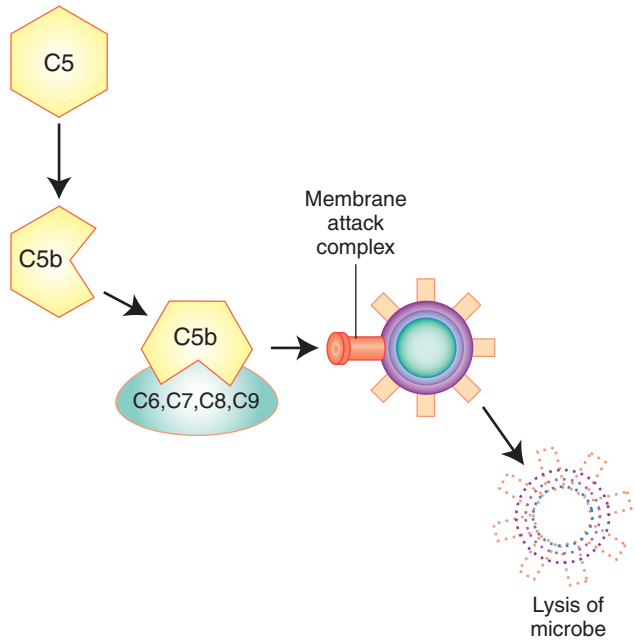

Figure 54-4 • Complement-mediated immune responses. Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

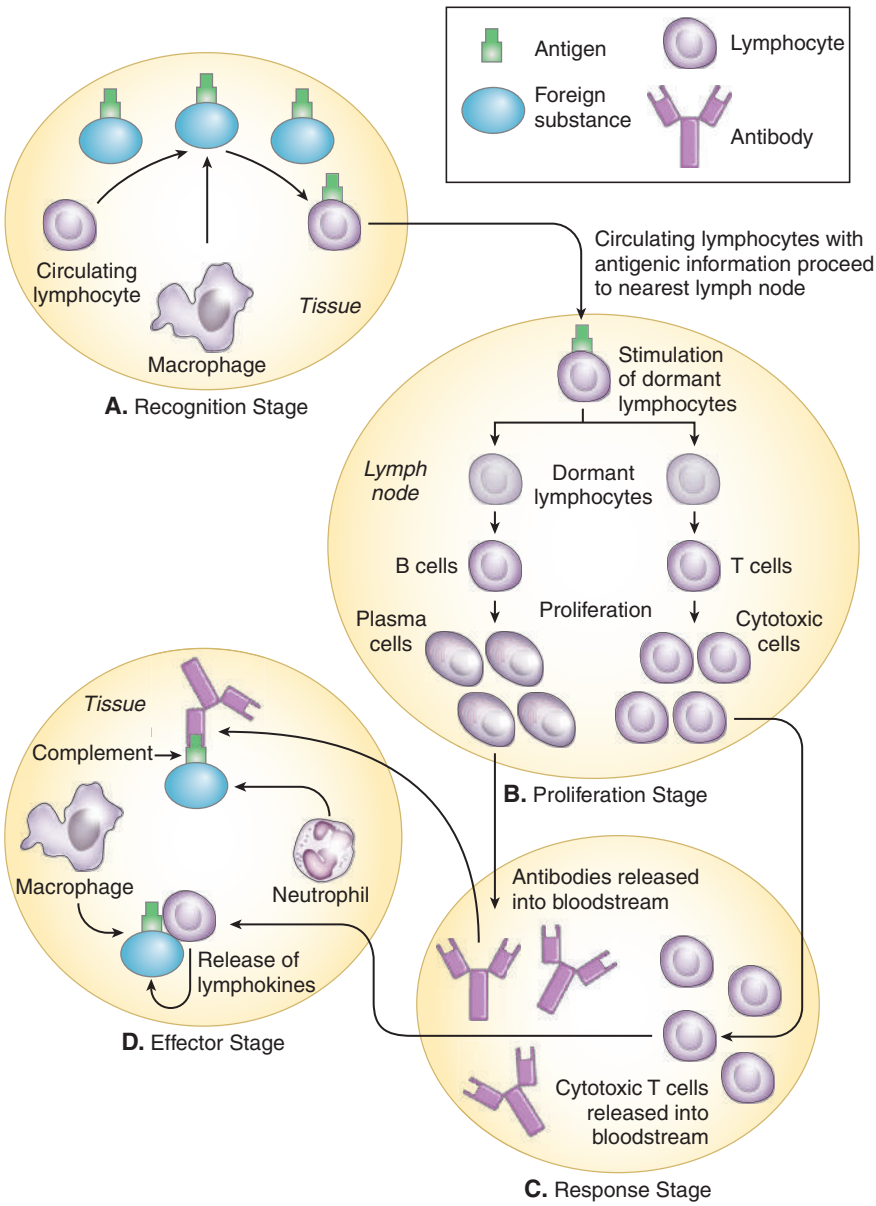

Figure 54-5 • Stages of the immune response. **A.** In the *recognition stage,* antigens are recognized by circulating lymphocytes and macrophages. **B.** In the *proliferation stage,* the dormant lymphocytes proliferate and differentiate into cytotoxic (killer) T cells or B cells responsible for formation and release of antibodies. **C.** In the *response stage,* the cytotoxic T cells and the B cells perform cellular and humoral functions, respectively. **D.** In the *effector stage,* antigens are destroyed or neutralized through the action of antibodies, complement, macrophages, and cytotoxic T cells.

four well-defined stages in an immune response: recognition, proliferation, response, and effector (see Fig. 54-5).

Recognition Stage

Recognition of antigens as foreign, or non-self, by the immune system is the initiating event in any immune response. Recognition involves the use of lymph nodes and lymphocytes for surveillance. Lymph nodes are widely distributed internally throughout the body and in the circulating blood, as well as externally near the body's surfaces. They continuously discharge small lymphocytes into the bloodstream. These lymphocytes patrol the tissues and vessels that drain the areas served by that node. Lymphocytes recirculate from the blood to lymph nodes and from the lymph nodes back into the bloodstream in a continuous circuit. Lymphocytes and other cells have "microbial sensors" that identify molecules on microbes and other microorganisms. The interaction of these sensors with the offending agent sets off a cascade aimed at destroying the microbe (Paul, 2013). Invading organisms have pathogen-associated molecular patterns (PAMPs) contained in their cell membranes that are recognized by the immune system cells. Once the receptors on the immune cells come into contact with the PAMPs, the immune response is triggered (Grossman & Porth, 2014). Macrophages play an important role in helping the circulating lymphocytes process the antigens. Both macrophages and neutrophils have receptors for antibodies and complement; as a result, they coat microorganisms with antibodies, complement, or both, thereby enhancing phagocytosis.

In a streptococcal throat infection, for example, the streptococcal organism gains access to the mucous membranes of the throat. A circulating lymphocyte moving through the tissues of the throat comes in contact with the organism.

The lymphocyte recognizes the antigens on the microbe as different (non-self) and the streptococcal organism as antigenic (foreign). This triggers the second stage of the immune response—proliferation.

Proliferation Stage

The circulating lymphocytes containing the antigenic message return to the nearest lymph node. Once in the node, these sensitized lymphocytes stimulate some of the resident T and B lymphocytes to enlarge, divide, and proliferate. T lymphocytes differentiate into cytotoxic (or killer) T cells, whereas B lymphocytes produce and release antibodies. Enlargement of the lymph nodes in the neck in conjunction with a sore throat is one example of the immune response.

Response Stage

In the response stage, the differentiated lymphocytes function in either a humoral or a cellular capacity. This stage begins with the production of antibodies by the B lymphocytes in response to a specific antigen. The cellular response stimulates the resident lymphocytes to become cells that attack microbes directly rather than through the action of antibodies. These transformed lymphocytes are known as cytotoxic (killer) T cells.

Viral rather than bacterial antigens induce a cellular response. This response is manifested by the increasing number of T lymphocytes (lymphocytosis) seen in the blood tests of people with viral illnesses such as infectious mononucleosis. (Cellular immunity is discussed in further detail later in this chapter.) Most immune responses to antigens involve both humoral and cellular responses, although one usually predominates. For example, during transplant rejection, the cellular response involving T cells predominates, whereas in the bacterial pneumonias and sepsis, the humoral response involving B cells plays the dominant protective role (see Chart 54-1).

Effector Stage

In the effector stage, either the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reaches and connects with the antigen on the surface of the foreign invader. This initiates activities involving interplay of antibodies (humoral immunity), complement, and action by the cytotoxic T cells (cellular immunity).

Chart 54-1

Comparison of Cellular and Humoral Immune Responses

Humoral Responses (B Cells)

- Bacterial phagocytosis and lysis
- Anaphylaxis
- Allergic hay fever and asthma
- Immune complex disease
- Bacterial and some viral infections

Cellular Responses (T Cells)

- Transplant rejection
- Delayed hypersensitivity (tuberculin reaction)
- Graft-versus-host disease
- Tumor surveillance or destruction
- Intracellular infections
- Viral, fungal, and parasitic infections

Humoral Immune Response

The humoral response is characterized by the production of antibodies by B lymphocytes in response to a specific antigen. Whereas B lymphocytes are responsible for the production of antibodies, both the macrophages of natural immunity and the special T lymphocytes of cellular immunity are involved in recognition.

Antigen Recognition

Several theories explain the mechanisms by which B lymphocytes recognize the invading antigen and respond by producing antibodies. It is known that B lymphocytes recognize and respond to invading antigens in more than one way.

The B lymphocytes respond to some antigens by directly triggering antibody formation; however, in response to other antigens, they need the assistance of T cells to trigger antibody formation. With the help of macrophages, the T lymphocytes are believed to recognize the antigen of a foreign invader. The T lymphocyte picks up the antigenic message, or "blueprint," of the antigen and returns to the nearest lymph node with that message. B lymphocytes stored in the lymph nodes are subdivided into thousands of clones, which are stimulated to enlarge, divide, proliferate, and differentiate into plasma cells capable of producing specific antibodies to the antigen. Other B lymphocytes differentiate into B-lymphocyte clones with a memory for the antigen. These memory cells are responsible for the more exaggerated and rapid immune response in a person who is repeatedly exposed to the same antigen.

Role of Antibodies

Antibodies are large proteins, called *immunoglobulins,* that consist of two subunits, each containing a light and a heavy peptide chain held together by a chemical link composed of disulfide bonds. Each subunit has one portion that serves as a binding site for a specific antigen and another portion that allows the antibody molecule to take part in the complement system.

Antibodies defend against foreign invaders in several ways, and the type of defense used depends on the structure and composition of both the antigen and the immunoglobulin. The antibody molecule has at least two combining sites, or Fab fragments (see Fig. 54-6). One antibody can act as a cross-link between two antigens, causing them to bind or clump together. This clumping effect, referred to as agglutination, helps clear the body of the invading organism by facilitating phagocytosis. Some antibodies assist in the removal of offending organisms through opsonization. In this process, the antigen–antibody molecule is coated with a sticky substance that also facilitates phagocytosis.

Antibodies also promote the release of vasoactive substances, such as histamine and slow-reacting substances, two of the chemical mediators of the inflammatory response. Antibodies do not function in isolation; rather, they mobilize other components of the immune system to defend against the invader.

The body can produce five different types of immunoglobulin (Ig). Each of the five types, or classes, is identified by a specific letter of the alphabet, IgA, IgD, IgE, IgG, and IgM. Classification is based on the chemical structure and biologic role of the individual immunoglobulin. Major characteristics of the immunoglobulins are summarized in Chart 54-2. The normal laboratory values for the three major Igs (IgA, IgG, and IgM) can be found in Table 57-1 in Chapter 57;

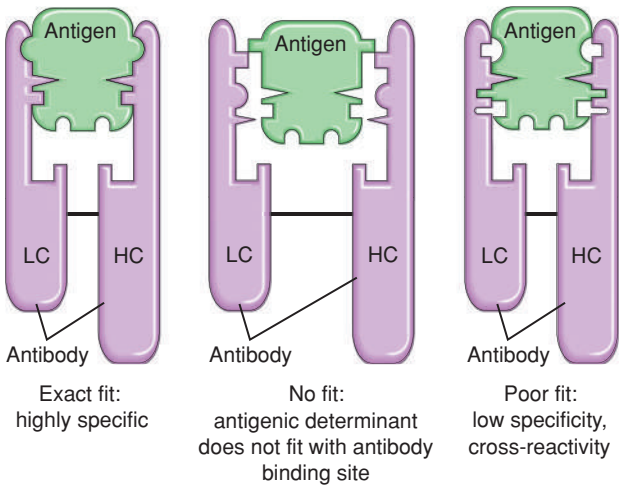

Figure 54-6 • Antigen–antibody binding. (***Left***) A highly specific antigen–antibody complex. (***Center***) No match and, therefore, no immune response. (***Right***) Poor fit or match with low specificity; antibody reacts to antigen with similar characteristics, producing cross-reactivity. HC, heavy chain; LC, light chain.

Chart 54-2

Major Characteristics of the Immunoglobulins

IgG (75% of Total Immunoglobulin)

- Appears in serum and tissues (interstitial fluid)
- Assumes a major role in blood-borne and tissue infections
- Activates the complement system
- Enhances phagocytosis
- Crosses the placenta

IgA (15% of Total Immunoglobulin)

- Appears in body fluids (blood, saliva, tears, and breast milk, as well as pulmonary, gastrointestinal, prostatic, and vaginal secretions)
- Protects against respiratory, gastrointestinal, and genitourinary infections
- Prevents absorption of antigens from food
- Passes to neonate in breast milk for protection

IgM (10% of Total Immunoglobulin)

- Appears mostly in intravascular serum
- Appears as the first immunoglobulin produced in response to bacterial and viral infections
- Activates the complement system

IgD (0.2% of Total Immunoglobulin)

- Appears in small amounts in serum
- Possibly influences B-lymphocyte differentiation, but role is unclear

IgE (0.004% of Total Immunoglobulin)

- Appears in serum
- Takes part in allergic and some hypersensitivity reactions
- Combats parasitic infections

Ig immunoglobulin.

Antigen–Antibody Binding

The portion of the antigen involved in binding with the antibody is referred to as the antigenic determinant. The most efficient immunologic responses occur when the antibody and antigen fit like a lock and key. Poor fit can occur with an antibody that was produced in response to a different antigen. This phenomenon is known as cross-reactivity. For example, in acute rheumatic fever, the antibody produced against *Streptococcus pyogenes* in the upper respiratory tract may cross-react with the patient's heart tissue, leading to heart valve damage.

Cellular Immune Response

The T lymphocytes are primarily responsible for cellular immunity. Stem cells continuously migrate from the bone marrow to the thymus gland, where they develop into T cells. Despite the partial degeneration of the gland at puberty, T cells continue to develop in the thymus gland. Several types of T cells exist, each with designated roles in the defense against bacteria, viruses, fungi, parasites, and malignant cells. T cells attack foreign invaders directly rather than by producing antibodies.

Cellular reactions are initiated, with or without the assistance of macrophages, by the binding of an antigen to an antigen receptor located on the surface of a T cell. The T cells then carry the antigenic message, or blueprint, to the lymph nodes, where the production of other T cells is stimulated. Some T cells remain in the lymph nodes and retain a memory for the antigen. Other T cells migrate from the lymph nodes into the general circulatory system and ultimately to the tissues, where they remain until they either come in contact with their respective antigens or die (Grossman & Porth, 2014).

Types of T Lymphocytes

T cells include effector T cells, suppressor T cells, and memory T cells. The two major categories of effector T cells—helper T cells (also referred to as $CD4^+$ cells) and cytotoxic T cells (also referred to as $CD8^+$ cells)—participate in the destruction of foreign organisms. T cells interact closely with B cells, indicating that humoral and cellular immune responses are not separate, unrelated processes but rather are branches of the immune response that interact.

Helper T cells are activated on recognition of antigens and stimulate the rest of the immune system. When activated, helper T cells secrete cytokines, which attract and activate B cells, cytotoxic T cells, NK cells, macrophages, and other cells of the immune system. Cytokines are proteins produced by the cells of the immune system that determine the actions of the immune system cells. Separate subpopulations of helper T cells produce different types of cytokines and determine whether the immune response will be the production of antibodies or a cell-mediated immune response. Helper T cells also produce lymphokines, one category of cytokines (see Table 54-2).

Cytotoxic T cells (killer T cells) attack the antigen directly by altering the cell membrane, causing cell lysis (disintegration), and releasing cytolytic enzymes and cytokines. Lymphokines can recruit, activate, and regulate other lymphocytes and WBCs. These cells then assist in destroying the invading organism. Delayed-type hypersensitivity is an example of an immune reaction that protects the body from antigens through the production and release of lymphokines (see later discussion).

Suppressor T cells have the ability to decrease B-cell production, thereby keeping the immune response at a level

TABLE 54-2 Cytokines of Innate and Adaptive Immunity

Cytokines	Source	Biologic Activity
Interleukin 1 (IL-1)	Macrophages, endothelial cells, some epithelial cells	Wide variety of biologic effects; activates endothelium in inflammation; induces fever and acute-phase response; stimulates neutrophil production
Interleukin 2 (IL-2)	$CD4^+$, $CD8^+$ T cells	Growth factor for activated T cells; induces synthesis of other cytokines; activates cytotoxic T lymphocytes and NK cells
Interleukin 3 (IL-3)	$CD4^+$ T cells	Growth factor for progenitor hematopoietic cells
Interleukin 4 (IL-4)	$CD4^+$ T_H2 cells, mast cells	Promotes growth and survival of T, B, and mast cells; causes T_H2 cell differentiation; activates B cells and eosinophils and induces IgE-type responses
Interleukin 5 (IL-5)	$CD4^+$ T_H2 cells	Induces eosinophil growth and development
Interleukin 6 (IL-6)	Macrophages, endothelial cells, T lymphocytes	Stimulates the liver to produce mediators of acute-phase inflammatory response; also induces proliferation of antibody-producing cells by the adaptive immune system
Interleukin 7 (IL-7)	Bone marrow stromal cells	Primary function in adaptive immunity; stimulates pre-B cells and thymocyte development and proliferation
Interleukin 8 (IL-8)	Macrophages, endothelial cells	Primary function in adaptive immunity; chemoattracts neutrophils and T lymphocytes; regulates lymphocyte homing and neutrophil infiltration
Interleukin 10 (IL-10)	Macrophages, some T-helper cells	Inhibitor of activated macrophages and dendritic cells; decreases inflammation by inhibiting T_H1 cells and release of interleukin 12 from macrophages
Interleukin 12 (IL-12)	Macrophages, dendritic cells	Enhances NK cell cytotoxicity in innate immunity; induces T_H1 cell differentiation in adaptive immunity
Type I interferons (IFN-α, IFN-β)	Macrophages, fibroblasts	Inhibit viral replication, activate NK cells, and increase expression of MHC-I molecules on virus-infected cells
Interferon-γ (IFN-γ)	NK cells, $CD4^+$ and $CD8^+$ T lymphocytes	Activates macrophages in both innate immune responses and adaptive cell-mediated immune responses; increases expression of MHC I and II and antigen processing and presentation
Tumor necrosis factor-α (TNF-α)	Macrophages, T cells	Induces inflammation, fever, and acute-phase response; activates neutrophils and endothelial cells; kills cells through apoptosis
Chemokines	Macrophages, endothelial cells, T lymphocytes	Large family of structurally similar cytokines that stimulate leukocyte movement and regulate the migration of leukocytes from the blood to the tissues
Granulocyte-monocyte CSF (GM-CSF)	T cells, macrophages, endothelial cells, fibroblasts	Promotes neutrophil, eosinophil, and monocyte maturation and growth; activates mature granulocytes
Granulocyte CSF (G-CSF)	Macrophages, fibroblasts, endothelial cells	Promotes growth and maturation of neutrophils consumed in inflammatory reactions
Monocyte CSF (M-CSF)	Macrophages, activated T cells, endothelial cells	Promotes growth and maturation of mononuclear phagocytes

CSF, colony-stimulating factor; MHC, major histocompatibility complex; NK, natural killer; IgE, immunoglobulin E; T_H1, T-helper type 1; T_H2, T-helper type 2.
Adapted from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

that is compatible with health (e.g., sufficient to fight infection adequately without attacking the body's healthy tissues). Memory cells are responsible for recognizing antigens from previous exposure and mounting an immune response (see Table 54-3).

Null Lymphocytes and Natural Killer Cells

Null lymphocytes and NK cells are other lymphocytes that assist in combating organisms. These cells are distinct from B cells and T cells and lack the usual characteristics of those cells. Null lymphocytes, a subpopulation of lymphocytes, destroy antigens already coated with antibody. These cells have special receptor sites on their surface that allow them to connect with the end of antibodies; this is known as antibody-dependent, cell-mediated cytotoxicity.

NK cells are a class of lymphocytes that recognize infected and stressed cells and respond by killing these cells and by secreting macrophage-activating cytokine. The helper T cells contribute to the differentiation of null and NK cells.

Complement System

Circulating plasma proteins, known as complement, are made in the liver and activated when an antibody connects with its antigen. Complement plays an important role in the defense against microbes. Destruction of an invading or attacking organism or toxin is not achieved merely by the binding of the antibody and antigens; it also requires activation of complement, the arrival of killer T cells, or the attraction of macrophages. Complement has three major physiologic functions: defending the body against bacterial infection, bridging natural and acquired

TABLE 54-3 Lymphocytes Involved in Immune Responses

Type of Immune Response	Cell Type	Function
Humoral	B lymphocyte	Produces antibodies or immunoglobulins (IgA, IgD, IgE, IgG, IgM)
Cellular	T lymphocyte	
	Helper T	Attacks foreign invaders (antigens) directly Initiates and augments inflammatory response
	Helper T_1	Increases activated cytotoxic T cells
	Helper T_2	Increases B-cell (BG8) antibody production
	Suppressor T	Suppresses the immune response
	Memory T	Remembers contact with an antigen and on subsequent exposures mounts an immune response
	Cytotoxic T (killer T)	Lyses cells infected with virus; plays a role in graft rejection
Nonspecific	Non-T or non-B lymphocyte Null cell	Destroys antigens already coated with antibody
	Natural killer cell (granular lymphocyte)	Defends against microorganisms and some types of malignant cells; produces cytokines

immunity, and disposing of immune complexes and the by-products associated with inflammation (Grossman & Porth, 2014).

The proteins that comprise complement interact sequentially with one another in a cascading effect. The complement cascade is important to modifying the effector arm of the immune system. Activation of complement allows important events, such as removal of infectious agents and initiation of the inflammatory response, to take place. These events involve active parts of the pathway that enhance chemotaxis of macrophages and granulocytes, alter blood vessel permeability, change blood vessel diameters, cause cells to lyse, alter blood clotting, and cause other points of modification. These macrophages and granulocytes continue the body's defense by devouring the antibody-coated microbes and by releasing bacterial products.

The complement cascade may be activated by any of three pathways: classic, lectin, and alternative. The classic pathway is triggered after antibodies bind to microbes or other antigens and is part of the humoral type of adaptive immunity. The lectin pathway is activated when a plasma protein (mannose-binding lectin) binds to terminal mannose residue on the surface glycoproteins of microbes. The alternative pathway is triggered when complement proteins are activated on microbial surfaces. This pathway is part of natural immunity.

Complement components, prostaglandins, leukotrienes, and other inflammatory mediators all contribute to the recruitment of inflammatory cells, as do chemokines, a group of cytokines. The activated neutrophils pass through the vessel walls to accumulate at the site of infection, where they phagocytize complement-coated microbes (Grossman & Porth, 2014). This response is usually therapeutic and can be lifesaving if the cell attacked by the complement system is a true foreign invader. However, if that cell is part of the human organism, the result can be devastating disease and even death. Many autoimmune diseases and disorders characterized by chronic infection are thought to be caused in part by continued or chronic activation of complement, which in turn results in chronic inflammation. The RBCs and platelets have complement receptors and, as a result, play an important role in the clearance of immune complexes that consist of antigen, antibody, and components of the complement system (Grossman & Porth, 2014).

Immunomodulators

Antimicrobial agents and vaccines have yielded considerable therapeutic success and the immune system usually works effectively; however, many infectious diseases remain difficult clinical challenges. Treatment success may be compromised by defects of the immune system; in this case, enhancement of the host immune response may be therapeutically beneficial. An immunomodulator (also known as a biologic response modifier) affects the host via direct or indirect effects on one or more components of the immunoregulatory network. Interferons, colony-stimulating factors, and monoclonal antibodies (MoAbs) are examples of agents used to help enhance the immune system (Page & Liles, 2015).

Interferons

Interferon, one type of biologic response modifier, is a nonspecific viricidal protein that is naturally produced by the body and is capable of activating other components of the immune system. Interferons continue to be investigated to determine their roles in the immune system and their potential therapeutic effects in disorders characterized by disturbed immune responses. These substances have antiviral and antitumor properties. In addition to responding to viral infection, interferons are produced by T lymphocytes, B lymphocytes, and macrophages in response to antigens. They are thought to modify the immune response by suppressing antibody production and cellular immunity. They also facilitate the cytolytic role of macrophages and NK cells. Interferons are used to treat immune-related disorders (e.g., multiple sclerosis) and chronic inflammatory conditions (e.g., chronic hepatitis). Research continues to evaluate the effectiveness of interferons in treating cancers (Booy, Hofland, & van Eijck, 2015) and acquired immunodeficiency syndrome.

Colony-Stimulating Factors

Colony-stimulating factors are a group of naturally occurring glycoprotein cytokines that regulate production, differentiation, survival, and activation of hematopoietic cells. Erythropoietin stimulates RBC production. Thrombopoietin plays a key regulatory role in the growth and differentiation of bone marrow cells. Interleukin 5 (IL-5) stimulates the growth and survival of eosinophils and basophils. Stem cell factor and IL-3 serve as stimuli for multiple hematopoietic cell lines. Granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and macrophage colony-stimulating factor all serve as growth factors for specific cell lines. These cytokines have attracted considerable interest for their potential role in immunomodulation (Page & Liles, 2015).

Monoclonal Antibodies

MoAbs have become available through technologic advances, enabling investigators to grow and produce targeted antibodies for specific pathologic organisms. This type of specificity allows MoAbs to destroy pathologic organisms and spare normal cells. The specificity of MoAbs depends on identifying key antigen proteins that are present on the surface of tumors, but not on normal tissues. When the MoAb attaches to the cell surface antigen, it blocks an important signal transduction pathway for communication between the malignant cells and the extracellular environment. The results may include an inability to initiate apoptosis, reproduce, or invade surrounding tissues. To date, more than 1000 tumor antigens have been identified (Glassman & Balthasar, 2014). See Chapter 58 for a discussion on the use of MoAbs in cancer.

Advances in Immunology

Genetic Engineering

One of the more remarkable evolving technologies is genetic engineering, which uses recombinant deoxyribonucleic acid (DNA) technology. Two facets of this technology exist. The first permits scientists to combine genes from one type of organism with genes of a second organism. This type of technology allows cells and microorganisms to manufacture proteins, monokines, and lymphokines, which can alter and enhance immune system function. The second facet of recombinant DNA technology involves gene therapy. If a particular gene is abnormal or missing, experimental recombinant DNA technology may be capable of restoring normal gene function. For example, a recombinant gene is inserted onto a virus particle. When the virus particle splices its genes, the virus automatically inserts the missing gene and theoretically corrects the genetic anomaly. Extensive research into recombinant DNA technology and gene therapy is ongoing (Geering & Fussenegger, 2015).

Stem Cells

Stem cells are capable of self-renewal and differentiation; they continually replenish the body's entire supply of both RBCs and WBCs. Some stem cells, described as totipotent cells, have tremendous capacity to self-renew and differentiate. Embryonic stem cells, described as pluripotent, give rise to numerous cell types that are able to form tissues. Research has shown that stem cells can restore an immune system that has been destroyed (Kessler, 2015). Stem cell transplantation has been carried out in humans with certain types of immune dysfunction, such as severe combined immunodeficiency; clinical trials using stem cells are under way in patients with a variety of disorders having an autoimmune component, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis. Research with embryonic stem cells has enabled investigators to make substantial gains in developmental biology, gene therapy, therapeutic tissue engineering, and the treatment of a variety of diseases (Kessler, 2015). However, along with these remarkable opportunities, many ethical challenges arise, which are largely based on concerns about safety, efficacy, resource allocation, and human cloning.

Cancer and Immunotherapy

It has long been understood that the immune system plays a role in fighting off malignancies. Recent advances in cancer treatment have sought to augment the body's natural antitumor activity and to shut down the pathways that allow malignancies to elude the immune system, which has led to the development of such treatments as MoAbs, cancer vaccines, immune adjuvants, immune checkpoint inhibitors, and cytokines (Kannan et al., 2013). These immunotherapeutic treatments are designed to stimulate the patient's immune system to mount its own defense against the cancer and have shown very promising results in a number of different cancer types. See Chapter 58 for a discussion on the use of immunotherapy in cancer.

Assessment of the Immune System

An assessment of immune function begins during the health history and physical examination. Areas to be assessed include nutritional status; infections and immunizations; allergies; disorders and disease states, such as autoimmune disorders, cancer, and chronic illnesses; surgeries; medications; and blood transfusions. In addition to inspection of general characteristics, palpation of the lymph nodes and examinations of the skin, mucous membranes, and respiratory, gastrointestinal, musculoskeletal, genitourinary, cardiovascular, and neurosensory systems are performed (see Chart 54-3).

Health History

The history should note the patient's age along with information about past and present conditions and events that may provide clues to the status of the patient's immune system.

Gender

There are differences in the immune system functions of men and women. For example, many autoimmune diseases have a higher incidence in females than in males, a phenomenon believed to be correlated with sex hormones. Sex hormones have long been recognized for their role in reproductive function; in the past two decades, research has revealed that these hormones are integral signaling modulators of the immune system. Sex hormones play definitive roles in lymphocyte maturation, activation, and synthesis of antibodies and cytokines. In autoimmune disease, expression of sex hormones is altered, and this change contributes to immune dysregulation (Ngo, Steyn, & McCombe, 2014).

Gerontologic Considerations

Immunosenescence is a complex route in which the aging process stimulates changes in the immune system (Shekarabi & Asgari, 2014). Some of the changes that occur in immunosenescence include, but are not limited to, bone marrow defects, dysfunction of the thymus gland, and impaired lymphocytes. Cellular changes occur as the result of aging and include impaired neutrophil function, decreased amount of circulating macrophages, impaired dendritic cell function, and reduced T-cell activation (Müller & Pawelec, 2014). As the immune system undergoes age-associated alterations, its response to infections progressively deteriorates. The capacity for self-renewal of hematopoietic stem cells diminishes. There is a notable decline in the total number of phagocytes, coupled with an intrinsic reduction in their activity. The cytotoxicity of NK cells decreases, contributing to a decline in humoral immunity (Müller & Pawelec, 2014). Acquired immunity may be negatively affected; the efficacy of vaccines is frequently decreased in older

Chart 54-3 ASSESSMENT

Assessing for Immune Dysfunction

Be alert for the following signs and symptoms:

Respiratory System

- Changes in respiratory rate
- Cough (dry or productive)
- Abnormal lung sounds (wheezing, crackles, rhonchi)
- Rhinitis
- Hyperventilation
- Bronchospasm

Cardiovascular System

- Hypotension
- Tachycardia
- Dysrhythmia
- Vasculitis
- Anemia

Gastrointestinal System

- Hepatosplenomegaly
- Colitis
- Vomiting
- Diarrhea

Genitourinary System

- Frequency and burning on urination
- Hematuria
- Discharge

Musculoskeletal System

- Joint mobility, edema, and pain

Skin

- Rashes
- Lesions
- Dermatitis
- Hematomas or purpura
- Edema or urticaria
- Inflammation
- Discharge

Neurosensory System

- Cognitive dysfunction
- Hearing loss
- Visual changes
- Headaches and migraines
- Ataxia
- Tetany

adults (Goronzy & Weyand, 2013). Inflammatory cytokines tend to increase with age.

Older adults have increased the incidence of infections, autoimmune diseases, metabolic diseases, osteoporosis, and neurologic disorders (Müller & Pawelec, 2014).The increased incidence of autoimmune diseases may be from a decreased ability of antibodies to differentiate between self and non-self. Failure of the surveillance system to recognize mutant or abnormal cells also may be responsible, in part, for the high incidence of cancer associated with increasing age.

Age-related changes in many body systems also contribute to impaired immunity (see Table 54-4). For example,

TABLE 54-4 Age-Related Changes in Immunologic Function

Body System	Changes	Consequences
Immune	Impaired function of B and T lymphocytes Failure of lymphocytes to recognize mutant or abnormal cells Decreased antibody production Failure of immune system to differentiate "self" from "non-self" Suppressed phagocytic immune response	Suppressed responses to pathogenic organisms with increased risk for infection Increased incidence of cancers Anergy (lack of response to antigens applied to the skin [allergens]) Increased incidence of autoimmune diseases Absence of typical signs and symptoms of infection and inflammation Dissemination of organisms usually destroyed or suppressed by phagocytes (e.g., reactivation or spread of tuberculosis)
Gastrointestinal	Decreased gastric secretions and motility Decreased phagocytosis by the liver's Kupffer cells Altered nutritional intake with inadequate protein intake	Proliferation of intestinal organisms resulting in gastroenteritis and diarrhea Increased incidence and severity of hepatitis B; increased incidence of liver abscesses Suppressed immune response
Urinary	Decreased kidney function and changes in lower urinary tract function (enlargement of prostate gland, neurogenic bladder); altered genitourinary tract flora	Urinary stasis and increased incidence of urinary tract infections
Pulmonary	Impaired ciliary action due to exposure to smoke and environmental toxins	Impaired clearance of pulmonary secretions; increased incidence of respiratory infections
Integumentary	Thinning of skin with less elasticity; loss of adipose tissue	Increased risk of skin injury, breakdown, and infection
Circulatory	Impaired microcirculation	Stasis and pressure ulcers
Neurologic function	Decreased sensation and slowing of reflexes	Increased risk of injury, skin ulcers, abrasions, and burns

postmenopausal females are at a greater risk for urinary tract infections due to residual urine, urinary incontinence, and estrogen deficiency (Mody & Juthani-Mehta, 2014). Secondary changes, including malnutrition and poor circulation, as well as the breakdown of natural mechanical barriers such as the skin, place the aging immune system at even greater disadvantage against infection (Carlsson, Haglin, Rosendahl, et al., 2013).

The effects of the aging process and psychological stress interact, with the potential to negatively influence immune integrity (Epel & Lithgow, 2014). Consequently, continual assessment of the physical and emotional status of older adults is imperative, because early recognition and management of factors influencing immune response may prevent or mitigate the high morbidity and mortality seen with illness in the older adult population (Müller & Pawelec, 2014).

Nutrition

The relationship of infection to nutritional status is a key determinant of health. Traditionally, this relationship focused on the effect of nutrients on host defenses and the effect of infection on nutritional needs. This has expanded in scope to encompass the role of specific nutrients in acquired immune function—the modulation of inflammatory processes and the virulence of the infectious agent itself. Iron and the immune system are linked in homeostasis and pathology, thus making it essential for maximum function (Cassat & Skaar, 2013). The list of nutrients affecting infection, immunity, inflammation, and cell injury has expanded from traditional proteins to several vitamins, multiple minerals, and, more recently, specific lipid components of the diet. One review looked at the role of Vitamins A, C, D, E, and K in treatment of pancreatic cancer but concluded that not enough evidence based on clinical trials is available to fully support the use of these vitamins as an intervention (Davis-Yadley & Malafa, 2015). The role of micronutrients and fatty acids on the response of cells and tissues to hypoxic and toxic damage has been recognized, suggesting that there is another dimension to the relationship. Deficiencies in micronutrients have been connected to impairment in various body functions, including immunity. Zinc deficiency in particular has been linked to the development of a number of diseases. Zinc plays an important role in homeostasis, immune function, and apoptosis, among other functions (Müller & Pawelec, 2014).

The effects exerted by polyunsaturated fatty acids on immune system functions are under investigation. Studies suggest that these elements play a role in diminishing the incidence and severity of inflammatory disorders. Recent studies suggest that diets high in olive oil are not as immunosuppressive as diets rich in fish oil. The contribution of immune modulation by lipids to the high risk of infectious complications associated with the use of parenteral nutrition is unclear; however, a recent meta-analysis revealed that the use of glutamine-supplemented parenteral nutrition decreased the incidence of infections postoperatively (Yue, Tian, Wang, et al., 2013).

Depletion of protein reserves results in atrophy of lymphoid tissues, depression of antibody response, reduction in the number of circulating T cells, and impaired phagocytic function. As a result, susceptibility to infection is greatly increased. During periods of infection or serious illness, nutritional requirements may be further altered, potentially contributing to depletion of protein, fatty acid, vitamin, and trace elements and causing even greater risk of impaired immune response and sepsis. Nutritional intake that supports a competent immune response plays an important role in reducing the incidence of infections; patients whose nutritional status is compromised have a delayed postoperative recovery and often experience more severe infections and delayed wound healing. The nurse must assess the patient's nutritional status, caloric intake, and quality of foods ingested. There is evidence that nutrition plays a role in the development of cancer and that diet and lifestyle can alter the risk of cancer development as well as other chronic diseases (Supic, Jagodic, & Magic, 2013). The nurse must assume a proactive role in ensuring the best possible nutritional intake for all patients as a vital step in preventing disease and poor outcomes (Slawson, Fitzgerald, & Morgan, 2013).

Immunization

The patient is asked about childhood and adult immunizations, including vaccinations to provide protection against influenza, pneumococcal disease (Pneumovax), pertussis, herpes simplex, and the usual childhood diseases (e.g., measles, mumps). Herpes simplex virus infections have a significant impact on health, causing a wide range of diseases (e.g., oral and genital herpes). Education about the importance of adhering to the recommended schedule for adult vaccines should be initiated.

Infection

Known past or present exposure to tuberculosis is assessed, and the dates and results of any tuberculin tests (purified protein derivative [PPD] test) and chest x-rays are documented. Recent exposure to any infections and the exposure dates are elicited. The nurse must assess whether the patient has been exposed to any sexually transmitted infections (STIs) or blood-borne pathogens such as hepatitis B, C, and D viruses and human immune deficiency virus (HIV). A history of STIs such as gonorrhea, syphilis, human papillomavirus infection, and chlamydia can alert the nurse that the patient may have been exposed to HIV or hepatitis. Patients who have had an ischemic stroke or transient ischemic attack (TIA) are at risk for infection following the event (Ross, Lee, & Brewer, 2014). In an effort to fight infection, patients mount a peripheral immune response (PIR) consisting of neutrophilia, lymphocytopenia, and elevated monocytes (Ross et al., 2014). Researchers are investigating the time course, trajectory, and significance of the PIR following stroke or TIA (Ross et al., 2014); (Ross & Lee, 2015) (see Chart 54-4).

A history of past and present infections and the dates and types of treatments, along with a history of any multiple persistent infections, fevers of unknown origin, lesions or sores, or any type of drainage, as well as the response to treatment, are obtained.

Allergy

The patient is asked about any allergies, including types of allergens (e.g., pollens, dust, plants, cosmetics, food, medications, vaccines, latex), the symptoms experienced, and seasonal variations in occurrence or severity in the symptoms. A history of testing and treatments, including prescribed and over-the-counter medications that the patient has taken or is currently taking for these allergies and the effectiveness of the treatments, is obtained. All medication and food allergies are listed on an allergy alert sticker and placed on the front of the patient's health or medical record to alert others. Continued assessment for potential allergic reactions in the patient is vital. See Chapter 56 for more information on allergies.

Chart 54-4 NURSING RESEARCH PROFILE

Peripheral Immune Response Trajectories

Ross, A.M., & Lee, C. (2015). Description and identification of the peripheral immune response trajectories over time in first-time and recurrent stroke/transient ischemic attack. Journal of Neuroscience Nursing, 47(5), 256–262.

Purpose

It is not known how the immune response changes over time in patients after a stroke or transient ischemic attack (TIA). The purpose of this study was to describe the peripheral immune response (PIR) trajectories over time following a first-time and recurrent stroke or transient ischemic attack. The two aims were first to compare changes in the PIR over time in patients with a first versus a recurrent stroke or TIA, and second to identify trajectories of change in the PIR in patients after a stroke or TIA.

Design

This was a secondary analysis of data collected during a retrospective cross-sectional study on the PIR in the acute phase of care after a stroke or TIA. Data for the parent study were collected using a detailed retrospective medical record review. Descriptive statistics and latent growth mixture modeling were used to investigate the changes in PIR over time.

Findings

Of the 192 adult men and women included in the study 84 (44%) had a first-time stroke or TIA and 108 (56%) had a recurrent event. Participants with recurrent stroke or TIA had a persistent elevation in lymphocyte percentage compared to a significant decline in lymphocyte percentage observed in patients with a first-time event. The first trajectory (80% of the sample) had persistently lower lymphocyte percentages and higher neutrophil percentages over time, while the second trajectory (20% of the sample) had higher lymphocyte percentages and lower neutrophil percentages over time.

Nursing Implications

Nurses monitoring laboratory values after stroke or TIA need to recognize that different trajectories of PIRs exist. This may have future implications for identification of patients who may benefit from novel immune therapies. Nurses caring for patients who have any signs of depressed immune function need to be more vigilant in their assessments, watching for possible signs and symptoms of infection.

Disorders and Diseases

Autoimmune Disorders

Autoimmune disorders affect people of both genders of all ages, ethnicities, and social classes. Autoimmune disorders are a group of disorders that can affect almost any cell or tissue in the body (Grossman & Porth, 2014). As mentioned previously, they tend to be more common in women because estrogen tends to enhance immunity. Androgen, on the other hand, tends to be immunosuppressive. Autoimmune diseases are a leading cause of death by disease in females of reproductive age.

The patient is asked about any autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, multiple sclerosis, or psoriasis. The onset, severity, remissions and exacerbations, functional limitations, treatments that the patient has received or is currently receiving, and effectiveness of the treatments are described. The occurrence of different autoimmune diseases within a family strongly suggests a genetic predisposition to more than one autoimmune disease (Brooks & Renaudineau, 2015) (see Chart 54-5).

Neoplastic Disease

If there is a history of cancer in the family, more information is obtained, including the type of cancer, age at onset, and relationship (maternal or paternal) of the patient to the affected family members. Dates and results of any cancer screening tests for the patient are documented.

A history of cancer in the patient is also obtained, along with the type of cancer, date of diagnosis, and treatment modalities used. Immunosuppression contributes to the development of cancers; however, cancer itself is immunosuppressive, as is the treatment for cancer. Large tumors can release antigens into the blood, and these antigens combine with circulating antibodies and prevent them from attacking the tumor cells. Furthermore, tumor cells may possess special blocking factors that coat tumor cells and prevent their destruction by killer T lymphocytes. During the early development of tumors, the body may fail to recognize the tumor antigens as foreign and subsequently fail to initiate destruction of the malignant cells. Hematologic cancers, such as leukemia and lymphoma, are associated with altered production and function of WBCs and lymphocytes.

All treatments that the patient has received or is currently receiving, such as radiation or chemotherapy, are recorded in the health history. In addition, the nurse should elicit information related to complementary or alternative modalities that have been used and the response to these efforts. Radiation destroys lymphocytes and decreases the ability to mount an effective immune response. The size and extent of the irradiated area determine the extent of immunosuppression. Whole-body irradiation may leave the patient totally immunosuppressed. Chemotherapy and other cancer treatments also affect bone marrow function, destroying cells that contribute to an effective immune response and resulting in immunosuppression (Morrison, 2014).

Chronic Illness and Surgery

The health assessment includes a history of chronic illness, such as diabetes, renal disease, chronic obstructive pulmonary disease (COPD), or fibromyalgia. The onset and severity of illnesses, as well as treatment that the patient is receiving for the illness, are obtained. Chronic illness may contribute to immune system impairments in various ways. Kidney injury is associated with a deficiency in circulating lymphocytes. In addition, immune defenses may be altered by acidosis and uremic toxins. In diabetes, an increased incidence of infection has been associated with vascular insufficiency, neuropathy, and poor control of serum glucose levels. Recurrent respiratory tract infections are associated with COPD as a result of altered inspiratory and expiratory function and ineffective airway clearance. In addition, a history of organ transplantation or surgical removal of the spleen, lymph nodes, or thymus is noted, because these conditions may place the patient at risk for impaired immune function (Bronte & Pittet, 2013).

Special Problems

Conditions such as burns and other forms of injury and infection may contribute to altered immune system function. Major burns

Chart 54-5 GENETICS IN NURSING PRACTICE

Immunologic Disorders

An immunologic disorder is a disorder of an individual's immune system, which is a network of cells, tissues, and organs that work together to defend the body against attacks by foreign invaders such as bacteria, parasites, and fungi that can cause infection. A number of immunologic disorders have a known inheritance pattern, while others are noted to have a genetic abnormality that is influenced by environmental exposures. Therefore, the pattern of inheritance is unclear in some immunologic disorders. Examples of immunologic disorders caused by a genetic abnormality include:

- Adenosine deaminase deficiency (autosomal recessive)
- Alopecia areata
- Alopecia totalis
- Asthma
- Ataxia telangiectasia (autosomal recessive)
- Autoimmune polyglandular syndrome
- Bruton agammaglobulinemia (X linked)
- Burkitt lymphoma
- Crohn's disease
- Diabetes, type 1
- DiGeorge syndrome (Autosomal dominant)
- Familial Mediterranean fever
- Job syndrome (autosomal dominant and recessive)
- Purine nucleoside phosphorylase deficiency (autosomal dominant)
- Severe combined immunodeficiency (primarily X linked)
- Wiskott–Aldrich syndrome (X linked)

Nursing Assessments

Family History Assessment Specific to Immunologic Disorders

- Collect a family history for both maternal and paternal relatives for three generations.
- Assess family history for other family members with histories of immunologic disorders.
- Obtain information about family members with a history of recurrent infections or illness.
- Recognize ethnic risk (non-Ashkenazi Jewish, Armenian, Arab, and Turkish are at greater risk for Familial Mediterranean fever; Caucasians have a higher incidence of Crohn's disease)
- Assess genetic and inherited pattern of any disease
  - Similar disorder in two or more close relatives
  - History of miscarriages, birth defects, and developmental delays
  - History of consanguineous marriage

Patient Assessment

- Assess for symptoms such as changes in respiratory status associated with asthma (e.g., wheezing, or airway hyperresponsiveness; mucosal edema; and mucus production).
- Gather information regarding immunizations and whether an altered response to any immunization has occurred.
- Assess for symptoms of immunodeficiency disorders, such as unexplained weight gain or loss, skin rashes, changes in hair texture or distribution, joint or muscle pain, intolerance to cold, irregular menstrual periods, abdominal discomfort, or the presence of diarrhea.
- Identify pattern of sickness with regard to frequency of colds, respiratory infections, or history of illness that tends to linger.
- Obtain history of childhood illnesses and details of the illness experience.
- Assess for medical history of frequent or recurrent infections.
- Learn about susceptibility to infections, assess for patterns (frequency, length of illness, severity of symptoms), and recognize infections that would be atypical for age.
- Inquire about environmental exposures (e.g., smoke, chloroform, metal or dust particles, paint).
- Ask about exposure to other viruses such as Epstein Barr or Influenza.

cause impaired skin integrity and compromise the body's first line of defense. Loss of large amounts of serum occurs with burn injuries and depletes the body of essential proteins, including immunoglobulins. The physiologic and psychological stressors associated with surgery or injury stimulate cortisol release from the adrenal cortex; increased serum cortisol also contributes to suppression of normal immune responses (Eng, Kokolus, Reed, et al., 2014).

Medications and Blood Transfusions

A list of past and present medications is obtained. In large doses, antibiotics, corticosteroids, cytotoxic agents, salicylates, nonsteroidal anti-inflammatory drugs, and anesthetic agents can cause immune suppression (see Table 54-5).

A history of blood transfusions is obtained, because previous exposure to foreign antigens through transfusion may be associated with abnormal immune function. In addition, although the risk of HIV transmission through blood transfusion is extremely low in patients, still some risk remains.

The patient is also asked about the use of herbal agents and over-the-counter medications. Because many of these products have not been subjected to rigorous testing, their effects have not been fully identified. It is important, therefore, to ask patients about their use of these substances, to document their use, and to educate patients about untoward effects that may alter immune responsiveness.

Lifestyle Factors

Like any other body system, the functions of the immune system are interrelated with other body systems. Poor nutritional status, smoking (Sheils, Katki, Freedman, et al., 2014), excessive consumption of alcohol, illicit drug use, STIs, and occupational or residential exposure to environmental radiation and pollutants have been associated with impaired immune function and are assessed in a detailed patient history. Although factors that are not consistent with a healthy lifestyle are predominately responsible for ineffective immune function, positive lifestyle factors can also negatively affect immune function and require assessment. For example, rigorous exercise or competitive exercise—usually considered a positive lifestyle factor—can be a physiologic stressor and cause negative effects on immune response (Jin, Paik, Kwak, et al., 2015). This outcome is compounded if the person also faces stressful environmental conditions while undergoing exercise. Given the cumulative impact of various environmental stressors on the immune system, every effort should be made to minimize the person's exposure to stressors other than the exercise performed (Jin et al., 2015).

Psychoneuroimmunologic Factors

Patient assessment must also address psychoneuroimmunologic factors. The bidirectional pathway between the brain and

TABLE 54-5 Selected Medications and Effects on the Immune System

Drug Classification (and Examples)	Effects on the Immune System
Antibiotics (in large doses)	**Bone marrow suppression**
Ceftriaxone (Rocephin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
Cefuroxime sodium (Ceftin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
Chloramphenicol (Chloromycetin)	Leukopenia, aplastic anemia
Dactinomycin (Cosmegen)	Agranulocytosis, neutropenia
Fluoroquinolones (ciprofloxacin [Cipro], levofloxacin [Levaquin])	Hemolytic anemia, methemoglobinemia, eosinophilia, leukopenia, pancytopenia
Gentamicin sulfate (Garamycin)	Agranulocytosis, granulocytosis
Macrolides (erythromycin, Azithromycin [Zithromax], Clarithromycin [Biaxin])	Neutropenia, leukopenia
Penicillins	Agranulocytosis
Streptomycin	Leukopenia, neutropenia, pancytopenia
Vancomycin (Vancocin, Vancoled)	Transient leukopenia
Antithyroid Drugs	
Propylthiouracil (PTU)	Agranulocytosis, leukopenia
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) (in large doses)	**Inhibit Prostaglandin Synthesis or Release**
Aspirin	Agranulocytosis
COX-2 inhibitors (celecoxib [Celebrex])	Anemia, allergy, no other major adverse effects
Ibuprofen (Advil, Motrin)	Leukopenia, neutropenia
Indomethacin (Indocid, Indocin)	Agranulocytosis, leukopenia
Phenylbutazone	Pancytopenia, agranulocytosis, aplastic anemia
Adrenal Corticosteroids	**Immunosuppression**
Prednisone	Immunosuppression
Antineoplastic Agents (cytotoxic agents)	**Immunosuppression**
Cyclophosphamide (Cytoxan)	Leukopenia, neutropenia
Mechlorethamine HCl (Mustargen)	Agranulocytosis, neutropenia
Cyclosporine (Neoral)	Leukopenia, inhibits T-lymphocyte function
Antimetabolites	**Immunosuppression**
Pyrimidine antagonist (Fluorouracil [5-FU])	Leukopenia, eosinophilia
Folic acid antagonist (Methotrexate)	Leukopenia, aplastic bone marrow
Purine antagonist (Mercaptopurine[(6-MP])	Leukopenia, pancytopenia

COX, cyclo-oxygenase.

immune system is referred to as psychoneuroimmunology (Fagundes, Lindgren, & Kiecolt-Glaser, 2013). The immune response is regulated and modulated in part by neuroendocrine influences. Lymphocytes and macrophages have receptors that can respond to neurotransmitters and endocrine hormones. Lymphocytes can produce and secrete adrenocorticotropic hormone and endorphine-like compounds. Cells in the brain, especially in the hypothalamus, can recognize prostaglandins, interferons, and interleukins, as well as histamine and serotonin, all of which are released during the inflammatory process. Like all other biologic systems functioning to maintain homeostasis, the immune system is integrated with other psychophysiologic processes and is regulated and modulated by the brain. These relationships may have immunologic consequences.

Conversely, the immune processes can affect neural and endocrine function, including behavior. Growing evidence indicates that a measurable immune system response can be positively influenced by biobehavioral strategies such as relaxation and imagery techniques, biofeedback, humor, hypnosis, and conditioning (Bennett, Parsons, Ben-Moshe, et al., 2014); (Palsson & van Tilburg, 2015). Therefore, the assessment should address the patient's general psychological status and the patient's use of and response to these strategies.

Physical Assessment

During the physical examination (see Chart 54-3), the skin and mucous membranes are assessed for lesions, dermatitis, purpura (subcutaneous bleeding), urticaria, inflammation, or any discharge. Any signs of infection are noted. The patient's temperature is recorded, and the patient is observed for chills and sweating. The anterior and posterior cervical, supraclavicular, axillary, and inguinal lymph nodes are palpated for enlargement; if palpable nodes are detected, their location, size, consistency, and reports of tenderness on palpation are noted. Joints are assessed for tenderness, swelling, increased warmth, and limited range of motion. The patient's respiratory, cardiovascular, genitourinary, gastrointestinal, and neurosensory systems are evaluated for signs and symptoms indicative of immune dysfunction. Any functional limitations or disabilities the patient may have are also assessed.

Diagnostic Evaluation

A series of blood tests and skin tests, as well as bone marrow biopsy, may be performed to evaluate the patient's immune competence. Specific laboratory and diagnostic tests are discussed in greater detail along with individual disease processes in subsequent chapters in this unit. Selected laboratory

Chart 54-6

Selected Tests for Evaluating Immunologic Status

Various laboratory tests may be performed to assess immune system activity or dysfunction. The studies assess leukocytes and lymphocytes, humoral immunity, cellular immunity, phagocytic cell function, complement activity, hypersensitivity reactions, specific antigen–antibodies, or human immunodeficiency virus infection.

Humoral (Antibody-Mediated) Immunity Tests

- B-cell quantification with monoclonal antibody
- In vivo immunoglobulin synthesis with T-cell subsets
- Specific antibody response
- Total serum globulins and individual immunoglobulins (electrophoresis, immunoelectrophoresis, single radial immunodiffusion, nephelometry, and isohemagglutinin techniques)

Cellular (Cell-Mediated) Immunity Tests

- Total lymphocyte count
- T-cell and T-cell-subset quantification with monoclonal antibody
- Delayed hypersensitivity skin test
- Cytokine production
- Lymphocyte response to mitogens, antigens, and allogenic cells
- Helper and suppressor T-cell functions

and diagnostic tests used to evaluate immune competence are summarized in Chart 54-6.

Nursing Management

The nurse needs to be aware that patients undergoing evaluation for possible immune system disorders experience not only physical pain and discomfort with certain types of diagnostic procedures but also many psychological reactions. It is the nurse's role to counsel, educate, and support patients throughout the diagnostic process. Many patients may be extremely anxious about the results of diagnostic tests and the possible implications of those results for their future health, employment, and personal relationships. This is an ideal time for the nurse to provide counseling and education, should these interventions be warranted.

CRITICAL THINKING EXERCISES

1. An 80-year-old woman presents to her primary provider for evaluation of a recurrent urinary tract infection for which she has received several courses of antibiotics. What diagnostic tests would you expect to be prescribed? What is the rationale for these tests? What further assessment data would you want to obtain from this patient?
2. A 40-year-old woman with systemic lupus erythematosus (SLE) is admitted to the hospital for a kidney transplant and is prescribed immunosuppressant medications. Describe how her altered immune system would affect the care you provide. Develop an evidence-based education plan for the patient and her family before hospital discharge. Discuss the criteria used to assess the strength of the evidence for your education plan.
3. A 35-year-old woman with rheumatoid arthritis presents with an acute flare-up of her symptoms and is prescribed corticosteroids. What are your priority nursing observations and assessments? Identify priorities for patient education appropriate for the new prescription of steroids.

CHAPTER 55

Management of Patients with Immune Deficiency Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Identify the pathophysiology, clinical manifestations, and nursing management of patients with primary immune deficiency disorders (PIDD).
2. Describe the modes of transmission of human immune deficiency virus (HIV) infection and prevention strategies.
3. Explain the pathophysiology associated with the clinical manifestations of HIV and Acquired Immune Deficiency Syndrome (AIDS) and the purpose of antiretroviral therapy (ART).
4. Use the nursing process as a framework for care of the patient with HIV/AIDS.
5. Identify resources available to patient and family that promote self-management of immune deficiency disorders.

GLOSSARY

candidiasis: fungal infection, usually of skin or mucous membranes, caused by Candida species
enzyme immunoassay (EIA): a blood test that can determine the presence of antibodies to HIV in the blood or saliva; a variant of this test is called enzyme-linked immunosorbent assay (ELISA)
HIV-1: Human immunodeficiency virus 1 is a specific type of retrovirus isolated and recognized as the etiologic agent of acquired immunodeficiency syndrome
HIV encephalopathy: clinical syndrome characterized by a progressive decline in cognitive, behavioral, and motor functions
immune reconstitution inflammatory syndrome (IRIS): a syndrome that results from rapid restoration of pathogen-specific immune responses to opportunistic infections
Kaposi sarcoma: malignancy that involves the epithelial layer of blood and lymphatic vessels commonly found among HIV-infected persons
latent reservoir: the integrated HIV provirus within the $CD4^+$ T cell during the resting memory state; does not express viral proteins and is invisible to the immune system and antiviral medications
Mycobacterium avium complex (MAC): opportunistic infection caused by mycobacterial organisms that commonly causes a respiratory illness but can also infect other body systems
opportunistic infection: illness caused by various organisms, some of which usually do not cause disease in people with normal immune systems
peripheral neuropathy: disorder characterized by sensory loss, pain, muscle weakness, and wasting of muscles in the hands or legs and feet
Pneumocystis pneumonia (PCP): common opportunistic lung infection; pathogen implicated is most commonly a fungus
polymerase chain reaction: a sensitive laboratory technique that can detect and quantify HIV in a person's blood or lymph nodes
post-exposure prophylaxis (PEP): taking antiretroviral medicines as soon as possible, but no more than 72 hours (3 days) after possible HIV exposure; two to three drugs are usually prescribed which must be taken for 28 days.
pre-exposure prophylaxis (PrEP): prevention method for HIV-negative people who are at high risk of HIV infection; involves taking a specific combination of HIV medicines daily; use with condoms and other prevention tools.
progressive multifocal leukoencephalopathy: opportunistic infection that infects brain tissue and causes damage to the brain and spinal cord
retrovirus: a virus that carries genetic material in ribonucleic acid (RNA) instead of DNA and contains reverse transcriptase
reverse transcriptase: enzyme that transforms single-stranded RNA into a double-stranded DNA
viral load test: measures the quantity of HIV RNA or DNA in the blood
viral set point: amount of virus present in the blood after the initial burst of viremia and the immune response that follows
wasting syndrome: involuntary weight loss consisting of both lean and fat body mass

Introduction

The human immune system is complex and multidimensional. It works to protect against invasion by foreign substances, protect against the proliferation of neoplastic cells, and plays a key role in inflammation and healing. Patients with primary or secondary immune system disorders require care from nurses who are knowledgeable about the pathophysiology, diagnostic procedures, and interventions that are used in the management of these disorders.

PRIMARY IMMUNE DEFICIENCIES

The majority of primary immune deficiency diseases (PIDDs) are diagnosed in infancy, with a male-to-female ratio of 5 to 1. However, some PIDDs are not diagnosed until adolescence or early adulthood, when the gender distribution equalizes. Diagnosis at this stage frequently is confounded by frequent use of antibiotics that mask symptoms. On occasion, adults present with clinical episodes of infectious diseases that are beyond the scope of normal immunocompetence. Examples include infections that are unusually persistent, recurrent, or resistant to treatment and those involving unexpected dissemination of disease or atypical pathogens.

Pathophysiology

More than 270 different genes are associated with PIDDs that are recognized by the International Union of Immunological Societies (Hernandez-Trujillo, Orange, Roy, et al., 2015). These rare genetic diseases prevent the body from developing normal

immune responses resulting in a complex group of disorders with a wide array of clinical presentations. Many present during the first year of life and may be chronic, debilitating, and costly (National Institute of Allergies and Infectious Diseases [NIAID], 2015).

Clinical Manifestations

Major signs and symptoms include multiple infections despite aggressive treatment, infections with unusual or opportunistic organisms, failure to thrive or poor growth, and a positive family history (Costa-Carvalho, Grumach, Franco, et al., 2014). Table 55-1 contains selected PIDDs along with some of their clinical manifestations.

Assessment and Diagnostic Findings

There is often a considerable delay between the onset of symptoms and time of diagnosis of PIDD (Lehman, Hernandez-Trujillo, & Ballow, 2015). Because of the genetic origins of PIDD, family history should be carefully assessed but epidemiologic data about specific infectious agents should be considered as well (Costa-Carvalho et al., 2014).

Laboratory tests are used to identify antibody deficiencies, cellular (T-cell) defects, neutrophil disorders and complement deficiencies (Blaese, Stiehm, Bonilla, et al., 2013). A complete blood cell count with manual differential should always be analyzed first. Lymphopenia may indicate an immunologic abnormality; serum Ig levels (IgG, IgM, and IgA) and antibody responses to vaccines should be assessed to detect a humoral immune defect. Age-matched normal ranges need to be used since antibody levels change as the person ages (Younger, Epland, Zampelli, et al., 2015).

Prevention

Live vaccines are contraindicated in patients with antibody deficiency disorders (Younger et al., 2015). The patient is incapable of generating antibodies and the live substance in the vaccine can cause disease. Family planning should be addressed in terms of future pregnancies; in some situations, prenatal in utero testing of a fetus can determine whether the infant will be affected (Blaese et al., 2013).

Medical Management

A pattern of unusually frequent, opportunistic, or severe infections generates the possibility of a PIDD and initial testing or referral to an immunologist (Younger et al., 2015). Patients with neutropenia are at increased risk for developing severe infections despite substantial advances in supportive care. Epidemiologic shifts occur periodically and must be detected early because they influence prophylactic, empiric, and specific strategies for medical management. Attention to infection control practices is important, especially with the emergence of multidrug-resistant organisms.

Hematopoietic stem cell transplantation (HSCT) is a curative modality. The stem cells may be from embryos or adults. Toxicity and reduced efficacy are frequent limitations of HSCT. See Chapter 58 for further discussion of HSCT.

Another therapy involves the use of cells as vehicles for the delivery of genes or gene products. Gene therapy has had many adverse effects; the first studies in human participants revealed numerous toxicities with this therapy. Knowledge of these toxicities is being used in planning further studies to increase tolerability (Blaese et al., 2013).

Pharmacologic Therapy

Pharmacologic treatment depends upon the type and severity of presenting infection and the particular PIDD diagnosis (see Table 55-1). Prophylactic drug treatment prevents some bacterial and fungal infections but it must be used with caution because it has been implicated in the emergence of resistant organisms. The choices for empiric therapy include combination regimens and monotherapy. Specific choices depend on local factors (epidemiology, susceptibility/resistance patterns, availability, cost). Patients with antibody deficiencies receive regular Ig replacement therapy including both IV immunoglobulin (IVIG) and subcutaneous immunoglobulin (SCIG) to provide functional antibodies (Cherin, Marie, Michallet, et al., 2016).

The procedural guidelines for management of IVIG are described in Procedural Guidelines 55-1.

Nursing Management

Many patients with PIDDs have comorbid autoimmune disorders, such as thyroid disease, rheumatoid arthritis, cytopenias, and inflammatory bowel disease (Younger et al., 2015). Many patients require immunosuppression to ensure engraftment of depleted bone marrow during transplantation procedures. For this reason, nursing care must be meticulous. Appropriate hand hygiene and infection prevention precautions are essential. See Chapter 1, Chart 1-4 for hand hygiene methods and Chart 1-5 for a summary of infection prevention precautions. Institutional policies and procedures related to infection prevention care must be followed scrupulously until definitive evidence demonstrates that precautions are unnecessary. Continual monitoring of the patient's condition is critical, so early signs of impending infection may be detected and treated before they seriously compromise the patient's status.

Patients and caregivers in the home are taught how to administer medications, including regular Ig replacement therapy, if prescribed. Instruction is provided to the patient and family about how to administer the therapy at home (see Chart 55-1). Nurses provide ongoing education and support for the patient and family.

ACQUIRED IMMUNE DEFICIENCY

Immune deficiency can be acquired due to medical treatment such as chemotherapy (see Chapter 58) or infection from agents such as human immune deficiency virus (HIV). Advances have been made in treating HIV infection and acquired immune deficiency syndrome (AIDS); however, AIDS remains a critical public health issue in communities across the country and around the world. Prevention, early detection, and ongoing treatment remain important aspects of care for persons living with HIV infection or AIDS, sometimes referred to as PLHIV.

HIV Infection and AIDS

Since the disease now known as AIDS was first identified more than 35 years ago, remarkable progress has been made

TABLE 55-1 Selected Primary Immune Deficiency Disorders (PIDDs)

Disorder	Characteristics
Autoimmune lymphoproliferative syndrome (ALPS)	Unusually high numbers of lymphocytes accumulate in the lymph nodes, liver, and spleen leading to enlargement of those organs. Causes numerous autoimmune problems including low levels of red blood cells, platelets, and neutrophils.
Autoimmune polyglandular syndrome type 1 (APS-1). (also called autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED])	Causes a diverse range of symptoms, including autoimmunity against different types of organs and candidiasis, a fungal infection caused by *Candida* yeast.
CARD9 Deficiency and other syndromes of susceptibility to candidiasis	Results in susceptibility to fungal infections such as candidiasis; fungi are usually present on the skin; does not cause severe problems in healthy people.
Chronic granulomatous disease (CGD)	May be caused by mutations in one of five different genes. Phagocytes are unable to kill certain bacteria and fungi resulting in increased susceptibility to infections.
Common variable immunodeficiency (CVID)	Caused by a variety of genetic abnormalities resulting in defective ability of immune cells to produce normal amounts of antibodies, resulting in frequent bacterial or viral infections of the upper airway, sinuses, and lungs.
Congenital neutropenia syndromes	Characterized by low levels of neutrophils from birth.
CTLA4 Deficiency	Autoimmunity, low levels of antibodies, and excessive numbers of lymphocytes which infiltrate the gut, lungs, bone marrow, central nervous system, kidneys resulting in recurrent infections.
DOCK8 Deficiency	Genetic defect named after mutated gene responsible for the disease which causes decreased numbers and defective function of immune cells and recurrent infections.
GATA2 Deficiency	Can manifest as five different syndromes with a wide variety of symptoms including severe infections, respiratory problems, hearing loss, leg swelling, and cancer. These symptoms can appear early in childhood but also later on in life.
Glycosylation disorders with immune deficiency	Defects in glycosylation, which refers to the attachment of sugars to proteins; can disrupt the immune system resulting in immune deficiency.
Hyper-immunoglobulin E syndrome (HIES). Also called Job syndrome	Results from mutations in a gene that encodes a signaling module called STAT3 resulting in recurrent bacterial infections of skin and lungs.
Hyper-immunoglobulin M (hyper-IgM) syndromes	Immune system fails to produce normal IgA, IgG, and IgE antibodies but can produce normal or elevated IgM. Infants usually develop severe respiratory infections.
Interferon gamma, interleukin 12, interleukin 23 deficiencies	Interferon gamma, interleukin 12, and interleukin 23 are key signals that raise alert against bacteria and other infectious microbes; deficiencies result in susceptibility to infections caused by bacteria and viruses.
Leukocyte adhesion deficiency (LAD)	Phagocytes are unable to move to the site of an infection resulting in an inability to fight pathogens resulting in recurrent, life-threatening infections and poor wound healing.
NF-kB Essential modifier (NEMO) mutations	Mutations in the NEMO gene cannot "turn on" other genes especially those involved in inflammation and the immune response and are, therefore, highly susceptible to infections with mycobacteria.
PI3 Kinase disease	Genetic mutations overactivate an important immune signaling pathway causing a change reaction that disrupts the infection-fighting B and T cells resulting in a weakened immune system and frequent bacterial and viral infections.
PLCG2-associated antibody deficiency and immune dysregulation (PLAID)	Rare disorder with allergic response to cold (cold urticaria) as the most distinct symptom.
Severe combined immune deficiency (SCID)	Group of rare, life-threatening disorders caused by mutations in different genes involved in development and function of T and B cells; infants appear healthy at birth but are highly susceptible to severe infections.
Warts, hypogammaglobulinemia, infections, and myelokathexis syndrome (WHIMS)	Low levels of white blood cells, especially neutrophils, which predispose to frequent infections and persistent warts.
Wiskott–Aldrich syndrome (WAS)	Problems with B and T cells and platelets resulting in prolonged episodes of bleeding, recurrent bacterial and fungal infections and increased risk of cancers and autoimmune diseases.

Procedural Guideline 55-1

Managing Immunoglobulin Therapy

Immunoglobulin therapy is an important treatment for a variety of disease states that are characterized by deficient production of antibodies. Immunoglobulin can be administered for replacement therapy as an IV infusion or subcutaneous (SC) injection. It can safely be administered in outpatient as well as inpatient settings.

Equipment (as Needed)

- Single-use tourniquet
- Single-use scissors or clippers for hair removal
- IVIG solution, tubing, connector, catheter, or syringe
- Chlorhexidine gluconate, povidone–iodine, or alcohol swabs
- Nonlatex gloves
- Transparent dressing, bandage, or sterile gauze
- Padded, appropriate-length arm board
- Tape
- Topical analgesics
- Preservative-free 0.9% NaCl flush solution
- Electronic infusion pump

Implementation

Nursing Actions	Rationale
1. Verify prescription for IVIG therapy and identify patient.	1. Serious errors can be avoided by careful checking. Immunoglobulin is supplied in a 5% solution or a lyophilized powder with a reconstituting diluent prepared from Cohn fraction II obtained from pools of 1,000–20,000 donors. Currently, a number of different IV preparations are approved for use and have been shown to be effective and safe by the U.S. Food and Drug Administration. Immunoglobulin can also be administered via SC injection.
2. Check for allergies (i.e., latex, iodine).	2. Checking for allergies reduces risk of allergic reaction.
3. Explain procedure to patient.	3. Knowledge increases patient comfort and cooperation.
4. Perform hand hygiene, and put on disposable nonlatex gloves.	4. Asepsis is essential to prevent infection. The use of nonlatex gloves prevents exposure of nurse to patient's blood and of patient and nurse to latex.
5. Obtain height and weight of patient before treatment.	5. Obtaining height and weight helps verify accurate dosing.
6. Assess baseline vital signs before, during, and after treatment.	6. An elevated temperature at the beginning of treatment may be an indication to delay the therapy to avoid misinterpreting this as an adverse reaction.
7. Premedicate with acetaminophen/paracetamol (Tylenol) and diphenhydramine (Benadryl) as prescribed 30 minutes before the start of infusion therapy. Corticosteroids may be prescribed as well.	7. Premedicating may help avert adverse reactions. Corticosteroids may be used to prevent possible severe reactions in patients who are perceived to be at risk.
8. Verify the route and dose of IVIG therapy.	8. IVIG can be administered via the IV or SC routes. The optimal dose is determined by the patient's response. In most instances, an IV dose of 200–800 mg/kg of body weight is administered every 3–4 weeks to ensure adequate serum levels of immunoglobulin G (IgG).
9. Insert IV cannula or catheter according to Guidelines for Starting a Peripheral Intravenous Infusion, as needed.	9. Patient may need IV access, may have a port or long-term catheter for an IV infusion.
10. Administer the IV infusion at a slow rate, not to exceed 3 mL/min, usually at 100–200 mL/h.	10. Administer according to manufacturer's instructions. Beginning at a slow rate helps minimize adverse reactions.
11. Continually assess the patient for adverse reactions.	11. Be aware of complaints of a tickle or lump in the throat as the precursor to laryngospasm that precedes bronchoconstriction. Caution should be exercised when changing IVIG products, because they are not biologically equivalent. Understand that long-term tolerance of an older IVIG product does not necessarily imply tolerance to a newer product, even if it is technically superior.
12. Stop IV infusion at the first sign of reaction.	12. Initiate the institutional protocol to be followed in an emergent situation. Patients who have an IgA deficiency have IgE antibodies to IgA, which requires administration of plasma or immunoglobulin replacement from IgA-deficient patients. Because all IV immunoglobulin preparations contain some IgA, they may cause an anaphylactic reaction in patients with IgE anti-IgA antibodies.
13. Administer SC immunoglobulin as orders.	13. The pharmacokinetics of IgG differ when smaller doses are given more frequently, as is commonly done with SC regimens.

Adapted from Cherin, P., Marie, I., Michallet, M., et al. (2016). Management of adverse events in the treatment of patients with immunoglobulin therapy: A review of evidence. Autoimmunity Reviews, 15, 71–81.

Chart 55-1 HOME CARE CHECKLIST

Home Administration of Ig Replacement Therapy

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of immune deficiency on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State what types of changes are needed (if any) to maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and intravenous supply vendor.
- State how to obtain medical supplies and carry out dressing changes, IV access site care, and other prescribed regimens.
- Identify the benefits and expected outcome of regular Ig replacement therapy.
- State rationale for prophylactic use of acetaminophen/paracetamol (Tylenol) and diphenhydramine (Benadryl) before treatment begins.
- State the rationale for prehydration on the day before infusion.
- Demonstrate how to prepare regular Ig replacement therapy.
- Demonstrate how to administer regular Ig replacement therapy.
- Demonstrate how to clean and maintain IV equipment, as applicable.
- Identify side effects and adverse effects of regular Ig replacement therapy.
- Demonstrate how to monitor for adverse effects of regular Ig replacement therapy.
- Describe to whom, how, and when to report adverse effects of regular Ig replacement therapy.
- Describe appropriate actions to take for adverse effects.
- Verbalize understanding of emergency measures for anaphylactic shock.

ADL, activities of daily living; IADL, independent activities of daily living.

in improving the length and quality of life for people living with HIV disease. During the first decade, progress was associated with the recognition and treatment of opportunistic diseases and introduction of prophylaxis against **opportunistic infections** (illnesses caused by various organisms, some of which usually do not cause disease in people with normal immune systems). The second decade witnessed progress in the development of highly active antiretroviral drug therapies (HAART) as well as continuing progress in the treatment of opportunistic infections. The third decade has focused on issues of preventing new infections, adherence to antiretroviral therapy (ART), development of second-generation combination medications that affect different stages of the viral life cycle, and continued need for an effective vaccine. The HIV antibody test, an **enzyme immunoassay** (**EIA**; or a variant of this test called *enzyme-linked immunosorbent assay* [ELISA]), became available in 1984, allowing early diagnosis of the infection before the onset of symptoms. Since then, HIV infection has been best managed as a chronic disease, most appropriately in an outpatient care setting, whereas AIDS may involve acute conditions that require hospitalization.

AIDS is defined as the occurrence of life-threatening opportunistic infections, malignancies, neurologic diseases, and other specific illnesses that occur in patients with HIV infection with a CD4 count <200 cells/mm^3 (NACO, 2021).

Epidemiology

Criteria for a confirmed case of HIV infection can be met by laboratory evidence along with clinical evidence but laboratory evidence is mandatory (e.g., patient signs and symptoms). A case of HIV infection can be classified in one of five HIV infection stages (0, 1, 2, 3, or unknown). Stage 0 indicates early HIV infection, inferred from laboratory testing; stages 1, 2, and 3 are based on the CD4$^+$ T-lymphocyte count; while cases with no information on CD4$^+$ T-lymphocyte count or percentage are classified as stage unknown (Selik, Mokotoff, Branson, et al., 2014). See Table 55-2 for further explanation of stages.

In light of intensive efforts globally, the HIV pandemic has been addressed but the burden remains significant. According to the World Health Organization (WHO) (2015a), there were approximately 36.9 million people living with HIV at the end of 2014 with 2.0 million people becoming newly infected with HIV in 2014 globally. Sub-Saharan Africa is the most affected region, with 25.8 million people living with HIV in 2014 and almost 70% of the global total of new HIV infections. About 51% of people with HIV know that they are infected; 40% of those needing ART are accessing treatment globally. Forty-seven percent of adults living with HIV/AIDS are female (17.4 million) (WHO, 2015b), many of whom are in their child-bearing years. The diagnosis and treatment of HIV infection remain highly dependent upon the geographic location of where the person is living.

Magnitude of Problem in India

The recent epidemiological data by the National AIDS Control Association (NACO, 2020) showed that the prevalence rate of AIDS was 0.22% among adult population aged 15 to 49 with an estimated 0.23% prevalence among males and 0.20% among females of the same age group. In the last 10 years, there has been a 33.3% decline in the AIDS prevalence among adults. The North East states of Mizoram and Nagaland secured the top two spots with a prevalence rate of 2.37% and 1.44%, respectively. The lowest prevalence was recorded in the state of Jammu and Kashmir (0.06%). As per the statistical data available in 2020, the total number of people living with HIV (PLHIV) was 23.19 lakhs (NACO, 2020). The national PLHIV rate was estimated to be 1721 per 1 million population. Mizoram had the highest rate of PLHIV with 17,207 per million population, while in Nagaland, the rate of PLHIV was 10,421 per million. The incidence rate of HIV in India was 0.04/1000 uninfected population in the year 2020 (NACO, 2020). The new HIV infection has shown a decline of 89% from the peak seen in 1997. The new HIV infection was estimated to be around 57,550 in the year 2020 (National Guidelines for HIV Care and Treatment, 2021).

HIV Transmission

Inflammation and breaks in the skin or mucosa result in the increased probability that an HIV exposure will lead to infection. Human immune deficiency virus type 1 (HIV-1) is transmitted in body fluids (blood, seminal fluid, vaginal secretions, amniotic fluid, and breast milk) that contain infected cells. Higher amounts of HIV and infected cells in the body fluid are associated with

TABLE 55-2 HIV Infection Stages 1, 2, and 3 Based on Age-Specific Laboratory Data

	Age on Date of CD4+ T-lymphocyte Test					
	<1 year		1–5 years		≥6 years	
Stage	Cells/IL	%	Cells/IL	%	Cells/IL	%
1	≥1,500	≥34	≥1,000	≥30	≥500	≥26
2	750–1,499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

If a stage-3-defining opportunistic illness has been diagnosed, then the stage is 3 regardless of CD4+ T-lymphocyte test.

Stage-3-Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent (only among children aged less than 6 years)
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive (only in persons aged 6 years or older)
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii,* disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary (only in persons aged 6 years or older) disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii (previously known as "*Pneumocystis carinii*") pneumonia (PCP)
Pneumonia, recurrent (only in persons aged 6 years or older)
Progressive multifocal leukoencephalopathy
Salmonella septicemia (recurrent)
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV

Adapted from Selik, R., Mokotoff, E., Branson, B., et al. (2014). Revised surveillance case definition for HIV infection—United States, 2014. Morbidity and Mortality Weekly Report, 63(RR03), 1–10.

the probability that the exposure will result in infection. Mother-to-child transmission of HIV-1 may occur in utero, at the time of delivery, or through breast-feeding, but most perinatal infections are thought to occur after exposure during delivery. HIV is not transmitted through casual contact (see Chart 55-2).

Blood and blood products can transmit HIV to recipients. However, the risk associated with transfusions has been virtually eliminated as a result of voluntary self-deferral, completion of a detailed health history, extensive testing, heat treatment of clotting factor concentrates, and more effective virus inactivation methods. Donated blood is tested for antibodies to HIV-1, human immunodeficiency virus type 2 ([retrovirus identified in 1986 in patients with AIDS in Western Africa]), and the p24 antigen; since 1999, additional testing has been performed.

Chart 55-2 RISK FACTORS

Risks Associated with HIV Infection

- Sharing infected injection drug use equipment
- Having sexual relations with infected individuals (both male and female)
- Infants born to mothers with HIV infection and/or who are breast-fed by HIV-infected mothers
- People who received organ transplants, HIV-infected blood, or blood products (especially between 1978 and 1985)

Gerontologic Considerations

A growing number of adults aged 50 and older have HIV/AIDS (National Institute on Aging [NIA], 2015). Many were diagnosed with HIV in their younger years and are benefitting from effective treatment. However, thousands of older adults unknowingly become infected with HIV every year. Older adults are less likely than younger people to get tested. Signs of HIV/AIDS can be mistaken for the aches and pains of normal aging. Older adults might be coping with other diseases common to aging that can mask the signs of HIV/AIDS.

Tillman and Mark (2015) examined published research on the frequency of HIV and sexually transmitted infection (STI)

testing among older adults (aged 50 and older), factors related to HIV and STI testing among older adults, and the perspectives and practices of older adults and health care providers related to patient-provider communication regarding sexual health. They found that low rates of HIV and STI testing were influenced by low perceived risk of infection by older adults and their health care providers. Providers bring societal age and gender biases to their perceptions of patient sexuality, which influence their communication about sexual health with older adult patients. Providers' assumptions that discussions about sexual health will offend their patients, as well as their own discomfort with talking to older adults about sex, inhibit them from assessing risk factors that may indicate a need for HIV and STI testing. Older adults living with HIV/AIDS also experience the development of other comorbidities such as cardiovascular disease and diabetes occurring within that specific demographic population, and HIV/AIDS becomes a contributing, but not necessarily primary, cause of mortality.

Prevention of HIV Infection

Nurses need to help in efforts to prevent HIV infection by educating how to eliminate or reduce risks associated with HIV infection and AIDS. HIV is transmitted through the exchange of some infected body fluids (see Chart 55-2). While behavioral interventions such as encouraging the use of condoms are highly effective in reducing the transmission of HIV, the HIV-negative person must be motivated and have the freedom to choose to use the method. In some situations, however, that freedom is absent. For example, a lack of freedom exists in a discordant couple (those in which only one partner has HIV) if the husband refuses to use condoms and the wife's cultural and religious beliefs require intercourse with her husband. In this context, pre-exposure prophylaxis (PrEP) might be appropriate. PrEP involves taking one pill containing two HIV medications (tenofovir disoproxil fumarate 300 mg and emtricitabine 200 mg [Truvada]) daily in order to avoid the risk of sexual HIV acquisition in adults and adolescents age 12 and older (Comerford, 2015). HIV status should be checked every 3 months to be sure that the person has not become infected. The ultimate goal of PrEP is to reduce the acquisition of HIV infection with its resulting morbidity, mortality, and cost to individuals and society (US Public Health Service, 2014).

Preventive Education

Prevention of HIV infection is achieved through: (a) behavioral interventions have been effective in reducing the risk of acquiring or transmitting HIV by ensuring that people have the information, motivation, and skills necessary to reduce their risk; (b) HIV testing, because most people change behaviors to protect their partners if they know they are infected with HIV; and (c) linkage to treatment and care, which enables individuals with HIV to live longer, healthier lives and reduce their risk of transmitting HIV (CDC, 2015c). The CDC (2014a), through the HIV/AIDS Prevention Research Synthesis Project, provides information about evidence-based behavioral interventions that can be used in a number of settings with targeted populations. Strategies to protect against infection are outlined in Chart 55-3. Other than abstinence, consistent and correct use of condoms (see Chart 55-4) is the only effective method to decrease the risk of sexual transmission of HIV infection. When latex male condoms are used consistently and correctly during vaginal or anal intercourse, they are highly effective in preventing the sexual transmission of HIV (CDC, 2013). Nonlatex condoms made of natural materials such as lambskin are available for people with latex allergy but will not protect against HIV infection. A male condom should be used for oral contact with the penis, and a dental dam (a flat piece of latex used by dentists to isolate a tooth for treatment) or an altered condom can be used for oral contact with the vagina or rectum. Medical male circumcision, when safely provided by well-trained health professionals, reduces the risk of heterosexually acquired HIV infection in men by approximately 60%. This is a key intervention in generalized epidemic settings with high HIV prevalence and a low male circumcision rate (WHO, 2015a).

The polyurethane female condom, which is an effective contraceptive, provides a physical barrier that prevents exposure to genital secretions containing HIV, such as semen and vaginal fluid, and is inserted by the woman. Other safe and effective woman-controlled methods such as microbicides remain elusive although clinical trials continue globally. Microbicides are gels, films, or *suppositories* that can kill or neutralize viruses and bacteria; *vaginal* and *rectal* microbicides are being researched to see if they can prevent sexual transmission of HIV.

Total abstinence from addictive drugs might not be a realistic short-term goal. Using a harm reduction framework, the nurse works with people who inject drugs to assist them to increase their healthy behaviors. Harm reduction frameworks use practical strategies and ideas aimed at reducing negative consequences associated with drug use and a movement for social justice built on a belief in, and respect for, the rights of people who use drugs. Therefore, under this framework,

Chart 55-3 HEALTH PROMOTION

Protecting Against HIV Infection

All patients should be advised to:

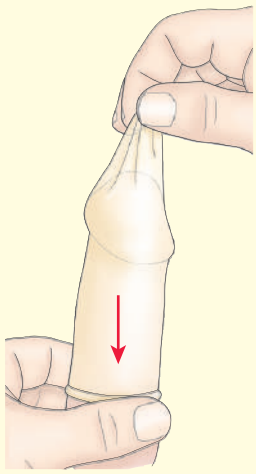
- Abstain from exchanging sexual fluids (semen and vaginal fluid).
- Reduce the number of sexual partners to one.
- Always use latex condoms. If the patient is allergic to latex, nonlatex condoms should be used; however, they will not protect against HIV infection.
- Not reuse condoms.
- Avoid using cervical caps or diaphragms without using a condom as well.
- Always use dental dams for oral–genital or anal stimulation.
- Avoid anal intercourse, because this practice may injure tissues; if not possible, use lubricant—there are water and silicone-based products designed for anal sex.
- Avoid manual–anal intercourse ("fisting").
- Avoid sharing needles, razors, toothbrushes, sex toys, or blood-contaminated articles.
- Consider PrEP if regularly engage in high-risk behaviors.

Patients who are HIV seropositive should also be advised to:

- Take ART regularly to achieve viral suppression.
- Inform previous, present, and prospective sexual and drug-using partners of their HIV-positive status. If the patient is concerned for their safety, advise the patient that many states have established mechanisms through the public health department in which professionals are available to notify exposed contacts.
- Avoid having unprotected sex with another HIV-seropositive person. Cross-infection with that person's HIV can increase the severity of infection.
- Not donate blood, plasma, body organs, or sperm.

ART, antiretroviral therapy; PrEP, pre-exposure prophylaxis.

Chart 55-4 PATIENT EDUCATION



The Correct Way to Use a Male Condom

The nurse instructs the patient to:

1. Put on a new condom before any kind of sex.
2. Hold the condom by the tip to squeeze out the air.

3. Unroll the condom all the way over the erect penis.

4. Have sex.
5. Hold the condom so it cannot come off the penis.
6. Pull out.
7. Use a new condom if you want to have sex again or if you want to have sex in a different place (e.g., in the anus and then in the vagina).
8. *Note:* Keep condoms cool and dry. Never use skin lotions, baby oil, petroleum jelly, or cold cream as lubricants; the oil in these products will cause the latex condom to break. Products made with water (such as K-Y jelly or glycerin) are safer to use.

needle exchange programs are usually free and do not promote increased drug use; on the contrary, they have been found to decrease the incidence of blood-borne infections in people who inject drugs. Nurses should refer clients to needle exchange programs in their neighborhood whenever available. If new needles and syringes are not available, cleaning used needles and syringes with bleach may reduce the risk of HIV (CDC, 2015d). Sharing of drug-use equipment is a high-risk behavior for a number of blood-borne infections and should be avoided.

Related Reproductive Education

Because HIV infection in women often occurs during the child-bearing years, family planning issues need to be addressed. Attempts to achieve pregnancy by couples in which only one partner has HIV (known as discordant couples) expose the unaffected partner to the virus. Efforts at artificial insemination using processed semen from an HIV-infected partner continue. Studies are needed, because HIV has been found in the spermatozoa of patients with HIV infection, and it is possible that HIV can replicate in the male germ cell. Women considering pregnancy need to have accurate information about the risks of transmitting HIV infection to themselves, their partner, and their future children, and about the benefits of taking ART to reduce perinatal HIV transmission. Women in resource-rich settings who are HIV positive should be instructed not to breast-feed their infants, because HIV is transmitted through breast milk.

An increased risk of HIV infection in women is associated with hormonal contraceptive use, but a cause-and-effect relationship has not been established (Sharma & Walmsley, 2015). Women who are HIV negative and who use hormonal contraceptives to prevent pregnancy should be encouraged to use methods to block HIV infection including PrEP; providers should explore drug–drug interactions between hormonal contraceptives and ART in women infected with HIV (Sharma & Walmsley, 2015).

Prevention in Lesbian, Gay, Bisexual, and Transgender

Many health care providers are insufficiently prepared to meet the unique health needs of those who identify as lesbian, gay, bisexual, and transgender (LGBT). LGBT youth, in particular, are at higher risk for contracting HIV (Bosse, Nesteby, & Randall, 2015); (Johnson & Amella, 2013). At the same time, this population experiences significant challenges due to family rejection, lack of social support, stigma, isolation, minority stress, as well as abuse and harassment (Bosse, Nesteby, & Randall, 2015); (Johnson & Amella, 2013). Nurses need to be nonjudgmental in order to be effective in educating this population about prevention methods.

Reducing the Risk of Transmission to Health Care Providers

Standard Precautions

Implementation of appropriate hand hygiene measures (see Chart 1-4 for further information on hand hygiene methods) remains the most effective measure to prevent transmission of organisms. To reduce the risk of exposure of health care workers to HIV, the CDC developed standard precautions (see Chart 55-5) which are designed to reduce the risk of transmission of pathogens. Standard precautions are used when working with all patients in all health care settings, regardless of their diagnosis or presumed infectious status.

Post-Exposure Prophylaxis for Health Care Providers

Post-exposure prophylaxis (PEP) includes taking antiretroviral medicines as soon as possible, but no more than 72 hours (3 days) after possible HIV exposure; two to three drugs are usually prescribed which must be taken for 28 days.

Health care workers who are exposed to a needle stick involving HIV-infected blood in a health care setting have a 0.23% risk of becoming HIV infected; the risk of infection due to occupational exposure is very low. A tertiary care center reported occupational exposure of 105 healthcare workers to blood and body fluids. 85% of the exposure was due to

Chart 55-5

Recommendations for Standard Precautions

1. **Hand hygiene**: Use after touching blood, body fluids, secretions, excretions, or contaminated items; immediately after removing gloves; and between patient contacts.
2. **Personal protective equipment**:
   - *Gloves:* Use for touching blood, body fluids, secretions, excretions, and contaminated items, and for touching mucous membranes and nonintact skin.
   - *Gown:* Use during procedures and patient care activities when contact of clothing/exposed skin with blood or body fluids, secretions, and excretions is anticipated.
   - *Mask, eye protection (goggles), face shield*[1]: Use during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, and secretions, especially suctioning or endotracheal intubation.
3. **Soiled patient care equipment**: Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; and perform hand hygiene.
4. **Environmental control**: Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas.
5. **Textiles and laundry**: Handle in a manner that prevents transfer of microorganisms to others and to the environment.
6. **Needles and other sharps**: Do not recap, bend, break, or hand manipulate used needles; if recapping is required, use a one-handed scoop technique only; use safety features when available; and place used sharps in a puncture-resistant container.
7. **Patient resuscitation**: Use mouthpiece, resuscitation bag, and other ventilation devices to prevent contact with mouth and oral secretions.
8. **Patient placement**: Prioritize for single-patient room if patient is at increased risk for transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk for acquiring infection or developing adverse outcome following infection.
9. **Respiratory hygiene/cough etiquette** (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter, such as triage and reception areas in emergency departments and physician offices): Instruct symptomatic people to cover mouth and nose when sneezing or coughing, use tissues and dispose in no-touch receptacle, observe hand hygiene after soiling of hands with respiratory secretions, and wear surgical mask if tolerated.

[1]During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols (e.g., severe acute respiratory syndrome), wear a fit-tested N95 or higher respirator in addition to gloves, gown, and face/eye protection.

needle stick injuries. 16 of them were exposed to body fluids of HIV-positive people (Priya, Krishnan, Jayalakshmi, et al., 2015). Occupational exposure is considered an urgent medical concern and should be managed immediately after possible exposure—the sooner the better; every hour counts (CDC, 2015e). The CDC is suggesting that these post-exposure guidelines be followed after occupational and other exposures such as sexual assault. Chart 55-6 provides the strategies and emphasizes the need for quick action.

Chart 55-6

Post-HIV Exposure Prophylaxis for Health Care Providers

If you sustain an occupational exposure to HIV, take the following actions immediately:

- Alert your supervisor and initiate the occupational exposure reporting system used in the setting.
- Determine the HIV status of the exposure source (i.e., patient) when possible to guide appropriate use of HIV post-exposure prophylaxis (PEP). Use rapid-testing if the HIV status of the patient is unknown. Get counseling at the time of exposure and at follow-up appointments
- The Govt of India/concerned health agency is supplying the ARV drugs.
- Exposed health care providers (HCP) are advised to use precautions (e.g., use of barrier contraception and avoidance of blood or tissue donations, pregnancy, and, if possible, breast-feeding) to prevent secondary transmission, especially during the first 6–12 weeks after exposure.
- For exposures for which three drug PEP is prescribed, HCPs are informed regarding the following:
  - Possible drug toxicities (e.g., rash and hypersensitivity reactions that could imitate acute HIV seroconversion and the need for monitoring)
  - Possible drug interactions
  - The need for adherence to PEP regimens

Undergo early reevaluation after exposure:

- Regardless of whether an HCP is taking PEP, reevaluation of exposed HCP within 72 hours after exposure is strongly recommended, as additional information about the exposure or the source patient may be available.

Follow-up with HIV testing and appointments. At a minimum, this follow-up should include:

- HIV testing at baseline and at 6 weeks, 12 weeks, and 6 months after exposure; alternatively, if the HCP is certain that a fourth-generation combination HIV p24 antigen–HIV antibody test is being utilized, then HIV testing could be performed at baseline, 6 weeks after exposure, and 4 months after exposure
- Complete blood counts and renal and hepatic function tests (at baseline and 2 weeks after exposure; further testing may be indicated if abnormalities are detected)

Note: All HIV testing results should preferably be given to the exposed HCP during face-to-face appointments.

Updated US Public Health Service guidelines for the management of occupational exposures to human immunodeficiency virus and recommendations for post-exposure prophylaxis. Infection Control and Hospital Epidemiology, 34(9), 875–892.

Vaccination

In the face of a global pandemic, the search for an effective vaccine against the HIV remains an urgent priority (Fauci & Marston, 2015). The first U.S. government-sponsored phase I trial of an HIV vaccine was launched in 1987 and intensive efforts worldwide using a variety of strategies continue.

Pathophysiology

Because HIV is an infectious disease, it is important to understand how HIV-1 integrates itself into a person's immune system and how the immune response plays a pivotal role in the course of HIV disease. This knowledge is also essential for understanding medication therapy and vaccine development. Viruses are intracellular parasites. HIV is in the subfamily of

lentiviruses and is a retrovirus because it carries its genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA) (Grossman & Porth, 2014).

Two genetically different but closely related forms of HIV (HIV-1 and HIV-2) have been identified. The course of illness is slower when infection is caused by HIV-2, which seems to be more common in Western Africa compared to HIV-1, which is more common in other regions of the globe. Blood tests may be used to screen for both forms of HIV. As shown in Figure 55-1A, HIV consists of a viral core containing viral RNA, surrounded by an envelope consisting of protruding glycoproteins.

All viruses target specific cells. HIV targets cells with $CD4^+$ receptors, which are expressed on the surface of T lymphocytes, monocytes, dendritic cells, and brain microglia. Mature T cells (T lymphocytes) are composed of two major subpopulations that are defined by cell surface receptors of $CD4^+$ or $CD8^+$. Approximately two thirds of peripheral blood T cells are $CD4^+$, and approximately one third are $CD8^+$. Most people have about 700 to 1,000 $CD4^+$ cells/mm^3, but a level as low as 500 cells/mm^3 can be considered within normal limits. During stage 0, which is also known as acute/recent infection, most varieties of HIV-1 use the chemokine cell receptor molecule CCR5 (R5 virus) for entry to T cells in addition to the $CD4^+$ receptor, which suggests that the R5 variant is preferred to a different variant (CXCR4) but the preferred coreceptor can shift over the course of infection.

The HIV life cycle is complex (see Fig. 55-1B) and consists of the following steps (Grossman & Porth, 2014):

1. **Attachment/Binding:** In this first step, the GP120 and GP41 glycoproteins of HIV bind with the host's uninfected $CD4^+$ receptor and chemokine coreceptors, usually CCR5, which results in fusion of HIV with the $CD4^+$ T-cell membrane.
2. **Uncoating/Fusion:** Only the contents of HIV's viral core (two single strands of viral RNA and three viral enzymes: reverse transcriptase, integrase, and protease) are emptied into the $CD4^+$ T cell.

Physiology/Pathophysiology

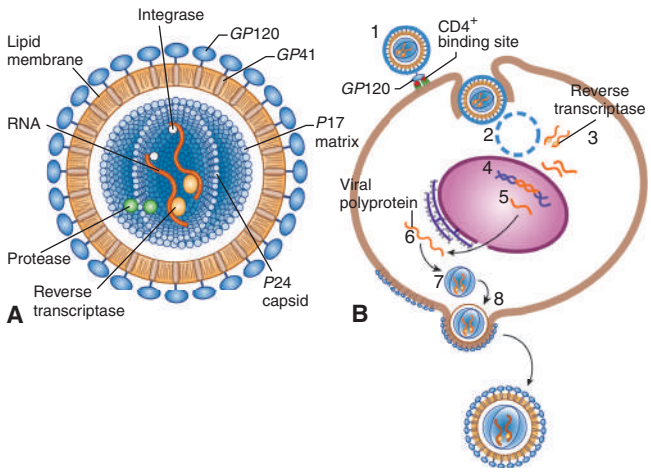

Figure 55-1 • **A**. Structure of HIV-1 virus. The virus surrounded by a lipid envelope. **B**. Life cycle of HIV-1. Reprinted with permission from Grossman, S., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

3. **DNA synthesis:** HIV changes its genetic material from RNA to DNA through action of reverse transcriptase, resulting in double-stranded DNA that carries instruction for viral replication.
4. **Integration:** New viral DNA enters the nucleus of the $CD4^+$ T cell and through action of integrase is blended with the DNA of the $CD4^+$ T cell, resulting in permanent, lifelong infection. Prior to this, the uninfected person has been only exposed to, not infected with, HIV. With this step, HIV infection is permanent.
5. **Transcription:** When the $CD4^+$ T cell is activated, the double-stranded DNA forms single-stranded messenger RNA (mRNA), which builds new viruses.
6. **Translation:** The mRNA creates chains of new proteins and enzymes (polyproteins) that contain the components needed in the construction of new viruses.
7. **Cleavage:** The HIV protease enzyme cuts the polyprotein chain into the individual proteins that make up the new virus.
8. **Budding:** New proteins and viral RNA migrate to the membrane of the infected $CD4^+$ T cell, exit from the cell, and start the process all over.

In resting (nondividing) $CD4^+$ cells, HIV survives in a latent state as an integrated **provirus** that produces few or no viral particles. These resting $CD4^+$ T cells can be stimulated to produce new particles if something activates them, such as another infection. When a resting T cell that harbors this integrated DNA (also known as provirus) becomes activated against HIV or other microbes, the cell begins to produce new copies of both RNA and viral proteins. Consequently, whenever the infected $CD4^+$ cell is activated, HIV replication and budding occur, which can destroy the host cell. Newly formed HIV released into the blood can infect other $CD4^+$ cells.

A mutation of CCR5 that is common in Caucasians, but not other ethnic groups, has been identified. About 1% of Caucasians lack functional CCR5 and are highly protected against HIV infection even if exposed (although protection is not absolute); about 18% are not markedly protected against infection but, if infected, demonstrate significantly slower rates of disease progression. CCR5 levels on T cells influence HIV acquisition, disease progression rates, viral load, and immune recovery during ART (Gornalusse, Mummidi, Gaitan, et al., 2015).

HIV-1 mutates quickly, at a relatively constant rate, with about 1% of the virus's genetic material changing annually. HIV-1 exhibits substantial genetic diversity, and several different genotypes of HIV-1 exist throughout the world. There is a major group (group M), which consists of subtypes A through L, and a more diverse collection of outliers, which has been referred to as groups N and O. Subtype B HIV-1 viruses predominate in the Western world; this genetic variation is one of the major reasons why effective vaccine development has been such a challenge.

Stages of HIV Infection

There are five stages of HIV infection based on clinical history, physical examination, laboratory evidence (Selik et al., 2014), signs and symptoms, and associated infections and malignancies. See Table 55-2.

The period from infection with HIV to the development of HIV-specific antibodies is known as **primary infection or acute HIV infection** (previously known as the window period) and is part of stage 0 (Selik et al., 2014). Acute HIV infection is the

interval between the appearance of detectable HIV RNA and the first detection of antibodies. Its duration also depends on the design of the antibody immunoassay and the sensitivity of the immunoassay during seroconversion (CDC, 2014b). Initially, there is a period during which those who are HIV positive test negative on the HIV antibody blood test, although they are infected and highly infectious, because their viral loads are very high. About 40% to 80% of patients develop clinical symptoms of a nonspecific viral illness (e.g., fever, fatigue, or rash) lasting 1 to 2 weeks. After 2 to 3 weeks, antibodies to the glycoproteins of the HIV envelope can be detected in the sera of people infected with HIV, but most of these antibodies lack the ability to totally control the virus. By the time neutralizing antibodies can be detected (stage 1), HIV-1 is firmly established in the host.

Primary or acute infection is characterized by high levels of viral replication, widespread dissemination of HIV throughout the body, and destruction of $CD4^+$ T cells, which leads to dramatic drops in $CD4^+$ T-cell counts (normally 500 to 1,500 cells/mm^3 of blood). The host responds to the HIV infection through a $CD4^+$ T-cell response that causes other immune cells, such as $CD8^+$ lymphocytes, to increase their killing of infected, virus-producing cells. The body produces antibody molecules in an effort to contain the free HIV particles (outside cells) and assist in their removal. During this stage, the virus is widely disseminated in lymphoid tissue, and a latent reservoir within resting memory $CD4^+$ T cells is created.

The amount of virus in the body after the initial immune response subsides is referred to as the viral set point, which results in an equilibrium between HIV levels and the immune response that may be elicited. This can last for years and is inversely correlated with disease prognosis. The higher the viral set point, the poorer the prognosis. After the viral set point is reached, a chronic stage persists in which the immune system cannot eliminate the virus despite its best efforts. This set point varies greatly from patient to patient and dictates the subsequent rate of disease progression; on average, 8 to 10 years can pass before a major HIV-related complication develops. In this prolonged, chronic stage, patients feel well and have few, if any, symptoms. Apparent good health continues because $CD4^+$ T-cell levels remain high enough to preserve immune defensive responses, but over time, the number of $CD4^+$ T cells continues to decrease.

Stage 2 occurs when $CD4^+$ T-lymphocyte cells are between 200 and 499, stage 3 when the count drops below 200 cells/mm^3 of blood and at this point, the person is considered to have AIDS for surveillance purposes. HIV disease progression is classified from less to more severe; once a case is classified into a surveillance severity stage, it cannot be reclassified into a less severe stage even if the $CD4^+$ T-lymphocytes increase, which often occurs when a person receives ART. A stage 3 diagnosis has implications for services (e.g., disability benefits, housing, and food stamps), because these programs are often linked to living with severe immune dysfunction.

Assessment and Diagnostic Findings in HIV Infection

During the first stage of HIV infection, the patient may be asymptomatic or may exhibit various signs and symptoms such as fatigue or skin rash. Patients who are in later stages of HIV infection may have a variety of symptoms related to their immunosuppressed state. The staging system requires laboratory evidence of HIV infection in order to diagnose HIV or AIDS (see Table 55-2).

HIV Tests

Several screening tests are used to diagnose HIV infection, and others are used to determine the stage and severity of the infection. A serologic testing algorithm for recent HIV seroconversion (STARHS) analyzes HIV-positive blood samples to determine whether an HIV infection is recent or has been ongoing. As per NACO guidelines, all pregnant ladies are tested for HIV in India. There are three types of HIV diagnostic tests: antibody tests, antigen/antibody tests, and nucleic acid (RNA) tests. Antibody tests detect antibodies, not HIV itself, while antigen and RNA tests directly detect HIV. The updated CDC recommendations (2014b) tests for HIV antigens and HIV nucleic acid because studies from populations at high risk for HIV demonstrated that antibody testing alone might miss a considerable percentage of HIV infections detectable by virologic tests, especially during stage 0.

Blood tests can detect HIV infection sooner after exposure than oral fluid tests because the level of antibody in blood is higher than it is in oral fluid. Likewise, antigen/antibody and RNA tests detect infection in blood before antibody tests. Some newer antigen/antibody laboratory tests can sometimes find HIV as soon as 3 weeks after exposure to the virus. No antigen/antibody or RNA tests are available for oral fluid.

Follow-up testing is performed if the initial test result is positive to ensure a correct diagnosis. These tests include (CDC, 2015f):

- antibody *differentiation test,* which distinguishes HIV-1 from antibodies
- *HIV-1 nucleic acid test,* which looks for the virus RNA directly

Table 55-3 identifies common blood tests used for screening.

Since negative perceptions and judgments associated with being HIV infected continue to persist, stigma remains one of the biggest social challenges (Chambers, Rueda, Baker, et al., 2015). When the result of the HIV antibody test is received, it is carefully explained to the patient in private (see Chart 55-7). All test results are confidential. Education and counseling about the test result and about preventing transmission are essential. The patient's psychological response to a positive test result may include feelings of panic, depression, and hopelessness. The social and interpersonal consequences of a positive test result can be devastating. The patient may lose their sexual partner, housing, and their job because of disclosure. He or she may be subjected to physical abuse and, although illegal, experience discrimination in employment as well as social ostracism. For these reasons and others, patients who test positive may need ongoing counseling as well as referrals for social, financial, medical, and psychological support services. They

TABLE 55-3 HIV Screening Blood Tests

Laboratory Test	Indications
HIV-1/HIV-2 immunoassay	Tests for both HIV-1 and HIV2 antibodies
HIV/1-HIV-2 antigen/antibody combination immunoassay	Tests for both antibody and virus for both HIV-1 and HIV-2
HIV-1 differentiation assay	Differentiates HIV-1 from HIV-2
HIV-1 nucleic acid amplification test	Tests directly for virus
HIV-1 p24 antigen	Tests directly for virus

Chart 55-7

HIV Test Results: Implications for Patients

Interpretation of Positive Test Results

- Antibodies to HIV are present in the blood (the patient has been infected with the virus, and the body has produced antibodies).
- HIV is active in the body, and the patient can transmit the virus to others.
- Despite HIV infection, the patient does not necessarily have AIDS.
- The patient is not immune to HIV (the antibodies do not indicate immunity).

Interpretation of Negative Test Results

- Antibodies to HIV are not present in the blood at this time, which can mean that the patient has not been infected with HIV or, if infected, the body has not yet produced antibodies (stage 0).
- The patient should continue taking precautions. The test result does not mean that the patient is immune to the virus, nor does it mean the patient is not infected; it just means that the body may not have produced antibodies yet. If viral test used, a negative result is more consistent with the conclusion that the patient is uninfected.

AIDS, acquired immune deficiency syndrome; HIV, human immune deficiency virus.

must be connected to health care services to evaluate their stage of HIV infection and develop the treatment plan. Patients whose test results are seronegative may develop a false sense of security, possibly resulting in continued high-risk behaviors or feelings that they are immune to the virus. These patients may need ongoing counseling to help modify high-risk behaviors and to encourage returns for repeated testing. Other patients may experience anxiety regarding the uncertainty of their status. In addition to screening for HIV, patients should be screened for other blood-borne infections such as hepatitis; other STIs such as syphilis; and other infections associated with T-cell immunity such as tuberculosis (TB).

Staging

Two surrogate markers are used routinely to assess immune function and level of HIV viremia: $CD4^+$ T-cell count ($CD4^+$ count) and plasma HIV RNA (viral load). $CD4^+$ count should be measured in all patients at entry into care. **Viral load tests** use target amplification methods to quantify HIV RNA or DNA levels in the plasma. Target amplification methods include reverse transcriptase–polymerase chain reaction (RT-PCR) and nucleic acid sequence–based amplification (NAT). A widely used viral load test measures plasma HIV RNA levels. Currently, these tests are used to track viral load and response to treatment of HIV infection. RT-PCR is also used to detect HIV in high-risk seronegative people before antibodies are measurable, to confirm a positive EIA result, and to screen neonates. HIV culture or quantitative plasma culture and plasma viremia are additional tests that measure viral burden, but they are used infrequently. Viral load is a better predictor of the risk of HIV disease progression than the $CD4^+$ count. The lower the viral load, the longer the time to AIDS diagnosis and the longer the survival time. The key goal of ART is to achieve and maintain durable viral suppression.

Treatment of HIV Infection

Antiretroviral treatment guidelines for HIV-infected adults and adolescents that have been recommended by NACO are followed across the country (ART guidelines, NACO, 2013). The $CD4^+$ count serves as the major laboratory indicator of immune function and prophylaxis for opportunistic infections, and is the strongest predictor of subsequent disease progression and survival New drugs that offer new mechanisms of action, improvements in potency and activity even against multidrug-resistant viruses, dosing convenience, and tolerability have been approved. The overarching goal of ART is to suppress HIV replication to a level below which drug-resistant mutations do not emerge; related goals are to (1) reduce HIV-associated morbidity and prolong the duration and quality of survival, (2) restore and preserve immunologic function, (3) maximally and durably suppress plasma HIV viral load, and (4) prevent HIV transmission (ART Guidelines, NACO, 2013). ART is now recommended for all HIV-infected patients regardless of their viral load or $CD4^+$ count (ART Guidelines, NACO, 2013). Optimal viral suppression is defined generally as a viral load persistently below the level of detection (HIV RNA less than 20 to 75 copies/mL, depending on the assay used). Clinicians, in partnership with patients, make treatment decisions based on a number of factors, including whether the patient has already taken ART or is ART-naive and the willingness of the patient to adhere to the lifelong treatment regimen.

Achieving viral suppression requires the use of ART with at least two, and preferably three, active drugs from two or more drug classes and should occur within the first 12 to 24 weeks of therapy especially if the patient is new to ART (Panel, 2016). More than 25 antiretroviral (ARV) drugs (see Table 55-4) in 6 classes are Food and Drug Administration (FDA) approved for the treatment of HIV infection. The different drug classes of ART target some of the steps in the HIV/host cycle (see Fig. 55-1). These six classes include the nucleoside/nucleotide reverse transcriptase inhibitors (step 3), non-nucleoside reverse transcriptase inhibitors (step 3), protease inhibitors (step 6), a fusion inhibitor (step 1), a CCR5 antagonist (step 1), and integrase strand transfer inhibitors (step 4). In addition, two drugs (cobicistat and ritonavir) are used to improve the pharmacokinetic profiles of some of the other ART drugs. Some pharmaceutical companies have combined two to three agents into one tablet or capsule. The Panel (2016) provides clear directions regarding which medications should be prescribed for both ART-naive and experienced patients.

Viral loads are often not suppressed because the patient is not adhering to the treatment plan. Psychosocial barriers such as depression and other mental illnesses, neurocognitive impairment, low health literacy, low levels of social support, stressful life events, high levels of alcohol consumption and active substance use, homelessness, poverty, nondisclosure of HIV serostatus, denial, stigma, and inconsistent access to medications affect adherence to ART. Failure to adopt practices that facilitate adherence, such as linking medication taking to daily activities or using a medication reminder system or a pill organizer, is also associated with treatment failure (Panel, 2016). Simplifying treatment regimens and decreasing the number of medications that must be taken each day increase patients' adherence to therapy. Although antiretroviral regimens have become less complex, side effects create barriers to adherence and inadequate dosing can lead to viral resistance. It is difficult to predict patients' adherence to medication regimens, but a positive relationship between the patient and health care provider is associated with better adherence. Individualized plans of care that consider housing and social support issues, in addition to health indicators including possible drug–drug

TABLE 55-4 Antiretroviral Agents[a]

Generic Name (Abbreviation) and Trade Names (Italic)	Food Interactions	Adverse Effects
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		
Abacavir (ABC) *Ziagen* *Trizivir* (ABC/ZDV/3TC) *Epzicom* (ABC/3TC) *Triumeq* (ABC/3TC/DTG)	Take without regard to meals.	Hypersensitivity reaction, which can be fatal; symptoms may include fever, rash, nausea, vomiting, diarrhea, abdominal pain, malaise or fatigue, loss of appetite, and respiratory symptoms such as sore throat, cough, shortness of breath.
Didanosine (ddl) *Videx* *EC*	Take half hour before or 2 hours after meals.	Pancreatitis, peripheral neuropathy, retinal changes, nausea, diarrhea, lactic acidosis with fatty degeneration of the liver, insulin resistance/diabetes.
Emtricitabine (FTC) *Emtriva*	Take without regard to meals.	Minimal toxicity, hyperpigmentation/skin discoloration. Severe acute exacerbation of hepatitis.
Atripla (FTC/EFV/TDF)	Take on empty stomach to reduce side effects.	Minimal toxicity, lactic acidosis with hepatic steatosis.
Complera (FTC/RPV/TDF)	Take with a snack.	Peripheral neuropathy, lipodystrophy, pancreatitis, lactic acidosis with hepatic steatosis (higher incidence with d4 T than with other NRTIs), hyperlipidemia, rapidly progressive ascending neuromuscular weakness (rare).
Stribild (FTC/EVG/c/TDF)	Take with a snack.	
Truvada (FTC/TDF)	Take without regard to meals.	
Lamivudine (3TC) *Epivir* *Combivir* (3TC/ZDV)	Take without regard to meals.	
Epzicom (3TC/ABC) *Trizivir* (ABC/3TC/ZDV)		
Stavudine (d4 T) *Zerit*		
Tenofovir disoproxil fumarate (TDF) *Viread*	Take without regard to meals.	Asthenia, headache, diarrhea, nausea, vomiting, and flatulence; kidney insufficiency; lactic acidosis with hepatic steatosis.
Zidovudine (AZT or ZDV) *Retrovir* *Combivir* (3TC/AZT) *Trizivir* (ABC/3TC/AZT)	Take without regard to meals.	Bone marrow suppression; macrocytic anemia or neutropenia; nail pigmentation, GI intolerance, headache, insomnia, asthenia; lactic acidosis with hepatic steatosis.
Non-Nucleoside Reverse Transcriptase Inhibitors		
Efavirenz (EFV) *Sustiva* *Atripla (EFV/TDF/FTC)*	Take on empty stomach.	Rash (rare cases of Stevens–Johnson syndrome have been reported), central nervous system symptoms (dizziness, somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired concentration, amnesia, agitation, depersonalization, hallucinations, and euphoria), increased transaminase levels, false-positive cannabinoid test, teratogenic in monkeys and potentially teratogenic in humans during first trimester of pregnancy.
Etravirine (ETR) *Intelence*	Take following a meal.	Rash, including Stevens–Johnsons syndrome, hypersensitivity reaction, nausea.
Nevirapine (NVP) *Viramune* *XR*	Take without regard to meals.	Rash including Stevens–Johnson syndrome, symptomatic hepatitis including fatal hepatic necrosis has been reported. Single dose has been used in developing countries to prevent vertical transmission.
Rilpivirine (RPV) *Edurant* *Complera (RPV/TDF/FTC)*	Take with a meal of between 400 and 600 calories.	Rash, depression, insomnia, headache, hepatotoxicity.
Protease Inhibitors		
Atazanavir (ATV) *Reyataz* *Evotaz (ATV/c)*	Take with a snack.	Indirect hyperbilirubinemia; prolonged PR interval (some patients experience asymptomatic first-degree AV block); EKG changes; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia. Check creatinine clearance.
Darunavir (DRV) *Prezista* *Prezcobix (DRV/c)*	Take with a snack.	Skin rash (10%), Stevens–Johnson syndrome, diarrhea, nausea, headache, cold-like symptoms (including runny nose or sore throat), inflammation of the liver, abnormal liver function tests, fever, and abnormally high cholesterol and triglyceride levels have been reported.
Fosamprenavir (FPV) *Lexiva*	Tablets may be taken with or without food.	Skin rash (19%), diarrhea, nausea, vomiting, headache, hyperlipidemia, transaminase elevation, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia.

(*Continued*)

(*Continued*)

Indinavir (IDV) *Crixivan*	For unboosted IDV: Should be taken 1 hour before or 2 hours after meals; may take with skim milk or low-fat meal. For RTV-boosted IDV: Can be taken with or without food.	Nephrolithiasis, GI intolerance, nausea, indirect hyperbilirubinemia, hyperlipidemia, headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, alopecia, hemolytic anemia, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia.
Lopinavir + ritonavir (LPV/r) *Kaletra*	Liquid forms are taken with a snack; no restrictions for tablet.	GI intolerance, nausea, vomiting, diarrhea, asthenia, hyperlipidemia (especially hypertriglyceridemia), elevated serum transaminase, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, EKG changes.
Nelfinavir (NFV) *Viracept*	Take with a snack.	Diarrhea, hyperlipidemia, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, serum transaminase elevation.
Ritonavir (RTV) *Norvir*	Take with a snack.	GI intolerance, nausea, vomiting, diarrhea, paresthesias (circumoral and extremities), hyperlipidemia (especially hypertriglyceridemia), hepatitis, asthenia, taste perversion, hyperglycemia, fat maldistribution, possible increased bleeding in patients with hemophilia. Lower doses used as a booster.
Saquinavir (SQV) *Invirase*	Take with meals or within 2 hours after meal.	GI intolerance, nausea, diarrhea, abdominal pain and dyspepsia, headache, hyperlipidemia, elevated transaminase enzymes, hyperglycemia, fat maldistribution, possible increased bleeding episodes in patients with hemophilia, EKG changes.
Tipranavir (TPV) *Aptivus*	Take with a snack.	Serious liver problems, bleeding on the brain, skin rash (21%), increased cholesterol and triglyceride levels, and changes in body fat; women taking birth control pills that contain estrogen may be more likely to develop a rash. Individuals with hemophilia may have increased bleeding. Take with RTV, if prescribed.
Fusion Inhibitor		
Enfuvirtide (T-20) *Fuzeon*	Injected subcutaneously, so meals are not an issue.	Local injection site reactions—almost 100% of patients (pain, erythema, induration, nodules and cysts, pruritus, ecchymosis); increased rate of bacterial pneumonia; hypersensitivity reaction—symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases.
Integrase Inhibitor (INSTIs)		
Dolutegravir (DTG) *Tivicay*	Take without regard to meals.	Hypersensitivity reaction including rash, constitutional symptoms, and organ dysfunction, insomnia, headache.
Elvitegravir (EVG)	Take with a snack.	Nausea, diarrhea.
Vitekta *Stribild (EVG/c/FTC/TDF)*	Take with a snack.	Nausea, diarrhea, renal impairment, decrease in bone density, acute exacerbation of hepatitis, lactic acidosis.
Raltegravir (RAL) *Isentress*	Take without regard to meals.	Rash including Stevens–Johnson syndrome, diarrhea, nausea, headache, fever, insomnia.
CCR5 Antagonist		
Maraviroc (MVC) *Selzentry*	Take without regard to meals; requires CCR5 tropism blood test before starting.	Cough, fever, dizziness, headache, orthostatic hypotension, nausea, bladder irritation; possible liver problems and cardiac events; an increased risk for some infections; a slight increase in cholesterol levels.

AV, atrioventricular; EKG, electrocardiogram; GI, gastrointestinal.

[a]This information changes often. Check the Panel and also the U.S. Food and Drug Administration website, http://www.fda.gov/forpatients/illness/hivaids/ucm118915.htm) for current information when using ART.

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents (Panel). (2016). Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Department of Health and Human Services. Retrieved on 5/12/16 at: www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf. Appendix B, Tables 1 through 6.

interactions, are essential. Self-reported adherence measures can distinguish clinically meaningful patterns of medication-taking behaviors; therefore, nurses should assess if patients can describe how they are taking their ART.

Chart 55-8 summarizes strategies that health care providers can encourage to promote treatment regimen adherence. Every health care encounter should be used as an opportunity to briefly review the treatment regimen, identify any new issues, and reinforce successful behaviors.

Laboratory tests evaluate whether ART is effective for a specific patient. An adequate $CD4^+$ response for most patients on ART is an increase in $CD4^+$ count in the range of 50 to 150 mm^3 per year, generally with an accelerated response in the first 3 months (Panel, 2016). Viral load should be measured at baseline and on a regular basis thereafter because viral load is the most important indicator of response to ART.

Adverse effects associated with all HIV treatment regimens include hepatotoxicity, nephrotoxicity, and osteopenia, along with increased risk of cardiovascular disease and myocardial infarction (see Table 55-4). Many of the antiretroviral agents may cause fat redistribution syndrome and metabolic alterations such as dyslipidemia and insulin resistance, which put the patient at risk for early-onset heart disease and diabetes. The fat redistribution syndrome (lipodystrophy) consists of lipoatrophy (localized subcutaneous fat loss in the face, arms, legs, and buttocks) and lipohypertrophy (central visceral fat [lipomata] accumulation in the abdomen, although possibly in the breasts, dorsocervical region [buffalo hump], and within the

Chart 55-8

Promoting Adherence to ART

Strategies	Examples
Use a multidisciplinary team approach. Provide an accessible, trustworthy health care team.	• Nonjudgmental providers, nurses, social workers, pharmacists, and medication managers.
Strengthen early linkage to care and retention in care.	• Encourage health care team participation in linkage to and retention in care.
Assess patient readiness to start ART.	
Evaluate patient's knowledge about HIV disease, prevention and treatment and, on the basis of the assessment, provide HIV-related information.	• Consider the patient's current knowledge base, provide information about HIV, including the natural history of the disease, HIV viral load and $CD4^+$ count and expected clinical outcomes according to these parameters, and therapeutic and prevention consequences of nonadherence.
Identify facilitators, potential barriers to adherence, and necessary medication management skills before starting ART medication.	• Assess patient's cognitive competence and any impairment. • Assess behavioral and psychosocial challenges including depression, mental illnesses, levels of social support, high levels of alcohol consumption and active substance use, nondisclosure of HIV serostatus and stigma. • Identify and address language and literacy barriers. • Assess beliefs, perceptions, and expectations about taking ART (e.g., impact on health, side effects, disclosure issues, consequences of nonadherence). • Ask about medication taking skills and foreseeable challenges with adherence (e.g., past difficulty keeping appointments, adverse effects from previous medications, issues managing other chronic medications, need for medication reminders and organizers). • Assess structural issues including unstable housing, lack of income, unpredictable daily schedule, lack of prescription drug coverage, lack of continuous access to medications.
Provide needed resources.	• Provide or refer for mental health and/or substance abuse treatment. • Provide resources to obtain prescription drug coverage, stable housing, social support, and income and food security.
Involve the patient in ARV regimen selection.	• Review regimen potency, potential side effects, dosing frequency, pill burden, storage requirements, food requirements, and consequences of nonadherence. • Assess daily activities and tailor regimen to predictable and routine daily events. • Consider use of fixed-dose combination formulation. • Assess if cost/co-payment for drugs can affect access to medications and adherence.
Assess adherence at every clinic visit.	• Monitor viral load as a strong biologic measure of adherence. • Use a simple behavioral rating scale. • Employ a structured format that normalizes or assumes less-than-perfect adherence and minimizes socially desirable or "white coat adherence" responses. • Ensure that other members of the health care team also assess adherence.
Use positive reinforcement to foster adherence success.	• Inform patients of low or nondetectable levels of HIV viral load and increases in $CD4^+$ cell counts. • When needed, consider providing incentives and rewards for achieving high levels of adherence and treatment success.
Identify the type of and reasons for nonadherence.	• Failure to fill the prescription(s). • Failure to understand dosing instructions. • Complexity of regimen (e.g., pill burden, size, dosing schedule, food requirements). • Pill aversion. • Pill fatigue. • Adverse effects. • Inadequate understanding of drug resistance and its relationship to adherence. • Cost-related issues. • Depression, drug and alcohol use, homelessness, poverty. • Stigma. • Nondisclosure. • Other potential barriers.
Select from among available effective treatment adherence interventions.	• Use evidence-based interventions to promote adherence. • Use adherence-related tools to complement education and counseling interventions (e.g., pill boxes, dose planners, reminder devices). • Use community resources to support adherence (e.g., visiting nurses, community workers, family, peer advocates). • Use patient prescription assistance programs. • Use motivational interviews.

(*Continued*)

(*Continued*)

Systematically monitor retention in care.	• Record and follow-up on missed visits.
On the basis of any problems identified through systematic monitoring, consider options to enhance retention in care given resources available	• Provide outreach for those patients who drop out of care. • Use peer or paraprofessional treatment navigators. • Employ incentives to encourage clinic attendance or recognize positive clinical outcomes resulting from good adherence. • Arrange for directly observed therapy (if feasible).

Adapted from Panel on Antiretroviral Guidelines for Adults and Adolescents (Panel). (2016). Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents. Department of Health and Human Services. Retrieved on 5/12/16 at: www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf Table 13. Strategies to Improve Adherence to Antiretroviral Therapy and Retention in Care.

muscle and liver). Facial wasting, characterized as a sinking of the cheeks, eyes, and temples caused by the loss of fat tissue under the skin, may be treated by injectable fillers such as poly-L-lactic acid (Sculptra) (see Fig. 55-2). These changes can disturb the body image of people living with HIV/AIDS and may be a reason they decline or stop ART nurses could use an instrument such as the assessment of body change distress (ABCD) questionnaire that assesses subjective report of bodily changes and body dissatisfaction and the impact of bodily changes on psychosocial variables, quality of life, and HIV self-care behaviors (Blashill, Wilson, Baker, et al., 2014).

Nursing Alert: Nurses must recognize the differences among common laboratory tests used to diagnose and assess HIV infection and guide therapy. For example, the EIA is a diagnostic screening test that determines the presence of antibodies to HIV. The RT-PCR test, which measures viral load, is used along with the $CD4^+$ count, which indicates the level of immune dysfunction, to assess the stage and severity of HIV infection. It is important to assess the extent of damage to the immune system before initiation of ART and/or prophylactic treatment for opportunistic infections.

Drug Resistance

Drug resistance is the ability of pathogens to withstand the effects of medications that should be toxic to them. There are two major components of ART resistance: (1) transmission of drug-resistant HIV at the time of initial infection and (2) selective drug resistance in patients who are receiving nonsuppressive regimens. Genotypic and phenotypic resistance assays are used to assess viral strains and inform selection of treatment strategies. Genotypic assays detect drug-resistant mutations present in relevant viral genes while phenotypic assays measure the ability of a virus to grow in different concentrations of ART drugs. Resistance testing in persons who are chronically infected is recommended at the time of entry into HIV care. Although no definitive prospective data exist to support the choice of one type of resistance testing over another, genotypic testing is generally preferred because of lower cost, more rapid turnaround time, the assay's ability to detect mixtures of wild-type and resistant virus, and the relative ease of interpreting test results. If therapy is deferred, repeat testing soon before initiation of ART should be considered because the patient may have acquired drug-resistant virus (i.e., superinfection) (Panel, 2016).

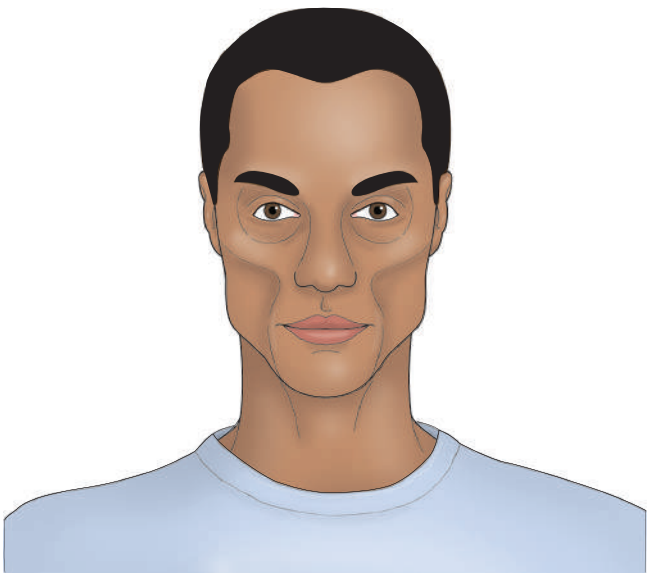

Figure 55-2 • Facial lipoatrophy.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (**IRIS**) results from rapid restoration of organism-specific immune responses to infections that cause either the deterioration of a treated infection or new presentation of a subclinical infection. This syndrome typically occurs during the initial months after beginning ART and is associated with a wide spectrum of organisms, most commonly mycobacteria, herpes viruses, and deep fungal infections. IRIS is characterized by fever, respiratory and/or abdominal symptoms, and worsening of the clinical manifestations of an opportunistic infection or the appearance of new manifestations. IRIS is treated with anti-inflammatory medications such as cortisone. The nurse should be alert to the possibility of IRIS, especially in the 3-month period after treatment with ART is initiated, because this syndrome is associated with significant morbidity and patients often require hospital admission.

Paradoxical tuberculosis-associated immune reconstitution inflammatory syndrome (TB-IRIS) is a serious complication that arises during successful ART in patients with HIV-TB co-infection who are receiving TB treatment. In the majority of patients, TB-IRIS occurs within the first few weeks of ART but can occur much later. Patients with HIV-TB co-infection with low $CD4^+$ counts who start ART are at high risk of developing TB-IRIS. Although the immunopathogenesis of TB-IRIS is still not completely understood, the explosive restoration of T-cell function is believed to play a distinct role (Goovaerts, Jennes, Massinga-Loembé, et al., 2015).

Clinical Manifestations

Patients with HIV/AIDS experience a number of symptoms related to the disease, side effects of treatment, and other comorbidities,

Chart 55-9 NURSING RESEARCH PROFILE

Symptom Self-Management Using Technology

Schnall, R., Wantland, D., Velez, O., et al. (2014). Feasibility testing of a web-based symptom self-management system for persons living with HIV. Journal of the Association of Nurses in AIDS Care. 25(4), 364–371.

Purpose

The purpose of this study was to explore the feasibility of using a web-based tool to provide tailored symptom management strategies for persons living with HIV. The web-based system provided tailored strategies for six symptoms: (a) depression, (b) anxiety, (c) fatigue, (d) diarrhea, (e) neuropathy, and (f) nausea. The hypothesis was that using the tool would decrease symptom intensity and frequency.

Design

This quantitative study used repeated-measures to test the components of the web-based system on symptom frequency and intensity, use of symptom management strategies, and engagement with health care providers over a 12-week period. Symptom intensity and frequency was measured by the items related to the six symptoms using the HIV Sign and Symptom Check List-Revised tool. Engagement with care was measured by the Engagement with Health Care Provider Scale.

Findings

The average age of participants was 50 years; the majority were male and most had completed high school ($N = 42$). At baseline, the most frequently reported symptom was fatigue, followed by anxiety. There was a trend toward a decrease in symptom frequency over time for all symptoms except diarrhea, and engagement with health care providers improved. One purpose of a feasibility study is to demonstrate the ability to recruit and retain study participants, which was achieved. Forty-two participants were recruited in 30 days, which demonstrates the interest of patients to use web-based tools to assist with symptom self-management. Almost 80% of the participants completed the 12-week longitudinal study.

Nursing Implications

Web-based tools have the potential to support patients to self-manage symptoms and are accessible to anyone who can access the internet. Patients are interested in and willing to use the web-based tool to manage HIV-related symptoms. Use of this tool decreased symptom intensity and increased engagement with health care providers. This sample was not particularly well educated and yet the intervention was effective. Use of multiple sources of health information should be encouraged by nurses in order to support patients in becoming more informed in self-management strategies.

including pancreatitis, hepatitis, and cardiometabolic abnormalities. The clinical manifestations of HIV/AIDS are widespread and may involve virtually any organ system. Patients in stage 3 or AIDS (see Table 55-2) are severely immune depressed and can develop opportunistic infections. Nurses need to understand the causes, signs and symptoms, and interventions, including self-management strategies that can enhance the quality of life for patients throughout the different stages of the illness. Symptom assessment tools can be used to assess patients' symptom intensity and severity. People with HIV/AIDS use a variety of self-management strategies to minimize common symptoms (Schnall, Wantland, Velez, et al., 2014) (see Chart 55-9).

Respiratory Manifestations

Shortness of breath, dyspnea (labored breathing), cough, chest pain, and fever are associated with various opportunistic infections, such as those caused **by** *Pneumocystis jirovecii, Mycobacterium avium-intracellulare,* cytomegalovirus (CMV), and *Legionella* species.

Pneumocystis Pneumonia

***Pneumocystis* pneumonia (PCP)** is caused by *P. jirovecii* (formerly *P. carinii*) (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents [OI-Panel], 2015) and the incidence has declined substantially with widespread use of PCP prophylaxis, which is used to prevent PCP, and ART. The most common manifestations of PCP are subacute onset of progressive dyspnea, fever, nonproductive cough, and chest discomfort that worsens within days to weeks. In mild cases, pulmonary examination usually is normal at rest. With exertion, tachypnea, tachycardia, and diffuse dry (cellophane) rales may be auscultated. Oral thrush is a common co-infection. Fever is apparent in most cases and may be the predominant symptom. Hypoxemia is the most characteristic laboratory abnormality, along with elevated lactate dehydrogenase levels. Because clinical presentation, blood tests, and chest radiographs are not pathognomonic for PCP, and because the organism cannot be cultivated routinely, histopathologic or cytopathologic demonstration of organisms in tissue, bronchoalveolar lavage fluid, or induced sputum samples is required for a definitive diagnosis (OI-Panel, 2015).

Mycobacterium avium Complex

***Mycobacterium avium* complex (MAC)** disease is a common opportunistic infection that typically occurs in patients with $CD4^+$ T-lymphocyte ($CD4^+$) cell counts less than 50 cells/mm^3. MAC is caused by infection with different types of mycobacterium: *Mycobacterium avium, Mycobacterium intracellulare,* or *Mycobacterium kansasii.* Early symptoms may be minimal and can precede detectable mycobacteremia by several weeks and include fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain. A confirmed diagnosis of disseminated MAC disease is based on compatible clinical signs and symptoms coupled with the isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids (OI-Panel, 2015).

Tuberculosis

The estimated annual risk of reactivation with TB among those with untreated HIV infection and latent TB infection is 3% to 16% and approximates the lifetime risk for individuals without HIV infection who have latent TB infection. TB disease can occur at any $CD4^+$ T-lymphocyte ($CD4^+$ cell) count, although the risk increases with progressive immune deficiency. Testing for latent TB at the time of HIV diagnosis should be routine, regardless of an individual's risk of TB exposure. Individuals with negative diagnostic tests for latent TB who have stage 3 HIV infection should be retested once their $CD4^+$ count increases due to ART. Screening for symptoms (asking for cough of *any* duration) coupled with chest radiography is recommended to exclude TB disease in a patient with a positive skin test or interferon-gamma release assays. Latent TB in a person with

HIV infection is treated with isoniazid (INH), supplemented with pyridoxine (Aminoxin) to prevent peripheral neuropathy, for 9 months since it has proven efficacy, good tolerability, and infrequent severe toxicity.

TB disease can develop in the lungs as well as in extrapulmonary sites such as the central nervous system (CNS), bone, pericardium, stomach, peritoneum, and scrotum and initial diagnostic testing is directed at the anatomic site of symptoms or signs, such as the lungs, lymph nodes, and cerebrospinal fluid. TB in individuals with advanced immune deficiency can be rapidly progressive and fatal if treatment is delayed and such patients often have smear-negative sputum specimens. Therefore, after collection of available specimens for culture and molecular diagnostic tests, empiric treatment for TB is warranted in patients with clinical and radiographic presentation suggestive of HIV-related TB. Treatment of suspected TB in individuals with HIV infection is the same as for those who are HIV uninfected and should include an initial four-drug combination of isoniazid, rifampin (Rifadin), pyrazinamide, and ethambutol (Etibi) (OI-Panel, 2015).

Gastrointestinal Manifestations

The gastrointestinal manifestations of HIV infection and AIDS include loss of appetite, nausea, vomiting, oral and esophageal candidiasis, and chronic diarrhea. Gastrointestinal symptoms may be related to the direct inflammatory effect of HIV on the cells lining the intestines. Some of the enteric pathogens that occur most frequently, identified by stool cultures or intestinal biopsy, are *Cryptosporidium muris, Salmonella* species, *Isospora belli, Giardia lamblia,* cytomegalovirus (CMV), *Clostridium difficile,* and *M. avium-intracellulare.* In patients with AIDS, the effects of diarrhea can be devastating in terms of profound weight loss (more than 10% of body weight), fluid and electrolyte imbalances, perianal skin excoriation, weakness, and inability to perform the usual activities of daily living.

Candidiasis

Oropharyngeal and esophageal candidiasis (fungal infections) are common in patients with HIV infection. Oropharyngeal candidiasis is characterized by painless, creamy white, plaque-like lesions that can occur on the buccal surface, hard or soft palate, oropharyngeal mucosa, or tongue surface. Lesions can be easily scraped off with a tongue depressor or other instrument which is in contrast to lesions associated with oral hairy leukoplakia. In women with early-stage HIV infection, *Candida* vulvovaginitis usually presents the same as in women without HIV infection, with white adherent vaginal discharge associated with mucosal burning and itching of mild-to-moderate severity and sporadic recurrences (OI-Panel, 2015).

HIV Wasting Syndrome

Wasting syndrome is defined as the involuntary loss of more than 10% of one's body weight while having experienced diarrhea or weakness and fever for more than 30 days. Wasting refers to the loss of muscle mass, although part of the weight loss may also be due to loss of fat.

Oncologic Manifestations

Those with HIV/AIDS are at greater risk of developing certain cancers. These include Kaposi sarcoma (KS), lymphoma, and invasive cervical cancer. KS and lymphomas are discussed next. Cervical carcinoma is described later in the Gynecologic Manifestations section.

Kaposi Sarcoma

KS is caused by human herpesvirus-8 (HHV-8); affects eight times more men than women; and may spread through sexual contact. It involves the epithelial layer of blood and lymphatic vessels. AIDS-related KS exhibits a variable and aggressive course, ranging from localized cutaneous lesions to disseminated disease involving multiple organ systems. Cutaneous signs may be the first manifestation of HIV; they can appear anywhere on the body and are usually brownish pink to deep purple. They may be flat or raised and surrounded by ecchymosis (hemorrhagic patches) and edema (see Fig. 55-3). Rapid development of lesions involving large areas of skin is associated with extensive disfigurement and significant body image issues. The location and size of some lesions can lead to venous stasis, lymphedema, and pain. Ulcerative lesions disrupt skin integrity and increase discomfort and susceptibility to infection. The most common sites of visceral involvement are the lymph nodes, gastrointestinal tract, and lungs. Involvement of internal organs may eventually lead to organ failure, hemorrhage, infection, and death.

Diagnosis of KS is confirmed by biopsy of suspected lesions. Prognosis depends on the extent of the tumor, the presence of other symptoms of HIV infection, and the $CD4^+$ count. Death may result from tumor progression. More often, however, it results from other complications of HIV infection.

AIDS-Related Lymphomas

AIDS-related lymphomas include both Hodgkin lymphoma and non-Hodgkin lymphoma. Non-Hodgkin lymphoma is more common. AIDS-related lymphoma is usually aggressive; there are three main types: diffuse large B-cell; B-cell immunoblastic; and small noncleaved cell lymphoma. Symptoms include weight loss, night sweats, and fever. The complete blood count might be abnormal and a biopsy will confirm the diagnosis (National Cancer Institute [NCI], 2015).

Neurologic Manifestations

HIV-related brain changes have profound effects on cognition, including motor function, executive function, attention, visual memory, and visuospatial function. Neurologic dysfunction

Figure 55-3 • Lesions of the AIDS-related Kaposi sarcoma. Whereas some patients may have lesions that remain flat, others experience extensively disseminated, raised lesions with edema. From DeVita, V. T., Jr., Hellman, S., & Rosenberg, S. (Eds.). (1993). AIDS: Etiology, diagnosis, treatment, and prevention (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

results from direct effects of HIV on nervous system tissue, opportunistic infections, primary or metastatic neoplasm, cerebrovascular changes, metabolic encephalopathies, or complications secondary to therapy. Immune system response to HIV infection in the CNS includes inflammation, atrophy, demyelination, degeneration, and necrosis.

Peripheral Neuropathy

Peripheral neuropathy is the most common neurologic symptom at any stage of HIV infection. It may be a side effect of some ART drugs, and may occur in a variety of patterns, with distal sensory polyneuropathy or distal symmetric polyneuropathy the most frequently occurring type. It can lead to significant pain of feet and hands and functional impairment. Patients use a variety of physical and psychological self-management strategies to minimize this symptom (Nicholas, Corless, & Evans, 2014).

HIV Encephalopathy

HIV encephalopathy was formerly referred to as AIDS dementia complex (see Chart 55-10). It is a clinical syndrome that is characterized by a progressive decline in cognitive, behavioral, and motor functions as a direct result of HIV infection. HIV has been found in the brain and cerebrospinal fluid (CSF) of patients with HIV encephalopathy. The brain cells infected by HIV are predominantly the $CD4^+$ cells of monocyte–macrophage lineage. HIV infection is thought to trigger the release of toxins or lymphokines that result in cellular dysfunction, inflammation, or interference with neurotransmitter function rather than cellular damage.

Signs and symptoms may be subtle and difficult to distinguish from fatigue, depression, or the adverse effects of treatment for infections and malignancies. Early manifestations include memory deficits, headache, difficulty concentrating, progressive confusion, psychomotor slowing, apathy, and ataxia. Later stages include global cognitive impairments, delay in verbal responses, a vacant stare, spastic paraparesis, hyperreflexia, psychosis, hallucinations, tremor, incontinence, seizures, mutism, and death.

Confirming the diagnosis of HIV encephalopathy can be difficult. Extensive neurologic evaluation includes a computed tomography scan, which may indicate diffuse cerebral atrophy and ventricular enlargement. Other tests that may detect abnormalities include magnetic resonance imaging, analysis of CSF through lumbar puncture, and brain biopsy.

Cryptococcus Neoformans

A fungal infection, *Cryptococcus neoformans* is another common opportunistic infection among patients with AIDS, and it causes neurologic disease. Cryptococcal meningitis is characterized by symptoms such as fever, headache, malaise, stiff neck, nausea, vomiting, mental status changes, and seizures. Diagnosis is confirmed by CSF analysis.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating CNS disorder that affects the oligodendroglia. Clinical manifestations often begin with mental confusion and rapidly progress to include blindness, aphasia, muscle weakness, paresis (partial or complete paralysis), and death. ART has greatly reduced the threat of mortality associated with this disorder.

Chart 55-10

Care of the Patient with HIV Encephalopathy

Chronic Confusion

- Assess mental status and neurologic functioning.
- Monitor for medication interactions, infections, electrolyte imbalance, and depression.
- Frequently orient the patient to time, place, person, reality, and the environment.
- Use simple explanations.
- Instruct the patient to perform tasks in incremental steps.
- Provide memory aids (clocks and calendars).
- Provide memory aids for medication administration.
- Post activity schedule.
- Give positive feedback for appropriate behavior.
- Educate caretakers about orienting patient to time, place, person, reality, and the environment.
- Encourage the patient to designate a responsible person to assume power of attorney.

Disturbed Sensation

- Assess sensory impairment.
- Decrease amount of stimuli in the patient's environment.
- Correct inaccurate perceptions.
- Provide reassurance and safety if the patient displays fear.
- Provide a secure and stable environment.
- Educate caregivers about recognizing inaccurate sensory perceptions.
- Provide caregivers techniques to correct inaccurate perceptions.
- Instruct the patient and caregivers to report any changes in the patient's vision to the patient's health care provider.

Risk for Injury

- Assess the patient's level of anxiety, confusion, or disorientation.
- Assess the patient for delusions or hallucinations.
- Remove potentially dangerous objects from the patient's environment.
- Structure the environment for safety (ensure adequate lighting, avoid clutter, provide bed rails if needed).
- Supervise smoking.
- Do not let the patient drive a car if confusion is present.
- Instruct the patient and caregiver in home safety.
- Provide assistance as needed for ambulation and in getting in and out of bed.
- Pad headboard and side rails if the patient has seizures.

Self-Care Deficits

- Encourage activities of daily living within the patient's level of ability.
- Encourage independence, but assist if the patient cannot perform an activity.
- Demonstrate any activity that the patient is having difficulty accomplishing.
- Monitor food and fluid intake.
- Weigh patient weekly.
- Encourage the patient to eat, and offer nutritious meals, snacks, and adequate fluids.
- If patient is incontinent, establish a routine toileting schedule.
- Educate caregivers about meeting the patient's self-care needs.

Other Neurologic Disorders

Other infections involving the nervous system include *Toxoplasma gondii,* CMV, and *Mycobacterium tuberculosis* infections.

Depressive Manifestations

Depression and apathy are neuropsychiatric complications of HIV infection. Estimates suggest that the prevalence of current depression is between 30% and 40% in persons with HIV/AIDS. Similarly, apathy, which refers to reduced, self-initiated, cognitive, emotional, and behavioral activity, is also commonly reported among those living with a diagnosis of HIV with rates as high as 65% (Bryant, Whitehead, Burrell, et al., 2015). Alcohol and cocaine use—both current and former—have been associated with depression and apathy in this population, and depression has been associated with less adherence with ART.

Integumentary Manifestations

Cutaneous manifestations are associated with HIV infection and the accompanying opportunistic infections and malignancies. KS (described earlier) and opportunistic infections such as herpes zoster and herpes simplex are associated with painful vesicles that disrupt skin integrity. Molluscum contagiosum is a viral infection characterized by deforming plaque formation. Seborrheic dermatitis is associated with an indurated, diffuse, scaly rash involving the scalp and face. Patients with AIDS may also exhibit a generalized folliculitis associated with dry, flaking skin or atopic dermatitis, such as eczema or psoriasis. Many patients treated with the antibacterial agent trimethoprim–sulfamethoxazole (TMP–SMZ) develop a drug-related rash that is pruritic with pinkish-red macules and papules (Comerford, 2015). Patients with any of these rashes experience discomfort, have body image changes, and are at increased risk for infection from disrupted skin integrity.

Gynecologic Manifestations

Persistent, recurrent vaginal candidiasis may be the first sign of HIV infection in women. Past or present genital ulcers are a risk factor for the transmission of HIV infection. Women with HIV infection are more susceptible to genital ulcers and venereal warts and have increased rates of incidence and recurrence of these conditions. Ulcerative STIs such as chancroid, syphilis, and herpes are more severe in women with HIV infection. Human papillomavirus (HPV) causes venereal warts and is a risk factor for cervical intraepithelial neoplasia, a cellular change that is frequently a precursor to cervical cancer. Women who are HIV seropositive and have cervical carcinoma present at a more advanced stage of disease and have more persistent and recurrent disease and a shorter interval to recurrence and death than women without HIV infection.

Women with HIV are at increased risk for pelvic inflammatory disease, a reportable infection, and the associated inflammation may increase HIV transmission to the uninfected sexual partner. Moreover, women with HIV infection appear to have a higher incidence of menstrual abnormalities, including amenorrhea or bleeding between periods, than do women without HIV infection.

Medical Management

Treatment of Opportunistic Infections

Guidelines for the treatment of opportunistic infections should be consulted for the most current recommendations (OI-Pzanel, 2015). Although ART is highly effective in keeping the $CD4^+$ cell count high, opportunistic infections continue to cause considerable morbidity and mortality for three main reasons: (1) many patients are unaware of their HIV infection and present with an opportunistic infection as the initial indicator of their disease, (2) some patients are aware of their HIV infection but do not take antiretroviral agents because of psychosocial or economic factors, and (3) others receive prescriptions for antiretroviral medications but fail to attain adequate virologic and immunologic response as a result of issues related to adherence, pharmacokinetics, or unexplained biologic factors.

Pneumocystis Pneumonia

Persons in stage 3 HIV infection should receive chemoprophylaxis to prevent PCP with trimethoprim–sulfamethoxazole (TMP–SMX) if they have $CD4^+$ counts less than 200 cells/mm^3 or a history of oropharyngeal candidiasis (OI-Panel, 2015). Once the $CD4^+$ count improves, prophylaxis can be discontinued. When a person is diagnosed with PCP, TMP–SMX is the treatment of choice, lowering the dose if there is abnormal renal function. Adjunctive corticosteroids (Prednisone) are indicated as early as possible, preferentially within 72 hours after starting specific PCP therapy. Treatment duration is usually 21 days; rates of adverse reaction to TMP–SMX are high including rash (30% to 55%) (including Stevens–Johnson syndrome), fever (30% to 40%), leukopenia (30% to 40%), hepatitis (20%), thrombocytopenia (15%), azotemia (1% to 5%), and hyperkalemia. Because long-term survival is possible for patients in whom ART is effective, individuals with AIDS and severe PCP should be given the option to choose mechanical ventilation and critical care management if their functional status is such that it would be appropriate, just as with patients without HIV infection. Paradoxical IRIS has been reported following PCP and starting ART (OI-Panel, 2015).

Mycobacterium avium Complex

Initial treatment of MAC disease should consist of two or more antimycobacterial drugs to prevent or delay the emergence of resistance. Clarithromycin (Biaxin) is the preferred first agent; however, azithromycin (Zithromax) can be substituted for clarithromycin when drug interactions or intolerance to clarithromycin preclude its use. Ethambutol is the recommended second drug (OI-Panel, 2015).

Cryptococcal Meningitis

Cryptococcosis among patients with HIV infection most commonly occurs as a subacute meningitis or meningoencephalitis with fever, malaise, and headache. Treating cryptococcosis consists of three phases: induction, consolidation, and maintenance therapy. The preferred induction treatment for cryptococcal meningitis and other forms of extrapulmonary cryptococcosis is the IV lipid formulation of amphotericin B in combination with fluconazole (Diflucan). Serious potential adverse effects of amphotericin B include anaphylaxis, kidney and hepatic impairment, electrolyte imbalances, anemia, fever, and severe chills. After at least 2 weeks of successful induction therapy—defined as substantial clinical improvement and a negative CSF culture after repeat lumbar puncture—amphotericin B and flucytosine can be discontinued. Follow-up or consolidation therapy is then initiated with oral fluconazole daily which should continue for at least 8 weeks (OI-Panel, 2015).

Cytomegalovirus Retinitis

Retinitis caused by CMV is a leading cause of blindness in patients with AIDS. Oral valganciclovir (Valcyte), IV ganciclovir

(Cytovene), IV ganciclovir followed by oral valganciclovir, IV foscarnet (Foscavir), IV cidofovir (Vistide), and a ganciclovir intraocular implant coupled with valganciclovir are all effective treatments for CMV retinitis (OI-Panel, 2015). All of these drugs have significant toxicities (bone marrow suppression, neutropenia, hepatitis, renal toxicity, seizures, etc.) and are used with caution (Comerford, 2015).

Antidiarrheal Therapy

Although many forms of diarrhea respond to treatment, it is not unusual for this condition to recur and become a chronic problem for the patient with HIV infection. Therapy with octreotide acetate (Sandostatin), a synthetic analog of somatostatin, has been shown to effectively manage chronic severe diarrhea. High concentrations of somatostatin receptors have been found in the gastrointestinal tract and in other tissues. Somatostatin inhibits many physiologic functions, including gastrointestinal motility and intestinal secretion of water and electrolytes.

Chemotherapy

Kaposi Sarcoma

KS can be treated with local therapy, radiation therapy, chemotherapy, and biologic therapy depending upon the location of the lesions.

Lymphoma

There is no standard treatment for AIDS-related peripheral or systemic lymphoma. The treatment plan is adjusted for each patient and usually includes one or more of combination chemotherapy, high-dose chemotherapy and stem cell transplant. There are many ongoing clinical trials (using monoclonal antibodies; different treatment combinations) that patients with AIDS-related lymphoma may be eligible to enter (NCI, 2015).

Antidepressant Therapy

Treatment for depression in people with HIV infection involves cognitive behavioral therapy integrated with pharmacotherapy. If depressive symptoms are severe and of sufficient duration, treatment with antidepressants may be initiated. Antidepressants such as imipramine (Tofranil), desipramine (Norpramin), and fluoxetine (Prozac) may be used, because these medications also alleviate the fatigue and lethargy that are associated with depression. A psychostimulant such as methylphenidate (Ritalin) may be used in low doses in patients with neuropsychiatric impairment. Electroconvulsive therapy may be an option for patients with severe depression who do not respond to pharmacologic interventions.

Nutrition Therapy

Alterations in lipid metabolism are associated with HIV infection and ART. Malnutrition increases the risk of infection and the incidence of opportunistic infections. Nutrition therapy should be part of the overall management plan and should be tailored to meet the nutritional needs of the patient, whether by oral diet, enteral tube feedings, or parenteral nutritional support, if needed. As with all patients, a healthy diet is essential for the patient with HIV infection. For all patients with AIDS who experience unexplained weight loss, calorie counts and weight monitoring should be obtained to evaluate nutritional status and initiate appropriate therapy. The goal is to maintain the ideal weight and, when necessary, to increase weight.

Appetite stimulants have been successfully used in patients with AIDS-related anorexia. Megestrol acetate (Megace), a synthetic oral progesterone preparation, promotes significant weight gain and inhibits cytokine IL-1 synthesis. In patients with HIV infection, it increases body weight primarily by increasing body fat stores. Dronabinol (Marinol), which is a synthetic tetrahydrocannabinol (THC), the active ingredient in marijuana, has been used to relieve nausea and vomiting associated with cancer chemotherapy. After beginning dronabinol therapy, almost all patients with HIV infection experience a modest weight gain. The effects on body composition are unknown.

Oral supplements may be used when the diet is deficient in calories and protein. Ideally, oral supplements should be lactose free (people with HIV infection may be intolerant to lactose), high in calories and easily digestible protein, low in fat with the fat easily digestible, palatable, inexpensive, and tolerated without causing diarrhea. Nutritional supplements have been developed specifically for people with HIV infection and AIDS. Parenteral nutrition is the final option because of its prohibitive cost and associated risks, including possible infection.

Complementary, Alternative, and Integrative Health Therapies

People with HIV infection report use of complementary, alternative, and integrative therapies. Combined with traditional therapies, these may improve the patient's overall well-being. However, there can be adverse drug–drug interactions between certain therapies.

Many patients who use these therapies do not report their use to their health care providers. To obtain a complete health history, the nurse should ask about the patient's use of complementary, alternative, and integrative therapies. Patients may need to be encouraged to report their use of these therapies to their primary provider. Problems may arise, for example, when patients are using complementary, alternative, and integrative therapies while participating in clinical drug trials; alternative therapies can have significant adverse side effects, making it difficult to assess the effects of the medications in the clinical trial. The nurse needs to become familiar with the potential adverse side effects of these therapies. The nurse who suspects that complementary, alternative, and integrative therapies is causing a side effect needs to discuss this with the patient, the alternative therapy provider, and the primary provider. The nurse needs to view complementary, alternative, and integrative therapies with an open mind and try to understand the importance of this treatment to the patient. This approach will improve communication with the patient and reduce conflict.

Supportive Care

Patients who are weak and debilitated as a result of chronic illness associated with HIV infection and AIDS typically require many kinds of supportive care. Nutritional support may be as simple as providing assistance in obtaining or preparing meals. For patients with more advanced nutritional impairment resulting from decreased intake, wasting syndrome, or gastrointestinal malabsorption associated with diarrhea, parenteral feedings may be required. Imbalances that result from nausea, vomiting, and profuse diarrhea often necessitate IV fluid and electrolyte replacement.

Management of skin breakdown associated with KS, perianal skin excoriation, or immobility entails thorough and meticulous

skin care that involves regular turning, cleansing, and applications of medicated ointments and dressings. To combat pain associated with skin breakdown, abdominal cramping, peripheral neuropathy, or KS, the nurse administers analgesic agents at regular intervals around the clock. Patients with a history of drug abuse will need to have tailored approaches for pain management. Relaxation and guided imagery may help reduce pain and anxiety.

Pulmonary symptoms, such as dyspnea and shortness of breath, may be related to opportunistic infections, KS, or fatigue. For patients with these symptoms, oxygen therapy, relaxation training, and energy conservation techniques may be effective. Patients with severe respiratory dysfunction may require mechanical ventilation. Before mechanical ventilation is instituted, the procedure is explained to the patient and the caregiver.

As noted previously, with the advent of ART, there are generally more positive outcomes than could be achieved a few years ago, and a patient mechanically ventilated has a reasonable likelihood of survival. However, if the patient decides to forego mechanical ventilation, their wishes must be followed. Ideally, the patient has prepared an advance directive identifying preferences for treatments and end-of-life care, including hospice care. If the patient has not identified preferences in advance, treatment options are described so that the patient can make informed decisions and have those wishes respected.

Nurses should anticipate that patients as well as family and friends will need support and time to share concerns. In some family systems, more than one person might be living with HIV/AIDS.

NURSING PROCESS

The Patient with HIV/AIDS

The nursing care of patients with HIV/AIDS is challenging because of the potential for any organ system to be involved due to infections or cancer. In addition, this disease is complicated by many emotional, social, and ethical issues. The plan of care for the patient with AIDS (see Chart 55-11) is individualized to meet the needs of the patient. Care includes many of the interventions and concerns cited in the Supportive Care section.

Assessment

Nursing assessment includes identification of potential risk factors, including a history of risky sexual practices or IV/injection drug use. The patient's physical status and psychological status are assessed. All factors affecting immune system functioning are thoroughly explored. A number of instruments can be used to assess symptoms and self-management strategies (Fierz, Nicca, & Spirig, 2013).

Nutritional Status

Nutritional status is assessed by obtaining a dietary history and identifying factors that may interfere with oral intake, such as anorexia, nausea, vomiting, oral pain, or difficulty swallowing. In addition, the patient's ability to purchase, prepare, and store food safely is assessed. Weight history (i.e., changes over time), anthropometric measurements, and blood urea nitrogen (BUN), serum protein, albumin, and transferrin levels provide objective measurements of nutritional status.

Skin Integrity

The skin and mucous membranes are inspected daily for evidence of breakdown, ulceration, or infection. The oral cavity is monitored for redness, ulcerations, and the presence of creamy-white patches indicative of candidiasis. Assessment of the perianal area for excoriation and infection in patients with profuse diarrhea is important. Wounds are cultured to identify infectious organisms.

Respiratory Status

Respiratory status is assessed by monitoring the patient for cough, sputum production (i.e., amount and color), shortness of breath, orthopnea, tachypnea, and chest pain. The presence and quality of breath sounds are investigated. Other measures of pulmonary function include chest x-ray results, arterial blood gas values, pulse oximetry, and pulmonary function test results.

Neurologic Status

Neurologic status is determined by assessing level of consciousness; orientation to person, place, and time; and memory lapses. Mental status is assessed as early as possible to provide a baseline. The patient is also assessed for sensory deficits (visual changes, headache, or numbness and tingling in the extremities), motor involvement (altered gait, paresis, or paralysis), and seizure activity.

Fluid and Electrolyte Balance

Fluid and electrolyte status is assessed by examining the skin and mucous membranes for turgor and dryness. Dehydration may be indicated by increased thirst, decreased urine output, postural hypotension, weak and rapid pulse, and urine-specific gravity of 1.025 or more. Electrolyte imbalances, such as decreased serum sodium, potassium, calcium, magnesium, and chloride, typically result from profuse diarrhea. The patient is assessed for signs and symptoms of electrolyte deficits, including decreased mental status, muscle twitching, muscle cramps, irregular pulse, nausea and vomiting, and shallow respirations.

Knowledge Level

The patient's level of knowledge about the disease, modes of disease transmission, and adherence to ART are evaluated. In addition, the level of knowledge of family (biologic and family of choice) and friends is assessed. The patient's psychological reaction to the diagnosis of HIV infection or AIDS is important to explore. Reactions vary among patients and may include denial, anger, fear, shame, withdrawal from social interactions, and depressive symptoms. It is often helpful to gain an understanding of how the patient has dealt with illness and major life stresses in the past. The patient's resources for support are also identified.

Diagnosis

Nursing Diagnoses

The list of potential nursing diagnoses is extensive because of the complex nature of HIV/AIDS. However, based on the assessment data, major nursing diagnoses may include the following:

- Impaired skin integrity related to cutaneous manifestations of HIV infection, excoriation, and diarrhea
- Diarrhea related to enteric pathogens or HIV infection
- Risk for infection related to immune deficiency
- Activity intolerance related to weakness, fatigue, malnutrition, impaired fluid and electrolyte balance, and hypoxia associated with pulmonary infections
- Chronic confusion related to cognitive changes associated with HIV encephalopathy
- Ineffective airway clearance related to infection, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue

Chart 55-11 PLAN OF NURSING CARE

Care of the Patient with AIDS

NURSING DIAGNOSIS: Diarrhea related to enteric pathogens or HIV infection
GOAL: Resumption of usual bowel habits

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's normal bowel habits.	1. Provides baseline for evaluation	• Exhibits return to normal bowel patterns • Reports decreasing episodes of diarrhea and abdominal cramping • Identifies and avoids foods that irritate the gastrointestinal tract • Takes appropriate therapy as prescribed • Exhibits normal stool cultures • Maintains adequate fluid intake • Maintains body weight and reports no additional weight loss • States rationale for avoiding smoking • Enrolls in program to stop smoking • Uses medication as prescribed • Maintains adequate fluid status • Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst
2. Assess for diarrhea: frequent, loose stools; abdominal pain or cramping, volume of liquid stools, and exacerbating and alleviating factors.	2. Detects changes in status, quantifies loss of fluid, and provides basis for nursing measures
3. Obtain stool cultures, and administer antimicrobial therapy as prescribed.	3. Identifies pathogenic organism; therapy targets specific organism
4. Initiate measures to reduce hyperactivity of bowel. a. Maintain food and fluid restrictions as prescribed. Suggest BRAT diet (*b*ananas, *r*ice, *a*pplesauce, *t*ea, and *t*oast). b. Discourage smoking. c. Avoid bowel irritants such as fatty or fried foods, raw vegetables, and nuts. Offer small, frequent meals.	4. Promotes bowel rest, which may decrease acute episodes a. Reduces stimulation of bowel b. Eliminates nicotine, which acts as bowel stimulant c. Prevents stimulation of bowel and abdominal distention and promotes adequate nutrition
5. Administer anticholinergic antispasmodics and opioids or other medications as prescribed.	5. Decreases intestinal spasms and motility
6. Maintain fluid intake of at least 3 L/day unless contraindicated.	6. Prevents hypovolemia

NURSING DIAGNOSIS: Risk for infection related to immune deficiency
GOAL: Absence of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor for infection: fever, chills, and diaphoresis; cough; shortness of breath; oral pain or painful swallowing; creamy-white patches in oral cavity; urinary frequency, urgency, or dysuria; redness, swelling, or drainage from wounds; vesicular lesions on face, lips, or perianal area.	1. Allows for early detection of infection, essential for prompt initiation of treatment. Repeated and prolonged infections contribute to patient's debilitation.	• Identifies reportable signs and symptoms of infection • Reports signs and symptoms of infection if present • Exhibits and reports absence of fever, chills, and diaphoresis • Exhibits normal (clear) breath sounds without adventitious breath sounds • Maintains weight • Reports adequate energy level without excessive fatigue • Reports absence of shortness of breath and cough • Exhibits pink, moist oral mucous membranes without fissures or lesions • Takes appropriate therapy as prescribed • Experiences no infection • States rationale for strategies to avoid infection • Modifies activities to reduce exposure to infection or infectious persons • Practices "safer sex" • Avoids sharing eating utensils and toothbrush • Exhibits normal body temperature • Uses recommended techniques to maintain cleanliness of skin, skin lesions, and perianal area • Has others handle pet excreta and cleanup • Uses recommended cooking techniques
2. Educate patient or caregiver about need to report possible infection.	2. Allows early detection of infection
3. Monitor white blood cell (WBC) count and differential.	3. Elevated WBC count possibly associated with infection
4. Obtain cultures of wound drainage, skin lesions, urine, stool, sputum, mouth, and blood as prescribed. Administer antimicrobial therapy as prescribed.	4. Assists in determining offending organism to initiate appropriate treatment
5. Instruct patient in ways to prevent infection. a. Clean kitchen and bathroom surfaces with disinfectants. b. Clean hands thoroughly after exposure to body fluids. c. Avoid exposure to others' body fluids or sharing eating utensils. d. Turn, cough, and deep breathe, especially when activity is decreased. e. Maintain cleanliness of perianal area. f. Avoid handling pet excreta or cleaning litter boxes, birdcages, or aquariums. g. Cook meat and eggs thoroughly.	5. Minimizes exposure to infection and transmission of HIV infection to others
6. Maintain aseptic technique when performing invasive procedures such as venipunctures, bladder catheterizations, and injections.	6. Prevents hospital-acquired infections

(*Continued*)

(*Continued*)

NURSING DIAGNOSIS: Ineffective airway clearance related to *Pneumocystis* pneumonia, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue
GOAL: Improved airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess and report signs and symptoms of altered respiratory status, tachypnea, the use of accessory muscles, cough, color and amount of sputum, abnormal breath sounds, dusky or cyanotic skin color, restlessness, confusion, or somnolence.	1. Indicates abnormal respiratory function	• Maintains normal airway clearance: – Respiratory rate <20 breaths/min – Unlabored breathing without the use of accessory muscles and flaring nares (nostrils) – Skin color pink (without cyanosis) – Alert and aware of surroundings – Arterial blood gas values normal – Normal breath sounds without adventitious breath sounds
2. Obtain sputum sample for culture as prescribed. Administer antimicrobial therapy as prescribed.	2. Aids in identification of pathogenic organisms	• Begins appropriate therapy
3. Provide pulmonary care (cough, deep breathing, postural drainage, and vibration) every 2–4 hours.	3. Prevents stasis of secretions and promotes airway clearance	• Takes medication as prescribed • Reports improved breathing • Maintains clear airway
4. Assist patient in attaining semi- or high Fowler position.	4. Facilitates breathing and airway clearance	• Coughs and takes deep breaths every 2–4 hours as recommended
5. Encourage adequate rest periods.	5. Maximizes energy expenditure and prevents excessive fatigue	• Demonstrates appropriate positions and practices postural drainage every 2–4 hours
6. Initiate measures to decrease viscosity of secretions. a. Maintain fluid intake of at least 3 L/day unless contraindicated. b. Humidify inspired air as prescribed. c. Consult with primary provider concerning the use of mucolytic agents delivered through nebulizer or intermittent positive pressure breathing treatment.	6. Facilitates expectoration of secretions; prevents stasis of secretions	• Reports reduced breathing difficulty when in semi- or high Fowler position • Practices energy-conserving strategies and alternates rest with activity • Demonstrates reduction in thickness (viscosity) of pulmonary secretions • Reports increased ease in coughing up sputum • Uses humidified air or oxygen as prescribed and indicated
7. Perform tracheal suctioning as needed.	7. Removes secretions if patient is unable to do so	• Indicates need for assistance with removal of pulmonary secretions
8. Administer oxygen therapy as prescribed.	8. Increases availability of oxygen	• Understands need for and cooperates with endotracheal intubation and the use of a mechanical ventilator
9. Assist with endotracheal intubation; maintain ventilator settings as prescribed.	9. Maintains ventilation	• Verbalizes concerns about respiratory difficulty, intubation, and mechanical ventilation

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to decreased oral intake
GOAL: Intake of nutrients sufficient to meet metabolic needs

Nursing Interventions	Rationale	Expected Outcomes
1. Assess nutritional status with height, weight, age; blood urea nitrogen, serum protein, albumin, transferrin, hemoglobin, and hematocrit levels; and cutaneous anergy.	1. Provides objective measurement of nutritional status	• Identifies factors limiting oral intake, and uses resources to promote adequate dietary intake • Reports increased appetite • States understanding of nutritional needs • Identifies ways to reduce factors that limit oral intake • Rests before meals • Eats in pleasant, odor-free environment • Arranges meals to coincide with visitors' visits • Reports increased dietary intake • Uses oral hygiene before meals
2. Obtain dietary history, including likes and dislikes and food intolerances.	2. Defines need for nutritional education; helps individualize interventions	
3. Assess factors that interfere with oral intake.	3. Provides basis and directions for interventions	
4. Consult with dietitian to determine patient's nutritional needs.	4. Facilitates meal planning	
5. Reduce factors limiting oral intake. a. Encourage patient to rest before meals.	5. Addresses factors limiting intake. a. Minimizes fatigue, which can decrease appetite	

(*Continued*)

(*Continued*)

b. Plan meals so that they do not occur immediately after painful or unpleasant procedures.	b. Decreases noxious stimuli	
c. Encourage patient to eat meals with visitors or others when possible.	c. Limits social isolation	
d. Encourage patient to prepare simple meals or to obtain assistance with meal preparation if possible.	d. Limits energy expenditure	
e. Serve small, frequent meals: 6/day.	e. Prevents overwhelming patient	
f. Limit fluids 1 hour before meals and with meals.	f. Reduces satiety	
6. Instruct patient in ways to supplement nutrition: consume protein-rich foods (meat, poultry, fish) and carbohydrates (pasta, fruit, breads).	6. Provides additional proteins and calories	• Takes analgesic agents before meals as prescribed • Identifies ways to increase protein and caloric intake • Identifies foods high in protein and calories • Consumes foods high in protein and calories • Reports decreased rate of weight loss • Maintains adequate caloric intake • States rationale for enteral or parenteral nutrition if needed • Demonstrates skill in preparing alternate sources of nutrition
7. Consult with primary provider and dietitian about alternative feeding (enteral or parenteral nutrition).	7. Provides nutritional support if patient is unable to take sufficient amounts by mouth	
8. Consult with social worker or community liaison about financial assistance if patient cannot afford food.	8. Increases availability of resources and nutrition	

NURSING DIAGNOSIS: Deficient knowledge related to means of preventing HIV transmission
GOAL: Increased knowledge concerning means of preventing disease transmission

Nursing Interventions	Rationale	Expected Outcomes
1. Instruct patient, family, and friends about routes of transmission of HIV.	1. Knowledge about disease transmission can help prevent spread of disease; may also alleviate fears.	• Patient, family, and friends state means of transmission • Reports and demonstrates practices to reduce exposure of others to HIV • Demonstrates knowledge of safer sexual practices • Identifies means of preventing disease transmission • States that sexual partners are informed about patient's positive HIV status in blood • Avoids IV/injection drug use and sharing of drug equipment with others • Understands risks and benefits associated with PrEP
2. Instruct patient, family, and friends about means of preventing transmission of HIV.	2. Reduces transmission risk	
a. Avoid sexual contact with multiple partners, and use precautions if sexual partner's HIV status is not certain.	a. The risk of infection increases with the number of sexual partners, male or female, and sexual contact with those who engage in high-risk behaviors.	
b. Use condoms during sexual intercourse (vaginal, anal, oral–genital); avoid mouth contact with the penis, vagina, or rectum; avoid sexual practices that can cause cuts or tears in the lining of the rectum, vagina, or penis.	b. Risk of HIV transmission is reduced.	
c. Avoid sex with sex workers and others at high risk.	c. Many sex workers are infected with HIV through sexual contact with multiple partners or IV/injection drug use.	
d. Do not use IV/injection drugs; if addicted and unable or unwilling to change behavior, use clean needles and syringes.	d. Clean needles and syringes are the only way to prevent HIV transmission for those who continue to use drugs. Taking precautions is important for those who are antibody positive to prevent transmitting HIV.	
e. Women who may have been exposed to HIV through sexual or drug practices should consult with a physician before becoming pregnant; consider the use of antiretroviral agents if pregnant.	e. HIV can be transmitted from mother to child in utero; the use of antiretroviral agents during pregnancy significantly reduces perinatal transmission of HIV.	
f. Consider using PrEP	f. Taking ART before engaging in high-risk activity seems to protect against infection.	

(*Continued*)

(*Continued*)

NURSING DIAGNOSIS: Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
GOAL: Decreased sense of social isolation

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's usual patterns of social interaction.	1. Establishes basis for individualized interventions	• Shares with others the need for valued social interaction • Demonstrates interest in events, activities, and communication • Verbalizes feelings and reactions to diagnosis, prognosis, and life changes • Identifies modes of transmission of HIV • States ways of preventing transmission of HIV to others while maintaining contact with valued friends and relatives • Reveals HIV/AIDS diagnosis to others when appropriate • Identifies resources (i.e., family, friends, and support groups such as Indian Network for positive people (INP Plus), Saathi, ASHA, etc (see Resources section) • Uses resources when appropriate • Accepts offers of assistance and support • Reports decreased sense of isolation • Maintains contacts with those of importance to him or her • Develops or continues hobbies that effectively serve as diversion or distraction
2. Observe for behaviors indicative of social isolation, such as decreased interaction with others, hostility, noncompliance, sad affect, and stated feelings of rejection or loneliness.	2. Promotes early detection of social isolation, which may be manifested in several ways	
3. Provide instruction concerning modes of transmission of HIV.	3. Provides accurate information, corrects misconceptions, and alleviates anxiety	
4. Assist patient to identify and explore resources for support and positive mechanisms for coping (e.g., contact with family, friends)	4. Enables mobilization of resources and supports	
5. Allow time to be with patient other than for medications and procedures.	5. Promotes feelings of self-worth and provides social interaction	
6. Encourage participation in diversional activities such as reading, television, or handcrafts.	6. Provides distraction	

Collaborative Problems: Opportunistic infections; impaired breathing; wasting syndrome and fluid and electrolyte imbalances; adverse reaction to medications
Goal: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Opportunistic Infections		
1. Monitor vital signs including temperature.	1. Changes in vital signs such as increases in pulse rate, respirations, blood pressure, and temperature may indicate infection.	• Exhibits stable vital signs • Experiences control of infection • Identifies signs and symptoms correctly and experiences no complications • Identifies signs and symptoms that are reportable to the primary provider • Takes medications as prescribed
2. Obtain laboratory specimens, and monitor test results.	2. Smears and cultures can identify causative agents such as bacteria, fungi, and protozoa, and sensitivity studies can identify antibiotics or other medications effective against the causative agent.	
3. Instruct the patient and caregiver about signs and symptoms of infection and the need to report them early.	3. Early recognition of symptoms facilitates prompt treatment and avoids extra complications.	
Impaired Breathing		
1. Monitor respiratory rate and pattern.	1. Rapid shallow breathing, diminished breath sounds, and shortness of breath may indicate respiratory failure resulting in hypoxia.	• Maintains stable respiratory rate and pattern within the normal limits • Exhibits no adventitious lung sounds; normal breath sounds • Has stable pulse rate and blood pressure within normal limits, and exhibits no evidence of hypoxia • Oxygen saturation levels within acceptable range
2. Auscultate the chest for breath sounds and abnormal lung sounds.	2. Crackles and wheezes may indicate fluid in the lungs, which disrupts respiratory function and alters the blood's oxygen-carrying capacity.	
3. Monitor pulse rate, blood pressure, and oxygen saturation levels.	3. Changes in pulse rate, blood pressure, and oxygen levels may indicate the development of respiratory or cardiac failure.	

(*Continued*)

(*Continued*)

Wasting Syndrome and Fluid and Electrolyte Disturbances		
1. Monitor weight and laboratory values for nutritional status.	1. Weight loss, malnutrition, and anemia are common in HIV infection and increase risk of superinfection.	• Maintains stable weight • Eats a nutritious diet • Attains and maintains hemoglobin, hematocrit, and ferritin levels within normal limits
2. Monitor intake and output and laboratory values for fluid and electrolyte imbalance (potassium, sodium, calcium, phosphorus, magnesium, and zinc).	2. Chronic diarrhea, inadequate oral intake, vomiting, and profuse sweating deplete electrolytes. Small intestine inflammation may impair the absorption of fluids and electrolytes.	• Sustains fluid and electrolyte balance within normal limits
3. Monitor for and report signs and symptoms of dehydration.	3. Fluid loss results in decreased circulating volume leading to tachycardia, dry skin and mucous membranes, poor skin turgor, elevated urine specific gravity, and thirst. Early detection allows early treatment.	• Exhibits no signs and symptoms of dehydration
Reactions to Medications		
1. Monitor for medication interactions.	1. People with HIV infection receive many medications for HIV and for disease complications. Early detection of medication interactions is necessary to prevent complications.	• Experiences no serious side effects or complications from medications • Correctly describes medication regimen and complies with therapy, including adaptations in eating routines and type of food used with prescribed medications
2. Monitor for and promptly report side effects from antiretroviral agents.	2. Side effects from antiretroviral agents can be life threatening. Serious side effects include anemia, pancreatitis, peripheral neuropathy, mental confusion, and persistent nausea and vomiting. Corrective measures need to be instituted.	
3. Instruct the patient and caregiver in the medication regimen.	3. Knowledge of the medication purpose, correct administration, side effects, and strategies to manage or prevent side effects promotes safety and greater compliance with treatment.	

- Acute and chronic pain related to impaired perianal skin integrity secondary to diarrhea, KS, and peripheral neuropathy
- Imbalanced nutrition: less than body requirements related to decreased oral intake
- Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
- Grieving related to changes in lifestyle and roles and unfavorable prognosis
- Deficient knowledge related to HIV infection, means of preventing HIV transmission, ART, and self-management strategies

Collaborative Problems/Potential Complications

Possible complications may include the following:

- Opportunistic infections
- Impaired breathing or respiratory failure
- Wasting syndrome and fluid and electrolyte imbalance
- Adverse effects of medications
- Body image changes

Planning and Goals

Goals for the patient may include achievement and maintenance of skin integrity, resumption of usual bowel patterns, absence of infection, improved activity tolerance, coherent thought processes, improved airway clearance, increased comfort, improved nutritional status, increased socialization, expression of grief, increased knowledge regarding disease prevention and self-care, and absence of complications.

Nursing Interventions

Promoting Skin Integrity

The skin and oral mucosa are assessed routinely for changes in appearance, location and size of lesions, and evidence of infection and breakdown. The patient is encouraged to maintain a balance between rest and mobility whenever possible. Patients who are immobile are assisted to change position at least every 2 hours and more often as needed. Devices such as alternating-pressure mattresses and low-air-loss beds are used to prevent skin breakdown. Patients are encouraged to avoid scratching, to use nonabrasive, nondrying soaps, and to apply nonperfumed skin moisturizers to dry skin. Regular oral care is also encouraged.

Medicated lotions, ointments, and dressings are applied to affected skin surfaces as prescribed. Adhesive tape is avoided. Skin surfaces are protected from friction and rubbing by keeping bed linens free of wrinkles and avoiding tight or restrictive clothing. Patients with foot lesions are advised to wear cotton socks and shoes that do not cause the feet to perspire. Antipruritic, antibiotic, and analgesic agents are given as prescribed.

The perianal region is assessed frequently for impairment of skin integrity and infection. The patient is instructed to keep the area as clean as possible. The perianal area is cleaned after each bowel movement with nonabrasive soap and water to prevent further excoriation and breakdown of the skin and infection. If the area is very painful, soft cloths or cotton sponges may be less irritating than washcloths. In addition, sitz baths or gentle irrigation may facilitate cleaning and promote comfort. The area is dried thoroughly after cleaning. Topical lotions or ointments may be prescribed to promote healing. Wounds are cultured if infection is suspected so that the appropriate antimicrobial treatment can be initiated. Debilitated patients may require assistance in maintaining hygienic practices.

Promoting Usual Bowel Patterns

Bowel patterns are assessed for diarrhea. The nurse monitors the frequency and consistency of stools and the patient's reports of abdominal pain or cramping associated with bowel movements. Factors that exacerbate frequent diarrhea are also assessed. The quantity and volume of liquid stools are measured to document fluid volume losses. Stool cultures are obtained to identify pathogenic organisms.

The patient is counseled about ways to decrease diarrhea. The primary provider may recommend restriction of oral intake to rest the bowel during periods of acute inflammation associated with severe enteric infections. As the patient's dietary intake is increased, foods that act as bowel irritants, such as raw fruits and vegetables, popcorn, carbonated beverages, spicy foods, and foods of extreme temperatures, should be avoided. Small, frequent meals help to prevent abdominal distention. Medications, such as anticholinergic agents, antispasmodic agents, or opioids, can be prescribed to decrease diarrhea by reducing intestinal spasms and motility. Administering antidiarrheal agents on a regular schedule may be more beneficial than administering them on an as-needed basis. Antibiotics and antifungal agents may also be prescribed to combat pathogens identified by stool cultures. Assessment of the patient's self-care strategies is essential.

Preventing Infection

The patient and caregivers are instructed to monitor for signs and symptoms of infection: fever; chills; night sweats; cough with or without sputum production; shortness of breath; difficulty breathing; oral pain or difficulty swallowing; creamy-white patches in the oral cavity; unexplained weight loss; swollen lymph nodes; nausea; vomiting; persistent diarrhea; frequency, urgency, or pain on urination; headache; visual changes or memory lapses; redness, swelling, or drainage from skin wounds; and vesicular lesions on the face, lips, or perianal area. The nurse also monitors laboratory test results that indicate infection, such as the white blood cell count and differential. Cultures of specimens from wound drainage, skin lesions, urine, stool, sputum, mouth, and blood are obtained to identify pathogenic organisms and the most appropriate antimicrobial therapy.

Improving Activity Tolerance

Activity tolerance is assessed by monitoring the patient's ability to ambulate and perform activities of daily living. Patients may be unable to maintain their usual levels of activity because of weakness, fatigue, shortness of breath, dizziness, and neurologic involvement. Assistance in planning daily routines that maintain a balance between activity and rest may be necessary. In addition, patients benefit from instructions about energy conservation techniques, such as sitting while washing or preparing meals. Personal items that are frequently used should be kept within the patient's reach. Measures such as relaxation and guided imagery may be beneficial because they decrease anxiety, which contributes to weakness and fatigue.

Collaboration with other members of the health care team may uncover other factors associated with increasing fatigue and strategies to address them. For example, if fatigue is related to anemia, administering epoetin alfa (Epogen) as prescribed may relieve fatigue and increase activity tolerance.

Maintaining Coherent Thought Processes

The patient is assessed for alterations in mental status that may be related to neurologic involvement, metabolic abnormalities, infection, side effects of treatment, and coping mechanisms. Manifestations of neurologic impairment may be difficult to distinguish from psychological reactions to HIV infection, such as anger and depression.

If the patient experiences altered mental or cognitive status, family and support network members are instructed to speak to the patient in simple, clear language and give the patient sufficient time to respond to questions. Reorientation to surroundings and location is conducted as needed. The patient's support network is encouraged to orient the patient to the daily routine by talking about what is taking place during daily activities and providing the patient with a regular daily schedule for medication administration, grooming, meal times, bedtimes, and awakening times. Posting the schedule in a prominent area (e.g., on the refrigerator), providing nightlights for the bedroom and bathroom, and planning safe leisure activities allow the patient to maintain a regular routine in a safe manner. Activities that the patient previously enjoyed are encouraged. These should be easy to accomplish and fairly short in duration. The nurse encourages the social support network to remain calm and not to argue with the patient while protecting the patient from injury. Around-the-clock supervision may be necessary, and strategies can be implemented to prevent the patient from engaging in potentially dangerous activities, such as driving, using the stove, or mowing the lawn. Strategies for improving or maintaining functional abilities and for providing a safe environment are used for patients with HIV encephalopathy and other cognitive impairments (see Chart 55-10).

Improving Airway Clearance

Respiratory status, including rate, rhythm, the use of accessory muscles, and breath sounds, as well as mental status and skin color, must be assessed at least daily. Any cough and the quantity and characteristics of sputum are documented. Sputum specimens are analyzed for infectious organisms. Pulmonary therapy (coughing, deep breathing, postural drainage, percussion, and vibration) is provided as often as every 2 hours to prevent stasis of secretions and to promote airway clearance. Because of weakness and fatigue, many patients require assistance in attaining a position (such as a high Fowler position or semi-Fowler position) that facilitates breathing and airway clearance. Adequate rest is essential to minimize energy expenditure and prevent excessive fatigue. The fluid volume status is evaluated so that adequate hydration can be maintained. Unless contraindicated because of kidney or cardiac disease, daily intake of 3 L of fluid is encouraged. Humidified oxygen may be prescribed, and nasopharyngeal or tracheal suctioning, intubation, and mechanical ventilation may be necessary to maintain adequate ventilation.

Relieving Pain and Discomfort

The patient is assessed for the quality and severity of pain associated with impaired perianal skin integrity, the lesions of KS, and peripheral neuropathy. In addition, the effects of pain on elimination, nutrition, sleep, affect, and communication are explored, along with exacerbating and relieving factors. Cleaning the perianal area, as described previously, can promote comfort. Topical anesthetic medications or ointments may be prescribed. The use of soft cushions or foam pads may increase comfort while sitting. The patient is instructed to avoid foods that act as bowel irritants. Antispasmodic and antidiarrheal medications may be prescribed to reduce the discomfort and frequency of bowel movements. If necessary, systemic analgesic agents may also be prescribed. Pain from KS is frequently described as a sharp, throbbing pressure, and heaviness, if lymphedema is present. Pain management may include the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids plus nonpharmacologic approaches such as relaxation techniques. When NSAIDs are given to patients who are receiving ART, hepatic and hematologic status must be monitored (Comerford, 2015).

The patient with pain related to peripheral neuropathy frequently describes it as burning, numbness, and "pins and needles." Pain management approaches may include topical ointments, opioids, and tricyclic antidepressants. Tricyclic antidepressants can be helpful in controlling the symptoms of neuropathic pain (Comerford, 2015). They also potentiate the actions of opioids and can be used to relieve pain without increasing the dose of the opioid.

Improving Nutritional Status

Nutritional status is assessed by monitoring weight; dietary intake; and serum albumin, BUN, protein, and transferrin levels. The patient is also assessed for factors that interfere with oral intake, such as anorexia, oral and esophageal candida infection, nausea, pain, weakness, fatigue, and lactose intolerance. Based on the results of assessment, the nurse can implement specific measures to facilitate oral intake. The dietitian is consulted to determine the patient's nutritional requirements.

Control of nausea and vomiting with antiemetic medications given on a regular basis may increase the patient's dietary intake. Inadequate food intake resulting from pain caused by oral lesions or a sore throat may be managed by administering prescribed opioids and viscous lidocaine (the patient is instructed to rinse the mouth and swallow). Additionally, the patient is encouraged to eat foods that are easy to swallow and to avoid spicy or sticky food items and foods that are excessively hot or cold. Oral hygiene before and after meals is encouraged. If fatigue and weakness interfere with intake, the nurse encourages the patient to rest before meals. If the patient is hospitalized, meals should be scheduled so that they do not occur immediately after painful or unpleasant procedures. The patient with diarrhea and abdominal cramping is encouraged to avoid foods that stimulate intestinal motility and abdominal distention, such as fiber-rich foods or lactose, if the patient is intolerant to lactose. The patient is instructed about ways to enhance the nutritional value of meals. Adding eggs, butter, or fortified milk (milk to which powdered skim milk has been added to increase the caloric content) to gravies, soups, or milkshakes can provide additional calories and protein. High-calorie, nutritional foods such as puddings, powders, milkshakes, and nutritional supplements may also be useful. Patients who cannot maintain their nutritional status through oral intake may require enteral feedings or parenteral nutrition.

Decreasing the Sense of Isolation

People with AIDS are at risk for double stigmatization. They have what society refers to as a "dreaded disease," and they may have a lifestyle that differs from what is considered acceptable by many people. The diagnosis might prompt disclosure about hidden lifestyles or behaviors to family, friends, coworkers, and health care providers. As a result, people with HIV infection may be overwhelmed with emotions such as anxiety, guilt, shame, and fear. They also may be faced with multiple losses, such as loss of financial security, normal roles and functions, self-esteem, privacy, ability to control bodily functions, ability to interact meaningfully with the environment, and sexual functioning as well as rejection by sexual partners, family, and friends. Some patients may harbor feelings of guilt because of their lifestyle or because they may have infected others in current or previous relationships. Other patients may feel anger toward sexual partners who transmitted the virus to them. Infection control measures used in the hospital or at home may further contribute to the patient's emotional isolation. Any or all of these stressors may cause the patient with AIDS to withdraw both physically and emotionally from social contact.

Nurses are in a key position to provide an atmosphere of acceptance and understanding for people with AIDS and their social networks. The patient's usual level of social interaction is assessed as early as possible to provide a baseline for monitoring changes in behaviors that suggest social isolation (e.g., decreased interaction with staff or family, hostility, nonadherence). Patients are encouraged to express feelings of isolation and loneliness, with the assurance that these feelings are not unique or abnormal.

Providing information about how to protect themselves and others may help patients avoid social isolation. Patients, family, and friends must be reassured that HIV is not spread through casual contact. Education of ancillary personnel, nurses, and physicians helps reduce factors that might contribute to patients' feelings of isolation. Patient care conferences that address the psychosocial issues associated with HIV/AIDS may help sensitize the health care team to patients' needs.

Coping With Grief

The nurse can help the patient verbalize feelings and explore and identify resources for support and mechanisms for coping, especially when the patient is grieving anticipated losses. The patient is encouraged to maintain contact with family, friends, and coworkers and AIDS support groups. If possible, losses are identified and addressed. The patient is encouraged to continue usual activities whenever possible. Consultations with mental health counselors are useful for many patients and their families.

Improving Knowledge of HIV

The patient and family are educated about HIV infection, means of preventing HIV transmission, ART, and appropriate self-care measures. Information about the purpose of the medications, their correct administration, side effects, and strategies to manage or prevent side effects is provided. The patient is instructed to avoid others with active infections, such as upper respiratory infections.

Monitoring and Managing Potential Complications

Opportunistic Infections. Patients who are severely immunosuppressed are at risk for opportunistic infections. Therefore, anti-infective agents may be prescribed and laboratory tests obtained to monitor their effect. Signs and symptoms of opportunistic infections, including fever, malaise,

difficulty breathing, nausea or vomiting, diarrhea, difficulty swallowing, and any occurrences of swelling or discharge, should be reported as treated as indicated.

Respiratory Failure. Impaired breathing is a major complication that increases the patient's discomfort and anxiety and may lead to respiratory and cardiac failure. The respiratory rate and pattern are monitored, and the lungs are auscultated for abnormal breath sounds. The patient is instructed to report shortness of breath and increasing difficulty in carrying out usual activities. Pulse rate and rhythm, blood pressure, and oxygen saturation are monitored. Suctioning and oxygen therapy may be prescribed to ensure an adequate airway and to prevent hypoxia. Mechanical ventilation may be necessary for the patient who cannot maintain adequate ventilation as a result of pulmonary infection, fluid and electrolyte imbalance, or respiratory muscle weakness. Arterial blood gas values are used to guide ventilator settings. If the patient is intubated, methods must be established to allow communication with the nurse and others. The patient receiving mechanical ventilation will require support to cope with the stress associated with intubation and ventilator assistance. The use of mechanical ventilation should be consistent with the patient's decisions about end-of-life treatment. Further discussion of end-of-life care can be found in Chapter 59.

Wasting Syndrome. Wasting syndrome and fluid and electrolyte disturbances, including dehydration, are common complications of stage 3 of infection. The patient's nutritional and electrolyte status is evaluated by monitoring weight gains or losses, skin turgor, ferritin levels, hemoglobin and hematocrit values, and electrolyte levels. Fluid and electrolyte status is monitored on an ongoing basis; fluid intake and output and urine-specific gravity may be monitored daily if the patient is hospitalized with complications. The skin is assessed for dryness and adequate turgor. Vital signs are monitored for decreased systolic blood pressure or increased pulse rate on sitting or standing. Signs and symptoms of electrolyte disturbances, such as muscle cramping, weakness, irregular pulse, decreased mental status, nausea, and vomiting, are documented and reported to the primary provider. Serum electrolyte values are monitored, and abnormalities are reported.

The nurse helps the patient select foods that will replenish electrolytes, such as oranges and bananas (potassium) and cheese and soups (sodium). A fluid intake of 3 L or more per day, unless contraindicated, is encouraged to replace fluid lost with diarrhea, and measures to control diarrhea are initiated. If fluid and electrolyte imbalances persist, the nurse administers IV fluids and electrolytes as prescribed. Effects of parenteral therapy are monitored.

Side Effects of Medications. Adverse effects are of concern in patients who receive many medications to treat HIV infection or its complications. Many medications can cause severe toxic effects. Patients and their caregivers need to know which signs and symptoms of side effects should be reported immediately to their primary provider (see Table 55-4).

In addition to medications used to treat HIV infection, other medications that may be required include opioids, tricyclic antidepressants, and NSAIDs for pain relief; medications for treatment of opportunistic infections; antihistamines (diphenhydramine [Benadryl]) for relief of pruritus; acetaminophen/paracetamol (Tylenol) or aspirin for management of fever; and antiemetic agents for control of nausea and vomiting. Concurrent use of these medications can cause many drug interactions, resulting in hepatic and hematologic abnormalities. Therefore, careful monitoring of laboratory test results is essential.

During each contact with the patient, the nurse not only asks about side effects, but also about how well the patient is adhering to the medication regimen. To promote adherence, the nurse should assist the patient to organize and plan the medication schedule.

Body Image Changes. Body image changes often occur in patients with HIV and are an important collaborative problem. The nurse helps the patient verbalize feelings and explore and identify resources for support and mechanisms for coping with body image changes. Consultations with mental health counselors may be indicated for patients adjusting to body image changes.

Promoting, Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Patients, families, and friends are educated about the routes of transmission of HIV. As discussed earlier, the nurse discusses precautions the patient can use to avoid transmitting HIV sexually (see Charts 55-2 and 55-3) or through sharing of body fluids, especially blood. Patients and their families or caregivers must receive instructions about how to prevent disease transmission, including handwashing techniques and methods for safely handling and disposing of items soiled with body fluids. Clear guidelines about avoiding and controlling infection, keeping regular health care appointments, symptom management, nutrition, rest, and exercise are necessary (see Chart 55-12). The importance of personal and environmental hygiene is emphasized. Caregivers are taught hand hygiene and appropriate infection prevention precautions (see Chapter 1, Charts 1-4 and 1-5). Kitchen and bathroom surfaces should be cleaned regularly with disinfectants to prevent growth of fungi and bacteria. Patients with pets are encouraged to have another person clean areas soiled by animals, such as birdcages and litter boxes. If this is not possible, patients should use gloves to clean the area and then wash their hands afterward. Patients are advised to avoid exposure to others who are sick or who have been recently vaccinated, especially with live vaccine. The importance of avoiding smoking, excessive alcohol, and over-the-counter and street drugs is emphasized. Patients who are HIV positive or who inject drugs are instructed not to donate blood. IV/injection drug users who are unwilling to stop using drugs are advised to avoid sharing drug equipment with others.

Caregivers in the home are taught how to administer medications, including IV preparations. The medication regimens used for patients with HIV infection and AIDS are often complex and expensive. Patients receiving combination therapies for the treatment of HIV infection and its complications require careful education about the importance of taking medications as prescribed and explanations and assistance in fitting the medication regimen into their lives (see Chart 55-8). If the patient requires enteral or parenteral nutrition, instruction is provided to the patient and family about how to administer nutritional therapies at home. Nurses provide ongoing education and support for the patient and family.

Continuing and Transitional Care. Many people with HIV/AIDS remain in their community and continue their usual daily activities, whereas others can no longer work or maintain their independence. Families or caregivers may need assistance in providing supportive care. Many community-based

Chart 55-12 HOME CARE CHECKLIST

Infection Prevention for the Patient with Immune Deficiency

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of immune deficiency on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., hygiene, activity) necessary to decrease risk for infection.
  - Maintain good hand hygiene technique before eating, after using the bathroom, and before and after performing health care procedures.
  - Maintain total body hygiene and foot care to prevent bacterial and fungal diseases.
  - Maintain skin integrity, using cream and emollients to prevent or manage dry, chafed, or cracked skin.
  - Maintain good oral hygiene and dental checkups.
  - Avoid people with infections, recent vaccinations, and crowds.
  - Perform deep breathing; use incentive spirometer every 4 hours while awake if mobility is restricted.
  - Provide adequate lubrication with gentle vaginal manipulation during sexual intercourse; avoid anal intercourse.
- State changes in home environment necessary to decrease risk for infection.
  - Avoid cleaning birdcages and litter boxes; consider avoiding garden work (soil) and fresh flowers in stagnant water.
  - Identify the rationale for frequent cleaning of kitchen and bathroom surfaces with disinfectant.
- Verbalize understanding of ways to maintain a nutritious diet and adequate calories and necessary changes to decrease risk of infection.
  - State the reason for avoiding the eating of raw fruits and vegetables, cooking all foods thoroughly, and immediately refrigerating all leftover food.
- Identify rationale and benefits of avoiding alcohol, tobacco, and unprescribed medications.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify signs and symptoms of infection to report to the primary provider, such as fever; chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems with urination or changes in the character of the urine; red, swollen, or draining wounds; sores or lesions on the body; persistent vaginal discharge with or without itching; and severe fatigue.
- Demonstrate how to monitor for signs of infection.
- Describe to whom, how, and when to report signs of infection.
- Describe appropriate actions to take should infection occur.

ADL, activities of daily living; IADL, independent activities of daily living.

organizations provide a variety of services for people living with HIV infection and AIDS; nurses can help identify these services.

Home, community-based, transitional, and hospice nurses are in an excellent position to provide the support and guidance that is so often needed in the home setting. Home care nurses are key to the safe and effective administration of parenteral antibiotics, chemotherapy, and nutrition in the home.

During home visits, the nurse assesses the patient's physical and emotional status and home environment. The patient's adherence to the therapeutic regimen is assessed, and strategies are suggested to assist with adherence. The patient is assessed for progression of disease and for adverse side effects of medications. Previous education is reinforced, and the importance of keeping follow-up appointments is stressed.

Complex wound care or respiratory care may be required in the home. Patients and families are often unable to meet these skilled care needs without assistance. Nurses may refer patients to community programs that offer a range of services for patients, friends, and families, including help with housekeeping, hygiene, and meals; transportation and shopping; individual and group therapy; support for caregivers; telephone networks for the homebound; and legal and financial assistance. These services are typically provided by both professionals and nonprofessional volunteers. A social worker may be consulted to identify sources of financial support, if needed.

Home care and hospice nurses are increasingly called on to provide physical and emotional support to patients and families as patients with AIDS enter the terminal stages of disease. This support takes on special meaning when people with AIDS lose friends and when family members fear the disease or feel anger concerning the patient's lifestyle. The nurse encourages the patient and family to discuss end-of-life decisions and to ensure that care is consistent with those decisions, all comfort measures are employed, and the patient is treated with dignity at all times.

Evaluation

Expected patient outcomes may include:

1. Maintains skin integrity
2. Resumes usual bowel habits
3. Experiences no infections
4. Maintains adequate level of activity tolerance
5. Maintains usual thought processes
6. Maintains effective airway clearance
7. Experiences increased sense of comfort and less pain
8. Maintains adequate nutritional status
9. Experiences decreased sense of social isolation
10. Progresses through grieving process
11. Reports increased understanding of AIDS, prevention of HIV transmission, and ART, and participates in self-management strategies as possible
12. Remains free of complications

Detailed outcomes are included in the plan of nursing care for a patient with AIDS (see Chart 55-11).

National AIDS Control Program (NACP)–India

The Govt. of India has been implementing National AIDS Control Program (NACP) successfully since 1992. The first edition of NACP concentrated on awareness creation, measures to improve accessibility of safe blood, and preventive services

for at risk groups. NACP II revision was done in 1999. The National AIDS prevention policy was initiated in 2002 to consolidate the strategies toward capacity building to tackle the AIDS epidemic on long-term basis and to accelerate the preventive and control measures. As a part of the program, national antiretroviral therapy program was initiated and adolescent counseling and testing centers were opened.

The third phase of the program (NACP III) was launched in 2007 with the objective of halting and reversing the HIV epidemic in India. Scientifically evolved and strategically implemented NACP III touched its target through strengthening central, state, district, and gross root level technical, managerial, and administrative resources.

The fourth phase of the program (NACP IV), launched in July 2015, concentrates on reducing the incidence through intensifying the preventive measures to control spread among high-risk groups and vertical transmission.

The second priority of NACP IV is to intensify information, education, and counseling services to facilitate behavior change among general public and high-risk groups. The third component of the program is to provide comprehensive care, support, and services to those people living with HIV. The program will adopt measures to integrate the PLHIV into the mainstream by ending discrimination through insurance and other social safety initiatives.

It also aims at capacity building of NGOs in high-epidemic northeastern states. Strengthening the managerial, information, and surveillance systems at all levels from the central down the peripheral level will be implemented in phase IV of the program.

National Strategic Plan 2017–2024 for Prevention of HIV/AIDS and STI

The Ministry of Health and Family Welfare, Govt. of India, is committed to end AIDS epidemic by 2030.

After the NACP implementation, the incidence rate has reduced by 64% in the 10-year period between 2000–2010 but subsequently incidence rate declined slowly. There was 0.28% incidence of AIDS in 2012, which reduced to only 0.26% in 2015.

To intensify and accelerate the activities and efforts to ensure target achievement by the year 2030, the government and NACO have floated the national strategic plan for 7-year period (2017–2024) on December 1st, 2017, World AIDS Day. To make substantial progress, NSP has fixed aims for 2020 and 2024. By the year 2020, the target of 90-90-90 is aimed, which means 90% of the country's people tested positive know their HIV status, 90% of the tested positive people are treated, and 90% of the treated people achieve effective viral load reduction. Similarly, by 2024 the planners aim to achieve 95% of the target of ending AIDS and 85% reduction in number of new cases (NACO, 2017).

The Five Priorities of NSP

1. Speed up the prevention of HIV among the at-risk group and key population namely injectable drug users, transgenders, male-to-male sex partners, female sex workers, truck drivers who go for long travel, and male single migrants
2. Provision of high-quality HIV testing and access to comprehensive ART for all
3. Elimination of vertical transmission of HIV and syphilis from mother to child
4. Collaboration with NGOs, civil community societies, and people living with HIV for effective program implementation
5. Reorganization and transformation of the existing strategic information system into efficient patient centric one (Adopted from the National Strategic Plan 2017–2024, NACO, 2017)

The NSP plan calls for a more concerted effort to reduce high-risk behavior among target population groups of injectable drug users, transgenders, as well as adolescents through the following proposed interventions:

- Mobile testing units are planned to achieve the target of 90-90-90 for facility-based testing, community-based testing, and self-testing.
- Multipronged approach is proposed to address high-risk behavior among adolescent population through enhancing awareness through sexual and reproductive health education and by integrating the adolescent program with the National Health Mission.
- Prevention of parent-to-child transmission by integrated testing and counseling of all pregnant women.
- Prevention, early diagnosis, and treatment of co-morbid infections such as tuberculosis, Hepatitis B and C, and sexually transmitted infections.
- Effective treatment regimens with efforts to improve adherence to treatment and reduce the number of dropouts from treatment.
- Improvement in ART adherence by community involvement and collaboration with NGOs.
- Revamping the communication system to a more patient centric and effective one.

NACP V (2021 to 2026)

The NACP V focuses on lengthening the survival with an improved quality of life for PLHIV through prompt early identification, initiation, and compliance to ART. It aims at zero new infection, zero new deaths attributable to AIDS, and zero discrimination for PLHIV. The current stage of NACP employs more patient-centered and community-oriented testing and treatment services.

National AIDS Control Organization (NACO)

The NACO is a branch of the Ministry of Health and Family Welfare of the Government of India. It controls and implements the activities of National AIDS Control Programme in India. Under the NACO's leadership, 35 HIV prevention and control societies are functioning. The aims of the NACO are AIDS prevention and treatment of people living with HIV. Through state AIDS control societies and NGOs, the NACO creates wide awareness and life skills programs for high-risk adolescent population.

Activities of the NACO

1. **Prevention of AIDS:** Targeted activities such as sensitization programs, facilitation of voluntary testing services, and promotion of safe behaviors are carried out for the at-risk groups such as commercial sex workers, transgender population, homosexuals, drug addicts, migrant laborers, and truck drivers.
2. **Information, education, and communication (IEC):** Mass communication and multimedia communication strategies are utilized for the creation of awareness about the mode of transmission, methods of prevention, availability of free testing and treatment services.

3. **Testing:** Free testing and counseling services are provided for all at-risk individuals and volunteers by the NACO.
4. **Treatment services:** Free treatment of first-line, second-line, and third-line ART is delivered to all those who are enrolled under the National Aids Control Programme. Currently, single-window HIV and TB treatment delivery is carried out at all ART centers.
5. **Laboratory services:** Under the NACO directions, free diagnostic services are available. Quality-ensured testing of viral load and CD4 count are carried out. The state-level and six national-level laboratories are involved in the testing of viral loads, etc.
6. **Collaboration and partnership:** In collaboration with towering personalities, NGOs, and Ministry of Health and Family Welfare officials, the NACO carries out its prevention and facilitation of treatment services.
7. **Strategic information and leadership:** The NACO provides strategic plans and evidence-based guidelines.

HIV/AIDS (Control and Prevention) ACT, 2017

To end discrimination on the basis of HIV, the Government of India has enacted a law called HIV/AIDS (Control and Prevention) Act 2017. All the healthcare providers and every nurse in India must be aware of the HIV/AIDS Act, 2017, and its implications. Salient aspects of the law are presented below.

- The preamble of HIV/AIDS Act prohibits discrimination of any kind toward "people living with HIV (PLHIV)" and they are entitled equal rights like other citizens. The act prohibits unfair treatment in employment or educational institutions or any business establishments.
- Only on the basis of written assessment and certification from qualified healthcare provider that the occupation poses risk of transmission of HIV to other persons in the workplace or unfit to perform duties, HIV-positive person may be denied employment.
- The act prohibits discontinuation of medical/healthcare services or unfair treatment in healthcare facility on the basis of HIV status.
- PLHIV are entitled to privileges and power to hold private and public office. They have the right to reside, or for entertainment, in any place they like and should not be denied accommodation.
- The law prohibits testing any individual for HIV without his or her consent and it should be done after appropriate pretest counseling. The results of the test should be announced only by the physician who is treating the individual or the qualified counselor with proper posttest counseling.
- The test results can be informed to the sexual partner or spouse by the physician or counselor in person after counseling.
- Or the HIV-positive person may be encouraged or counseled to reveal the test result.
- The act does not make it obligatory on his or her part to identify the sexual partner and inform.
- It should be noted by the nurses that they are not entitled to reveal the test results to anyone. Healthcare providers including nurses may reveal to other healthcare professional involved in his or her care so that the appropriate transmission prevention can be taken.
- The healthcare agency is legally obligated to protect the documents and keep it confidential.
- The healthcare agency is obligated legally to give training on universal precaution to all its employees and ensure availability of resources for following universal precaution and postexposure prophylaxis.

International Agencies on AIDS Control

The global action against HIV is the sponsored program by many nongovernmental organizations such as the International AIDS Society, the Global Fund, UNAIDS, and World Health Organization (HIV.gov, 2021).

1. **The Global Fund:** It aims at stepping up the efforts to end AIDS, malaria, and tuberculosis. The Global Fund spends more than $4 billion a year toward this cause. Concerted efforts of the Global Fund resulted in 50% reduction in new cases and AIDS-related mortality.
2. **International AIDS Society:** The International Aids Society is the largest association in the world dedicated to AIDS control. It has membership from more than 170 countries across the globe. Through research and scholarly activities, it aims at providing evidence-based guidelines for HIV and AIDS prevention and control. It also engages in capacity building through organizing international HIV conferences.
3. **UNAIDS:** It is another international organization which has focused on global efforts to end public health threat posed by HIV within the year 2030 so that the sustainable development goals can be achieved.
4. **World Health Organization:** It is the strategic global body of the United Nations in health-related matter that contributes greatly to mitigate the effects of HIV, hepatitis, and sexually transmitted infections through one of its departments, the Department of Global HIV, Hepatitis, and Sexually Transmitted Infection Programmes (HHS).

Counseling Services for HIV

The NACO (2016) mandates adherence to the guidelines for testing and counseling for HIV. Prior to HIV screening test, all patients need to undergo pretest counseling and informed consent needs to be obtained. The five Cs of testing, namely, consent, confidentiality, counseling, correctness of result, and contact detail of the partner, need to be adhered to (NACO, 2016). Audiovisual privacy needs to be ensured during testing. If the screening test result is positive, then the confirmatory test should be performed in dedicated standalone testing centers to facilitate further treatment and follow-up (NACO, 2016).

Pretest Counseling

- Ensure that history taking and assessment are carried out with adequate privacy.
- Provide information about HIV, the mode of transmission, the window period, and the importance of testing.
- Educate about menstrual and reproductive hygiene, use of condoms, etc.
- Educate about the need for partner testing.
- Ensure that the personal information and the results will be maintained confidentially.
- Clarify the doubts of the patients with an open mind and acceptance. Apply the communication techniques such as listening, questioning, and appropriate use of body language while interacting.
- Perform quick assessment for signs and symptoms of sexually transmitted diseases.

Post-test Counseling

Post-test counseling may be needed for both persons with positive and those with negative screening test results.

- **Counseling for individuals with negative test results:** Provide information about the test results. Educate about the need for maintaining menstrual and sexual hygiene, and effective use of condoms.
- **Counseling for individuals with positive results:** Individuals need to be educated about the test results. Educate about undergoing further confirmatory test. Counsel the need for testing the sexual partner. Fill the linkage form for undergoing the confirmatory test at the integrated counseling and testing center. The following points need to be considered while counseling the patients:
  - The test's positive result may be a crisis.
  - The patients may need time to share their feelings, desperation, fear about social implications, etc. Some may deny their test status.
  - Showing concern and acceptance by the nurse is very important to facilitate successful coping with the HIV.
  - Explain that the ART is totally free of cost. Explain about the need for taking medicines as prescribed, their side effects, and the advantages of consuming a nutritious diet.
  - Explain the need for testing of the sexual partner if he or she is untested.
  - Assess the risk for depression, suicidal thoughts, and other mental health issues that may arise following the test's positivity.
  - In case of any such issues, provide follow-up counseling and further referral to a mental health specialist.
  - Facilitate coping by referring the patient to PLHIV support groups.
  - Clarify the patient's doubts and concerns.

Rehabilitation of PLHIV/Patients With AIDS

HIV is a chronic condition and the rehabilitation in the context of HIV is defined as a dynamic process including any prevention and/or treatment activities and services that address body impairments, activity limitations, and social participation restrictions for an individual (Perazzo et al., 2018). The nurse needs to address all the aspects of improving the quality of life by reducing the possibility of opportunistic infections and risk reduction related to CAD or other comorbid conditions. Social isolation is shown to cause depression and nonadherence. Nurses can work with the patient with HIV, family members, consulting physician, physiotherapist, occupational therapist, social worker, and support group team members.

Some of rehabilitative interventions are the following:

- Physiotherapy
- Self-management education skills in relation to medication adherence
- Dietary modification
- Abstinence from smoking and alcohol
- Conducting PLHIV support group meetings
- Occupational therapy consultations

Emotional and Ethical Concerns

Nurses in all settings are called on to provide care for patients with HIV infection. In doing so, they encounter not only the physical challenges of this epidemic but also emotional and ethical concerns. The concerns raised by health care professionals involve issues such as fear of infection, responsibility for giving care, values clarification, confidentiality, developmental stages of patients and caregivers, and poor prognostic outcomes.

Many patients with HIV infection have engaged in "stigmatized" behaviors. Because these behaviors challenge some traditional religious and moral values, nurses may feel reluctant to care for these patients. In addition, health care providers may still have fear and anxiety about disease transmission despite education concerning infection control and the low incidence of transmission to health care providers (see Chart 55-13). Nurses are encouraged to examine their personal beliefs and to use the process of values clarification to approach controversial issues.

Nurses are responsible for protecting the patient's right to privacy by safeguarding confidential information. Inadvertent disclosure of confidential patient information may result in personal, financial, and emotional hardships for the patient. The controversy surrounding confidentiality concerns the circumstances in which information may be disclosed to others. Health care team members need accurate patient information to conduct assessment, planning, implementation, and evaluation of patient care. Failure to disclose HIV status could compromise the quality of patient care. Sexual partners of patients infected with HIV should know about the potential for infection and the need to engage in safer sex practices, as well as the possible need for testing and health care.

During the early years of the AIDS epidemic, the mortality rate was high. But medication advances have controlled the disease progression, resulting in what is called "functional cure" or HIV remission, which is characterized by viral loads at low or undetectable levels (Vanham, Buvé, Florence, et al., 2014). Many strategies have been used by nurses to cope with the stress associated with caring for patients with AIDS. Education and provision of up-to-date information help to alleviate apprehension and prepare nurses to deliver safe, high-quality patient care. Interdisciplinary meetings allow participants to support one another and provide comprehensive patient care. Staff support groups give nurses an opportunity to solve problems and explore values and feelings about caring for patients with AIDS and their families; they also provide a forum for grieving. Other sources of support include nursing administrators, and peers.

CRITICAL THINKING EXERCISES

1. A 43-year-old man who is an IV drug user and in a committed relationship wants to reduce the risk of HIV infection. What is the evidence base on strategies to reduce risk from use of IV/injection drugs? What is the evidence about the effectiveness of needle exchange programs? What is the evidence for the effectiveness of PrEP? How would you determine the strength of the evidence and how would you present information to him?
2. A 20-year-old female college student comes to the student health clinic stating she had unprotected sex with a partner she suspects is HIV positive. What further questions do you have for her? What is your priority focus for her physical examination? What diagnostic tests and treatments may you anticipate?
3. A 45-year-old female tested positive for HIV started on ART at the integrated testing and treatment center. After few months, she did not come for the follow-up and did not collect her ART medicines. Describe your approach and plans to promote adherence with ART and other medications since the patient is taking multiple different medications many times during the day.

Chart 55-13 ETHICAL DILEMMA

Under What Circumstances May a Nurse Refuse to Care for a Patient?

Case Scenario

You are the charge nurse in the Intensive Care Unit (ICU). A 52-year-old male patient, who is married but is bisexual, is admitted with pneumocystic pneumonia. His bisexual status is unknown to his spouse. He appears malnourished and emaciated. His laboratory findings indicate he has HIV. His wife has been at his bedside daily but is unaware that he has HIV. The nurse assigned to care for him tells you, "I cannot believe what he has done to his wife! She is at his bedside and has no idea about his double lifestyle. I am a Christian and I want nothing to do with a man with no morals. I think someone needs to tell her the truth but it won't be me! I'm not going to take care of him—give me another assignment."

Discussion

Some health care providers may display a judgmental manner when providing care for patients with HIV/AIDS. The negative attitude often leads to a significant decrease in patient satisfaction regarding their health care. The Indian Nursing council (INC) clearly stipulates that nurses have an obligation to "provide fair and equal treatment to all patients" and also stipulates in its *Code of Ethics* for nurses in India, that nurses must provide fair and equitable treatment to all individuals regardless of gender, socioeconomic status, religious, culture, or sexual orientation

Analysis

- Does a nurse have the right to refuse treating a patient? What if a nurse refuses to care for a patient because he or she believes that by doing so the nurse may suffer harm or it may conflict with tenets of their religious beliefs?
- There are several statements that the staff nurse in this case makes with regard to this patient assignment. Analyze each of these in turn. Does the staff nurse demonstrate respect for the patient's autonomy? Is he or she adhering to the ethical principles of beneficence and nonmaleficence? Is the nurse's actions and statements in conflict with the Code of Ethics? see Chart 2-3
- What might be the legal implications of the staff nurse refusing this assignment? As the charge nurse, how would you act to ensure that applicable hospital policies are adhered to, that you do not permit any type of negligent or other potentially criminal act to occur, and that the patient and his partner receive just and equitable health care?
- What responsibility does the health care team have to the patient's wife? Since her health may be at risk due to her husband's disease, does the health care provider have an obligation to disclose the patient's diagnosis? Does the health care team have any responsibility to inform the patient's sexual partners of his HIV status? What health agencies must be notified of this patient's newly diagnosed HIV status?

CHAPTER 56

Assessment and Management of Patients with Allergic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the physiologic events involved with allergic reactions.
2. Describe the types of hypersensitivity.
3. Use appropriate parameters for assessment of the status of patients with allergic disorders.
4. Describe the pathophysiologic changes, clinical manifestations, and management of patients with allergic disorders.
5. Specify measures to prevent and manage anaphylaxis.
6. Use the nursing process as a framework for care of the patient with allergic rhinitis.
7. Discuss the different allergic disorders according to type.

GLOSSARY

allergen: substance that causes manifestations of allergy
allergy: inappropriate and often harmful immune system response to substances that are normally harmless
anaphylaxis: rapid clinical response to an immediate immunologic reaction between a specific antigen and antibody
angioneurotic edema: condition characterized by urticaria and diffuse swelling of the deeper layers of the skin (i.e., angioedema)
antibody: protein substance developed by the body in response to and interacting with a specific antigen
antigen: substance that induces the production of antibodies
antihistamine: medication that opposes the action of histamine
atopic dermatitis: type I hypersensitivity involving inflammation of the skin evidenced by itching, redness, and a variety of skin lesions
atopy: term often used to describe immunoglobulin E–mediated diseases (i.e., atopic dermatitis, asthma, and allergic rhinitis) with a genetic component
B cells: lymphocyte cells that are important in producing circulating antibodies
bradykinin: a substance that stimulates nerve fibers and causes pain
eosinophil: granular leukocyte
erythema: diffuse redness of the skin
hapten: incomplete antigen
histamine: substance in the body that causes increased gastric secretion, dilation of capillaries, and constriction of the bronchial smooth muscle
hypersensitivity: abnormal heightened reaction to a stimulus of any kind
immunoglobulins: a family of closely related proteins capable of acting as antibodies
leukotrienes: a group of chemical mediators that initiate the inflammatory response
mast cells: connective tissue cells that contain heparin and histamine in their granules
prostaglandins: unsaturated fatty acids that have a wide assortment of biologic activity
serotonin: chemical mediator that acts as a potent vasoconstrictor and bronchoconstrictor
T cells: lymphocyte cells that can cause graft rejection, kill foreign cells, or suppress production of antibodies
urticaria: hives

Introduction

The human body is bombarded by a host of potential invaders—allergens as well as microbial organisms—that constantly threaten its defenses. After penetrating those defenses, these allergens and organisms, if allowed to continue unimpeded, disrupt the body's enzyme systems and destroy its vital tissues. To protect against these agents, the body is equipped with an elaborate defense system.

The epithelial cells that coat the skin and make up the lining of the respiratory, gastrointestinal, and genitourinary tracts provide the first line of defense against microbial invaders. The structure and continuity of these surfaces and their resistance to penetration are initial deterrents to invaders.

One of the most effective defense mechanisms is the body's capacity to equip itself rapidly with antibodies individually designed to meet each new invader—namely, specific protein antigens. Antibodies react with antigens in a variety of ways: (1) by coating the antigens' surfaces if they are particular substances, (2) by neutralizing the antigens if they are toxins, and (3) by precipitating the antigens out of solution if they are dissolved. The antibodies prepare the antigens so that the phagocytic cells of the blood and the tissues can dispose of them. However, although this system is normally protective, in some cases the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity disorder.

ALLERGIC ASSESSMENT

Physiologic Overview

An allergic reaction is a manifestation of tissue injury resulting from interaction between an antigen and an antibody. Allergy is an inappropriate and often harmful response of the immune system to normally harmless substances, called **allergens** (e.g., dust, weeds, pollen, dander). Chemical mediators released in allergic reactions may produce symptoms that range from mild to life-threatening.

In allergic reactions, the body encounters allergens that are types of **antigens**, usually proteins that the body's defenses recognize as foreign, and a series of events occurs in an attempt to render the invaders harmless, destroy them, and remove them from the body. When lymphocytes respond to the antigens,

antibodies (protein substances that protect against antigens) are produced.

Antibodies combine with antigens in a special way, which has been likened to keys fitting into a lock. Antigens (the keys) fit only certain antibodies (the locks). Hence, the term *specificity* refers to the specific reaction of an antibody to an antigen. There are many variations and complexities in these patterns.

Function of Immunoglobulins

Antibodies that are formed by lymphocytes and plasma cells in response to an immunogenic stimulus constitute a group of serum proteins called immunoglobulins. Grouped into five classes (IgG, IgA, IgM, IgD, and IgE), immunoglobulins can be found in the lymph nodes, tonsils, appendix, and Peyer patches of the intestinal tract or circulating in the blood and lymph. These antibodies are capable of binding with a wide variety of antigens. Immunoglobulins of the IgE class are involved in allergic disorders and some parasitic infections. IgE-producing cells are located in the respiratory and intestinal mucosa. Two or more IgE molecules bind together to an allergen and trigger mast cells or basophils to release chemical mediators, such as histamine, serotonin, kinins, slow-reacting substances of anaphylaxis, and the neutrophil factor, which produces allergic skin reactions, asthma, and hay fever. Atopy refers to IgE-mediated diseases, such as allergic rhinitis, that have a genetic component. See Chapter 54 for more information on immunoglobulins.

Role of B Cells

B cells, or B lymphocytes, are programmed to produce one specific antibody. On encountering a specific antigen, B cells stimulate production of plasma cells, the site of antibody production. The result is the outpouring of antibodies for the purpose of destroying and removing the antigens.

Role of T Cells

T cells, or T lymphocytes, assist the B cells. T cells secrete substances that direct the flow of cell activity, destroy target cells, and stimulate the macrophages. The macrophages present the antigens to the T cells and initiate the immune response. They also digest antigens and assist in removing cells and other debris. Unlike a specific antibody, a T cell does not bind free antigens.

Function of Antigens

Antigens are divided into two groups: complete protein antigens and low–molecular-weight substances. Complete protein antigens, such as animal dander, pollen, and horse serum, stimulate a complete humoral response. See Chapter 54 for a discussion of humoral immunity. Low–molecular-weight substances, such as medications, function as **haptens** (incomplete antigens), binding to tissue or serum proteins to produce a carrier complex that initiates an antibody response. In an allergic reaction, the production of antibodies requires active communication between cells. When the allergen is absorbed through the respiratory tract, gastrointestinal tract, or skin, allergen sensitization occurs. Macrophages process the antigen and present it to the appropriate cells. These cells mature into allergen-specific secreting plasma cells that synthesize and secrete antigen-specific antibodies.

Function of Chemical Mediators

Mast cells, which are located in the skin and mucous membranes, play a major role in IgE-mediated immediate hypersensitivity. When mast cells are stimulated by antigens, powerful chemical mediators are released, causing a sequence of physiologic events that result in symptoms of immediate hypersensitivity (see Fig. 56-1). There are two types of chemical mediators: primary and secondary. Primary mediators are preformed and are found in mast cells or basophils. Secondary mediators are inactive precursors that are formed or released in response to primary mediators. Table 56-1 summarizes the actions of primary and secondary chemical mediators.

Primary Mediators

Histamine

Histamine, which is released by mast cells, plays an important role in the immune response. It is the first chemical mediator to be released in immune and inflammatory responses. It is synthesized and stored in high concentrations in body tissues exposed to environmental substances (Frandsen & Pennington, 2014). Histamine's effects peak 5 to 10 minutes after antigen contact and include the following: erythema; localized edema in the form of wheals; pruritus; contraction of bronchial smooth muscle, resulting in wheezing and bronchospasm; dilation of small venules and constriction of larger vessels; and increased secretion of gastric and mucosal cells, resulting in diarrhea (Abbas, Lichtman, & Pillai, 2014); (Fleisher, Shearer, Schroeder, et al., 2013). Histamine action results from stimulation of histamine-1 (H_1) and histamine-2 (H_2) receptors. H_1 receptors are found predominantly on bronchiolar and vascular smooth muscle cells; H_2 receptors are found on gastric parietal cells.

Certain medications are categorized by their action at these receptors. Diphenhydramine (Benadryl) is an example of an

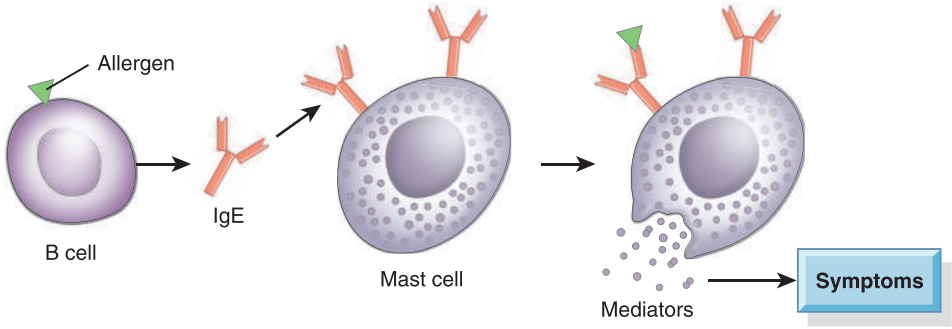

Figure 56-1 • Allergen triggers the B cell to make immunoglobulin E (IgE) antibody, which attaches to the mast cell. When that allergen reappears, it binds to the IgE and triggers the mast cell to release its chemicals. Courtesy of the U.S. Department of Health and Human Services, National Institutes of Health.

TABLE 56-1 Chemical Mediators of Hypersensitivity

Mediators	Action
Primary Mediators	
Preformed and Found in Mast Cells or Basophils	
Histamine (preformed in mast cells)	Vasodilation
	Smooth muscle contraction, increased vascular permeability, increased mucus secretions
Eosinophil chemotactic factor of anaphylaxis (preformed in mast cells)	Attracts eosinophils
Platelet-activating factor (requires synthesis by mast cells, neutrophils, and macrophages)	Smooth muscle contraction
	Incites platelets to aggregate and release serotonin and histamine
Prostaglandins (chemically derived from arachidonic acid; require synthesis by cells)	D and F series → bronchoconstriction
	E series → bronchodilation
	D, E, and F series → vasodilation
Basophil kallikrein (preformed in mast cells)	Frees bradykinin, which causes bronchoconstriction, vasodilation, and nerve stimulation
Secondary Mediators	
Inactive Precursors Formed or Released in Response to Primary Mediators	
Bradykinin (derived from precursor kininogen)	Smooth muscle contraction, increased vascular permeability, stimulates pain receptors, increased mucus production
Serotonin (preformed in platelets)	Smooth muscle contraction, increased vascular permeability
Heparin (preformed in mast cells)	Anticoagulant
Leukotrienes (derived from arachidonic acid and activated by mast cell degranulation) C, D, and E or slow-reacting substance of anaphylaxis	Smooth muscle contraction, increased vascular permeability

Adapted from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

antihistamine, a medication that displays an affinity for H_1 receptors. Cimetidine (Tagamet) and ranitidine (Zantac) target H_2 receptors to inhibit gastric secretions in peptic ulcer disease.

Eosinophil Chemotactic Factor of Anaphylaxis

Eosinophil chemotactic factor of anaphylaxis affects the movement of **eosinophils** (granular leukocytes) to the site of allergens. It is preformed in the mast cells and is released from disrupted mast cells.

Platelet-Activating Factor

Platelet-activating factor is responsible for initiating platelet aggregation and leukocyte infiltration at sites of immediate hypersensitivity reactions. It also causes vasodilation, bronchoconstriction, and increased vascular permeability (Frandsen & Pennington, 2014).

Prostaglandins

Prostaglandins produce smooth muscle contraction as well as vasodilation and increased capillary permeability. They sensitize pain receptors and increase the pain associated with inflammation. In addition, prostaglandins induce inflammation and enhance the effects of mediators of inflammatory response. Local manifestations include erythema, heat, and edema (Frandsen & Pennington, 2014).

Secondary Mediators

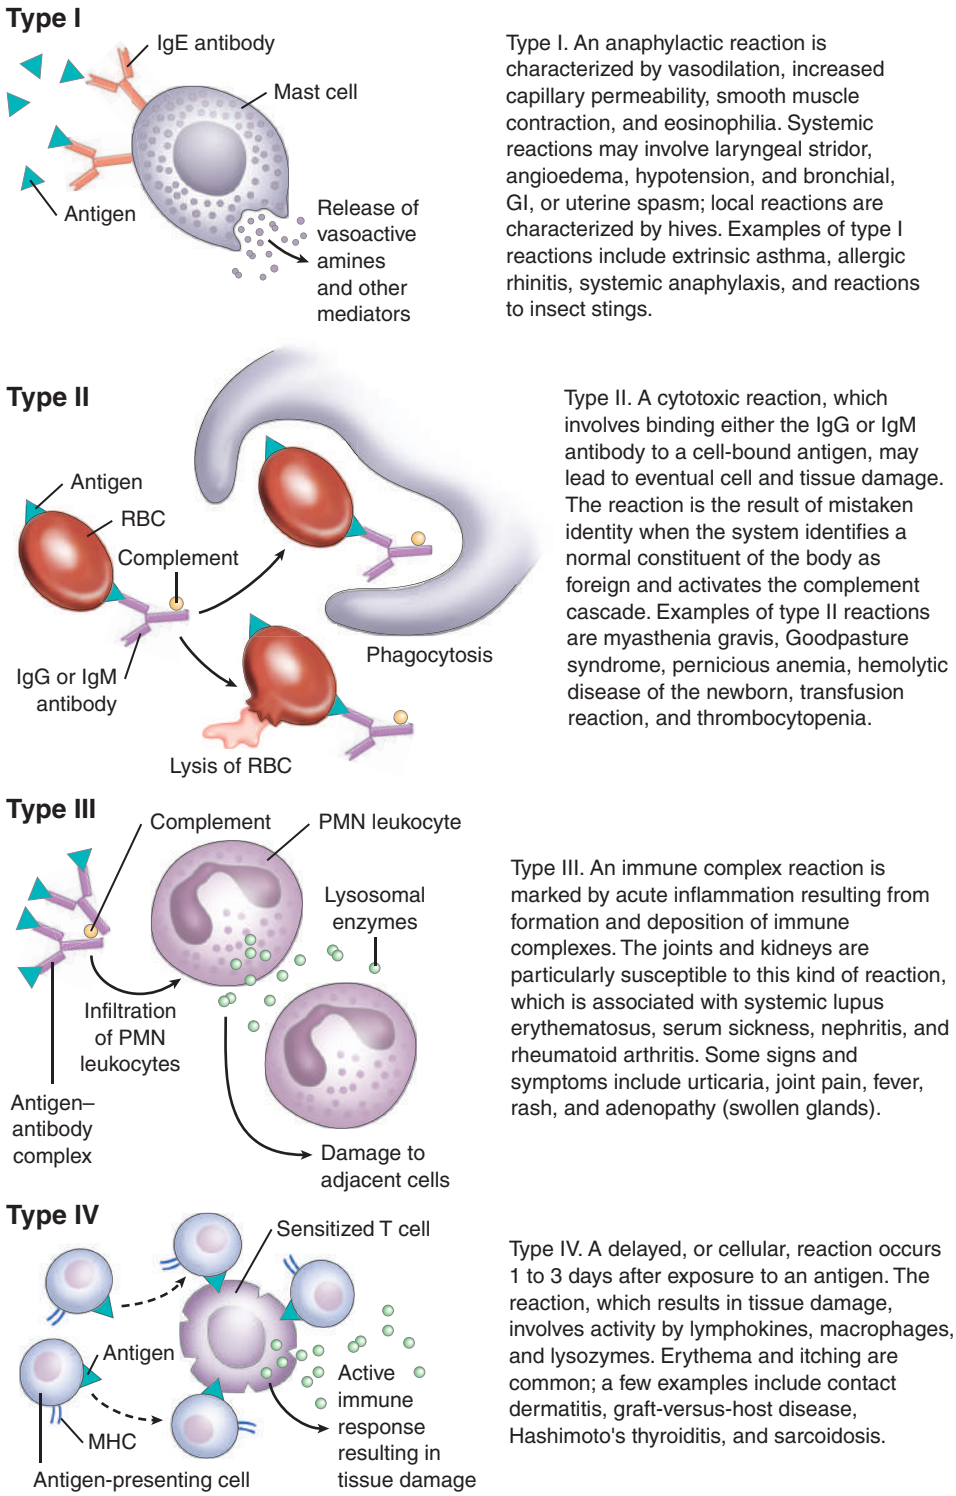
Leukotrienes

Leukotrienes are chemical mediators that initiate the inflammatory response. Many manifestations of inflammation can be attributed in part to leukotrienes. In addition, leukotrienes cause smooth muscle contraction, bronchial constriction, mucus secretion in the airways, and the typical wheal-and-flare reactions of the skin. Compared with histamine, leukotrienes are 100 to 1000 times more potent in causing bronchospasm.

Bradykinin

Bradykinin is a substance that has the ability to cause increased vascular permeability, vasodilation, hypotension, and contraction of many types of smooth muscle, such as the bronchi. Increased permeability of the capillaries results in edema. Bradykinin stimulates nerve cell fibers and produces pain.

Serotonin



Serotonin acts as a potent vasoconstrictor and causes contraction of bronchial smooth muscle.

Hypersensitivity

Although the immune system defends the host against infections and foreign antigens, immune responses can themselves cause tissue injury and disease. Hypersensitivity is an excessive or aberrant immune response to any type of stimulus (Abbas et al., 2014). It usually does not occur with the first exposure to an allergen. Rather, the reaction follows a re-exposure after sensitization, or buildup of antibodies, in a predisposed person. Injurious or pathologic immune reactions are classed as hypersensitivity reactions. To promote understanding of the immunopathogenesis of disease, hypersensitivity reactions have been classified into four specific types of reactions (see Fig. 56-2). Most allergic reactions are either type I or type IV hypersensitivity reactions.

Anaphylactic (Type I) Hypersensitivity

The most severe hypersensitivity reaction is anaphylaxis. An unanticipated severe allergic reaction that is rapid in onset, anaphylaxis is characterized by edema in many tissues, including the larynx, and is often accompanied by hypotension, bronchospasm, and cardiovascular collapse in severe cases. Type I or anaphylactic hypersensitivity is an immediate reaction beginning within minutes of exposure to an antigen. Primary chemical mediators are responsible for the symptoms of type I

Type I. An anaphylactic reaction is characterized by vasodilation, increased capillary permeability, smooth muscle contraction, and eosinophilia. Systemic reactions may involve laryngeal stridor, angioedema, hypotension, and bronchial, GI, or uterine spasm; local reactions are characterized by hives. Examples of type I reactions include extrinsic asthma, allergic rhinitis, systemic anaphylaxis, and reactions to insect stings.

Type II. A cytotoxic reaction, which involves binding either the IgG or IgM antibody to a cell-bound antigen, may lead to eventual cell and tissue damage. The reaction is the result of mistaken identity when the system identifies a normal constituent of the body as foreign and activates the complement cascade. Examples of type II reactions are myasthenia gravis, Goodpasture syndrome, pernicious anemia, hemolytic disease of the newborn, transfusion reaction, and thrombocytopenia.

Type III. An immune complex reaction is marked by acute inflammation resulting from formation and deposition of immune complexes. The joints and kidneys are particularly susceptible to this kind of reaction, which is associated with systemic lupus erythematosus, serum sickness, nephritis, and rheumatoid arthritis. Some signs and symptoms include urticaria, joint pain, fever, rash, and adenopathy (swollen glands).

Type IV. A delayed, or cellular, reaction occurs 1 to 3 days after exposure to an antigen. The reaction, which results in tissue damage, involves activity by lymphokines, macrophages, and lysozymes. Erythema and itching are common; a few examples include contact dermatitis, graft-versus-host disease, Hashimoto's thyroiditis, and sarcoidosis.

Figure 56-2 • Four types of hypersensitivity reactions. GI, gastrointestinal; Ig, immunoglobulin; PMN, polymorphonuclear; RBC, red blood cell.

hypersensitivity because of their effects on the skin, lungs, and gastrointestinal tract. If chemical mediators continue to be released, a delayed reaction may occur and may last for up to 24 hours.

Clinical symptoms are determined by the amount of the allergen, the amount of mediator released, the sensitivity of the target organ, and the route of allergen entry. Type I hypersensitivity reactions may include both local and systemic anaphylaxis.

Cytotoxic (Type II) Hypersensitivity

Type II, or cytotoxic, hypersensitivity occurs when the system mistakenly identifies a normal constituent of the body as foreign. This reaction may be the result of a cross-reacting antibody, possibly leading to cell and tissue damage.

Type II hypersensitivity reactions are associated with several disorders. For example, in myasthenia gravis, the body

mistakenly generates antibodies against normal nerve ending receptors. In Goodpasture syndrome, it generates antibodies against lung and renal tissue, producing lung damage and kidney injury (Grossman & Porth, 2014).

Immune Complex (Type III) Hypersensitivity

Type III, or immune complex, hypersensitivity involves immune complexes that are formed when antigens bind to antibodies. These complexes are cleared from the circulation by phagocytic action. If these type III complexes are deposited in tissues or vascular endothelium, two factors contribute to injury: the increased amount of circulating complexes and the presence of vasoactive amines. As a result, there is an increase in vascular permeability and tissue injury.

Delayed-Type (Type IV) Hypersensitivity

Type IV, or delayed-type, hypersensitivity (DTH), is an immune reaction in which T-cell–dependent macrophage activation and inflammation cause tissue injury. This type of reaction to the subcutaneous injection of antigen is often used as an assay for cell-mediated immunity (e.g., the purified protein derivative skin test for immunity to *Mycobacterium tuberculosis*) (Abbas et al., 2014).

Assessment

A comprehensive allergy history and a thorough physical examination provide useful data for the diagnosis and management of allergic disorders. An allergy assessment form is useful for obtaining and organizing pertinent information (see Chart 56-1).

The degree of difficulty and discomfort experienced by the patient because of allergic symptoms and the degree of improvement in those symptoms with and without treatment are assessed and documented. The relationship of symptoms to exposure to possible allergens is noted.

Diagnostic Evaluation

Diagnostic evaluation of the patient with allergic disorders commonly includes blood tests, smears of body secretions, skin tests, and the serum-specific IgE test (formerly known as radioallergosorbent test [RAST]). Results of laboratory blood studies provide supportive data for various diagnostic possibilities; however, they are not the major criteria for the diagnosis of allergic disease.

Complete Blood Count With Differential

The white blood cell (WBC) count is usually normal except with infection and inflammation (Pagana & Pagana, 2013). Eosinophils, which are granular leukocytes, normally make up 2% to 5% of the total number of WBCs. They can be found in blood, sputum, and nasal secretions. A level greater than 5% to 10% is considered abnormal and may be found in patients with allergic disorders (Fleisher et al., 2013).

Eosinophil Count

An actual count of eosinophils can be obtained from blood samples or smears of secretions. During symptomatic episodes, smears obtained from nasal secretions and sputum of patients with allergies usually reveal an increase in eosinophils, indicating an active allergic response (Fleisher et al., 2013).

Total Serum Immunoglobulin E Levels

High total serum IgE levels support the diagnosis of allergic disease. In the majority of cases, the antibody typically responsible for an allergic reaction belongs to the IgE isotype. Patients with this disorder are said to have an IgE-mediated allergic disease (Portnoy, 2015).

Skin Tests

Skin testing entails the intradermal injection or superficial application (epicutaneous) of solutions at several sites. Depending on the suspected cause of allergic signs and symptoms, many different solutions may be applied at separate sites. These solutions contain individual antigens representing an assortment of allergens most likely to be implicated in the patient's disease. Positive (wheal-and-flare) reactions are clinically significant when correlated with the history, physical findings, and results of other laboratory tests. Skin testing is considered the most accurate confirmation of allergy (Oppenheimer, Durham, Nelson, et al., 2014).

The results of skin tests complement the data obtained from the history. They indicate which of several antigens are most likely to provoke symptoms and indicate the intensity of the patient's sensitization. The dosage of the antigen (allergen) injected is also important. Most patients are hypersensitive to more than one allergen. Under testing conditions, they may not react (although they usually do) to the specific allergens that induce their attacks.

In cases of doubt about the validity of the skin tests, a serum-specific IgE test or a provocative challenge test may be performed. If a skin test is indicated, there is a reasonable suspicion that a specific allergen is producing symptoms in a patient with allergies. However, several precautionary steps must be observed before skin testing with allergens is performed:

- Testing is not performed during periods of bronchospasm.
- Epicutaneous tests (scratch or prick tests) are performed before other testing methods, in an effort to minimize the risk of systemic reaction.
- Emergency equipment must be readily available to treat anaphylaxis.

Types of Skin Tests

The methods of skin testing include prick skin tests, scratch tests, and intradermal skin testing (see Fig. 56-3). After negative prick or scratch tests, intradermal skin testing is performed with allergens that are suggested by the patient's history to be problematic. The back is the most suitable area of the body for skin testing because it permits the performance of many tests. A multitest applicator with multiple test heads is commercially available for simultaneous administration of antigens by multiple punctures at different sites. A negative response on a skin test cannot be interpreted as an absence of sensitivity to an allergen. Such a response may occur with insufficient sensitivity of the test or with the use of an inappropriate allergen in testing. Therefore, it is essential to observe the patient undergoing skin testing for an allergic reaction even if the previous response was negative.

Interpretation of Skin Test Results

Familiarity with and consistent use of a grading system are essential. The grading system used should be identified on a skin test record for later interpretation. A positive reaction, evidenced by the appearance of an urticarial wheal (round, reddened skin elevation) (see Fig. 56-4), localized erythema

Chart 56-1 ASSESSMENT

Allergy Assessment Form

Name _____ Age _____ Sex _____ Date _____

I. Chief complaint: _____

II. Present illness: _____

III. Collateral allergic symptoms: _____

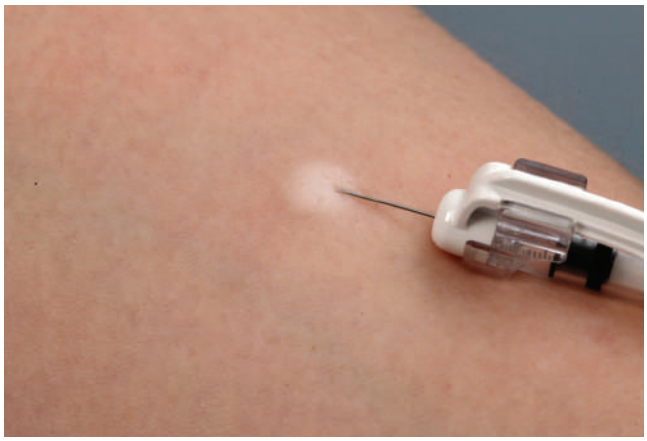

Figure 56-3 • Intradermal testing. A 0.5- or 1-mL sterile syringe with a 26/27-gauge intradermal needle is used to inject 0.02 to 0.03 mL of intradermal allergen. The needle is inserted with the bevel facing upward and the syringe parallel to the skin. The skin is penetrated superficially, and a small amount of the allergen solution is injected to create a bleb (raised area) approximately 5 mm in diameter. A separate sterile syringe and needle are used for each injection. From Taylor, C., Lillis C., LeMone, P., & Lynn, P. (2011). Fundamentals of nursing: The art and science of nursing care (7th ed.). Philadelphia, PA Lippincott Williams & Wilkins.

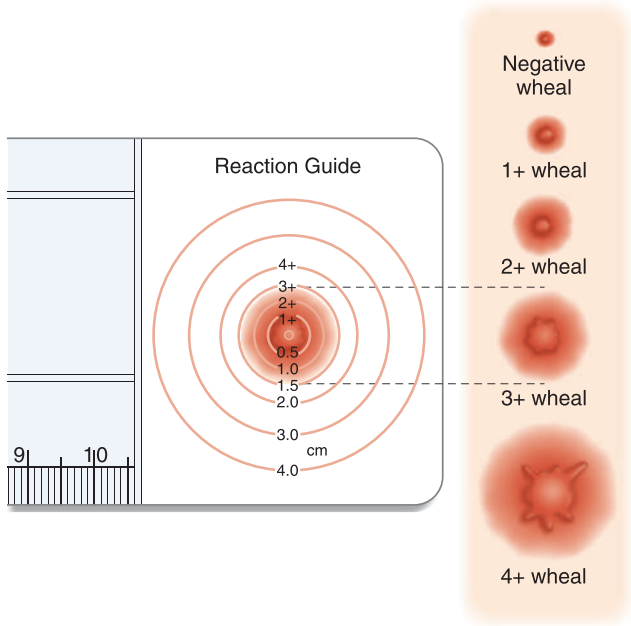

Figure 56-4 • Interpretation of reactions: Negative = wheal soft with minimal erythema; 1+ = wheal present (5 to 8 mm) with associated erythema; 2+ = wheal (7 to 10 mm) with associated erythema; 3+ = wheal (9 to 15 mm), slight pseudopodia possible with associated erythema; 4+ = wheal (12 mm+) with pseudopodia and diffuse erythema.

(diffuse redness) in the area of inoculation or contact, or pseudopodia (irregular projection at the end of a wheal) with associated erythema is considered indicative of sensitivity to the corresponding antigen. False-positive results may occur because of improper preparation or administration of allergen solutions.

Nursing Alert: Corticosteroids and antihistamines, including over-the-counter allergy medications, suppress skin test reactivity and should be stopped 48 to 96 hours before testing, depending on the duration of their activity. False-positive results may occur because of improper preparation or administration of allergen solutions.

Positive or negative skin tests are interpreted in the context of a patient's history, clinical signs, and exposure to allergens (Australasian Society of Clinical Immunology and Allergy [ASCIA], 2015). The following guidelines are used for the interpretation of skin test results:

- Skin tests are used most frequently with the diagnosis of allergic rhinitis (Baran, Ozcan, Selcuk, et al., 2014).
- Negative test results are helpful in ruling out food allergy.
- Positive skin tests correlate highly with food allergy (ASCIA, 2015).

The use of skin tests to diagnose immediate hypersensitivity to medications is limited, because metabolites of medications, not the medications themselves, are usually responsible for causing hypersensitivity.

Provocative Testing

Provocative testing involves the direct administration of the suspected allergen to the sensitive tissue, such as the conjunctiva, nasal or bronchial mucosa, or gastrointestinal tract (by ingestion of the allergen), with observation of target organ response. This type of testing is helpful in identifying clinically significant allergens in patients who have a large number of positive tests. Major disadvantages of this type of testing are the limitation of one antigen per session and the risk of producing severe symptoms, particularly bronchospasm, in patients with asthma.

Serum-Specific IgE Test

The serum-specific IgE test, formerly known as RAST, is an automated test performed on blood samples by a pathology laboratory. As the name suggests, it detects free antigen-specific IgE in serum as opposed to antigen-specific IgE bound to mast cells in the skin (ASCIA, 2015); (Portnoy, 2015). The advantages of this test over other tests include decreased risk of systemic reaction, stability of antigens, and lack of dependence on skin reactivity modified by medications. The major disadvantages include limited allergen selection and reduced sensitivity compared with intradermal skin tests, lack of immediate results, and higher cost (ASCIA, 2015).

ALLERGIC DISORDERS

There are two types of IgE-mediated allergic reactions: atopic and nonatopic disorders. Although the underlying immunologic reactions of the two types of disorders are the same, the predisposing factors and manifestations are different. Atopy is defined as the genetic predisposition to mount an IgE response to inhaled or ingested innocuous proteins (Fleisher et al., 2013). Atopic diseases consist of asthma, allergic rhinitis, and atopic dermatitis. All share a common pathogenesis, mediated by IgE, and are frequently present together in the same individual and in families. The nonatopic disorders lack the genetic component and organ specificity of the atopic disorders (Fleisher et al., 2013). Latex allergy (see later discussion) can present as an IgE-mediated anaphylaxis, type I reaction, or a type IV hypersensitivity referred to as contact dermatitis (American Academy of Allergy, Asthma, & Immunology [AAAAI], 2015); (Fleisher et al., 2013); (Habif, 2016).

Anaphylaxis

Anaphylaxis is a clinical response to an immediate (type I hypersensitivity) immunologic reaction between a specific antigen and an antibody. The reaction results from a rapid release of IgE-mediated chemicals, which can induce a severe, life-threatening reaction (Abbas et al., 2014).

Pathophysiology

Anaphylaxis is a type I IgE allergic reaction to an antigen, a foreign substance that has entered the body (Frandsen & Pennington, 2014). It is caused by the cross-links of an allergen with allergen-specific IgE antibodies found on the surface membrane of mast cells and basophils, leading to cellular degranulation. The subsequent release of histamine and other bioactive mediators causes activation of platelets, eosinophils, and neutrophils. Histamine, prostaglandins, and inflammatory leukotrienes are potent vasoactive mediators that are implicated in the vascular permeability changes, flushing, urticaria, angioedema, hypotension, and bronchoconstriction that characterize anaphylaxis. Smooth muscle spasm, bronchospasm, mucosal edema and inflammation, and increased capillary permeability result. Symptoms of anaphylaxis are sudden in onset and progress in severity over minutes to hours (Campbell, Li, Nicklas, et al., 2014).

Closely resembling anaphylaxis is an anaphylactoid reaction, which is caused by the release of mast cell and basophil mediators triggered by non–immunoglobulin E (IgE)-mediated events. This nonallergenic anaphylaxis reaction may occur with medications, food, exercise, or cytotoxic antibody transfusions. The reaction may be local or systemic. Local reactions usually involve urticaria and angioedema at the site of the antigen exposure. Although possibly severe, nonallergenic anaphylaxis reactions are rarely fatal. Systemic reactions occur within about 30 minutes after exposure and involve cardiovascular, respiratory, gastrointestinal, and integumentary organ systems. For the most part, the treatment of nonallergenic anaphylaxis reaction is identical to that of anaphylaxis.

Common causes of anaphylaxis are listed in Chart 56-2. Antibiotics and radiocontrast agents cause the most serious anaphylactic reactions. Penicillin is the most common medication to cause anaphylaxis. In a study of an outpatient adult population, the prevalence of penicillin allergy was found to be 12% (Albin & Agarwal, 2014). However, only 6% of these patients were referred to an allergist for testing. Patients with reported penicillin allergy who were evaluated with skin testing experienced decreased use of broad spectrum antibiotics and fewer anaphylactic reactions (Albin & Agarwal, 2014).

Clinical Manifestations

Anaphylactic reactions produce a clinical syndrome that affects multiple organ systems. Reactions may be categorized as mild, moderate, or severe. The time from the exposure to the antigen to the onset of symptoms is a good indicator of the severity of the reaction—the faster the onset, the more severe the reaction. The severity of previous reactions does not determine the severity of subsequent reactions, which could be the same or more or less

Chart 56-2

Common Causes of Anaphylaxis

Foods

Peanuts, tree nuts (e.g., walnuts, pecans, cashews, almonds), shellfish (e.g., shrimp, lobster, crab), fish, milk, eggs, soy, wheat

Medications

Antibiotics, especially penicillin and sulfa antibiotics, allopurinol, radiocontrast agents, anesthetic agents (lidocaine, procaine), vaccines, hormones (insulin, vasopressin, adrenocorticotropic hormone), aspirin, nonsteroidal anti-inflammatory drugs

Other Pharmaceutical/Biologic Agents

Animal serums (tetanus antitoxin, snake venom antitoxin, rabies antitoxin), antigens used in skin testing

Insect Stings

Bees, wasps, hornets, yellow jackets, ants (including fire ants)

Latex

Medical and nonmedical products containing latex

severe. The severity depends on the degree of allergy and the dose of allergen exposure (Campbell et al., 2014).

Mild systemic reactions consist of peripheral tingling and a sensation of warmth, possibly accompanied by a sensation of fullness in the mouth and throat. Nasal congestion, periorbital swelling, pruritus, sneezing, and tearing of the eyes can also be expected. The onset of symptoms begins within the first 2 hours after the exposure.

Moderate systemic reactions may include flushing, warmth, anxiety, and itching in addition to any of the milder symptoms. More serious reactions include bronchospasm and edema of the airways or larynx with dyspnea, cough, and wheezing. The onset of symptoms is the same as for a mild reaction.

Severe systemic reactions have an abrupt onset with the same signs and symptoms described previously. These symptoms progress rapidly to bronchospasm, laryngeal edema, severe dyspnea, cyanosis, and hypotension. Dysphagia (difficulty swallowing), abdominal cramping, vomiting, diarrhea, and seizures can also occur. Cardiac arrest and coma may follow. Severe reactions are also referred to as anaphylactic shock (see Chapter 8).

Prevention

Strict avoidance of potential allergens is an important preventive measure for the patient at risk for anaphylaxis. Those at risk for anaphylaxis from insect stings should avoid areas populated by insects and should use appropriate clothing, insect repellent, and caution to avoid further stings.

If avoidance of exposure to allergens is impossible, an auto-injector system for epinephrine will be prescribed. The patient should be instructed to carry and administer epinephrine to prevent an anaphylactic reaction in the event of exposure to the allergen. People who are sensitive to insect bites and stings, those who have experienced food or medication reactions, and those who have experienced idiopathic or exercise-induced anaphylactic reactions should always carry an emergency kit that contains epinephrine. The EpiPen and Auvi-Q are auto-injection devices that are commercially available for first aid that deliver premeasured doses of epinephrine (Comerford, 2015); (Frandsen & Pennington, 2014). The auto-injector system requires no preparation, and the self-administration technique is not complicated. The patient must be given an opportunity to demonstrate the correct technique for use; an EpiPen training device can be used for educating about the correct technique. Verbal and written information about the emergency kit, as well as strategies to avoid exposure to threatening allergens, must also be provided.

Screening for allergies before a medication is prescribed or first given is an important preventive measure. A careful history of any sensitivity to suspected antigens must be obtained before administering any medication, particularly in parenteral form, because this route is associated with the most severe anaphylaxis. Nurses caring for patients in any setting (hospital, home, outpatient diagnostic testing sites, long-term care facilities) must assess patients' risks for anaphylactic reactions. Patients are asked about previous exposure to contrast agents used for diagnostic tests and any allergic reactions, as well as reactions to any medications, foods, insect stings, and latex. People who are predisposed to anaphylaxis should wear medical identification such as a bracelet or necklace, which names allergies to medications, food, and other substances.

People who are allergic to insect venom may require venom immunotherapy, which is used as a control measure and not a cure. The most common serious allergic reactions to insect stings are from the Hymenoptera family, which includes bees, ants, wasps, and yellow jackets (Perez-Riverol, Justo-Jacomini, de Lima Zollner, et al., 2015). Venom is an effective treatment for people with systemic reactions to an insect sting. It reduces the systemic reaction, reduces the risk of future large local reactions, and improves quality of life (Ludman & Boyle, 2015).

Insulin-allergic patients with diabetes and those who are allergic to penicillin may require desensitization. Desensitization is based on controlled anaphylaxis, with a gradual release of mediators. Patients who undergo desensitization are cautioned to avoid lapses in therapy, because this may lead to the reappearance of the allergic reaction when the use of the medication is resumed.

Medical Management

Management depends on the severity of the reaction. Initially, respiratory and cardiovascular functions are evaluated. If the patient is in cardiac arrest, cardiopulmonary resuscitation (CPR) is instituted (Link, Berkow, Kudenchuk, et al., 2015). Supplemental oxygen is provided during CPR or if the patient is cyanotic, dyspneic, or wheezing. Epinephrine, in a 1:1000 dilution, is given subcutaneously in the upper extremity or thigh and may be followed by a continuous intravenous infusion. Most adverse events associated with administration of epinephrine (i.e., adrenaline) occur when the dose is excessive or is given intravenously. Patients at risk for adverse effects include older patients and those with hypertension, arteriopathies, or known ischemic heart disease.

Antihistamines and corticosteroids should not be given in place of epinephrine. However, they may also be given as adjunct therapy (Campbell et al., 2014).

Intravenous fluids (e.g., normal saline solution), volume expanders, and vasopressor agents are given to maintain blood pressure and normal hemodynamic status. In patients with episodes of bronchospasm or a history of bronchial asthma or chronic obstructive pulmonary disease, aminophylline and corticosteroids may also be given to improve airway patency and function. (See Chapter 8 for management of anaphylactic shock.)

Patients who have experienced anaphylactic reactions and received epinephrine should be transported to the local emergency department (ED) for observation and monitoring because of the risk for a "rebound" or delayed reaction 4 to 8 hours after the initial allergic reaction. However, the observation time should be individualized based on the severity of the anaphylaxis. Longer periods of observation should be considered for patients who ingested the allergen, required more than one dose of epinephrine, had hypotension or pharyngeal edema, or have a history of asthma (Campbell et al., 2014).

Nursing Management

If a patient is experiencing an allergic response, the nurse assesses the patient for signs and symptoms of anaphylaxis. Airway, breathing pattern, and vital signs are assessed. The patient is observed for signs of increasing edema and respiratory distress. Prompt notification of the rapid response team, the provider, or both is required. Rapid initiation of emergency measures (e.g., intubation, administration of emergency medications, insertion of intravenous lines, fluid administration, and oxygen administration) is important to reduce the severity of the reaction and to restore cardiovascular function. The nurse

documents the interventions used and the patient's vital signs and response to treatment.

The patient who has recovered from anaphylaxis needs an explanation of what occurred, instruction about avoiding future exposure to antigens, and how to administer emergency medications to treat anaphylaxis. The patient must be instructed about antigens that should be avoided and about other strategies to prevent recurrence of anaphylaxis. All patients who have experienced an anaphylactic reaction should receive a prescription for auto-injectable epinephrine devices. The nurse instructs the patient and family in their use and has the patient and family demonstrate correct administration (see Chart 56-3).

Allergic Rhinitis

Allergic rhinitis (hay fever, seasonal allergic rhinitis) is the most common form of respiratory allergy, which is presumed to be mediated by an immediate (type I hypersensitivity) immunologic reaction. The incidence of allergic rhinitis in India is 20%–30% (Chandrika, 2017). It is a common cause of hospital visits. Symptoms are similar to those of viral rhinitis (see Chapter 40) but are usually more persistent and demonstrate seasonal variation; rhinitis is considered to be the allergic form if the symptoms are caused by an allergen-specific IgE-mediated immunologic response. However, approximately one third of patients with rhinitis have associated conjunctivitis, sinusitis, and asthma (Baran et al, 2014); (Lehrer, Mullol, Agredo, et al., 2014). The proportion of patients with the allergic form of rhinitis increases with age. It often occurs with other conditions, such as asthma, and cystic fibrosis (Rosenfeld et al., 2015). If symptoms are severe, allergic rhinitis may interfere with sleep, leisure, school, and overall quality of life (Sheikh, 2015). Chronic rhinitis accounts for an average of 1 to 2 missed work days per patient per year. These patients experience a 36% reduction in on-the-job effectiveness and 38% loss of productivity (Sheikh, 2015).

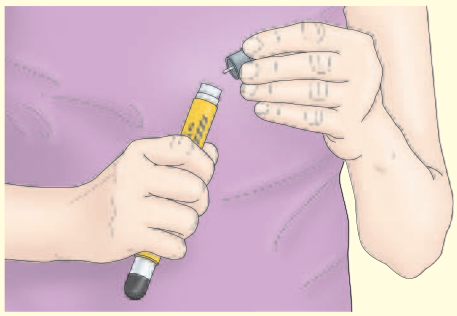
Early diagnosis and adequate treatment are essential to reduce complications and relieve symptoms.

Because allergic rhinitis is induced by airborne pollens or molds, it is characterized by the following seasonal occurrences (Sheikh, 2015): Common allergens causing allergic rhinitis in India are polyvalent house dust, pollen, house dust mites, fungi, dander, insect, and food (Chandrika, 2017).

Pathophysiology

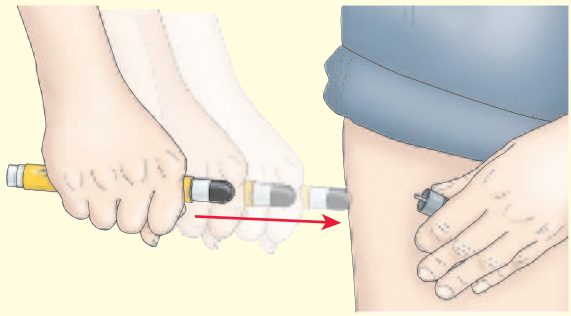
Sensitization begins by ingestion or inhalation of an antigen. On re-exposure, the nasal mucosa reacts by the slowing of ciliary action, edema formation, and leukocyte (primarily eosinophil) infiltration. Histamine is the major mediator of allergic reactions in the nasal mucosa. Tissue edema results from vasodilation and increased capillary permeability.

Clinical Manifestations



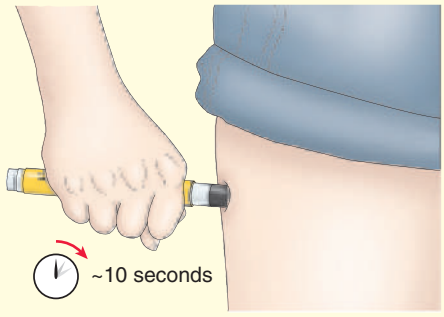
The four major signs and symptoms of allergic rhinitis include copious amounts of serous nasal discharge, nasal congestion,

Chart 56-3 PATIENT EDUCATION



Self-Administration of Epinephrine

The nurse instructs the patient to:



1. After removing the EpiPen autoinjector from its carrying tube, grasp the unit with the orange tip (injecting end) pointing downward. Form a fist around the unit with the orange tip down; with your other hand, remove the blue safety release cap.

2. Hold the black tip near outer thigh. Swing and **jab firmly** into the outer thigh until a click is heard with the device perpendicular (90-degree angle) to the thigh. Do NOT inject into buttocks.

3. Hold firmly against the thigh for approximately 10 seconds. Remove the unit from the thigh, and gently massage the injection area for 10 seconds. Call for medical help, if required. Carefully place the used autoinjector unit, needle-end first, into the device storage tube without bending the needle. Screw on the storage tube completely, and take it with you to the hospital emergency room.

sneezing, as well as nose and throat itching. Patients may experience post-nasal drip, itching, watery eyes, headache, and hyposomnia (Baran et al., 2014). Bronchial asthma is more persistent in patients with chronic rhinitis than in those with allergic rhinitis (Lehrer et al., 2014). The symptoms of this chronic condition depend on environmental exposure and intrinsic host responsiveness. Allergic rhinitis can affect quality of life by also producing sleep disturbance, impairment of daily activities, and missed school and work (Fleisher et al., 2013).

Assessment and Diagnostic Findings

Diagnosis of seasonal allergic rhinitis is based on history, physical examination, and diagnostic test results. Diagnostic tests include nasal smears, peripheral blood counts, total serum IgE, epicutaneous and intradermal testing, serum-specific IgE, and nasal provocation tests. Results indicative of allergy as the cause of rhinitis include increased IgE and eosinophil levels and positive reactions on allergen testing. False-positive and false-negative responses to these tests, particularly skin testing, may occur (Fleisher et al., 2013).

Medical Management

The goal of therapy is to provide relief from symptoms. Therapy may include one or all of the following interventions: avoidance therapy, pharmacologic therapy, and immunotherapy. Verbal instructions must be reinforced by written information. Knowledge of general concepts regarding assessment and therapy in allergic diseases is important so that the patient can learn to manage certain conditions as well as prevent severe reactions and illnesses.

Avoidance Therapy

In avoidance therapy, every attempt is made to remove the allergens that act as precipitating factors. Simple measures and environmental controls are often effective in decreasing symptoms. Examples include the use of air conditioners, air cleaners, humidifiers, and dehumidifiers; removal of dust-catching furnishings, carpets, and window coverings; removal of pets from the home or bedroom; the use of pillow and mattress covers that are impermeable to dust mites; and a smoke-free environment (Sheikh, 2015). Additional measures include changing clothing when coming in from outside, showering to wash allergens from hair and skin, and using an over-the-counter nasal irrigation device or saline nasal spray to reduce allergens in the nasal passages. Because multiple allergens are often implicated, multiple measures to avoid exposure to allergens are often necessary (Bleier, 2015); (Sheikh, 2015). High-efficiency particulate air (HEPA) purifiers and vacuum cleaner filters may also be used to reduce allergens in the environment. Research suggests that multiple avoidance strategies tailored to a person's risk factors can reduce the severity of symptoms, the number of work or school days missed because of symptoms, and the number of unscheduled health care visits for treatment (Sheikh, 2015). In many cases, it is impossible to avoid exposure to all environmental allergens, so pharmacologic therapy or immunotherapy is needed.

Pharmacologic Therapy

Antihistamines

Antihistamines, classified as H_1 receptor antagonists (or H_1 blockers), are used in the management of mild allergic disorders. H_1 blockers bind selectively to H_1 receptors, preventing the actions of histamines at these sites. They do not prevent the release of histamine from mast cells or basophils. The H_1 antagonists have no effect on H_2 receptors, but they do have the ability to bind to nonhistaminic receptors. The ability of certain antihistamines to bind to and block muscarinic receptors underlies several of the prominent anticholinergic side effects of these medications.

Oral antihistamines, which are readily absorbed, are most effective when given at the first occurrence of symptoms, because they prevent the development of new symptoms. The effectiveness of these medications is limited to certain patients with hay fever, vasomotor rhinitis, urticaria (hives), and mild asthma. They are rarely effective in other conditions or in any severe conditions (Frandsen & Pennington, 2014); (Hodgson & Kizior, 2014).

Antihistamines are frequently prescribed for the symptomatic relief of allergic rhinitis. The major side effects are drowsiness and dry mouth (Hwang & Patel, 2015); (Rosenfeld et al., 2015). Additional side effects include anxiety, agitation, urinary retention, blurred vision, anorexia, nausea, and vomiting (Frandsen & Pennington, 2014); (Hodgson & Kizior, 2014).

Antihistamines are contraindicated during pregnancy, in nursing mothers and newborns, in children and older adults, and in patients with hypersensitivity to the drugs whose conditions may be aggravated by muscarinic blockade (e.g., asthma, urinary retention, open-angle glaucoma, hypertension, prostatic hyperplasia) (Frandsen & Pennington, 2014); (Hodgson & Kizior, 2014); (Katzung & Trevor, 2015).

Second-generation or nonsedating H_1 receptor antagonists are newer types of antihistamines. Unlike first-generation H_1 receptor antagonists, they do not readily enter the brain from the blood (Fleisher, et al., 2013); (Frandsen & Pennington, 2014). They bind to peripheral rather than central nervous system H_1 receptors, causing less sedation. Examples of these medications are loratadine (Claritin), cetirizine (Zyrtec), and fexofenadine (Allegra). Selected H_1 antihistamines are shown in Table 56-2.

Antihistamines may also be combined with decongestants to reduce the nasal congestion associated with allergies. Most combination products are available as over-the-counter (nonprescription) medications; examples are loratadine/pseudoephedrine (Claritin-D) and cetirizine/pseudoephedrine (Zyrtec-D). Decongestants can cause an increase in blood pressure; therefore, patients with a history of hypertension should be cautioned about long-term use of any medication that contains decongestants (Bleier, 2015); (Hodgson & Kizior, 2014).

Adrenergic Agents

Adrenergic agents, which are vasoconstrictors of mucosal vessels, are used topically in nasal (Afrin) and ophthalmic (Alphagan P) formulations in addition to the oral route (pseudoephedrine [Sudafed]) (Frandsen & Pennington, 2014); (Hodgson & Kizior, 2014). The topical route (drops and sprays) causes fewer side effects than oral administration; however, the use of drops and sprays should be limited to a few days to avoid rebound congestion. Adrenergic nasal decongestants are applied topically to the nasal mucosa for the relief of nasal congestion. They activate the alpha-adrenergic receptor sites on the smooth muscle of the nasal mucosal blood vessels, reducing local blood flow, fluid exudation, and mucosal edema. Topical ophthalmic drops are used for symptomatic relief of eye irritations caused by allergies. Potential side effects include hypertension, dysrhythmias, palpitations, central nervous system stimulation, irritability, tremor, and tachyphylaxis (acceleration of hemodynamic status).

TABLE 56-2 Selected H_1 Antihistamines

H_1 Antihistamine	Contraindications	Major Side Effects	Nursing Implications and Patient Education
First-Generation H_1 Antihistamines (Sedating)			
Diphenhydramine (Benadryl)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, benign prostatic hyperplasia (BPH) or bladder neck obstruction, first and second trimester of pregnancy, older patients, hypertension.	Drowsiness, confusion, dizziness, dry mouth, nausea, vomiting, photosensitivity, urinary retention	Administer with food if gastrointestinal (GI) upset occurs. Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until central nervous system (CNS) response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Encourage the use of sunscreen and hat while outdoors. Assess for urinary retention; monitor urinary output.
Chlorpheniramine (Chlor-Trimeton)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, BPH or bladder neck obstruction, first and second trimester of pregnancy, older patients, hypertension.	Drowsiness, sedation, and dizziness, although less than other sedating agents; confusion, dry mouth, nausea, vomiting, urinary retention, epigastric distress, thickening of bronchial secretions	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Hydroxyzine (Atarax)	Allergy to hydroxyzine or cetirizine (Zyrtec), pregnancy, lactation, hypertension	Drowsiness; dry mouth; involuntary motor activity, including tremor and seizures	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Instruct patients to report tremors.
Second-Generation H_1 Antihistamines (Nonsedating)			
Cetirizine (Zyrtec)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Lactation Hypertension	Dry nasal mucosa, thickening of bronchial secretions	Can be taken without regard to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.
Desloratadine (Clarinex)	Allergy to loratadine (Alavert, Claritin) Lactation Use cautiously with renal or hepatic impairment, pregnancy, hypertension.	Somnolence, nervousness, dizziness, fatigue, dry mouth	Can be taken without regard to meals. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Loratadine (Alavert, Claritin)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Hypertension	Headache, nervousness, dizziness, depression, edema, increased appetite	Instruct patients to take on empty stomach (1 hour before or 2 hours after meals or food). Instruct patients to avoid alcohol and to use caution if driving or performing tasks that require alertness. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Fexofenadine (Allegra)	Allergy to any antihistamines Pregnancy Lactation Use cautiously with hepatic or renal impairment, older patients, hypertension.	Fatigue, drowsiness, GI upset	Should not be given within 15 minutes of ingestion of antacids. Instruct patients to use caution if driving or performing tasks that require alertness.Recommend the use of a humidifier.
Levocetirizine (Xyzal)	Hypersensitivity to any antihistamines End-stage renal disease Hemodialysis Use cautiously with pregnancy, lactation, older patients.	Drowsiness, GI disturbance, headache	Can be taken without regard to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.

Mast Cell Stabilizers

Intranasal cromolyn sodium (NasalCrom) is a spray that acts by stabilizing the mast cell membrane, thus reducing the release of histamine and other mediators of the allergic response. In addition, it inhibits macrophages, eosinophils, monocytes, and platelets involved in the immune response (Arcangelo & Peterson, 2013). Cromolyn interrupts the physiologic response to nasal antigens, and it is used prophylactically (before the exposure to allergens) to prevent the onset of symptoms and to treat symptoms once they occur. It is also used therapeutically in chronic allergic rhinitis. This spray is as effective as antihistamines but is less effective than intranasal corticosteroids in the treatment of seasonal allergic rhinitis. The patient must be informed that the beneficial effects of the medication may take a week or so to manifest. The medication is of no benefit in the treatment of nonallergic rhinitis. Adverse effects (e.g., sneezing, local stinging and burning sensations) are usually mild.

Corticosteroids

Intranasal corticosteroids are indicated in more severe cases of allergic and perennial rhinitis that cannot be controlled by more conventional medications, such as decongestants, antihistamines, and intranasal cromolyn. Examples of these medications include beclomethasone (Beconase, Qnasl), budesonide (Rhinocort), flunisolide (AeroSpan), and triamcinolone (Nasacort) (Comerford, 2015).

Because of their anti-inflammatory actions, corticosteroids are equally effective in preventing or suppressing the major symptoms of allergic rhinitis. These medications are given by metered-spray devices. If the nasal passages are blocked, a topical decongestant may be used to clear the passages before the administration of the intranasal corticosteroid. Patients must be aware that full benefit may not be achieved for several days to 2 weeks. Adverse effects of intranasal corticosteroids are mild and include drying of the nasal mucosa and burning and itching sensations caused by the vehicle used to administer the medication. Recommended use of this medication is limited to 30 days. Beclomethasone, budesonide, flunisolide, and triamcinolone are deactivated rapidly after absorption, so they do not achieve significant blood levels. Because corticosteroids suppress host defenses, they must be used with caution in patients with tuberculosis or untreated bacterial infections of the lungs. Patients taking corticosteroids are at risk for infection and suppression of typical manifestations of inflammation, because host defenses are compromised. Inhaled corticosteroids do not affect the immune system to the same degree as systemic corticosteroids (i.e., oral corticosteroids). Because corticosteroids are inhaled into the upper respiratory tract, tuberculosis or untreated bacterial infections of the lungs may become apparent and progress. Whenever possible, patients with tuberculosis or other bacterial infections of the lungs should avoid inhaled corticosteroids.

Oral and parenteral corticosteroids are used when conventional therapy has failed and symptoms are severe and of short duration (Frandsen & Pennington, 2014); (Hodgson & Kizior, 2014). They can control symptoms of allergic reactions such as hay fever, medication-induced allergies, and allergic reactions to insect stings. Because the response to corticosteroids is delayed, these agents have little or no value in acute therapy for severe reactions such as anaphylaxis.

Nursing Alert: Patients who receive high-dose or long-term corticosteroid therapy must be cautioned not to stop taking the medication suddenly. Doses are tapered when discontinuing this medication to avoid adrenal insufficiency.

The patient is also instructed about side effects, which include fluid retention, weight gain, hypertension, gastric irritation, glucose intolerance, and adrenal suppression. Further discussion of corticosteroids is provided in Chapter 32, Table 32-4.

Leukotriene Modifiers

Leukotrienes have many effects on the inflammatory cycle. Leukotriene modifiers, such as zafirlukast (Accolate) and montelukast (Singulair), block the synthesis or action of leukotrienes and prevent the signs and symptoms associated with asthma (see Table 56-3).

Leukotriene modifiers are for long-term use, and patients should be advised to take their medication daily. Patients take appropriate "rescue" medications for symptom exacerbation but continue to take the leukotriene modifier on a daily basis. The National Asthma Education and Prevention Program (NAEPP) suggests using a leukotriene modifier in conjunction with an inhaled corticosteroid for mild persistent asthma (National Institute of Allergy and Infectious Disease [NIAID], 2013).

Immunotherapy

Allergen desensitization (allergen immunotherapy, hyposensitization) is primarily used to treat IgE-mediated diseases by injections of allergen extracts. Immunotherapy, also referred to as allergy vaccine therapy, involves the administration of gradually increasing quantities of specific allergens to the patient until a dose is reached that is effective in reducing disease severity from natural exposure. This is an effective treatment for 80% to 90% of certain allergens such as grass and pollen (ASCIA, 2015); (Senti, von Moos, Graf, et al., 2015); (Sheikh, 2015). This type of therapy provides an adjunct to symptomatic pharmacologic therapy and can be used when avoidance of allergens is not possible. Specific immunotherapy has been used in the treatment

TABLE 56-3 Leukotriene Modifiers

Leukotriene Modifier	Available Formulations	Frequency of Dosing
Leukotriene-Receptor Antagonists		
Zafirlukast (Accolate)	Tablets: 10 mg; 20 mg	Taken twice a day
Montelukast (Singulair)	Tablets: 10 mg	Taken once a day in pm
	Chewable tablets: 4 mg; 5 mg	
	Granules: 4 mg/packet	
Leukotriene-Receptor Inhibitors		
Zileuton (Zyflo CR)	Tablets: 600 mg extended release	Taken twice a day within 1 hour after morning and evening meals

Chart 56-4

Immunotherapy: Indications and Contraindications

Indications

- Allergic rhinitis, conjunctivitis, or allergic asthma
- History of a systemic reaction to Hymenoptera and specific immunoglobulin E antibodies to Hymenoptera venom
- Desire to avoid the long-term use, potential adverse effects, or costs of medications
- Lack of control of symptoms by avoidance measures or the use of medications

Contraindications

- The use of beta-blocker or angiotensin-converting enzyme inhibitor therapy, which may mask early signs of anaphylaxis
- Presence of significant pulmonary or cardiac disease or organ failure
- Inability of the patient to recognize or report signs and symptoms of a systemic reaction
- Nonadherence of the patient to other therapeutic regimens and nonlikelihood that the patient will adhere to the immunization schedule (often weekly for an indefinite period)
- Inability to monitor the patient for at least 30 minutes after administration of immunotherapy
- Absence of equipment or adequate personnel to respond to allergic reaction if one occurs

of allergic disorders for many years. Goals of immunotherapy include reducing the level of circulating IgE, increasing the level of blocking antibody IgG, and reducing mediator cell sensitivity. Immunotherapy has been most effective for ragweed pollen; however, treatment for grass, tree pollen, cat dander, and house dust mite allergens has also been effective. Indications and contraindications for immunotherapy are presented in Chart 56-4.

Correlation of a positive skin test with a positive allergy history is an indication for immunotherapy if the allergen cannot be avoided. The benefit of immunotherapy has been fairly well established in instances of allergic rhinitis and bronchial asthma that are clearly due to sensitivity to one of the common pollens, molds, or household dust. Unlike antiallergy medication, allergen immunotherapy has the potential to alter the allergic disease course after 3 to 5 years of therapy. Because it may prevent the progression or development of asthma or multiple or additional allergies, it is also considered to be a potential preventive measure (Sheikh, 2015). The patient must understand what to expect and the importance of continuing therapy for several years before immunotherapy is accomplished. When skin tests are performed, the results are correlated with symptoms; treatment is based on the patient's needs rather than on the results of skin tests.

There are three methods of immunotherapy: subcutaneous immunotherapy (SIT), sublingual immunotherapy (SLIT), and epicutaneous immunotherapy (EPIT).

Subcutaneous Immunotherapy

The most common method of treatment is SIT, which consists of the serial injection of one or more antigens that are selected in each particular case on the basis of skin testing. This method provides a simple and efficient technique for targeting IgE antibodies to specific antigens. Specific treatment consists of injecting extracts of the allergens that cause symptoms in a particular patient. Injections begin with very small amounts and are gradually increased, usually at weekly intervals, until a maximum tolerated dose is attained. Although severe systemic reactions are rare, the risk of systemic and potentially fatal anaphylaxis exists. It tends to occur most frequently at the induction or "up-dosing" phase. Therefore, the patient must be monitored after administration of immunotherapy. Because of the risk of anaphylaxis, injections should not be given by a lay person or by the patient. The patient must remain in the office or clinic for at least 30 minutes after the injection and is observed for possible systemic symptoms. If a large, local swelling develops at the injection site, the next dose should not be increased, because this may be a warning sign of a possible systemic reaction (ASCIA, 2015); (Sheikh, 2015).

Maintenance booster injections are given at 2- to 4-week intervals, frequently for a period of several years, before the maximum benefit is achieved, although some patients will note early improvement in their symptoms. Long-term benefit seems to be related to the cumulative dose of vaccine given over time (ASCIA, 2015); (Sheikh, 2015).

Nursing Alert: Because the injection of an allergen may induce systemic reactions, such injections are given only in a setting where epinephrine is immediately available (i.e., primary provider's clinic).

Sublingual Immunotherapy

In April 2014, the U.S. Food and Drug Administration (FDA) approved the use of a SLIT. SLIT has been reported to have a 30% to 40% reduction in reactions and rescue medication usage in seasonal allergic rhinitis. Administration of SLIT includes a buildup phase that is followed by a treatment plan of three times per week with a rapid dissolving tablet or liquid containing allergen extracts. Recent studies show comparable efficacy of SLIT with SIT (Senti et al., 2015). Systemic side effects are rare but have been reported in patients who also report systemic reactions with SIT. Side effects include irritation, minor swelling or itching inside the mouth, and stomach upset and nausea.

Epicutaneous Immunotherapy

EPIT represents an alternative allergen immunotherapy with delivery of the allergen to the epidermis. Because the epidermis is less vascular, there is reduced risk of systemic allergic side effects due to inadvertent intravascular allergen delivery. Reports from the completed trials of EPIT may find potential application in the management of IgE-mediated allergies, but more research is needed to define an optimal regimen that balances clinical efficacy and safety (Senti et al., 2015).

Immunotherapy should not be initiated during pregnancy; for patients who have been receiving immunotherapy before pregnancy, the dosage should not be increased during pregnancy.

Therapeutic failure is evident when a patient does not experience a decrease of symptoms within 12 to 24 months, fails to develop increased tolerance to known allergens, and cannot decrease the use of medications to reduce symptoms. Potential causes of treatment failure include misdiagnosis of allergies, inadequate doses of allergen, newly developed allergies, and inadequate environmental controls.

NURSING PROCESS

The Patient with Allergic Rhinitis

Assessment

The examination and history of the patient reveal sneezing, often in paroxysms; thin and watery nasal discharge; itching

eyes and nose; lacrimation; and occasionally headache. The health history includes a personal or family history of allergy. The allergy assessment identifies the nature of antigens, seasonal changes in symptoms, and medication history. The nurse also obtains subjective data about how the patient feels just before symptoms become obvious, such as the occurrence of pruritus, breathing problems, and tingling sensations. In addition to these symptoms, hoarseness, wheezing, hives, rash, erythema, and edema are noted. Any relationship between emotional problems or stress and the triggering of allergy symptoms is assessed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Ineffective breathing pattern related to allergic reaction
- Deficient knowledge about allergy and the recommended modifications in lifestyle and self-care practices
- Ineffective coping with chronicity of condition and need for environmental modifications

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Anaphylaxis
- Impaired breathing
- Nonadherence to the therapeutic regimen

Planning and Goals

The goals for the patient may include restoration of a breathing pattern that provides adequate ventilation, increased knowledge about the causes and control of allergic symptoms, improved coping with alterations and modifications, and absence of complications.

Nursing Interventions

Improving Breathing Pattern

The patient is instructed and assisted to modify the environment to reduce the severity of allergic symptoms or to prevent their occurrence. The patient is also instructed to reduce exposure to people with upper respiratory tract infections. Adherence to medication schedules and other treatment regimens is encouraged and reinforced.

Promoting Understanding of Allergy and Allergy Control

Instruction includes strategies to minimize exposure to allergens and explanation about desensitization procedures and correct use of medications. The nurse informs and reminds the patient of the importance of keeping appointments for desensitization procedures, because dosages are usually adjusted on a weekly basis, and missed appointments may interfere with the dosage adjustment.

Patients need to understand the difference between rescue medications for allergy exacerbation and seasonal flares (e.g., antihistamines) and medications used for allergy control throughout the year (e.g., inhaled corticosteroids, leukotriene modifiers). Patients also need to understand that medications for allergy exacerbation and seasonal flares should be used only when the allergy is apparent. Continued use of these medications when not required can result in tolerance; consequently, the medications will be ineffective when needed.

Coping With a Chronic Disorder

Although allergic reactions are infrequently life-threatening, they require vigilance to avoid allergens and modification of the lifestyle or environment to prevent recurrence of symptoms. Allergic symptoms are often present year-round and create discomfort and inconvenience for the patient. Although patients may not feel ill during allergy seasons, they often do not feel well, either. The need to be alert for possible allergens in the environment may be tiresome, placing a burden on the patient's ability to lead a normal life. Stress related to these difficulties may in turn increase the frequency or severity of symptoms. To assist the patient in adjusting to these modifications, the nurse must have an appreciation of the difficulties encountered by the patient. The patient is encouraged to verbalize feelings and concerns in a supportive environment and to identify strategies to deal with them effectively.

Monitoring and Managing Potential Complications

Anaphylaxis and Impaired Breathing. Respiratory and cardiovascular functioning can be significantly altered during allergic reactions by the reaction itself or by the medications used to treat reactions. The respiratory status is evaluated by monitoring the respiratory rate and pattern and by assessing for breathing difficulties or abnormal lung sounds. The pulse rate and rhythm and blood pressure are monitored to assess cardiovascular status regularly or any time the patient reports symptoms such as itching or difficulty breathing. In the event of signs and symptoms suggestive of anaphylaxis, emergency medications and equipment must be available for immediate use. See Chapter 8 for treatment of anaphylactic shock.

Nonadherence to the Therapeutic Regimen. Knowledge about the treatment regimen does not ensure adherence. Having the patient identify potential barriers and explore acceptable solutions for effective management of the condition (e.g., installing tile floors rather than carpet, not exposing to known allergens, refraining from going into the dusty areas, avoiding foods that cause allergy) can increase adherence to the treatment regimen.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The patient is instructed about strategies to minimize exposure to allergens, the actions and adverse effects of medications, and the correct use of medications. The patient should know the name, dose, frequency, actions, and side effects of all medications taken.

Instruction about strategies to control allergic symptoms is based on the needs of the patient as determined by the results of tests, the severity of symptoms, and the motivation of the patient and family to deal with the condition. Suggestions for patients who are sensitive to dust and mold in the home are given in Chart 56-5.

If the patient is to undergo SIT immunotherapy, the nurse reinforces the primary provider's explanation regarding the purpose and procedure. Instructions are given regarding the series of injections, which usually are given initially every week and then at 2- to 4-week intervals. These instructions include remaining in the primary provider's office or the clinic for at least 30 minutes after the injection, so that emergency treatment can be given if the patient has a reaction; avoiding rubbing or scratching the injection site; and continuing with the series for the period of time required. In addition, the patient and family are instructed about emergency treatment of severe allergic symptoms.

Because antihistamines may produce drowsiness, the patient is cautioned about this and other side effects applicable to the medication. Operating machinery, driving a car, and performing activities that require intense concentration should be postponed. The patient is also informed about the dangers of drinking alcohol when taking antihistamines, because they tend to exaggerate the effects of alcohol.

Chart 56-5 HOME CARE CHECKLIST

Allergy Management

At the completion of education, the patient, caregiver, or both will be able to:

- State the impact of environmental allergens (e.g., dust, molds, perfumes, foods) on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in home environment necessary to minimize exposure to allergens.
  - Removing drapes, curtains, and venetian blinds and replacing them with pull shades; covering the mattress with a hypoallergenic cover that can be zipped; and removing rugs and replacing them with wood flooring or linoleum.
  - Reducing dust in the house as a whole by using steam or hot water for heating and using high-efficiency particulate air (HEPA) purifiers or air-conditioning.
  - Washing the floor and dusting and vacuuming daily, using clean filters, wearing a mask whenever cleaning is being done.
  - Replacing stuffed furniture with wood pieces that can easily be dusted.
  - Avoiding the use of tufted bedspreads, stuffed toys, and feather pillows and replacing them with washable cotton material.
  - Avoiding the use of any clothing that causes itching.
- Verbalize ways to reduce exposure to pollens or molds by identifying seasons of the year when pollen counts are high; wearing a mask at times of increased exposure (windy days and when grass is being cut); and avoiding contact with weeds, dry leaves, and freshly cut grass.
- State rationale for seeking air-conditioned areas at the height of the allergy season.
- State rationale for avoiding sprays and perfumes.
- State rationale for the use of hypoallergenic cosmetics.
- State rationale for taking prescribed medications as ordered.
- Identify specific foods that may cause allergic symptoms and develop a list of foods to avoid (e.g., fish, nuts, eggs, chocolate).
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, testing.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, independent activities of daily living.

The patient must be aware of the effects caused by overuse of the sympathomimetic agents in nose drops or sprays, because a condition referred to as rhinitis medicamentosa may result. After topical application of the medication, a rebound period occurs in which the nasal mucous membranes become more edematous and congested than they were before the medication was used. Such a reaction encourages the use of more medication, and a cyclic pattern results. The topical agent must be discontinued immediately and completely to correct this problem.

Nursing Alert: In rhinitis medicamentosa, the rebound reaction from the overuse of sympathomimetic nose drops or sprays worsens the congestion, causing the patient to use more of the medication and thus leads to more nasal congestion. This condition should not be confused with a patient developing tolerance to the drug.

Continuing and Transitional Care. Follow-up telephone calls to the patient are often reassuring to the patient and family and provide an opportunity for the nurse to answer any questions. The patient is reminded to keep follow-up appointments and informed about the importance of continuing with treatment. The importance of participating in health promotion activities and health screening is also emphasized.

Evaluation

Expected patient outcomes may include:

1. Exhibits a breathing pattern that provides adequate ventilation
   a. Demonstrates lungs clear on auscultation
   b. Exhibits absence of adventitious breath sounds (crackles, rhonchi, wheezing)
   c. Has a normal respiratory rate and pattern
   d. Reports no complaints of respiratory distress (shortness of breath, difficulty on inspiration or expiration)
2. Demonstrates knowledge about allergy and strategies to control symptoms
   a. Identifies causative allergens, if known
   b. States methods of avoiding allergens and controlling indoor and outdoor precipitating factors
   c. Removes from the environment items that retain dust
   d. Wears a dampened mask if dust or mold may be a problem
   e. Avoids smoke-filled rooms and dust-filled or freshly sprayed areas
   f. Uses air-conditioning for a major part of the day when allergens are high
   g. Takes antihistamines as prescribed; participates in hyposensitization program, if applicable
   h. Describes name, purpose, side effects, and method of administration of prescribed medications
   i. Identifies when to seek immediate medical attention for severe allergic responses
   j. Describes activities that are possible, including ways to participate in activities without activating the allergies
3. Adapts to the inconveniences of an allergy
   a. Relates the emotional aspects of the allergic response
   b. Demonstrates the use of measures to cope positively with allergy
4. Demonstrates absence of complications
   a. Exhibits vital signs within normal limits
   b. Reports no symptoms or episodes of anaphylaxis (urticaria, itching, peripheral tingling, fullness in the mouth and throat, flushing, difficulty swallowing, coughing, wheezing, or difficulty breathing)
   c. Demonstrates correct procedure to self-administer emergency medications to treat severe allergic reaction
   d. Correctly states medication names, dose and frequency of administration, and medication actions
   e. Correctly identifies side effects and untoward signs and symptoms to report to primary provider
   f. Discusses acceptable lifestyle changes and solutions for identified potential barriers to adherence to treatment and medication regimen

Contact Dermatitis

Contact dermatitis, a type IV delayed hypersensitivity reaction, is an acute or chronic skin condition caused by contact with an exogenous substance that elicits an allergic response. There are four basic types: allergic, irritant, phototoxic, and photo allergic (see Table 56-4). Eighty percent of cases are caused by excessive exposure to or additive effects of irritants (e.g., soaps, detergents, organic solvents). Skin sensitivity may develop after brief or prolonged periods of exposure, and the clinical picture may appear hours or weeks after the sensitized skin has been exposed.

Clinical Manifestations

Symptoms include itching, burning, erythema, skin lesions (vesicles and papules), and edema, followed by skin thickening, hardening, and scaling (Fonacier, Bernstein, Pancheco, et al., 2015). In severe responses, hemorrhagic bullae may develop. Repeated reactions may be accompanied by thickening of the skin and pigmentary changes. Secondary invasion by bacteria may develop in skin that is abraded by rubbing or scratching. Usually, there are no systemic symptoms unless the eruption is widespread (Habif, 2016).

Assessment and Diagnostic Findings

Determining allergens responsible requires a history, physical examination, and patch testing.

Assessment should include the date of onset, and any identifiable relationship to work environment and skin care products (Habif, 2016). The location of the lesions, distribution of the dermatitis, absence of other etiologies, and the history of exposure aid in determining the condition (Fonacier et al., 2015). Patch testing and environmental history of exposure to contact allergens are required to verify the diagnosis. Patch testing is indicated in cases in which inflammation persists despite avoidance therapy. The patch test most commonly used is the Thin-layer Rapid Use Epicutaneous (T.R.U.E.) test (Habif, 2016).

Atopic Dermatitis

Atopic dermatitis is a type I immediate hypersensitivity disorder characterized by inflammation and hyper reactivity of the skin. The term is used synonymously with atopic eczema (AAAAI, 2015). Other terms used to describe this kind of disorder include atopic eczema, atopic dermatitis, and atopic dermatitis/eczema syndrome (AEDS). In a revised classification system developed to clarify terminology, AEDS includes both allergic and nonallergic disorders (Habif, 2016). Currently, *atopic dermatitis* is the most commonly used term and will be used for the purpose of this discussion.

Atopic dermatitis is a chronic pruritis inflammatory skin disease. Increased serum IgE levels have been indicated in 80% of the patients with a family history of type 1 allergies, allergic rhinitis, and asthma. This disorder affects 15% to 30% of children and 2% to 10% of adults in developed countries (AAAAI, 2015). Most patients have significant elevations of serum IgE and peripheral eosinophilia. The eosinophil count may be increased depending on concomitant respiratory allergies (Habif, 2016).

Pruritus and hyperirritability of the skin are the most consistent features of atopic dermatitis and are related to large amounts of histamine in the skin. Excessive dryness of the skin with resultant itching is related to changes in lipid content, sebaceous gland activity, and sweating. In response to stroking of the skin, immediate redness appears on the skin. Pallor follows in 15 to 30 seconds and persists for 1 to 3 minutes. Patterns of inflammation result from scratching of erythematous papules. Lesions develop secondary to the trauma of scratching and appear in areas of increased sweating and hypervascularity.

TABLE 56-4 Types, Testing, and Treatment of Contact Dermatitis

Type	Etiology	Clinical Presentation	Diagnostic Testing	Treatment
Allergic	Results from contact of skin and allergenic substance; has a sensitization period of 10–14 days	Vasodilation and perivascular infiltrates on the dermis Intracellular edema Usually seen on dorsal aspects of hand	Patch testing (contraindicated in acute, widespread dermatitis)	Avoidance of offending material Aluminum acetate (Burow Solution, Domeboro Powder) or cool water compress Systemic corticosteroids (prednisone) for 7–10 days Topical corticosteroids for mild cases Oral antihistamines to relieve pruritus
Irritant	Results from contact with a substance that chemically or physically damages the skin on a nonimmunologic basis; occurs after first exposure to irritant or repeated exposures to milder irritants over an extended time	Dryness lasting days to months Vesiculation, fissures, cracks Hands and lower arms most common areas	Clinical picture Appropriate negative patch tests	Identification and removal of source of irritation Application of hydrophilic cream or petrolatum to soothe and protect Topical corticosteroids and compresses for weeping lesions Antibiotics for infection and oral antihistamines for pruritus
Phototoxic	Resembles the irritant type but requires sun and a chemical in combination to damage the epidermis	Similar to irritant dermatitis	Photo-patch test	Same as for allergic and irritant dermatitis
Photo allergic	Resembles allergic dermatitis but requires light exposure in addition to allergen contact to produce immunologic reactivity	Similar to allergic dermatitis	Photo-patch test	Same as for allergic and irritant dermatitis

Adapted from Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer.

Atopic dermatitis is chronic, with remissions and exacerbations. This condition has a tendency to recur, with remission from adolescence to 20 years of age (Habif, 2016).

Nurses should be aware that atopic dermatitis is often linked in a process called the atopic march that often leads to asthma, allergic rhinitis, or food allergy (Fonacier et al., 2015). It is the result of interactions between susceptibility genes, the environment, defective function of the skin barrier, and immunologic responses.

Medical Management

Treatment of patients with atopic dermatitis must be individualized. Guidelines for treatment include identification and avoidance of contact with the offending agents; elimination of inflammatory disorders and infections; prescription of topical corticosteroids and non-steroidal anti-inflammatory agents; preservation and restoration of the stratum corneum layer; and prescription of antipruritic agents, oral antibiotics, and oral immunosuppressants for severely affected patients (Fonacier et al., 2015); (Habif, 2016).

Itching can be decreased by wearing cotton fabrics; washing with a mild detergent; humidifying dry heat in winter; maintaining room temperature at 20°C to 22.2°C (68°F to 72°F); using antihistamines such as diphenhydramine; and avoiding animals, dust, sprays, and perfumes. Keeping the skin moisturized with daily baths to hydrate the skin and the use of topical skin moisturizers is encouraged. Topical corticosteroids are used to prevent inflammation, and any infection is treated with antibiotics to eliminate *Staphylococcus aureus* when indicated (Fonacier et al., 2015); (Habif, 2016).

The use of immunosuppressive agents, such as cyclosporine (Neoral, Sandimmune), tacrolimus (Prograf, Protopic), and pimecrolimus (Elidel), may be effective in inhibiting T cells and mast cells involved in atopic dermatitis (Fonacier et al., 2015); (Habif, 2016).

Research is needed to assess the effectiveness and the adverse side effects of medications used to treat atopic dermatitis.

Nursing Management

Patients who experience atopic dermatitis and their families require assistance and support from the nurse to cope with the disorder. The symptoms are often disturbing to the patient and disruptive to the family. The appearance of the skin may affect the patient's self-esteem and their willingness to interact with others. Instructions and counseling about strategies to incorporate preventive measures and treatments into the lifestyle of the family may be helpful.

The patient and family need to be aware of signs of secondary infection and of the need to seek treatment if infection occurs. The nurse also educates the patient and family about the side effects of medications used in treatment.

Dermatitis Medicamentosa (Drug Reactions)

Dermatitis medicamentosa, a type I hypersensitivity disorder, is the term applied to skin rashes associated with certain medications. Although people react differently to each medication, certain medications tend to induce eruptions of similar types. This disorder is the leading cause of fatal anaphylaxis, comprising 43% of deaths from anaphylaxis. All routes of administration are potentially fatal, but drugs given parenterally incur the greatest risk. Cutaneous rashes are among the most common adverse reactions to medications and occur in approximately 2% to 3% of hospitalized patients (Fleisher et al., 2013); (Habif, 2016).

In general, drug reactions appear suddenly with characteristics that are more intense than the somewhat similar eruptions of infectious origin, and, with the exception of bromide and the iodide rashes, disappear rapidly after the medication is withdrawn (Comerford, 2015). Rashes may be accompanied by systemic or generalized symptoms. On discovery of a medication allergy, patients are warned that they have a hypersensitivity to a particular medication and are advised not to take it again. Penicillin, cephalosporin, and sulfonamide antibiotics are most commonly implicated (Habif, 2016). Patients should carry information identifying the hypersensitivity with them at all times.

Skin eruptions related to medication therapy suggest more serious hypersensitivities. Frequent assessment and prompt reporting of the appearance of any eruptions are important so that early treatment can be initiated. Some cutaneous drug reactions may indicate involvement of other organs and are known as complex drug reactions. Patients who suspect that a new rash may be caused by a drug allergy (newly prescribed medications, especially antibiotics such as penicillin or sulfa medications) should stop taking the medication immediately and contact their prescribing clinician, who will determine whether the medication and the rash are related.

Urticaria and Angioneurotic Edema

Urticaria (hives) is a type I hypersensitive allergic reaction of the skin that is characterized by the sudden appearance of edematous, pink or red wheals of variable size from 2 to 4 mm, and general pruritus. They may involve any part of the body, including the mucous membranes (especially those of the mouth), the larynx (occasionally with serious respiratory complications), and the gastrointestinal tract. This is a common condition with approximately 10% to 20% of people having one episode during their lifetime. Urticaria is most commonly instigated by infections, allergic reaction to food, insect stings, and medications (American Osteopathic College of Dermatology, 2015).

Each hive remains for a few minutes to several hours before disappearing. They usually fade within 24 to 48 hours, but new lesions may be developing simultaneously at other skin sites (Bernstein, Lang, Khan, et al., 2014). The condition usually resolves in 3 weeks. However, if this sequence continues for longer than 6 weeks, the condition is called *chronic urticaria.*

Management of the condition includes eliminating the causative drug or food; avoiding the use of nonsteroidal anti-inflammatory drugs (NSAIDs); minimizing potential aggravators, including heat, stress, alcohol, and tight clothes; administering antihistamines, and possibly a short course of corticosteroids (Prednisone) (AAAAI, 2015); (American Osteopathic College of Dermatology, 2015); (Fleisher et al., 2013); (Habif, 2016).

Angioneurotic edema (i.e., angioedema) involves the deeper layers of the skin, resulting in more diffuse swelling rather than the discrete lesions characteristic of hives. It is manifested by non-pruritic, brawny, non-pitting edema with well-defined margins and erythema similar to urticaria (Bernstein et al., 2014). Urticaria and angioedema often occur together (Habif, 2016).

The regions most often involved in angioedema are the lips, eyelids, cheeks, hands, feet, genitalia, and tongue; the mucous

membranes of the larynx, bronchi, and gastrointestinal canal may also be affected, particularly in the hereditary type (see discussion in the following section). On occasion, this reaction covers the entire back. Swellings may appear suddenly, in a few seconds or minutes, or slowly in 1 or 2 hours. In the latter case, their appearance is often preceded by itching or burning sensations. Seldom does more than a single swelling appear at one time, although one may develop while another is disappearing. Infrequently, swelling recurs in the same region. Individual lesions usually resolve in 24 hours (Fleisher et al., 2013); (AAAAI, 2015). On rare occasions, swelling may recur with remarkable regularity at intervals of 3 to 4 weeks.

Several frequently prescribed medications, such as angiotensin-converting enzyme inhibitors (captopril [Capoten]) and penicillin, may cause angioedema. The nurse needs to be aware of all medications the patient is taking and be alert to the potential of angioedema as a side effect.

Hereditary Angioedema

Hereditary angioedema is a rare, potentially life-threatening, autosomal dominant disorder (Cicardi & Zuraw, 2015). Although not an immunologic disorder in the usual sense, this condition is included because of its resemblance to allergic angioedema and because of the potential seriousness of the condition. Symptoms are caused by edema of the skin, the respiratory tract, or the digestive tract. Attacks may be precipitated by trauma, or they may seem to occur spontaneously.

Clinical Manifestations

When skin is involved, the swelling usually is diffuse, does not itch, and usually is not accompanied by urticaria. Gastrointestinal edema may cause abdominal pain severe enough to be incapacitating. Typically, attacks last 2 to 4 days and resolve without intervention; however, attacks can occasionally affect the subcutaneous and submucosal tissues in the region of the upper airway and can be associated with respiratory obstruction and asphyxiation (Cicardi & Zuraw, 2015).

Medical Management

Attacks usually subside within 2 to 4 days, but during this time the patient should be observed carefully for signs of laryngeal obstruction, which may necessitate tracheostomy as a lifesaving measure. Epinephrine, antihistamines, and corticosteroids are usually used in treatment, although their success is limited. (Cicardi & Zuraw, 2015); (Fleisher et al., 2013); (Habif, 2016).

Cold Urticaria

Familial atypical cold urticaria (FACU) and acquired cold urticaria (ACU) are additional diseases within the spectrum of urticaria induced by temperature exposure. FACU is an autosomal dominant condition, inherited from one affected parent, and symptoms usually begin at birth within the first 6 months of life (Fleisher et al., 2013). ACU most frequently affects children and young adults (Fleisher et al., 2013); (Habif, 2016).

Clinical Manifestations

Patients with FACU break out in hives (i.e., urticaria) when exposed to cold. The urticaria may be prompted by exposure to cold weather or cold water or after coming in contact with cold objects. Lesions occur within a few hours and usually subside in 2 days (Fleisher et al., 2013). Symptoms include fever, chills, conjunctiva infection, sweating, headache, and arthralgia. During the attack, the patient may develop leukocytosis, an increase in the erythrocyte sedimentation rate (ESR) and raised C-reactive protein levels (Ciccarelli, De Martinis, & Ginaldi, 2014).

Cold urticaria is diagnosed by physical testing. Ice cube provocation testing involves applying an ice cube to the skin of the forearm for 1 to 5 minutes. A positive test results in development of urticaria at the site in a patient with ACU. Clinical manifestations of FACU can be precipitated by the patient merely entering a 4°C (39°F) room.

Medical Management

Prevention involves avoidance of cold stimuli. Treatment involves bed rest, warmth, and corticosteroids to treat an acute attack (Ciccarelli et al., 2014).

All patients with any form of cold urticaria should carry an auto-injectable epinephrine device for emergency use because hives can progress to anaphylaxis.

Food Allergy

IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in about 2% of the adult population; it is thought to occur in people who have a genetic predisposition combined with exposure to allergens early in life through the gastrointestinal or respiratory tract or nasal mucosa. More than 170 foods have been reported to cause IgE-mediated reactions (Sampson, Aceves, Brock, et al., 2014).

Almost any food can cause allergic symptoms. Any food can contain an allergen that results in anaphylaxis. The most common offenders are seafood (lobster, shrimp, crab, clams, fish), peanuts, tree nuts, berries, eggs, wheat, milk, and chocolate (Sampson et al., 2014). Peanut and tree nut (e.g., cashew, walnut) allergies are responsible for the most severe food allergy reactions. There is insufficient evidence that maternal diet during pregnancy or lactation affects the development of food allergies later in life (AAAAI, 2015); (NIAID, 2013); (Sampson et al., 2014).

One of the dangers of food allergens is that they may be hidden in other foods and not apparent to people who are susceptible to the allergen. For example, peanuts and peanut butter are often used in salad dressings and Asian, African, and Mexican cooking and may result in severe allergic reactions, including anaphylaxis. Previous contamination of equipment with allergens (e.g., peanuts) during preparation of another food product (e.g., chocolate cake) is enough to produce anaphylaxis in people with severe allergy (Fleischer, Sicherer, Greenhawt, et al., 2015).

Clinical Manifestations

Food allergy is the most common trigger for anaphylaxis. Symptoms occur in a few minutes to hours from exposure. The clinical symptoms are classic allergic symptoms (urticaria, dermatitis, wheezing, cough, laryngeal edema, angioedema) and gastrointestinal symptoms (itching; swelling of lips, tongue, and palate; abdominal pain; nausea; cramps; vomiting; and diarrhea) (NIAID, 2013); (Sampson et al., 2015).

Assessment and Diagnostic Findings

A careful diagnostic workup is required in any patient with suspected food hypersensitivity. Included are a detailed allergy

history, a physical examination, and pertinent diagnostic tests. Skin prick testing is used to identify the source of symptoms and assists in identifying specific foods as causative agents.

Medical Management

Therapy for food hypersensitivity includes elimination of the food responsible for the hypersensitivity (see Chart 56-6). Pharmacologic therapy is necessary for patients who cannot avoid exposure to offending foods and for patients with multiple food sensitivities not responsive to avoidance measures. Medication therapy involves the use of H_1 blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium. All patients with food allergies, especially seafood and nuts, should have an auto-injectable epinephrine (e.g., EpiPen or Auvi-Q) device prescribed. Another essential aspect of management is educating patients and family members about how to recognize and manage the early stages of an acute anaphylactic reaction (AAAAI, 2015); (Campbell et al., 2014). Many food allergies disappear with time, particularly in children.

Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about strategies to prevent its recurrence (see Chart 56-6). Patients' food allergies should be noted on their medical records, because there may be risk of allergic reactions not only to food but also to some medications containing similar substances (Sampson et al., 2014).

Latex Allergy

Latex allergy—the allergic reaction to natural rubber proteins—has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. The prevalence has been steadily declining, possibly because of the use of nonpowdered latex and latex-free gloves (Mayo Foundation for Medical Education and Research, 2015).

Natural rubber latex is derived from the sap of the rubber tree (*Hevea brasiliensis*). The conversion of the liquid rubber latex into a finished product entails the addition of more than 200 chemicals. The proteins in the natural rubber latex (Hevea proteins) or the various chemicals that are used in the manufacturing process are thought to be the source of the allergic reactions. Not all objects composed of latex have the same ability to stimulate an allergic response. For example, the antigenicity of latex gloves can vary widely depending on the manufacturing method used (AAAAI, 2015); (Mayo Foundation for Medical Education and Research, 2015).

Those at risk include 8% to 17% of health care workers, patients with atopic allergies or multiple surgeries, people working in factories that manufacture latex products, females, and 67% of patients with spina bifida (Fleisher et al., 2013). Because more food handlers, hairdressers, automobile mechanics, and police wear latex gloves, they are at risk for latex allergy. Patients are at risk for anaphylactic reactions as a result of contact with latex during medical treatments, especially surgical procedures. Food that has been handled by people wearing latex gloves may stimulate an allergic response. Cross-reactions have been reported in people who are allergic to certain food products, such as kiwis, bananas, pineapples, mangoes, passion fruit, avocados, and chestnuts (AAAAI, 2015); (Mayo Foundation for Medical Education and Research, 2015).

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, or aerosol. Allergic reactions are more likely with parenteral or mucous membrane exposure but can also occur with cutaneous contact or inhalation. The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or settle on skin, mucous membranes, or clothing. Mucosal exposure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from intravenous lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of medical and household items containing latex and a list of alternative products are found in Table 56-5. It is estimated that more than 40,000 medical devices and nonmedical products contain latex. Chemical additives used in the manufacture of nonlatex gloves and other items have been associated with allergic symptoms, although these otherwise have a low potential to stimulate an allergic response (AAAAI, 2015); (Mayo Foundation for Medical Education and Research, 2015).

Clinical Manifestations

Many different types of reactions to latex are possible (see Table 56-6). Irritant contact dermatitis, a nonimmunologic

Chart 56-6 HOME CARE CHECKLIST

Managing Food Allergies

At the completion of education, the patient, caregiver, or both will be able to:

- State the impact of food allergies on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Verbalize understanding of the need to maintain an allergen-free diet.
- Demonstrate reading of food labels to identify hidden allergens in food.
- Identify ways to manage an allergen-free diet when eating away from home.
- State the need to wear medical identification bracelet or necklace.
- List symptoms of food allergy.
- Demonstrate emergency administration of epinephrine.
- State the importance of replacing epinephrine when outdated.
- State the importance of prompt treatment of allergic reactions and health care follow-up.
- State how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, testing.
- Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.
- Identify the need for health promotion, disease prevention, and screening activities.

ADLs, activities of daily living; IADLs, independent activities of daily living.

TABLE 56-5 Selected Products Containing Natural Rubber Latex and Latex-Free Alternatives

Products Containing Latex	Examples of Latex-Safe Alternatives[a]
Hospital Environment	
Ace bandage (brown)	Ace bandage, white all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strips (3M), DuoDERM
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Derma Prene, neoprene, polymer, or vinyl gloves
IV catheters	Jelco, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing.
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper.
Penrose drains	Jackson-Pratt, Zimmer Hemovac drains
Prepackaged enema kits	Therevac, Fleet Ready-to-Use
Pulse oximeters	Nonin oximeters
Resuscitation bags	Laerdal, Puritan Bennett, *certain* Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Suction tubing	PVC (Davol, Laerdal)
Syringes—single use (Monoject, BD)	Terumo syringes, Abbott PCA Abboject
Tapes	Dermicel, Micropore
TheraBand	New Thera-band Exercisers, plastic tubing
Thermometer probes	Diatek probe covers
Tourniquets	X-Tourn straps (Avcor)
Home Environment	
Balloons	Mylar balloons
Condoms, diaphragms	Polyurethane products, Durex Avanti and Reality products (female condom)
Diapers, incontinence pads	Huggies, Always, *some* Attends
Feminine hygiene pads	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

ECG, electrocardiogram; IV, intravenous; PVC, polyvinyl chloride.

[a]Confirmation is essential to verify that all items are latex free before using, especially if risk of latex allergy is present.

response, may be caused by mechanical skin irritation or an alkaline pH associated with latex gloves. Common symptoms of irritant dermatitis include erythema and pruritus. These symptoms can be eliminated by changing the brand of gloves or by using powder-free gloves. The use of hand lotion before donning latex gloves can worsen the symptoms, because lotions may leach latex proteins from the gloves, thus increasing skin exposure and the risk of developing true allergic reactions (Mayo Foundation for Medical Education and Research, 2015).

Delayed hypersensitivity to latex, a type IV reaction mediated by T cells in the immune system, is localized to the area of exposure and is characterized by symptoms of contact dermatitis, including vesicular skin lesions, papules, pruritus, edema, erythema, and crusting and thickening of the skin. These symptoms usually appear on the back of the hands. This reaction is thought to be caused by chemicals that are used in the manufacturing of latex products. It is the most common allergic reaction to latex. Although usually not life-threatening, delayed hypersensitivity reactions often require major changes in the patient's home and work environment to avoid further exposure. People who are sensitized to latex are at increased risk for development of type I allergic reactions (AAAAI, 2015); (Mayo Foundation for Medical Education and Research, 2015).

Immediate hypersensitivity, a type I allergic reaction, is mediated by the IgE mast cell system (Abbas et al., 2014). Symptoms can include rhinitis, conjunctivitis, asthma, and anaphylaxis. Clinical manifestations have a rapid onset and can include urticaria, wheezing, dyspnea, laryngeal edema, bronchospasm, tachycardia, angioedema, hypotension, and cardiac arrest.

Localized itching, erythema, or local urticaria within minutes after exposure to latex is often the initial symptom. Symptoms of subsequent reactions can include generalized urticaria, angioedema, rhinitis, conjunctivitis, asthma, and anaphylactic shock minutes after dermal or mucosal exposure to latex. An increasing number of people who are allergic to latex experience severe reactions characterized by generalized urticaria, bronchospasm, and hypotension.

Assessment and Diagnostic Findings

The diagnosis of latex allergy is based on the history and diagnostic test results (Mayo Foundation for Medical Education and Research, 2015). Sensitization is detected by skin testing;

TABLE 56-6 Types of Reactions to Latex

Type of Reaction	Cause	Signs/Symptoms	Treatment
Irritant contact dermatitis	Damage to skin because of irritation and loss of epidermoid skin layer; not an allergic reaction. Can be caused by excessive use of soaps and cleansers, repeated hand washing, inadequate hand drying, mechanical irritation (e.g., sweating, rubbing inside powdered gloves), exposure to chemicals added during the manufacturing of gloves, and alkaline pH of powdered gloves. Reaction may occur with first exposure, is usually benign, and is not life-threatening.	*Acute*: Redness, edema, burning, discomfort, itching *Chronic*: Dry, thickened, cracked skin	Referral for diagnostic testing Avoidance of exposure to irritant Thorough washing and drying of hands Use of powder-free gloves with more frequent changes of gloves Changing glove types Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based skin agents with latex products, because they cause breakdown of the latex product
Allergic contact dermatitis	Delayed hypersensitivity (type IV) reaction. Usually affects only area in contact with latex; reaction is usually to chemical additives used in the manufacturing process rather than to latex itself. Cause of reaction is T-cell–mediated sensitization to additives of latex. Reaction is not life-threatening and is far more common than a type I reaction. Slow onset; occurs 18–24 hours after exposure. Resolves within 3–4 days after exposure. More severe reactions may occur with subsequent exposures.	Pruritus, erythema, swelling, crusty thickened skin, blisters, other skin lesions	Referral for diagnosis (patch tests) and treatment Thorough washing and drying of hands Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based products unless they are latex compatible Avoidance of identified causative agent, because continued exposure to latex products in presence of breaks in skin may contribute to latex protein sensitization
Latex allergy	Type I IgE-mediated immediate hypersensitivity to plant proteins in natural rubber latex. In sensitized people, antilatex IgE antibody stimulates mast cell proliferation and basophil histamine release. Exposure can be through contact with the skin, mucous membranes, or internal tissues, or through inhalation of traces of powder from latex gloves. Severe reactions usually occur shortly after parenteral or mucous membrane exposure. People with any type I reaction to latex are at high risk for anaphylaxis. Local swelling, redness, edema, itching, and systemic reactions, including anaphylaxis, occur within minutes after exposure.	Rhinitis, flushing, conjunctivitis, urticaria, laryngeal edema, bronchospasm, asthma, severe vasodilation angioedema, anaphylaxis, cardiovascular collapse, death	Immediate treatment of reaction with epinephrine, fluids, vasopressors, and corticosteroids, and airway and ventilator support, with close monitoring for recurrence for the next 12–14 hours Prompt referral for diagnostic evaluation Treatment and diagnostic evaluation in latex-free environment Assessment of all patients for symptoms of latex allergy Educating patients and family members about the disorder and the importance of preventing future reactions by avoiding latex (e.g., wearing medical identification, carrying EpiPen)

IgE, immunoglobulin E.

serum-specific IgE, EIA, or ELISA; or the level of Hevea latex-specific IgE antibody in the serum. Testing for the chemicals found in the rubber production that makes latex is performed using the patch test. Skin patch testing is the preferred method for patients with contact allergies. The T.R.U.E. test and other skin tests should be performed only by clinicians who have expertise in their administration and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent (Habif, 2016).

Medical Management

The best treatment available for latex allergy is the avoidance of latex-based products, although avoidance is often difficult because of the widespread use of such products. Patients who have experienced an anaphylactic reaction to latex should be instructed to wear medical identification. Antihistamines and an emergency kit containing epinephrine should be provided to these patients, along with instructions about emergency management of latex allergy symptoms. Patients should be counseled to notify all health care workers, as well as local paramedic and ambulance companies, about their allergy. Warning labels can be attached to car windows to alert police and paramedics about the driver's or passenger's latex allergy in case of a motor vehicle crash. People with latex allergy should be provided with a list of alternative products and referred to local support groups; they are also urged to carry their own supply of nonlatex gloves.

People with type I latex sensitivity may be unable to continue to work if a latex-free work environment is not possible. This may occur with surgeons, dentists, operating room personnel, or intensive care nurses. Occupational implications for employees with type IV latex sensitivity are usually easier to manage by changing to nonlatex gloves and avoiding direct contact with latex-based medical equipment. Although latex-specific immunotherapy has been attempted, this method of treatment remains experimental.

Nursing Management

The nurse can assume a pivotal role in the management of latex allergies in both patients and staff. All patients should be asked

about latex allergy, although special attention should be given to those at particularly high risk (e.g., patients with spina bifida, patients who have undergone multiple surgical procedures). Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short procedure units, and EDs need to pay particular attention to latex allergy. See Figure 4-1 in Chapter 4 for a latex allergy assessment form.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the person to latex. Patients with latex allergy are advised to notify their health care providers and to wear medical identification. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. They must also become knowledgeable about signs and symptoms of latex allergy and emergency treatment and self-injection of epinephrine in case of allergic reaction.

Nurses can be instrumental in establishing and participating in multidisciplinary committees to address latex allergy and to promote a latex-free environment. Latex allergy protocols and education of staff about latex allergy and precautions are important strategies to reduce this growing problem and to ensure assessment and prompt treatment of those affected by allergy to latex.

CRITICAL THINKING EXERCISES

1. You are the nurse working in a preoperative holding area. A 38-year-old patient tells you that she has had a reaction to latex in the past. What are the immediate nursing priorities in providing care to this patient? What assessment data are needed to determine if this patient has a latex allergy?
2. A 47-year-old postman presents to the ED complaining of difficulty breathing after being stung by a bee. He states that this has happened two other times in his recent past and seems to be worse each time. What are the priority interventions? What medication is the drug of choice for severe allergic reactions, and how is it given? Describe the strength of the evidence and criteria used to assess its strength.

CHAPTER 57

Assessment and Management of Patients with Rheumatic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the pathophysiology of rheumatic diseases.
2. Describe the assessment and diagnostic findings seen in patients with rheumatic diseases or disorders.
3. Use the nursing process as a framework for the care of patients with rheumatic disorders.
4. Describe the systemic effects of a connective tissue disease.
5. Devise an education plan for the patient with newly diagnosed rheumatic disease.
6. Identify modifications in interventions to accommodate changes in patients' functional ability that may occur with disease progression.

GLOSSARY

ankylosis: fixation or immobility of a joint
arthritis: inflammation of a joint
arthroplasty: replacement of a joint
cytokines: proteins that can be produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses
exacerbation: period when disease symptoms occur or increase
osteophyte: a bony outgrowth or protuberance; bone spur
pannus: proliferation of newly formed synovial tissue infiltrated with inflammatory cells
remission: period when disease symptoms are reduced or absent
rheumatic diseases: numerous disorders affecting skeletal muscles, bones, cartilage, ligaments, tendons, and joints
rheumatoid arthritis: a systemic autoimmune disease with symmetric arthritic manifestations and multiple extra-articular features
subchondral bone: bony plate that supports the articular cartilage
tophi: accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

Introduction

The rheumatic diseases encompass autoimmune, degenerative, inflammatory, and systemic conditions that affect the joints, muscles, and soft tissues of the body. Rheumatic diseases most commonly manifest the clinical features of arthritis (inflammation of a joint) and pain. There are more than 100 types of rheumatic diseases. The problems caused by rheumatic diseases include limitations in mobility and activities of daily living, pain, fatigue, altered self-image, and sleep disturbances, as well as systemic effects that can lead to organ failure and death. An understanding of rheumatic diseases and their effects on a patient's function and well-being is essential to developing an appropriate plan of nursing care.

Rheumatic Diseases

An estimated 52.5 (22.7%) million adults in the United States have self-reported arthritis or other rheumatologic disease. Approximately 22.7 million (43.2% of those diagnosed with arthritis) have arthritis-attributable activity limitation. By 2030, an estimated 67 million (25%) adults will have arthritis or a rheumatologic condition, and an estimated 25 million adults (37%) will report arthritis-attributable activity limitations (Barbour, Helmick, Theis, et al., 2013). Based on a large population study done with 51,741 samples across fifteen centers in India, the prevalence of rheumatoid arthritis (RA) is estimated to be 0.34% (Chopra, Ghorpade, Sarmukkadam, et al., 2012). In the state of Rajasthan, the prevalence was high (0.80%). Even though the prevalence of RA is less, the overall disease burden for the country is high with more than 5 million people suffering from RA.

Arthritis and other rheumatologic diseases and the physical limitations that occur with them are becoming more prominent and a larger public health issue, which can be attributed to the older adults.

Rheumatologic disease processes affect males and females of all ages and ethnic groups. Some disorders are more likely to occur at a particular time of life or to affect one gender more often than the other. In general, women are two to nine times more commonly affected by rheumatologic diseases than men (Barbour et al., 2013). The onset of these conditions may be acute or insidious, with a course possibly marked by periods of remission (a period when disease symptoms are reduced or absent) and exacerbation (a period when symptoms occur or increase). Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relief of systemic effects. Permanent changes and disability may result from these disorders.

Nurses need to understand the classification of rheumatic diseases. One system is to classify disease as either monoarticular (affecting a single joint) or polyarticular (affecting multiple joints). Another system is to classify the disease as either inflammatory or noninflammatory. Conditions that may secondarily affect the musculoskeletal structure are also considered in disease classification.

Pathophysiology

Each of the rheumatologic diseases exhibits unique pathophysiologic features. Three distinct characteristics of pathophysiology include inflammation, autoimmunity, and degeneration.

Inflammation

Inflammation is a complex physiologic process mediated by the immune system that occurs in response to harmful stimuli like damaged cells or antigens, which may include pathogens (e.g., viruses, bacteria). Inflammation is meant to protect the body from insult by removing the triggering antigen or event. In response to a triggering episode, the antigen stimulus activates the body's immune system to form antibodies like monocytes and T lymphocytes (also referred to as T cells). Next, the immunoglobulin antibodies form immune complexes with antigens. Phagocytosis of the immune complexes is initiated, generating an inflammatory reaction (joint effusion, pain, and edema) (see Fig. 57-1). Phagocytosis produces chemicals such as leukotrienes and prostaglandins. Leukotrienes contribute to the inflammatory process by attracting other white blood cells to the area. Prostaglandins act as modifiers to inflammation. In some cases, they increase inflammation; in other cases, they decrease it. Leukotrienes and prostaglandins produce enzymes such as collagenase that break down collagen, which is a vital part of a normal joint. The release of these enzymes in the joint causes edema and proliferation of synovial membrane. In patients with chronic inflammation, the immune response can deviate from normal. Instead of resolution of swelling and joint pain once the triggering event has subsided, pannus (proliferation of newly formed synovial tissue infiltrated with inflammatory cells) formation occurs. Destruction of the joint's cartilage and erosion of bone soon follow.

The immunologic inflammatory process begins when antigens are presented to T lymphocytes, leading to a proliferation of T and B cells. B cells (also referred to as plasma cells) are a source of antibody-forming cells. In response to specific antigens, plasma cells produce and release antibodies. Antibodies combine with corresponding antigens to form pairs, or immune complexes. The immune complexes build up and are deposited in synovial tissue or other organs in the body, triggering the inflammatory reaction that can ultimately damage the involved tissue.

Autoimmunity

A hallmark of rheumatologic diseases is autoimmunity, where the body mistakenly recognizes its own tissue as a foreign antigen. Autoimmunity leads to destruction of tissue via the same inflammatory process as discussed earlier, along with chronic and long-standing pain. Although focused in the joints, inflammation and autoimmunity also involve other areas. The blood vessels (vasculitis and arteritis), lungs, heart, and kidneys may be affected by the autoimmunity and inflammation. See Chapter 54 for more information on autoimmune disease. A large group of genes, called *human leukocyte antigen* (HLA) genes, has been linked to the immune response and the development of multiple rheumatologic diseases (Di Lorenzo, 2015).

Degeneration

In degenerative rheumatic diseases, inflammation also occurs, but as a secondary process. Although the cause of degeneration of the articular cartilage is poorly understood, the process is known to be metabolically active and therefore is more accurately called *degradation.* One theory of degradation is that genetic or hormonal influences, mechanical factors, and prior joint damage cause cartilage failure. Degradation of cartilage ensues, and increased mechanical stress on bone ends causes stiffening of bone tissue. Another theory is that bone stiffening occurs and results in increased mechanical stress on cartilage, which in turn initiates the processes of degradation. See Chapter 35 for more information on the structure and function of the articular system.

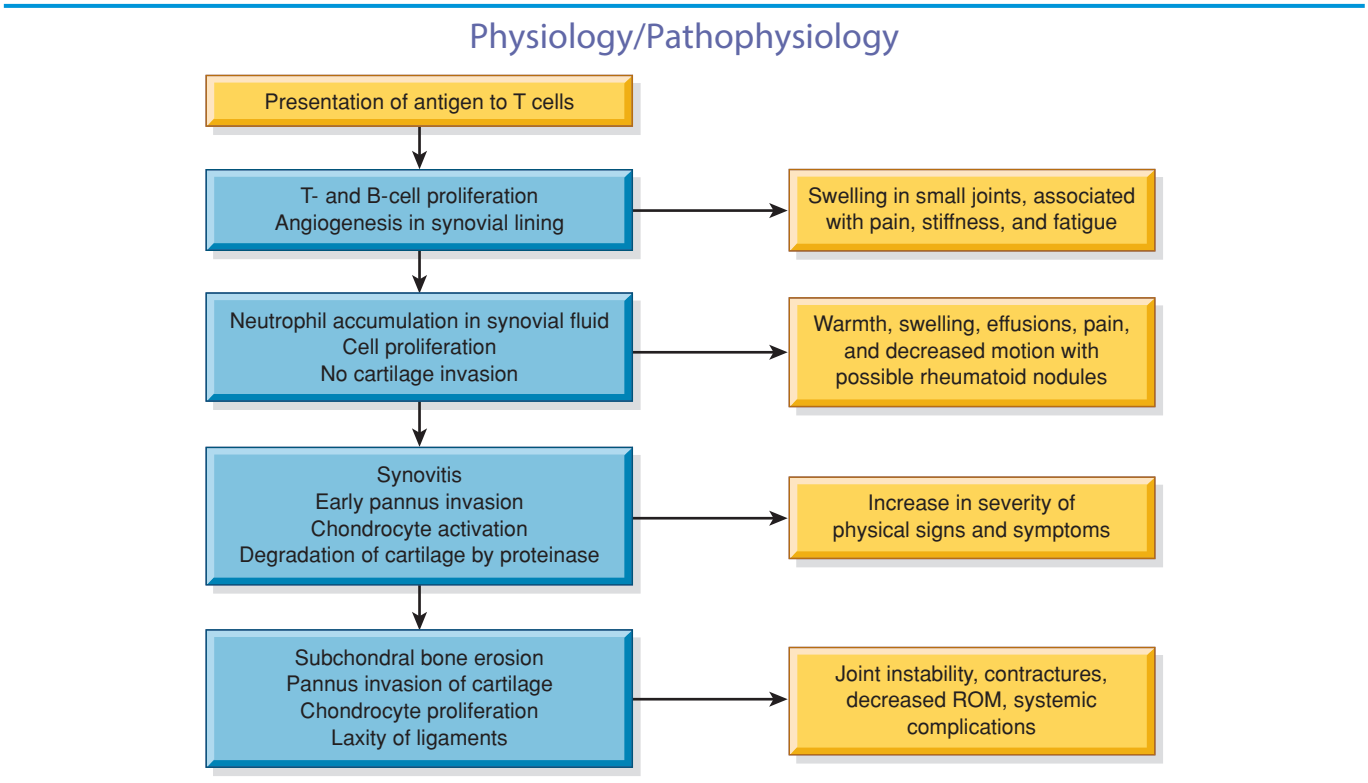

Figure 57-1 • Pathophysiology and associated physical signs of rheumatoid arthritis. ROM, range of motion.

Clinical Manifestations

The most common symptom in the rheumatic diseases is pain. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue.

Assessment and Diagnostic Findings

Assessment begins with a general health history, which includes the onset of symptoms and how they evolved, family history, past health history, and any other contributing factors. Because many of the rheumatic diseases are chronic conditions, the health history should also include information about the patient's perception of the problem, previous treatments and their effectiveness, the patient's support systems, and the patient's current knowledge base and the source of that information. A complete health history is followed by a complete physical assessment (see Chapter 3).

Assessment for rheumatic diseases combines the physical examination with a functional assessment. Inspection of the patient's general appearance occurs during the initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. The symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are also noted and recorded. Chart 57-1 outlines the important areas for consideration during the physical assessment. The functional assessment is a combination of history (what the patient reports that he or she can and cannot do) and examination (observation of activities, in which the patient demonstrates what he or she can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness)—for example, with shoulder or elbow involvement, the person may bend over to reach a fork rather than raising the fork to the mouth.

Chart 57-1 ASSESSMENT

Assessing for Rheumatic Disorders

In addition to the head-to-toe assessment or systems review, the following are important areas of consideration to be noted when performing the complete physical assessment of a patient with a known or suspected rheumatic disorder.

Manifestation	Significance
Skin (inquire and inspect)	
Rash, lesions	Associated with systemic lupus erythematosus (SLE) vasculitis, adverse effect of medication
Increased bruising	Associated with several rheumatic diseases and adverse effect of medication
Erythema	Sign of inflammation
Thinning	Adverse effect of medication
Warmth	Sign of inflammation
Photosensitivity	Associated with SLE, dermatomyositis, adverse effect of medication
Hair (inquire and inspect)	
Alopecia or thinning	Associated with rheumatic diseases or adverse effect of medication
Eye (inquire and inspect)	
Dryness, grittiness	Associated with Sjögren's syndrome (commonly occurring with rheumatoid arthritis [RA] and SLE)
Decreased acuity or blindness	Associated with temporal arteritis, medication complications
Cataracts	Adverse effect of medication
Decreased peripheral vision	Adverse effect of medication
Conjunctivitis, uveitis	Associated with ankylosing spondylitis and Reiter's syndrome
Ear (inquire)	
Tinnitus	Adverse effect of medication
Decreased acuity	Adverse effect of medication
Mouth (inquire and inspect)	
Buccal, sublingual lesions	Associated with vasculitis, dermatomyositis, adverse effect of medication
Altered sense of taste	Adverse effect of medication
Dryness	Associated with Sjögren's syndrome
Dysphagia	Associated with myositis
Difficulty chewing	Associated with decreased range of motion of jaw
Chest (inspect and inquire)	
Pleuritic pain	Associated with RA and SLE
Decreased chest expansion	Associated with ankylosing spondylitis
Activity intolerance (dyspnea)	Associated with pulmonary hypertension in scleroderma
Cardiovascular system (inquire, inspect, palpate)	
Blanching of fingers on exposure to cold	Associated with Raynaud's phenomenon
Peripheral pulses	Deficit may indicate vascular involvement or edema associated with medication effect or rheumatic diseases, especially SLE or scleroderma

(Continued)

(Continued)

Abdomen (inquire and palpate)	
Altered bowel habits	Associated with scleroderma, spondylosis, ulcerative colitis, decreased physical mobility, medication effect
Nausea, vomiting, bloating, and pain	Adverse effect of medication
Weight change (measure)	Associated with RA (decreased), adverse effect of medication (increased or decreased)
Genitalia (inquire and inspect)	
Dryness, itching	Associated with Sjögren's syndrome
Abnormal menses	Adverse effect of medication
Altered sexual performance	Fear of pain (or of pain caused by partner) and limitation of motion may affect sexual mobility.
Hygiene	Poor hygiene may be related to limitations in activities of daily living.
Urethritis, dysuria	Associated with ankylosing spondylitis and Reiter's syndrome
Lesions	Associated with vasculitis
Neurologic (inquire and inspect)	
Paresthesias of extremities; abnormal reflex pattern	Nerve compressions (e.g., carpal tunnel syndrome, spinal stenosis)
Headaches	Associated with temporal arteritis, adverse effect of medication
Musculoskeletal (inspect and palpate)	
Joint redness, warmth, swelling, tenderness, deformity—location of first joint involved, pattern of progression, symmetry, acute vs. chronic nature	Signs of inflammation
Joint range of motion	Decreased range of motion may indicate severity or progression of disease.
Surrounding tissue findings	
Muscle atrophy, subcutaneous nodules, popliteal cyst	Extra-articular manifestations
Muscle strength (grip)	Muscle strength decreases with increased disease activity.

Laboratory Studies

In Table 57-1, some of the most common laboratory studies are listed with their corresponding normal ranges and significance. Many of the tests require special laboratory techniques and may not be performed in every health care facility. The primary provider determines which tests are necessary based on symptoms, stage of disease, cost, and likely benefit. In some instances, tests are used to monitor the course of the disease.

Other Diagnostic Studies

Imaging studies commonly used for patients with rheumatic diseases include x-ray studies, computed tomography (CT) scans, magnetic resonance imaging (MRI) scans, and arthrography. See Chapter 35 for further information about these and other diagnostic studies.

Medical Management

The chronic nature of rheumatic conditions requires cooperation between the patient and the provider. The patient needs to understand the disease process and to be active in making good decisions for their care. Patient education regarding the disease process and treatment options is imperative to enable the patient to make informed decisions regarding their care. Management of rheumatologic diseases is based on the patient's symptom self-assessment, quality of life, and objective assessment by the provider (Schur & Moreland, 2016). Table 57-2 outlines goals and strategies for care of the patient with rheumatic diseases.

Pharmacologic Therapy

Medications are used with the rheumatic diseases to manage symptoms, to control inflammation, and, in some instances, to modify the disease. Useful medications include the salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and both biologic and nonbiologic disease-modifying antirheumatic drugs (DMARDs). As their name suggests, DMARDs have the ability to suppress the autoimmune response; alter disease progression; and stop or decrease further tissue damage on the joints, cartilage, and organs. DMARDs have been found to halt the progression of bone loss and destruction and can induce remission (Carter, Patty-Resk, Ruffing, et al., 2015). Nonbiologic DMARDs are thought to reduce proinflammatory cytokines (cell signaling proteins) and increase anti-inflammatory cytokines. Biologic DMARDs, in contrast, have been specifically engineered to target a certain cell or molecule within the immune system to treat the specific rheumatologic condition. Specific biologic DMARDs target tumor necrosis factor alpha (TNF-α), B cells, T cells, interleukin 1 (IL-1), and interleukin 6 (IL-6). Table 57-3 reviews commonly used medications.

Controlling the inflammation related to the disease process helps manage pain, but this is often a delayed response. Nonopioid medications are often used for pain management, especially early in the treatment program, until other measures can be instituted.

Nonpharmacologic Pain Management

Nonpharmacologic methods of pain management are important. Heat applications are helpful in relieving pain, stiffness, and

TABLE 57-1 Common Blood Studies for Rheumatic Diseases

Test	Normal Value	Significance
Serum		
Creatinine		
Metabolic waste excreted through the kidneys	0.7–1.4 mg/dL (62–124 mcmol/L)	Increase may indicate kidney damage in SLE, scleroderma, and polyarteritis.
Erythrocyte Count		
Measures circulating erythrocytes	*Men*: 4,600,000–6,200,000/mm^3 ($4.6–6.2 \times 10^{12}$/L) *Women*: 4,200,000–5,400,000/mm^3 ($4.2–5.4 \times 10^{12}$/L)	Decrease can be seen in RA, SLE.
Erythrocyte Sedimentation Rate (ESR)		
Measures the rate at which RBCs settle out of unclotted blood in 1 hour	Westergren: Men under 50 years: <15 mm/hr Men over 50 years: <20 mm/hr Women under 50 years: <25 mm/hr Women over 50 years: <30 mm/hr	Increase is usually seen in inflammatory connective tissue diseases. An increase indicates rising inflammation, resulting in clustering of RBCs, which makes them heavier than normal. The higher the ESR, the greater the inflammatory activity.
Hematocrit		
Measures the size, capacity, and number of cells present in blood	*Men*: 42%–52% *Women*: 35%–47%	Decrease can be seen in chronic inflammation (anemia of chronic disease); also, blood loss through GI bleed.
White Blood Cell Count		
Measures circulating leukocytes	4,500–11,000 cells/mm^3	Decrease may be seen in SLE.
VDRL (Venereal Disease Research Laboratory)		
Measures antibody to syphilis	Nonreactive	False-positive results are sometimes found with SLE.
Uric Acid		
Measures level of uric acid in serum	2.5–8 mg/dL (0.15–0.5 mmol/L)	Increase is seen with gout. During acute flare, levels may be normal. After flare has subsided, levels will be elevated in gout.
Serum Immunology		
Antinuclear Antibody (ANA)		
Measures antibodies that react with a variety of nuclear antigens If antibodies are present, further testing determines the type of ANA circulating in the blood (anti-DNA, anti-RNP).	Negative Healthy adults may also have a positive ANA.	Positive test may be associated with SLE, RA, scleroderma, Raynaud's disease, Sjögren's syndrome, necrotizing arteritis. The higher the titer, the greater the inflammation. The pattern of immunofluorescence (speckled, homogeneous, or nucleolar) helps determine the diagnosis.
Anti-DNA, DNA Binding		
Titer measurement of antibody to double-stranded DNA	Negative	High titer is seen in SLE; increases in titer may indicate an increase in disease activity.
Complement Levels—C3, C4		
Complement is a protein substance that binds with antigen–antibody complexes for the purpose of lysis. When the number of complexes increases markedly, complement is used for lysis, thus depleting the amount available in the blood.	*C3*: 80–170 mg/dL (0.8–1.7 g/L) *C4*: 18–51 mg/dL (180–510 mg/L)	Decrease may be seen in RA and SLE. Decrease indicates autoimmune and inflammatory activity.
C-Reactive Protein (CRP)		
Shows presence of abnormal glycoprotein due to inflammatory process	<1 mg/dL (<10 mg/L)	A positive reading indicates active inflammation.
Immunoglobulin Electrophoresis		
Measures the values of immunoglobulins	*IgA*: 80–400 mg/dL (0.8–4 g/L) *IgG*: 600–1,800 mg/dL (6–18 g/L) *IgM*: 55–250 mg/dL (0.55–2.5 g/L)	Increased levels are found in people who have autoimmune disorders.
Rheumatoid Factor (RF)		
Determines the presence of abnormal antibodies seen in connective tissue disease	Negative	Positive titer >1:80 Present in 80% of those with RA Positive RF may also suggest SLE, Sjögren's syndrome, or mixed connective tissue disease. The higher the titer (number at right of colon), the greater the inflammation.
Tissue Typing		
HLA-B27 Antigen		
Measures presence of HLA antigens, which are used for tissue recognition	Negative	Found in 80%–90% of those with ankylosing spondylitis and Reiter's syndrome

DNA, deoxyribonucleic acid; GI, gastrointestinal; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M; HLA, human leukocyte antigen; RA, rheumatoid arthritis; ; RNP, ribonucleoprotein; RBCs, red blood cells; SLE, system lupus erythematosus.

Adapted from Fischbach, F., & Dunning, M. B. (2015). A manual of laboratory and diagnostic tests (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

TABLE 57-2 Management Goals and Strategies for Rheumatic Diseases

Goals	Management Strategies
Suppress inflammation and the autoimmune response	Optimize pharmacologic therapy (anti-inflammatory and disease-modifying agents).
Control pain	Protect joints; ease pain with splints, thermal modalities, relaxation techniques.
Maintain or improve joint mobility	Implement exercise programs for joint motion, muscle strengthening, weight loss as appropriate, and overall health.
Maintain or improve functional status	Make use of adaptive devices and techniques.
Increase patient's knowledge of disease process	Provide and reinforce patient education.
Promote self-management by patient adherence with the therapeutic regimen	Emphasize compatibility of therapeutic regimen and lifestyle.

muscle spasm. Superficial heat may be applied in the form of warm tub baths or showers and warm moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Maximum benefit is achieved within 20 minutes after application. More frequent use for shorter lengths of time is most beneficial. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied.

Devices such as braces, splints, and assistive devices for ambulation (e.g., canes, crutches, walkers) ease pain by limiting movement or stress from putting weight on painful joints. Acutely inflamed joints can be rested by applying splints to limit motion. Splints also support the joint to relieve spasm. Canes and crutches can relieve stress from inflamed and painful weight-bearing joints while promoting safe ambulation. Cervical collars may be used to support the weight of the head and limit cervical motion. A metatarsal bar or special pads may be put into the patient's shoes if foot pain or deformity is present. A combination of methods may be required, because different methods often work better at different times.

TABLE 57-3 Selected Medications Used in Rheumatic Diseases

Medication	Action, Use, and Indication	Nursing Considerations
Salicylates		
Acetylated: Aspirin *Nonacetylated*: Choline trisalicylate (Arthropan, Trilisate), salsalate (Disalcid), sodium salicylate	*Action*: Anti-inflammatory, analgesic, antipyretic Acetylated salicylates are platelet aggregation inhibitors Anti-inflammatory doses will produce blood salicylate levels of 20–30 mg/dL	Administer with meals to prevent gastric irritation. Assess for tinnitus, gastric intolerance, GI bleeding, and purpura. Monitor for possible confusion in the older adult.
Nonsteroidal Anti-inflammatory Drugs (NSAIDs)		
Diclofenac (Voltaren), diflunisal (Dolobid), etodolac (Lodine), flurbiprofen (Ansaid), ibuprofen (Motrin), ketoprofen (Orudis, Oruvail), meclofenamate (Meclomen), meloxicam (Mobic), nabumetone (Relafen), naproxen (Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), sulindac (Clinoril), tolmetin sodium (Tolectin) *COX-2 enzyme blockers*: celecoxib (Celebrex)	*Action*: Anti-inflammatory, analgesic, antipyretic, platelet aggregation inhibitor Anti-inflammatory effect occurs 2–4 weeks after initiation All NSAIDs are useful for short-term treatment of acute gout attack NSAIDs are an alternative to salicylates for first-line therapy in several rheumatic diseases *Action*: Inhibit only COX-2 enzymes, which are produced during inflammation, and spare COX-1 enzymes, which can be protective to the stomach	Administer NSAIDs with food. Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects. Avoid salicylates; use acetaminophen/paracetamol for additional analgesia. Watch for possible confusion in older adults. Monitoring is the same as for other NSAIDs. Increased risk of cardiovascular events, including myocardial infarction and stroke Appropriate for older adults and patients who are at high risk for gastric ulcers
Disease-Modifying Antirheumatic Drugs (DMARDs)		
Antimalarials: Hydroxychloroquine (Plaquenil), chloroquine (Aralen)	*Action*: Anti-inflammatory, inhibit lysosomal enzymes Slow acting; onset may take 2–4 months. May be used in conjunction with other DMARD therapy. Useful in RA and SLE	Administer concurrently with NSAIDs. Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair. Emphasize need for ophthalmologic examinations (every 6–12 months).
Janus Kinase (JAK) inhibitors (Xeljanz)	*Action*: Enters the cell and binds to the active JAK site, inhibits autophosphorylation and JAK activation that inhibits cytokine production. May be used in combination with methotrexate or other nonbiologic DMARDs. May also be used as monotherapy	Administer twice a day. Do not administer with biologic DMARDs or potent immunosuppressants. Monitor lipids 4–8 weeks following initiation of therapy. Monitor liver enzymes routinely.
Sulfasalazine (Azulfidine)	*Action*: Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis Useful in RA, seronegative spondyloarthropathies	Administer concurrently with NSAIDs. Do not use in patients with allergy to sulfa medications or salicylates. Emphasize adequate fluid intake. Assess for GI upset, skin rash, headache, liver abnormalities, anemia.

(Continued)

(Continued)

Immunosuppressives: Methotrexate (Rheumatrex), azathioprine (Imuran), cyclophosphamide (Cytoxan)	*Action*: Nonbiologic immune suppression, affect DNA synthesis and other cellular effects Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease Methotrexate is generally the first-line agent for RA treatment; also useful in SLE. Methotrexate may be given orally or by intramuscular or subcutaneous injection	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections. Monitor CBC, liver enzymes, creatinine at 6 weeks after initiation, then every 2–3 months or accordingly. Advise patient of contraceptive measures because of teratogenicity.
Cyclosporine (Neoral)	*Action*: Nonbiologic immune suppression by inhibiting T lymphocytes Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs. Assess for toxic effects, such as bleeding gums, fluid retention, hair growth, tremors. Monitor blood pressure and renal function (creatinine) every 2 weeks until stable.
Immunomodulators		
Pyrimidine synthesis inhibitor: Leflunomide (Arava)	*Action*: Nonbiologic with antiproliferative and anti-inflammatory effects; used in moderate to severe RA May be used alone or in combination with other DMARDs	Long half-life; requires loading dose followed by daily administration. Assess for diarrhea, hair loss, skin rash, mouth sores. Monitor liver function tests. Contraindicated in pregnancy and breast-feeding Given orally
TNF blocking agents: Adalimumab (Humira), certolizumab pegol (Cimzia), etanercept (Enbrel), infliximab (Remicade), golimumab (Simponi)	*Action*: Biologic response modifier that binds to TNF, a cytokine involved in inflammatory and immune responses. Used in moderate to severe RA. Can be used alone or with methotrexate or other nonbiologic DMARDs. Adalimumab is given by subcutaneous injection every 2 weeks, but may be used every week if efficacy not reached. Certolizumab pegol is given by subcutaneous injection every 2 weeks. Etanercept is given by subcutaneous injection weekly. Infliximab is given intravenously over 2 hours or more. Medication must be refrigerated Golimumab is given by subcutaneous injection once a month. Golimumab SC is a second alternative that is administered intravenously every 8 weeks after initial 2 loading doses	Patient should be tested for tuberculosis before beginning this medication. Educate patient about subcutaneous self-injection. Monitor for injection site reactions. Educate patient about increased risk for infection and to withhold medication if fever occurs. Notify provider if any illness or infection occurs and medication is held.
T-cell costimulation modulator: Abatacept (Orencia)	*Action*: Blocks one of the pathways needed to fully activate T cells, decreasing inflammatory and immunologic responses. Used in moderate to severe RA unresponsive to TNF inhibitors. Used with methotrexate or DMARDs other than TNF inhibitors or anakinra	Administered IV initially, then transitions to subcutaneous dosage once weekly. Educate patient about subcutaneous self-injections given daily. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs. IV infusions are given every 4 weeks over 30-minute infusion.
B-cell production blocker: Rituximab (Rituxan)	*Action*: Binds to B-lymphocyte CD20 surface antigens. Used in refractory RA in patients with inadequate response to TNF antagonist. Given with methotrexate	Rituximab is given as two 1,000-mg doses via IV infusion separated by 2 weeks. Given on weeks 0 and 2, and then subsequent doses are infused 24 weeks later or based on clinical diagnosis (commonly given every 6 months). Premedicate with acetaminophen/paracetamol, antihistamine, and methylprednisolone (Solu-Medrol) 30 minutes prior to infusion of rituximab. Educate patient about increased risk of infection.
Human IL-1 receptor antagonist: Anakinra (Kineret)	*Action:* Blocks IL-1 receptors, decreasing inflammatory and immunologic responses. Used in moderate to severe RA. Can be used alone or with methotrexate or DMARDs other than TNF-blocking agents	Given daily by subcutaneous injection. Educate patient about subcutaneous self-injections given daily. Medication must be refrigerated. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs.

(Continued)

(Continued)

Human IL-6 receptor antagonist: Tocilizumab (Actemra)	*Action*: Binds to and inhibits IL-6 receptors, decreasing inflammatory and immunologic responses. Can be used alone or with methotrexate or in combination with other nonbiologic DMARDs	Administered IV every 4 weeks. Educate patient about increased risk of infection.
Corticosteroids		
Prednisone, prednisolone, hydrocortisone	*Action*: Anti-inflammatory. Used for shortest duration and at lowest dose possible to minimize adverse effects. Useful for unremitting RA, SLE, polymyalgia rheumatica, myositis, arteritis Fast acting; onset in days Intra-articular injections useful for joints unresponsive to NSAIDs	Assess for toxicity: Cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis. Joints most amenable to injections include ankles, knees, hips, shoulders, and hands. Repeated injections can cause joint damage. Use caution in patients diagnosed with diabetes, due to effects causing elevation in blood sugar.
Topical Analgesics		
Capsaicin (Zostrix)	*Action*: Analgesic	Instruct patient to apply sparingly, avoid areas of open skin, and avoid contact with eyes and mucous membranes. Wash hands carefully after application. Assess for local skin irritation.

CBC, complete blood count; CNS, central nervous system; COX, cyclooxygenase; GI, gastrointestinal; IL-1, interleukin 1; IL-6, interleukin 6; IM, intramuscular; IV, intravenous; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor; WBCs, white blood cells.

Exercise and Activity

The ongoing nature of most rheumatic diseases makes it important to maintain and, when possible, improve joint mobility and overall functional status. Appropriate programs of exercise have been shown to decrease pain and improve function (Miller, 2015). Changes in gait as well as joint limitations commonly require referral for rehabilitation therapy. An individualized exercise program is crucial to improve movement. Table 57-4 summarizes the exercises appropriate for patients with rheumatic diseases. Physical and occupational therapy programs and interventions are beneficial in improving physical activity and maintaining range of motion. Such interventions may include stretching exercises, muscle conditioning, aerobic exercise, massage, acupuncture, chiropractic and osteopathic manipulation. Other strategies for decreasing pain include muscle relaxation techniques, imagery, self-hypnosis, and distraction. The use of transcutaneous electrical nerve stimulation (TENS) unit has also been found to improve pain and enhance physical activity (Carter et al., 2015). A mild analgesic agent may be suggested before exercise to improve pain during exercise. A weight reduction program may be recommended to relieve stress on painful joints for some patients. Any patient who experiences acute or prolonged pain associated with exercise should report the symptoms to their primary provider for evaluation.

TABLE 57-4 Exercise to Promote Mobility

Type of Exercise	Purpose	Recommended Performance	Precautions
Range of motion	Maintain flexibility and joint motion	Active or active/self-assisted at least daily	Reduce the number of repetitions when inflammation is present
Isometric exercise	Improve muscle tone, static endurance, and strength; prepare for dynamic and weight-bearing exercises	Perform at 70% of maximal voluntary contraction daily	Monitor blood pressure; isometric exercises may increase blood pressure and decrease blood flow to muscles
Dynamic exercise	Maintain or increase dynamic strength and endurance; increase muscle power; enhance synovial blood flow; promote strength of bone and cartilage	Start with repetitions against gravity and add progressive resistance; perform 2–3 days per week	May increase biomechanical stress on unstable or misaligned joints
Aerobic exercise	Improve cardiovascular fitness and endurance	Perform 3–5 days per week for 20–30 minutes of moderate-intensity exercise	Progress slowly as activity tolerance and fitness improve
Pool exercise	Water supports or resists movement; warm water may provide muscle relaxation	Provide buoyant medium for performance of dynamic or aerobic exercise	Heated swimming pool; deep water to minimize joint compression; nonslip footwear for safety and comfort. Receive appropriate instruction in a program designed for people with arthritis

Adapted from Carter S. C., Patty-Resk, C., Ruffing, V., et al. (2015). Core curriculum for rheumatology nursing (1st ed.). Greenville, SC: Lyons Den Solutions, LLC.

The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE), activity levels may vary from day to day and even within a single day.

Sleep

Short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), may be prescribed to reestablish adequate sleep patterns and improve pain management (Papadakis, McPhee, & Rabow, 2015). Patients need restful sleep so that they can cope with pain, minimize physical fatigue, and deal with the changes related to having a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Stiffness, depression, and medications may also compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep.

Education about sleep hygiene strategies may help promote restorative sleep. These strategies include establishing a set time to sleep and a regular wake-up time, creating a quiet sleep environment with a comfortable room temperature, avoiding factors that interfere with sleep (e.g., the use of alcohol and caffeine), using relaxation exercises, and getting out of bed and engaging in another activity (e.g., reading) if unable to sleep.

Nursing Management

Chart 57-2 details the nursing diagnoses, interventions, and expected outcomes for the patient with a rheumatic disorder.

Gerontologic Considerations

The various rheumatologic disease conditions in the older adult pose unique challenges. These challenges relate to disability, cognitive changes, comorbid conditions, and diagnosis. Musculoskeletal problems are the most frequently reported conditions in older adults (Miller, 2015) and will be seen more frequently by health professionals in the coming years along with associated disability, especially among frail older adults.

Comorbid conditions pose a unique challenge in diagnosing rheumatologic disease in older adults because they have the potential to mask or alter presenting symptoms (Papadakis et al., 2015). The frequency, pattern of onset, clinical features, severity, and effects on function of the rheumatic disease in older patients may be different in very old patients. In addition, other medical conditions may take precedence over the rheumatic disease, which commonly becomes a secondary diagnosis and concern. Decreased vision and altered balance, often present in older adults, may be problematic if rheumatic disease in the lower extremities affects locomotion. The combination of decreased hearing and visual acuity, memory loss, and depression contributes to failure to follow the treatment regimen in older adult patients as well (Miller, 2015). Special techniques for promoting patient safety, self-management, and strategies such as memory aids for medications may be necessary.

Behavioral clues such as gait patterns, guarding, and joint flexion may aid the nurse in assessing the patient's pain when cognitive impairment is present. Older adults, especially men, may also neglect to communicate their pain unless elicited by the provider. Pain, in general, in this population that is not treated or undertreated may impact the quality of life for these patients, which can exacerbate all other medical conditions (Carter et al., 2015).

Older adults have an increased risk of osteoporosis. Pain, loss of mobility, diminished self-image, and increasing morbidity can result from progressive osteoporosis. Therefore, diagnosis and treatment of osteoporosis should not be overlooked in this population. Pharmacologic therapy (including analgesic agents), exercise, postural assistance, modification of activities of daily living, and psychological support are useful components of the treatment program for the older adult.

Identifying the effects of the rheumatic disease on the patient's lifestyle, independence, and psychological status is important and can improve the quality of life for older adults. Depressed mood is routinely found in those suffering from chronic joint disease. The body image and self-esteem of the older adult with rheumatic disease, combined with underlying depression, may interfere with the use of assistive devices such as canes. The use of adaptive equipment such as long-handled reachers or tongs may be viewed by the older adult as evidence of aging rather than as a means of increasing independence.

Because most rheumatologic diseases involve pain, especially with joints, some older adults may consider their symptoms as inevitable consequences of aging. In fact, many older adults expect and accept the immobility and self-care problems related to the rheumatic diseases and do not seek help, thinking that nothing can be done.

The older adult usually has a lifelong pattern of dealing with the stresses of daily life. Depending on the success of that pattern, the older adult can often maintain a positive attitude and self-esteem when faced with a rheumatic disease, especially if support is available. Previous stress management strategies are assessed. If these strategies have been effective, the patient is encouraged and supported in their use. If they were ineffective, the nurse assists the patient in identifying alternative strategies, encourages the use of new strategies, and assesses their effectiveness.

Pharmacologic treatment of rheumatic disease in older patients is more difficult than in younger patients. If therapeutic medications have an effect on the senses (hearing, cognition), this effect is intensified in the older adult. The cumulative effect of medications, in general, is accentuated because of the physiologic changes of aging. For example, decreased renal function in the older adult alters the metabolism of certain medications, such as NSAIDs. Older adults are more prone to side effects associated with the use of multiple-drug therapy.

Partly because of the more frequent contact of older adults with health care providers for a variety of health issues, overtreatment or inappropriate treatment is possible. Complaints of pain may be met with a prescription for an opioid analgesic agent rather than instructions for rest, the use of an assistive device, and local comfort measures such as heat or cold. Acetaminophen/paracetamol (Tylenol) may be appropriate and worth trying before other medications that pose a greater chance of side effects. NSAIDs can be used; however, studies report that long-term use of NSAIDs can increase the risks of peptic ulcers, hemorrhage and cardiovascular toxicity. New guidelines recommend NSAIDs should be used in conjunction with a proton pump inhibitor (i.e., omeprazole [Prilosec]) to decrease the likelihood of gastric ulcers forming, hemorrhage and cardiovascular toxicity (Fujita, Kutsumi, Sanuki, et al., 2013).

Intra-articular corticosteroid injections, with their usually rapid relief of symptoms, may be requested by the patient who is unaware of the consequences of too-frequent use of this

Chart 57-2 PLAN OF NURSING CARE

Care of the Patient with a Rheumatic Disorder

Nursing Diagnosis: Acute and chronic pain related to inflammation and increased disease activity, tissue damage, fatigue, or lowered tolerance level
Goal: Improvement in comfort level; incorporation of pain management techniques into daily life

Nursing Interventions	Rationale	Expected Outcomes
1. Provide variety of comfort measures: a. Application of heat or cold b. Massage, position changes, rest c. Foam mattress, supportive pillow, splints d. Relaxation techniques, diversional activities	1. Pain may respond to nonpharmacologic interventions, such as exercise, relaxation, and thermal modalities.	• Identifies factors that exacerbate or influence pain response • Identifies and uses pain management strategies • Verbalizes decrease in pain • Reports signs and symptoms of side effects in timely manner to prevent additional problems • Verbalizes that pain is characteristic of rheumatic disease • Establishes realistic pain relief goals • Identifies changes in quality or intensity of pain
2. Administer anti-inflammatory, analgesic, and slow-acting antirheumatic medications as prescribed.	2. Pain of rheumatic disease responds to individual or combination medication regimens.	
3. Individualize medication schedule to meet patient's need for pain management.	3. Previous pain experiences and management strategies may be different from those needed for persistent pain.	
4. Encourage verbalization of feelings about pain and chronicity of disease.	4. Verbalization promotes coping.	
5. Assess for subjective changes in pain.	5. The impact of pain on an individual's life often leads to misconceptions about pain and pain management techniques. 6. The individual's description of pain is a more reliable indicator than objective measurements such as change in vital signs, body movement, and facial expression.	

Nursing Diagnosis: Fatigue related to increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, and emotional stress/depression
Goal: Incorporates as part of daily activities strategies necessary to modify fatigue

Nursing Interventions	Rationale	Expected Outcomes
1. Provide instruction about fatigue. a. Describe relationship of disease activity to fatigue. b. Describe comfort measures while providing them. c. Develop and encourage a sleep routine (warm bath and relaxation techniques that promote sleep). d. Explain importance of rest for relieving systematic, articular, and emotional stress. e. Explain how to use energy conservation techniques (pacing, delegating, setting priorities). f. Identify physical and emotional factors that can cause fatigue.	1. The patient's understanding of fatigue will affect their actions. a. The amount of fatigue is directly related to the activity of the disease. b. Relief of discomfort can relieve fatigue. c. Effective bedtime routine promotes restorative sleep. d. Different kinds of rest are needed to relieve fatigue and are based on patient's need and response. e. A variety of measures can be used to conserve energy. f. Awareness of the various causes of fatigue provides the basis for measures to modify the fatigue.	• Self-evaluates and monitors fatigue pattern • Verbalizes the relationship of fatigue to disease activity • Uses comfort measures as appropriate • Practices effective sleep hygiene and routine • Makes use of various assistive devices (splints, canes) and strategies (bed rest, relaxation techniques) to ease different kinds of fatigue • Incorporates time management strategies in daily activities • Uses appropriate measures to prevent physical and emotional fatigue • Has an established plan to ensure well-paced, therapeutic activity schedule • Adheres to therapeutic program • Follows a planned conditioning program • Consumes a nutritious diet consisting of the five major groups and recommended daily allowance of vitamins and minerals
2. Facilitate development of appropriate activity/rest schedule.	2. Alternating rest and activity conserves energy while allowing most productivity.	
3. Encourage adherence to the treatment program.	3. Overall control of disease activity can decrease the amount of fatigue.	
4. Refer to and encourage a conditioning program.	4. Deconditioning resulting from lack of mobility, understanding, and disease activity contributes to fatigue.	
5. Encourage adequate nutrition, including source of iron from food and supplements.	5. A nutritious diet can help counteract fatigue.

(Continued)

Nursing Diagnosis: Impaired physical mobility related to decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices
Goal: Attains and maintains optimal functional mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage verbalization regarding limitations in mobility.	1. Mobility is not necessarily related to deformity. Pain, stiffness, and fatigue may temporarily limit mobility. The degree of mobility is not synonymous with the degree of independence. Decreased mobility may influence a person's self-concept and lead to social isolation.	• Identifies factors that interfere with mobility • Describes and uses measures to prevent loss of motion • Identifies environmental (home, school, work, community) barriers to optimal mobility • Uses appropriate techniques, assistive equipment, or both to aid mobility • Identifies community resources available to assist in managing decreased mobility
2. Assess need for occupational or physical therapy consultation. a. Emphasize range of motion of affected joints. b. Promote the use of assistive ambulatory devices. c. Explain the use of safe footwear. d. Use individual appropriate positioning/posture.	2. Therapeutic exercises, proper footwear, and/or assistive equipment may improve mobility. Correct posture and positioning are necessary for maintaining optimal mobility.	
3. Assist to identify environmental barriers.	3. Furniture and architectural adaptations may enhance mobility.	
4. Encourage independence in mobility and assist as needed. a. Allow ample time for activity. b. Provide rest period after activity. c. Reinforce principles of pacing and work simplification.	4. Changes in mobility may lead to a decrease in personal safety.	
5. Initiate referral to community health agency.	5. The degree of mobility may be slow to improve or may not improve with intervention.	

Nursing Diagnosis: Readiness for enhanced self-care related to contractures, fatigue, or loss of motion
Goal: Performs self-care activities independently or with the use of resources

Nursing Interventions	Rationale	Expected Outcomes
1. Assist patient to identify self-care deficits and factors that interfere with ability to perform self-care activities.	1. The ability to perform self-care activities is influenced by the disease activity and the accompanying pain, stiffness, fatigue, muscle weakness, loss of motion, and depression.	• Identifies factors that interfere with the ability to perform self-care activities • Identifies alternative methods for meeting self-care needs • Uses alternative methods for meeting self-care needs • Identifies and uses other health care resources for meeting self-care needs
2. Develop a plan based on the patient's perceptions and priorities on how to establish and achieve goals to meet self-care needs, incorporating energy conservation, and work simplification concepts. a. Provide appropriate assistive devices. b. Reinforce correct and safe use of assistive devices. c. Allow patient to control timing of self-care activities. d. Explore with the patient different ways to perform difficult tasks or ways to enlist the help of someone else.	2. Assistive devices may enhance self-care abilities. Effective planning for changes must include the patient, who must accept and adopt the plan.	
3. Consult with community health care agencies when individuals have attained a maximum level of self-care yet still have some deficits, especially regarding safety.	3. Individuals differ in ability and willingness to perform self-care activities. Changes in ability to care for self may lead to a decrease in personal safety.	

(Continued)

(Continued)

Nursing Diagnosis: Disturbed body image related to physical and psychological changes and dependency imposed by chronic illness
Goal: Adapts to physical and psychological changes imposed by the rheumatic disease

Nursing Interventions	Rationale	Expected Outcomes
1. Help patient identify elements of control over disease symptoms and treatment.	1. The individual's self-concept may be altered by the disease or its treatment.	• Verbalizes an awareness that changes taking place in self-concept are normal responses to rheumatic disease and other chronic illnesses
2. Encourage patient's verbalization of feelings, perceptions, and fears. a. Help to assess present situation and identify problems.	2. The individual's coping strategies reflect the strength of their self-concept.	• Identifies strategies to cope with altered self-concept

Nursing Diagnosis: Ineffective coping related to actual or perceived lifestyle or role changes
Goal: Use of effective coping behaviors for dealing with actual or perceived limitations and role changes

Nursing Interventions	Rationale	Expected Outcomes
1. Identify areas of life affected by disease. Answer questions and dispel possible myths. a. Assist to identify past coping mechanisms. b. Assist to identify effective coping mechanisms.	1. The effects of disease may be more or less manageable once identified and explored reasonably.	• Names functions and roles affected and not affected by disease process • Describes therapeutic regimen and states actions to take to improve, change, or accept a particular situation, function, or role
2. Develop plan for managing symptoms and enlisting support of family and friends to promote daily function.	2. By taking action and involving others appropriately, patient develops or draws on coping skills and community support.	

Collaborative Problems: Complications secondary to effects of medications
Goal: Absence or resolution of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Perform periodic clinical assessment and laboratory evaluation.	1. Skillful assessment helps detect early symptoms of side effects of medications.	• Adheres to monitoring procedures and experiences minimal side effects • Takes medication as prescribed and lists potential side effects • Identifies strategies to reduce or manage side effects • Reports that side effects or complications have subsided
2. Provide education about correct self-administration, potential side effects, and importance of monitoring.	2. The patient needs accurate information about medications and potential side effects to avoid or manage them.	
3. Counsel regarding methods to reduce side effects and manage symptoms.	3. Appropriate identification and early intervention may minimize complications.	
4. Administer medications in modified doses as prescribed if complications occur.	4. Modifications may help minimize side effects or other complications.	

treatment. In addition, exercise programs may not be instituted or may be ineffective because the patient expects results to occur quickly or fails to appreciate the effectiveness of a program of exercise. In fact, strength training is encouraged in the older adult with chronic diseases.

Diffuse Connective Tissue Diseases

Diffuse connective tissue disease refers to a group of systemic disorders that are chronic in nature and are characterized by diffuse inflammation and degeneration in the connective tissues. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities. They include RA, SLE, scleroderma, polymyositis, Sjögren's syndrome, polymyalgia rheumatica (PMR), and giant cell arteritis (GCA).

Rheumatoid Arthritis

RA is an autoimmune disease of unknown origin that affects 1% of the population worldwide, with females having a 2.5 times greater incidence than males. It may occur at any age but the onset commonly occurs between the third and sixth decade of life. The incidence of RA increases after the sixth decade of life (Carter et al., 2015). Risk factors for the development of RA include environmental factors such as pollution and smoking, family history of first-degree relatives, and illnesses such as bacterial and viral illnesses. Cigarette smoking is one modifiable risk factor that has been shown to be highly related to RA (Carter et al., 2015).

Pathophysiology

The exact mechanism of action for the etiology of RA is unknown. Research has, however, identified that the autoimmune reaction (see Fig. 57-1) originates in the synovial tissue. It is hypothesized that both environmental factors, such as cigarette smoking, and genetic factors coalesce to produce inflammatory and destructive synovial fluid, starting in the more distal joints. This RA synovium breaks down collagen, causing edema, proliferation of the synovial membrane, and ultimately pannus formation. Pannus destroys cartilage and erodes the bone. The consequence is the loss of articular surfaces and joint motion. Muscle fibers undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

The RA inflammatory process has also been implicated in other disease processes (i.e., arteriosclerosis). It is hypothesized that the RA disease process somehow interferes with the production of high-density lipoprotein cholesterol, which is the form of cholesterol responsible for decreasing cellular lipids and, therefore, is considered antiatherosclerotic.

The nervous system is also affected by the RA inflammatory process. The synovial inflammation can compress the adjacent nerve, causing neuropathies and paresthesias. Axonal degeneration and neuronal demyelination are also possible due to the infiltration of polymorphonuclear leukocytes, eosinophils, and mononuclear cells, causing necrotizing or occlusive vasculitis (Ramos-Remus, Duran-Barragan, & Castillo-Ortiz, 2012).

Clinical Manifestations

The American College of Rheumatology and the European League Against Rheumatism have collaborated and established new criteria for classifying RA. These criteria are based on a point system where a total score of 6 or greater is required for the diagnosis of RA. The scoring system is based on joint involvement (number of joints affected), serology (low positive or high positive rheumatoid factor [RF] or anti-citrullinated peptide antibody [ACPA]), abnormal results of the acute phase reactants (erythrocyte sedimentation rate [ESR] or C- reactive protein [CRP]), and duration of symptoms greater than 6 weeks. Patients diagnosed with RA who are excluded from these diagnostic criteria include: (1) patients who have one joint with synovitis that is not related to any other clinical disease and who also score at least 6 to 10 points on the scale, and (2) patients diagnosed with bony erosions on X-ray (Aletaha, Neogi, Silman, et al. 2010).

The initial clinical manifestations of RA include symmetric joint pain and morning joint stiffness lasting longer than 1 hour. Over the course of the disease, clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Symmetric joint pain, swelling, warmth, erythema, and lack of function are classic symptoms. Palpation of the joints reveals spongy or boggy tissue. Often, fluid can be aspirated from the inflamed joint. Characteristically, the pattern of joint involvement begins in the small joints of the hands, wrists, and feet (Klippel, Stone, Crofford, et al., 2008); (Papadakis et al., 2015). As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints are affected. The onset of symptoms is usually acute. Symptoms are usually bilateral and symmetric.

In the early stages of disease, even before the presentation of bony changes, limitation in function can occur when there is active inflammation in the joints. Joints that are hot, swollen, and painful are not easily moved. The patient tends to guard or protect these joints by immobilizing them. Immobilization for extended periods can lead to contractures, creating soft tissue deformity.

Deformities of the hands (e.g., ulnar deviation and swan neck deformity) and feet are common in RA (see Fig. 35-6 in Chapter 35). The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when one bone slips over another and eliminates the joint space. Deformities of RA differ from those seen with osteoarthritis (OA), such as Heberden's and Bouchard's nodes.

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, anemia, lymph node enlargement, and Raynaud's phenomenon (cold- and stress-induced vasospasm causing episodes of digital blanching or cyanosis). Rheumatoid nodules may be noted in patients with more advanced RA, and they develop at some time in the course of the disease in about 20% of patients (Papadakis et al., 2015). These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences such as the elbow, are varied in size, and can disappear spontaneously. Nodules occur only in people who have rheumatoid factor. The nodules often are associated with rapidly progressive and destructive disease. Other extra-articular features include arteritis, neuropathy, pericarditis, splenomegaly, and Sjögren's syndrome (dry eyes and dry mucous membranes).

Assessment and Diagnostic Findings

Several assessment findings are associated with RA: rheumatoid nodules, joint inflammation detected on palpation, and laboratory findings. The history and physical examination focus on manifestations, such as bilateral and symmetric stiffness, tenderness, swelling, and temperature changes in the joints. The patient is also assessed for extra-articular changes; these often include weight loss, sensory changes, lymph node enlargement, and fatigue. Symptoms and examination findings are often recorded using a Disease Activity Score-28 (DAS28) form to evaluate disease activity and help guide treatment decisions.

RA inflammatory processes have also been implicated in arterial wall stiffness and endothelial dysfunction. It is now believed that cardiovascular risks are similar to the risks of patients with diabetes. Therefore, cardiovascular risk assessment should be included in the patient's physical assessment (Palmer & El Miedany, 2014).

Rheumatoid factor is present in about 70% to 80% of patients with RA, but its presence alone is not diagnostic of RA, and its absence does not rule out the diagnosis. Antibodies to cyclic citrullinated peptide (anti-CCP) have a specificity of approximately 95% at detecting RA (Papadakis et al., 2015). The ESR and CRP tend to be significantly elevated in the acute phases of RA and are therefore useful in monitoring active disease and disease progression. The complete blood count (CBC) should be assessed to establish a baseline count especially prior to starting medications. Patients may exhibit anemia, and platelets may be elevated due to the inflammatory process. A tuberculin (TB) skin test should be done prior to the initiation of certain medications to rule out tuberculosis. In the event the patient has latent TB and has never been treated, the infection can be reactivated. Hepatitis B and Hepatitis C should also be assessed for diagnosis, which could impact treatment strategies if positive. If the client tests positive for hepatitis, the infection should be treated prior to starting medication. Liver and kidney monitoring is recommended for most DMARD therapy because it can cause elevation of the liver enzymes and can also affect kidney function.

X-ray, ultrasound, or both of the hands, wrists, and feet can be useful in establishing a baseline for joint evaluation, and assessing the joints for erosions and synovitis. Joint damage may occur within the first 6 to 12 months of diagnosis and should be followed as indicated. MRI can also be useful to detect small erosions that may not be visible on x-ray or ultrasound.

Arthrocentesis may also be performed on any affected joint. Results of the arthrocentesis may show synovial fluid that is cloudy, milky, or dark yellow and may contain numerous inflammatory components. Recommended tests to perform on synovial fluid include WBC with differential, cultures, gram stain and crystals (Sholter & Russell, 2016).

Medical Management

The goal of treatment at all phases of the RA disease process is to decrease joint pain and swelling, achieve clinical remission, decrease the likelihood of joint deformity, and minimize disability. Initial treatment delays have been implicated in greater long-term joint deformity. Aggressive and early treatment regimens are warranted.

Early Rheumatoid Arthritis

Once the diagnosis of RA is made, treatment should begin with either a nonbiologic or biologic DMARD. The goal of using DMARD therapy is preventing inflammation and joint damage. Recommended treatment guidelines include beginning with the nonbiologic DMARDs (methotrexate [Rheumatrex], leflunomide [Arava], sulfasalazine [Azulfidine]), or hydroxychloroquine (Plaquenil) within 3 months of disease onset. Care should be used with each of these medications, by performing routine blood testing for liver and kidney function, along with monitoring the CBC for anemia. Dosage may need to be modified for patients with renal impairment. Annual eye examinations are also recommended with the use of sulfasalazine and hydroxychloroquine (Carter et al., 2015).

After initiating treatment with a DMARD, patients generally report a beneficial effect within 6 weeks and tolerate the medication relatively well (Papadakis et al., 2015). However, some patients may take longer to see improvement. Research suggests that methotrexate combined with low-dose prednisone improves patient outcome compared to the use of methotrexate alone for early RA.

Another treatment approach for RA is the use of biologic DMARDs. These agents have been specifically engineered to target the most prominent proinflammatory mediators in RA—TNF-α, B cells, T cells, IL-1, and IL-6 (Klippel et al., 2008) (see Table 57-3). Biologic DMARDs are the first targeted therapy for RA. Clinical evidence suggests that biologic DMARDs work more quickly and show a greater delay in radiologic disease progression when compared to nonbiologic DMARDs (Klippel et al., 2008). The biologic DMARDs are more expensive and have fewer years of usage with the RA population. Therefore, they tend to be reserved for patients with persistent moderate-to-severe RA who have not responded adequately to synthetic DMARDs (Papadakis et al., 2015).

NSAIDs and specifically the cyclooxygenase 2 (COX2) enzyme blockers are used for pain and inflammation relief. NSAIDs, such as ibuprofen (Motrin) and naproxen (Naprosyn), are commonly prescribed because of their low cost and analgesic properties. They must be used, however, with caution in long-term chronic diseases because of the possibility of gastric ulcers. Several COX-2 enzyme blockers have been approved for treatment of RA. Cyclo-oxygenase is an enzyme that is involved in the inflammatory process. COX-2 medications block the enzyme involved in inflammation (COX-2) while leaving intact the enzyme involved in protecting the stomach lining (COX-1). As a result, COX-2 enzyme blockers are less likely to cause gastric irritation and ulceration than other NSAIDs; however, they are associated with increased risk of cardiovascular disease and must be used with caution (Karch, 2014). The nurse should be aware that no NSAIDs, not even the COX-2 inhibitors, prevent erosions or alter disease progression and, consequently, are medications useful only for symptom relief.

Additional analgesia may be prescribed for periods of extreme pain. Opioid analgesic agents are avoided because of the potential for continuing need for pain relief. Nonpharmacologic pain management techniques (e.g., relaxation techniques, heat and cold applications) are taught (Carter et al., 2015).

Moderate, Erosive Rheumatoid Arthritis

For moderate, erosive RA, a formal program with occupational and physical therapy is prescribed to educate the patient about principles of pacing activities, work simplification, range of motion, and muscle-strengthening exercises. The patient is encouraged to participate actively in the management program. The medication program is reevaluated periodically, and appropriate changes are made if indicated. Cyclosporine, an immunosuppressant, may be added to enhance the disease-modifying effect of methotrexate (Klippel et al., 2008). Combination therapy using one nonbiologic DMARD and one biologic DMARD is common.

Persistent, Erosive Rheumatoid Arthritis

For persistent, erosive RA, reconstructive surgery and corticosteroids are often used. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures and the threat of loss of independence is eminent. Surgical procedures include synovectomy (excision of the synovial membrane), tenorrhaphy (suturing of a tendon), arthrodesis (surgical fusion of the joint), surgical repair, and replacement of the joint. Surgery is not performed during exacerbations.

Systemic corticosteroids are used when the patient has unremitting inflammation and pain or needs a "bridging" medication while waiting for the slower DMARDs (e.g., methotrexate) to begin taking effect. Low-dose corticosteroid therapy is prescribed for the shortest time necessary to minimize side effects (Papadakis et al., 2015). Single large joints that are severely inflamed and fail to respond promptly to the measures outlined previously may be treated by local injection of a corticosteroid.

Advanced, Unremitting Rheumatoid Arthritis

For advanced, unremitting RA, immunosuppressive agents are prescribed because of their ability to affect the production of antibodies at the cellular level. These include high-dose methotrexate, cyclophosphamide (Cytoxan), and azathioprine (Imuran). However, these medications are highly toxic and can produce bone marrow suppression, anemia, gastrointestinal disturbances, severe birth defects, and rashes (Karch, 2014).

For most patients with RA, the emotional and possible financial burden of the disease can lead to depressive symptoms and sleep deprivation. The patient may require the short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), paroxetine (Paxil), or sertraline (Zoloft), to reestablish an adequate sleep pattern and manage depressive

symptoms. Patients may benefit from referrals for talk therapy or group support.

Nutrition Therapy

Patients with RA frequently experience anorexia, weight loss, and anemia. A dietary history identifies usual eating habits and food preferences. Two common problems seen in these patients are weight loss and rheumatoid cachexia (loss of skeletal muscle). Increased metabolism and decreased intake contribute to these losses. Increased and prolonged flares contribute to the increased expenditure as well. The dietician will counsel the patient about better food choices. Food selection should include the five major groups (grains, vegetables, fruits, dairy, and protein), with emphasis on foods high in vitamins, protein, and iron for tissue building and repair. For the patient who is extremely anorexic, small, frequent feedings with increased protein supplements may be prescribed. Supplemental vitamins and minerals may also be prescribed as needed. Boswellia, ginger, green tea, and turmeric have been studied for helping with inflammation and pain. However, the American College of Rheumatology does not recommend herbal supplements to treat RA as the U.S. Food and Drug Administration (FDA) does not regulate the safety and effectiveness of herbal supplements (Afshar, 2015).

Certain medications (i.e., oral corticosteroids) used in RA treatment stimulate the appetite and, when combined with decreased activity, may lead to weight gain. Therefore, patients may need to be counseled about eating a healthy, calorie-restricted diet.

Nursing Management

Nursing care of the patient with RA follows the basic plan of care presented earlier (see Chart 57-2). The most common issues for the patient with RA include pain, sleep disturbance, fatigue, altered mood, and limited mobility. The patient with newly diagnosed RA needs information about the disease to make daily self-management decisions and cope with having a chronic disease. Consultation with a dietician for assessment and assistance with appropriate food choices may be helpful.

Monitoring and Managing Potential Complications

Patients commonly have comorbid conditions such as cardiovascular disease that can lead to complications. It has been estimated that the primary cause of death for up to 40% of patients diagnosed with RA is cardiovascular disease. The cause of cardiovascular disease in these patients is thought to be due to elevated lipid values, chronic inflammation, dysfunction of the endothelium, and/or abnormal homocysteine levels (Palmer & El Miedany, 2014).

Medications used for treating RA may cause serious adverse effects. The primary provider bases the prescribed medication regimen on clinical findings and past medical history, and then, with the help of the nurse, monitors for side effects using periodic clinical assessments and laboratory testing. The nurse, who can be available for consultation between visits with the primary provider, works to help the patient recognize and deal with these side effects (see Table 57-3). Medication may need to be stopped or the dose reduced. If the patient experiences an increase in symptoms while the complication is being resolved or a new medication is being initiated, the nurse's counseling regarding symptom management may relieve potential anxiety and distress.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

Patient education is an essential aspect in nursing care of the patient with RA to enable the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly (Cottrell, Jonas, Bergsten, et al., 2013). Patient education focuses on the disorder itself, the possible changes related to the disorder, the therapeutic regimen prescribed to treat it, and the potential side effects of medications (see Nursing Research Profile in Chart 57-3). Patients undergoing surgery need education as well. The nurse works with the patient and family on strategies to maintain independence, function, and safety in the home (see Chart 57-4).

The patient and family are encouraged to verbalize their concerns and ask questions. Because RA commonly affects young women, major concerns may be related to the effects of the disease on childbearing potential, caring for family, or work responsibilities. The patient with a chronic illness may seek a "cure" or have questions about alternative therapies. There is not enough evidence of the effectiveness of complementary, alternative, and integrative health therapies, and more rigorous research is needed (Marcus, 2015).

Chart 57-3 NURSING RESEARCH PROFILE

Addressing Unmet Needs of Patients with Rheumatoid Arthritis

Cottrell, J. D., Jonas, M., Bergsten, U., et al. (2013). The nurse's role in addressing unmet treatment and management needs of patients with rheumatoid arthritis: Delphi-based recommendations. International Journal of Nursing Knowledge, 24(2), 66–76.

Purpose

Nurses spend a lot of time with patients with rheumatoid arthritis (RA). The purpose of this research was to evaluate the nurse's role in management of patients with RA.

Design

The modified Delphi methodology was the design for this study. Three rheumatology nurses developed a survey questionnaire. An additional group of 12 international rheumatology nurses, with extensive patient management experience, served as an expert panel. The survey was given to the panel of 12 rheumatology nurses in two online rounds and then in a third round during an in-person meeting.

Findings

The nurse has many roles in the management of patients with RA. In this study, the nurse's reported roles involved providing care, educating about treatment, performing a disease assessment, giving the patient treatment feedback, helping patients with unmet physical and emotional needs, and explaining complex treatments.

Nursing Implications

Rheumatology nurses are in a position to be able to expand the nursing role for patients diagnosed with RA. These nurses already perform the roles of caregiver and educator, and provide disease assessment. It is important for nurses to also address unmet patient needs, provide improved patient care, and perform additional functions for the patients to meet unmet physical and emotional needs.

Chart 57-4 HOME CARE CHECKLIST

The Patient with Rheumatoid Arthritis

At the completion of education, the patient, caregiver, or both will be able to:

- State the impact of rheumatoid arthritis on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity, rest) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate accurate and safe self-administration of medications.
- Describe and demonstrate the use of pain management techniques.
- Demonstrate ability to perform ADLs independently or with assistive devices/adaptive equipment.
- Verbalize ways to cope with stress successfully, plans for regular, safe exercise, and rationale for obtaining adequate rest.
- Demonstrate a relaxation technique.
- Verbalize a dietary plan that includes increased vitamins, protein, and iron for tissue building and repair
- State how to reach primary provider with questions or complications
- State time and date of follow-up appointments, testing
- Identify the need for health promotion, disease prevention, and screening activities
- Identify community resources for peer and caregiver/family information and support:
- Identify sources of support (e.g., friends, relatives, faith community)
- Identify phone numbers of support groups for people with chronic illness/disabilities and their caregivers/families
- State meeting locations and times

ADLs, activities of daily living; IADLs, independent activities of daily living.

Pain, fatigue, and depressive symptoms can interfere with the patient's ability to learn and should be addressed before the instruction is initiated. Various educational strategies may then be used, depending on the patient's previous knowledge base, interest level, degree of comfort, social or cultural influences, and readiness to learn. The nurse educates the patient about basic disease management and necessary adaptations in lifestyle. Some types of aerobic exercise and strength training should be discussed. Because suppression of inflammation and autoimmune responses requires the use of anti-inflammatory, disease-modifying antirheumatic, and immunosuppressive agents, the patient is taught about prescribed medications, including type, dosage, rationale, potential side effects, self-administration, and required monitoring procedures. If hospitalized, the patient is encouraged to practice new self-management skills with support from caregivers and significant others. The nurse then reinforces disease management skills during each patient contact. Barriers are assessed, and measures are taken to promote adherence to medications and the treatment program.

Continuing and Transitional Care

Depending on the severity of the disease and the patient's resources and supports, referral for home care may be warranted. For example, the patient who is an older adult or frail, has RA that limits function significantly, and lives alone may need referral for home care.

The impact of RA on everyday life is not always evident when the patient is seen in the hospital or in an ambulatory care setting. The increased frequency with which nurses see patients in the home provides opportunities for recognizing problems and implementing interventions aimed at improving the quality of life of patients with RA.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Adherence to the treatment program can be more easily monitored in the home setting, where physical and social barriers to adherence are more readily identified. For example, a patient who also has diabetes and requires insulin may be unable to fill the syringe accurately or unable to administer the insulin because of impaired joint mobility. Appropriate adaptive equipment needed for increased independence is often identified more readily when the nurse sees how the patient functions in the home. Any barriers to adherence are identified, and appropriate referrals are made.

For patients at risk for impaired skin integrity, the home care nurse can closely monitor skin status and also educate, provide, or supervise the patient and family in preventive skin care measures. The nurse also assesses the patient's need for assistance in the home and supervises home health aides, who may meet many of the needs of the patient with RA. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase. A home care nurse may visit the home to make sure that the patient can function as independently as possible despite mobility problems and can safely manage treatments, including pharmacotherapy.

Because many of the medications used to suppress inflammation are injectable, the nurse may administer the medication to the patient or educate about self-injection. These frequent contacts allow the nurse to reinforce other disease management techniques.

The nurse also assesses the patient's physical and psychological status, adequacy of symptom management, and adherence to the management plan. Patients should know which type of rheumatic disease they have, not just that they have "arthritis" or "arthritis of the knee." The importance of attending follow-up appointments is emphasized to the patient and family, and they should be reminded about the importance of participating in other health promotion activities and health screening.

Systemic Lupus Erythematosus

SLE is an inflammatory, autoimmune disorder that affects nearly every organ in the body. The overall incidence of SLE is estimated to be 1.8 to 7.6 per 100,000 persons (Centers for Disease Control and Prevention [CDC], 2015a). It occurs 6 to10 times more frequently in women than in men and occurs 3 times more in African American populations than among Caucasians (CDC, 2015a); (Lim, Bayakly, Helmick, et al., 2014). In addition to SLE, many other forms of adult lupus exist, including discoid lupus erythematosus (which primarily affects the skin on the face), subacute cutaneous lupus erythematous (sun exposed areas affected with sores), and drug-induced lupus (rarely includes brain or kidney effects and is usually temporary).

Pathophysiology

SLE starts with the body's immune system inaccurately recognizing one or more components of the cell's nucleus as foreign, seeing it as an antigen. The immune system starts to develop antibodies to the nuclear antigen. In particular, B cells begin to overproduce antibodies with the help of multiple cytokines such as B-lymphocyte stimulator (BLyS), which is overexpressed in SLE. The antibodies and antigens form antigen–antibody complexes and have the propensity to get trapped in the capillaries of visceral structures. The antibodies also act to destroy host cells. It is thought that those two mechanisms are responsible for the majority of the clinical manifestations of this disease process. It is hypothesized that the immunoregulatory disturbance is brought about by some combination of four distinct factors: genetic, immunologic, hormonal, and environmental (Carter et al., 2015).

Research into the genetic origins of SLE has thus far revealed that multiple genes are likely implicated in the development of SLE. In support of this theory, research with homozygous twins has shown a higher incidence of SLE, especially considering that the prevalence of SLE was low in other family members (Bartels, 2015). The large majority of SLE cases, however, remain sporadic and unrelated to family medical history.

Given the acute number of women with SLE compared with men, it is hypothesized that female sex hormones (estrogen) play a role in the predisposition to SLE. Estrogen may contribute to the body's response of overreacting to the body's own tissues.

Although genetics and hormones likely play a role in the predisposition of SLE, it is hypothesized that an exogenous or environmental trigger is implicated in the onset of the disease process. These triggers may include cigarette smoke, ultraviolet rays exposure from sunlight and fluorescent light bulbs, medications (sulfa drugs, penicillin, or antibiotic drugs), viral, infections, emotional stress, stress on the body (e.g., surgery, pregnancy), and silica dust exposure in the occupational setting (Carter et al., 2015).

Clinical Manifestations

SLE is an autoimmune, systemic disease that can affect any body system. The disease process involves chronic states where symptoms are minimal or absent and acute flares where symptoms and lab results are elevated. Systemic symptoms include fever, malaise, weight loss, and anorexia. The mucocutaneous, musculoskeletal, renal, nervous, cardiovascular, and respiratory systems are most commonly involved. Less commonly affected are the gastrointestinal tract and liver as well as the ocular system.

Some type of cutaneous system manifestation is experienced in 80% to 90% of patients with SLE (Bartels, 2015); (Klippel et al., 2008). Four of the 11 criteria used for diagnosing SLE by the American College of Rheumatology involve the cutaneous system. The most familiar skin manifestation (occurring in less than 50% of patients with SLE) is an acute cutaneous lesion consisting of a butterfly-shaped erythematous rash across the bridge of the nose and cheeks (see Fig. 57-2). Several other skin manifestations may occur in patients with SLE, including subacute cutaneous lupus erythematosus, which involves papulosquamous or annular polycyclic lesions, and a discoid rash, which is a chronic rash with erythematous papules or plaques and scaling and can cause scarring and pigmentation changes. In some cases, the only skin involvement may be a discoid rash. In some patients with SLE, the initial skin involvement is the precursor to more systemic involvement. The lesions often worsen during **exacerbations** (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet light (Bartels, 2015); (Klippel et al., 2008). Oral ulcers, which may accompany skin lesions, may involve the buccal mucosa or the hard palate, occur in crops, and are often associated with exacerbations. Other cutaneous manifestations include splinter hemorrhages, alopecia, and Raynaud's phenomenon.

Figure 57-2 • The characteristic butterfly rash of systemic lupus erythematosus.

Joint symptoms, with arthralgias, arthritis (synovitis), or both, occur in more than 90% of patients with SLE and are commonly the earliest manifestation of the disease process (Papadakis et al., 2015). Joint swelling, tenderness, and pain on movement are also common. Frequently, these are accompanied by morning stiffness.

The cardiac system is also commonly affected in SLE. Pericarditis is the most common cardiac manifestation (Bartels, 2015); (Klippel et al., 2008). Patients may present with substernal chest pain that is aggravated by movement or inspiration. Symptoms can be acute and severe or last for weeks at a time. Other cardiac symptoms may involve myocarditis, hypertension, cardiac dysrhythmias, and valvular incompetence. Women who have SLE are also at risk for early-onset atherosclerosis, making them much more likely to suffer myocardial infarction or stroke. These events, which are believed to be secondary to the accelerated atherosclerosis, may contribute to higher rates of death for women with SLE. Inflammation is believed to be the key factor in the development and progression of atherosclerosis (Bartels, 2015).

Nephritis as a result of SLE, also referred to as lupus nephritis, occurs due to a buildup of antibodies and immune complexes that cause damage to the nephrons. Serum creatinine levels and urinalysis are used in screening for renal involvement. Early detection allows for prompt treatment so that renal damage can be prevented. Renal involvement may lead to hypertension, which also requires careful monitoring and management (see Chapter 25).

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease. The varied and frequent neuropsychiatric presentations of SLE are now widely recognized and include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. These are generally demonstrated by subtle changes in behavior patterns or cognitive ability.

Assessment and Diagnostic Findings

Diagnosis of SLE is based on a complete history, physical examination, and blood tests. In addition to the general assessment performed for any patient with a rheumatic disease, assessment for known or suspected SLE has special features. The skin is inspected for erythematous rashes. Cutaneous erythematous plaques with an adherent scale may be observed on the scalp, face, or neck. Areas of hyperpigmentation or depigmentation may be noted, depending on the phase and type of disease. The patient should be questioned about skin changes (because these may be transitory) and specifically about sensitivity to sunlight or artificial ultraviolet light. The scalp should be inspected for alopecia and the mouth and throat for ulcerations reflecting gastrointestinal involvement.

Cardiovascular assessment includes auscultation for pericardial friction rub, possibly associated with myocarditis and accompanying pleural effusions. The pleural effusions and infiltrations, which reflect respiratory insufficiency, are demonstrated by abnormal lung sounds. Papular, erythematous, and purpuric lesions developing on the fingertips, elbows, toes, and extensor surfaces of the forearms or lateral sides of the hand that may become necrotic suggest vascular involvement.

Joint swelling, tenderness, warmth, pain on movement, stiffness, and edema may be detected on physical examination. The joint involvement is often symmetric and similar to that found in RA.

The neurologic assessment is directed at identifying and describing any central nervous system changes. The patient and family members are asked about any behavioral changes, including manifestations of neurosis or psychosis. Signs of depression are noted, as are reports of seizures, or other central nervous system manifestations.

The American College of Rheumatology has established criteria for the classification of SLE involving 11 distinct elements (American College of Rheumatology, 1997) (see Chart 57-5). The diagnosis of SLE is generally made if 4 of the 11 criteria are present, either serially or simultaneously.

The ANA is positive in more than 95% of patients with SLE, indicating exceptional specificity. Other laboratory tests include anti-DNA (antibody that develops against the patient's own DNA), anti-ds DNA (antibody against DNA that is highly specific to SLE, which helps differentiate it from drug-induced lupus), and anti-Sm (antibody against Sm, which is a specific protein found in the nucleus). Other blood work includes the CBC, which may reveal anemia, thrombocytopenia, leukocytosis, or leukopenia (Klippel et al., 2008).

Medical Management

SLE can be life-threatening, but advances in its treatment have led to improved survival and reduced morbidity. Acute disease requires interventions directed at controlling increased disease activity or exacerbations that can involve any organ system. Disease activity is a composite of clinical and laboratory features that reflect active inflammation secondary to SLE. Management of the more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy.

The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disabilities, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

Chart 57-5

Criteria for Classifying Systemic Lupus Erythematosus

The American College of Rheumatology (ACR) established criteria for the classification of systemic lupus erythematosus (SLE) in 1982. These were updated in 1997, and include four cutaneous, four systemic, and three laboratory criteria. Diagnosis is determined by evaluating presenting signs and symptoms, laboratory results, and the patient's medical history and medical history of family members. The ACR-established criteria are as follows:

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Nonerosive arthritis
- Pleuritis or pericarditis
- Kidney disease
- Neurologic disease
- Hematologic disorder
- Immunologic disorder
- Positive antinuclear antibody

Based on the 11 criteria above, a person is diagnosed with systemic lupus erythematosus if any 4 or more of the criteria are met at any time.

Arthritis and Rheumatism, 40(9), 1725; Tan, E. M., Cohen, A. S., Fries, J. F., et al. (1982). The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis and Rheumatism, 25(11), 1271–1277.

Pharmacologic Therapy

The mainstay of SLE treatment is based on pain management and nonspecific immunosuppression. Therapy includes monoclonal antibodies, corticosteroids, antimalarial agents, NSAIDs, and immunosuppressive agents. Each of these medications has potentially serious side effects, including organ damage.

Belimumab (Benlysta) is approved by the FDA for the treatment of SLE (Carter et al., 2015). Belimumab is a monoclonal antibody that specifically recognizes and binds to BLyS. BLyS acts to stimulate B cells to produce antibodies against the body's own nuclei, which is an integral part of the disease process in SLE. Belimumab acts to render BLyS inactive, preventing it from binding to B-cell surfaces and stimulating B-cell activity. This action then halts the production of unnecessary antibodies and decreases disease activity in SLE. Research suggests that belimumab reduces disease activity and flares in patients with SLE. Live vaccines are contraindicated while taking this medication, and caution should be used with all concurrent medications given the short duration that belimumab has been available.

Corticosteroids are another medication used topically for cutaneous manifestations, in low oral doses for minor disease activity, and in high doses for major disease activity. Intravenous (IV) administration of corticosteroids is an alternative to traditional high-dose oral administration. One of the most

important risk factors associated with the use of corticosteroids in SLE is osteoporosis and fractures. In fact, osteopenia is reported in 25% to 74% and osteoporosis in 1.4% to 68% of patients with SLE (Bultink, 2012).

An antimalarial medication approved by the FDA, hydroxychloroquine, is effective for managing cutaneous, musculoskeletal, and mild systemic features of SLE. The NSAIDs used for minor clinical manifestations are often used in conjunction with corticosteroids in an effort to minimize corticosteroid requirements.

Immunosuppressive agents (alkylating agents and purine analogues) are used because of their effect on overall immune function. These medications are generally reserved for patients who have serious forms of SLE that have not responded to conservative therapies. Examples include cyclophosphamide, azathioprine, mycophenolic acid (Myfortic), and methotrexate, which are contraindicated in pregnancy and have been used most frequently in SLE nephritis (Carter et al., 2015).

Nursing Management

Nursing care of the patient with SLE is based on the fundamental plan presented earlier in the chapter (see Chart 57-2). The most common nursing diagnoses include fatigue, impaired skin integrity, body image disturbance, and deficient knowledge for self-management decisions. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and the unpredictable course of SLE necessitate expert assessment skills and nursing care with sensitivity to the psychological reactions of the patient. In particular, patients with SLE report feelings of depression and anxiety as well as difficulty coping with the disease and the financial strain associated with it (Fonseca, Bernardes, Terroso, et al., 2014). The patient may benefit from participation in support groups, which can provide disease information, daily management tips, and social support. Because sun and ultraviolet light exposure can increase disease activity or cause an exacerbation, patients should be instructed to avoid exposure or to protect themselves with sunscreen and clothing.

Because of the increased risk of involvement of multiple organ systems, patients should understand the need for routine periodic screenings as well as health promotion activities. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations, given the increased risk of cardiovascular disease, including hypertension and atherosclerosis. Smoking tobacco accelerates complications in patients with SLE (Chasset, Frances, Barete, et al., 2015). In the healthy population, smoking increases the incidence of respiratory infections, lung cancer, risk of coronary artery disease; increases blood pressure, which can worsen kidney function; inhibits liver function (which can also inhibit treatment medications from working appropriately, such as hydroxychloroquine); increases the risk for skin diseases; and increases the risk for osteoporosis. Patients diagnosed with SLE are at even higher risk of developing lung cancer and other rare cancers. Therefore, smoking cessation programs should be offered to all patients who report smoking habits (Montes, Mocarzel, Lanzieri, et al, 2016).

The nurse educates the patient about the importance of continuing prescribed medications and addresses the changes and potential side effects that are likely to occur with their use. The patient is reminded of the importance of monitoring because of the increased risk of systemic involvement, including renal and cardiovascular effects.

Because of the immunosuppression associated with systemic corticosteroid usage, the nurse must watch for signs and symptoms of infection, especially with acutely ill patients.

The nurse should also screen the patient for osteoporosis, because long-term use of corticosteroids increases the incidence of osteoporosis. Patients should have a bone mineral density test performed at diagnosis and prior to beginning steroid use to determine a baseline status and then every 2 years thereafter. Educating the patient regarding calcium and Vitamin D supplementation daily is encouraged, along with the benefits of weight-bearing activities to support bone health (Cash & Glass, 2015).

Sjögren's Syndrome

Sjögren's syndrome is a systemic autoimmune disease that progressively affects the lacrimal and salivary glands of the body. More than 90% of patients affected are women, and the onset tends to begin between 35 and 50 years of age (Carter et al., 2015).

It is one of the most common autoimmune disorders, affecting approximately 1 out of 1000 people or 2 to 4 million people in the United States (Carter et al., 2015). Sjögren's syndrome is reported rarely and is an uncommon disease in India. One rheumatology center that caters 35 million people reported only 26 patients were affected with Sjögren's syndrome in the 10 years period from 1990–2000 (Misra, Hissaria, Tandon et al., 2003). Sjögren's syndrome very commonly manifests in conjunction with other autoimmune diseases such as RA or SLE.

Pathophysiology

B-cell–mediated antibodies infiltrate the exocrine glands, leading to gland dysfunction and gland destruction. This phenomenon seems to be somewhat regulated by genetics (HLA subtype). There also appears to be environmental triggers such as viruses. Given the clinical makeup and antibodies present, it may also be that Sjögren's disease is a subtype of SLE (Klippel et al., 2008).

Clinical Manifestations

The most common symptoms involve dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia). Some patients will complain that their eyes feel "gritty," as if there is sand present. The patient's eyes will exhibit increased redness and lack of tearing. These ocular symptoms can also lead to increased levels of anxiety and depression. The mouth will have dry and sticky mucous membranes. The reduced saliva production may lead to difficulty swallowing.

Sjögren's syndrome can also exhibit symptoms in many other organ systems. Vasculitis (5% to 10%) can manifest with palpable purpura on the skin (Quemeneur, Mouthon, Cacoub, et al., 2013). Lesions may ulcerate and can be painful. Optic neuritis, trigeminal neuralgia, and sensory neuropathy may be present, with symptoms such as burning pain in the extremities, numbness, vertigo, arthralgia, and/or myalgia. Raynaud's phenomenon, which involves blood vessel spasms leading to decreased circulation to the toes, fingers, nose and ears, is noted in 13% to 62% of patients (Klippel et al., 2008). Symptoms such as cough, dyspnea, and abdominal pain may also occur.

Assessment and Diagnostic Findings

The classification criteria for diagnosis of Sjögren's syndrome identify six distinct indices (Klippel et al., 2008):

- Ocular symptoms such as chronic dry eye (Keratoconjunctivitis Sicca).

- Positive ocular tests (evaluating tear production, corneal, and conjunctival damage). Ocular testing may include Schimer test or Rose Bengal staining tests.
- Oral symptoms, dry mouth.
- Histopathology evaluation (of salivary glands). This will help differentiate the cause of dry mouth from other causes, such as infection, malignancy, stones, and sarcoidosis.
- Salivary gland involvement.

Laboratory tests include autoantibodies to ribonucleoprotein particles (Ro[SS-A] and/or La[SS-B]), which act as antigens in this disease process. Other laboratory indices are also useful in diagnosing Sjögren's syndrome. Rheumatoid factor is present in 50% to 70% of patients. ANA, circulating DNA (cDNA), anti-CCP, and anticentromere antibody (ACA) are all potentially present in Sjögren's syndrome and in some cases may act as markers for disease activity (Moerman, Bootsma, Kroese, et al., 2013).

For vasculitis manifestations, a skin biopsy can yield useful information such as leukocytoclastic vasculitis found on histologic examination. If neurologic symptoms are present, nerve conduction studies, MRI, electroencephalograms, and cerebrospinal fluid testing may be used to aid in diagnosis and treatment planning.

Medical Management

There is no cure for Sjögren's syndrome, and treatment is aimed at symptom management. Artificial tears, drops such as pilocarpine (Piloptic), and ocular ointments such as topical cyclosporine are used for dry eyes. Tears normally drain through the lacrimal puncta to the nose, which can render artificial tears ineffective. Therefore, punctum plugs have become very important management tools. For dry mouth, systemic cholinergic agents such as cevimeline (Evoxac) are used regularly (Klippel et al., 2008). Biotene oral rinse may also be useful for some patients. Additional suggestions include eating small frequent meals; omitting spicy, salty, and irritating food; and avoiding smoking, excessive alcohol use, and drugs with anticholinergic side effects. For severe cases, biologic DMARDs such as rituximab and belimumab and nonbiologic DMARDs such as hydroxychloroquine are sometimes used, but evidence regarding their effectiveness is limited (Carter et al., 2015).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 57-2). The most frequent nursing diagnoses for the patient with Sjögren's syndrome are altered skin integrity, self-care deficit, and deficient knowledge of self-management techniques.

The nurse is in the unique position to reinforce the treatment regimen with the patient, especially involving the ocular treatments to avoid sequelae-like eye infections secondary to the dry eyes.

Scleroderma

Scleroderma is a compilation of autoimmune diseases affecting the connective tissue of the skin, blood vessel walls, and internal organs. There are two general types: localized (affecting only the cutaneous system) and systemic (routinely referred to as systemic sclerosis and affecting multiple organ systems). Scleroderma is a rare disease affecting 250 patients per million population (Klippel et al., 2008). Similar to other autoimmune diseases, women are affected three to five times more than men, and the onset occurs typically between the ages of 30 and 50 years. African American patients are affected much younger and have more diffuse symptoms with more severe lung disease. Scleroderma has a variable course with remissions and exacerbations (Varga, 2014).

Pathophysiology

The pathogenesis is poorly understood. Scleroderma commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues. Initially, the inflammatory response causes edema, with a resulting taut, smooth, and shiny skin appearance. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, major organs, and body systems (Varga, 2014). Both genetics and environmental factors can influence the disease process.

Clinical Manifestations

Scleroderma starts insidiously with Raynaud's phenomenon and swelling in the hands. Raynaud's phenomenon is observed in 90% of patients with scleroderma and can precede the official scleroderma diagnosis for years (Varga, 2014). The skin and subcutaneous tissues become increasingly hard and rigid and cannot be pinched up from the underlying structures. Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid (Jordan, Maurer, Toniolo, et al., 2015).

The changes within the body, although not visible directly, are vastly more important than the visible changes. Pulmonary hypertension is one problem that can result and is the leading cause of related death (Varga & Steen, 2015). The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of hardening (sclerosing) of the intestinal mucosa. Progressive kidney failure may occur.

The patient may manifest a variety of symptoms referred to as the CREST syndrome. *CREST* stands for *c*alcinosis (calcium deposits in the tissues), *R*aynaud's phenomenon, *e*sophageal hardening and dysfunction, *s*clerodactyly (scleroderma of the digits), and *t*elangiectasia (capillary dilation that forms a vascular lesion) (Papadakis et al., 2015).

Assessment and Diagnostic Findings

Assessment focuses on the sclerotic changes in the skin, contractures in the fingers, and color changes or lesions in the fingertips. Assessment of systemic involvement requires a systems review with special attention to gastrointestinal, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed, along with the impact the disease has had (or will have) on body image.

There is no one conclusive diagnostic test used to diagnose scleroderma. High-resolution CT is used to diagnose the presence of pulmonary hypertension. Pulmonary function tests and echocardiogram are recommended at diagnosis and yearly thereafter (Varga & Steen, 2015). Echocardiography identifies pericardial effusion (often present with cardiac involvement). Echocardiograms show some promise as well in detecting vascular changes in the early stages of the disease

process. Esophageal studies demonstrate decreased motility in most patients with scleroderma. Blood tests may detect ANAs, indicating a connective tissue disorder and possibly distinguishing the subgroup (diffuse or limited) of scleroderma. A positive ANA test result is common in patients with scleroderma (Varga, 2014).

Medical Management

Treatment of scleroderma depends on the clinical manifestations. All patients require counseling, during which realistic individual goals may be determined. Support measures include strategies to decrease pain and limit disability. A moderate exercise program is encouraged to prevent joint contractures. Patients are advised to avoid extreme temperatures and to use lotion to minimize skin dryness.

Pharmacologic Therapy

No medication regimen is effective in modifying the disease process in scleroderma, but various medications are used to treat organ system involvement. Calcium channel blockers and other antihypertensive agents may provide improvement in symptoms of Raynaud's phenomenon. Anti-inflammatory medications can be used to control arthralgia, stiffness, and general musculoskeletal discomfort. Proton pump inhibitors are used for symptoms of gastric reflux. Aspirin and HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors (statins) are used to help reduce cardiovascular risk factors. Given the propensity toward digital ulcers due to Raynaud's phenomenon and the potential for pulmonary hypertension, vasoactive medications such as epoprostenol (Flolan), bosentan (Tracleer), and sildenafil (Viagra) are used. Immunosuppressive agents such as cyclophosphamide and methotrexate have been used to improve skin and lung function. The antifibrotic agent imatinib mesylate is used to decrease fibrosis in various organs. Ultraviolet A irradiation is sometimes used to decrease the synthesis of collagen in dermal fibrosis and improve skin symptoms (Carter et al., 2015).

Nursing Management

Nursing care of the patient with scleroderma is based on the fundamental plan of nursing care presented earlier (see Chart 57-2). The most common nursing diagnoses are impaired skin integrity; self-care deficits; imbalanced nutrition: less than body requirements; and disturbed body image. The patient with advanced disease may also have impaired gas exchange, decreased cardiac output, impaired swallowing, and constipation.

Providing meticulous skin care and preventing the effects of Raynaud's phenomenon are major nursing challenges. See Chapter 24 for further discussion of Raynaud's phenomenon.

Polymyositis

Polymyositis is a group of diseases that are termed *idiopathic inflammatory myopathies* (Klippel et al., 2008). They are rare conditions, with an incidence estimated at 2 cases per 10,000 adults per year. Polymyositis is most commonly seen in women versus men (2:1) and usually seen between 40 and 50 years of age (Miller & Viegels, 2016).

Pathophysiology

Polymyositis is classified as autoimmune because autoantibodies are present. However, these antibodies do not cause damage to muscle cells, indicating only an indirect role in tissue damage. The pathogenesis is multifactorial, and a genetic predisposition is likely. Drug-induced disease is rare.

Clinical Manifestations

The onset may be very slow and insidious, with symptoms gradually worsening over weeks to months. Proximal muscle weakness is typically the first symptom. Muscle weakness is usually symmetric and diffuse. Common complaints include having difficulty rising from a chair, climbing steps, or holding up the head. Myalgia and muscle tenderness occur in 25% to 50% of patients. Dermatomyositis, a related condition, is most commonly identified by an erythematous smooth or scaly lesion found over the joint surface, which often occurs prior to symptoms of weakness in 50% to 60% of patients (Miller & Viegels, 2016).

Assessment and Diagnostic Findings

A complete history and physical examination help exclude other muscle-related disorders. As with other diffuse connective tissue disorders, no single test confirms polymyositis. An electromyogram is performed to rule out degenerative muscle disease. A muscle biopsy may reveal inflammatory infiltrate in the tissue. Serum studies indicate increased muscle enzyme activity.

Medical Management

Management involves high-dose corticosteroid therapy initially, followed by a gradual dosage reduction over several months as muscle enzyme activity decreases. Patients who do not respond to corticosteroids require the addition of an immunosuppressive agent, such as azathioprine, methotrexate, cyclosporine, or cyclophosphamide. The IV immune globulin given in combination with corticosteroids or another immunosuppressive agent has been noted to be beneficial (Carter et al., 2015). Plasmapheresis, lymphapheresis, and total-body irradiation have been used if there is no response to corticosteroids and immunosuppressive medications. The antimalarial agent hydroxychloroquine may be effective for skin rashes. Physical therapy is initiated slowly, with range-of-motion exercises to maintain joint mobility, followed by gradual strengthening exercises (Klippel et al., 2008).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 57-2). The most frequent nursing diagnoses for the patient with polymyositis are impaired physical mobility, fatigue, self-care deficit, and deficient knowledge of self-management techniques.

Patients with polymyositis may have symptoms similar to those of other inflammatory diseases. However, proximal muscle weakness is characteristic, making activities such as combing the hair, reaching overhead, and using stairs difficult. Therefore, the use of assistive devices may be recommended, and referral to occupational or physical therapy may be warranted.

Polymyalgia Rheumatica and Giant Cell Arteritis

PMR involves stiffness of muscles and pain in the neck, shoulder, and pelvic girdle. GCA is a form of vasculitis affecting the medium-sized and large arteries of the body (Klippel et al., 2008). GCA is also sometimes referred to as temporal arteritis because the majority of arteries affected are extracranial branches of the carotid artery. It is widely agreed, however, that both PMR and GCA represent a spectrum of one disease

(Papadakis et al., 2015). Both primarily affect individuals older than 50 years and are associated with the same HLA haplotype genetic markers. PMR and GCA occur predominately in Caucasians and often in first-degree relatives. PMR has an annual incidence rate of 52 cases per 100,000 people older than 50 years. GCA varies by geographic location and has the highest incidence in Scandinavian countries. PMR is two to three times more common than GCA (Klippel et al., 2008).

Pathophysiology

The underlying mechanism of action involved with PMR and GCA is unknown. It is clear, however, that the immune system is abnormally activated in both disease processes with increases in circulating monocytes that produce IL-1 and IL-6. These circulating monocytes make the endothelial linings of blood vessels more vulnerable to vasculitis (Klippel et al., 2008). Immunoglobulin deposits in the walls of inflamed temporal arteries suggest that an autoimmune process is at work.

Clinical Manifestations

PMR is characterized by severe proximal muscle discomfort with mild joint swelling. Severe aching in the neck, shoulder, and pelvic muscles is common. Stiffness is noticeable most often in the morning and after periods of inactivity. This stiffness can become so severe that patients struggle putting on a coat or combing their hair. Systemic features include low-grade fever, weight loss, malaise, anorexia, and depression. Because PMR usually occurs in people 50 years and older, it may be confused with, or dismissed as, an inevitable consequence of aging.

GCA may cause headaches, changes in vision, and jaw claudication. These symptoms should be evaluated immediately because of the potential for a sudden and permanent loss of vision if the condition is left untreated. PMR and GCA have a self-limited course, lasting several months to several years (Klippel et al., 2008).

Assessment and Diagnostic Findings

Assessment focuses on musculoskeletal tenderness, weakness, and decreased function. Careful attention should be directed toward assessing the head (for changes in vision, headaches, and jaw claudication). An MRI scan may be used in the assessment of extra-articular synovitis in patients with PMR, regardless of symptoms.

Often, diagnosis is difficult because of the lack of specificity of tests. A markedly high ESR is a screening test but is not definitive. The CRP level and platelet count also provide valuable data. In fact, simultaneous elevation in the ESR and CRP has a sensitivity of 98.6% and a specificity of 75.7% in making the diagnosis of GCA when coupled with clinical findings (Seetharaman, 2015). Diagnosis of both GCA and PMR is more likely to be made by eliminating other potential diagnoses. The dramatic and immediate response to treatment with corticosteroids is considered by some to be diagnostic.

In the case of GCA, biopsy of the temporal artery is the definitive diagnostic tool (Seetharaman, 2015). High-resolution MRI is an alternative or adjunct to the traditional temporal artery biopsy.

Medical Management

The treatment for patients with PMR (without GCA) is moderate doses of corticosteroids. Longer durations of corticosteroid treatment are required with patients who have higher baseline inflammatory markers. Gradual tapering of the corticosteroid treatment should be monitored. NSAIDs are sometimes given in mild disease. The treatment for patients with GCA is rapid initiation of and strict adherence to a regimen of corticosteroids. This is essential to avoid the complication of blindness. Aspirin is a useful adjunctive treatment that also helps reduce the risk of visual loss (Yurdakul, Bodur, Sivas, et al., 2015).

Nursing Management

Nursing care of the patient with PMR is based on the fundamental plan of nursing care presented earlier (see Chart 57-2). The most common nursing diagnoses are pain and deficient knowledge of medications.

A management concern is that the patient will take the prescribed medication, frequently corticosteroids, until symptoms improve and then discontinue the medication. The decision to discontinue the medication should be based on clinical and laboratory findings and the prescription. Nursing implications are related to helping the patient prevent and monitor adverse effects of medications (e.g., infections, diabetes, gastrointestinal problems, and depression) and adjust to those side effects that cannot be prevented (e.g., increased appetite and altered body image).

Nursing Alert: The nurse must emphasize to the patient the need for continued adherence to the prescribed medication regimen to avoid complications of GCA, such as blindness.

The loss of bone mass with corticosteroid use increases the risk of osteoporosis in this already at-risk population. Interventions to promote bone health, such as adequate dietary calcium and vitamin D, measurement of bone mineral density, weight-bearing exercise, smoking cessation, and reduction of alcohol consumption if indicated, should be emphasized.

Osteoarthritis (Degenerative Joint Disease)

OA is a noninflammatory degenerative disorder of the joints. It is the most common form of joint disease and is routinely referred to as degenerative joint disease. OA is classified as either primary (idiopathic), with no prior event or disease related to the OA, or secondary, resulting from previous joint injury or inflammatory disease, similar to RA (Papadakis et al., 2015). Unlike most of the disease processes discussed in this chapter, the pathophysiology of primary OA does not involve autoimmunity or inflammation. It can occur as an end result of an autoimmune disorder where joint destruction occurs. Another distinguishing characteristic of OA is that it is limited to the affected joints; there are no systemic symptoms associated with it.

OA often begins in the third decade of life and peaks between the fifth and sixth decades. By 40 years of age, 90% of the population has degenerative joint changes in their weight-bearing joints, even though clinical symptoms are usually absent (Papadakis et al., 2015). Women, especially those who are Hispanic or African American, are more commonly affected. The incidence of OA increases with age. It is estimated that over 85% of the general population over 65 years of age has radiographic changes indicating OA (Cash & Glass, 2015). Overall prevalence of knee osteoarthritis among Indian population was 28.7%, with women having higher prevalence (31.6%) than men (Prakash Pal, Singh, & Chaturvedi et Al., 2016). Although OA is usually thought of as a disease of aging, it also affects younger patients and results in significant losses in work-related productivity and higher costs (CDC, 2015).

Pathophysiology

All joints consist of bone, particularly subchondral bone or the bony plate to which the articular cartilage is attached. This articular cartilage is a lubricated, smooth tissue that protects the bone from damage with physical activity. Between the articular cartilage of the bones forming the joint is a space (called the *joint space*) that allows for movement. To aid in fluidity, each joint contains synovial fluid to help lubricate and protect the joint's movement. With OA, the articular cartilage breaks down, leading to progressive damage to the underlying bone and eventual formation of **osteophytes** (bone spurs) that protrude into the joint space. The result is that the joint space is narrowed, leading to decreased joint movement and the potential for more damage. Consequently, the joint can progressively degenerate (see Fig. 57-3). Understanding of OA pathophysiology has been greatly expanded beyond what was previously thought of as simply "wear and tear" related to aging. The basic degenerative process in the joint exemplified in OA is presented in Figure 57-4. In addition to the degeneration, an infectious arteritis can occur. See Chapter 37 for discussion of septic (infectious) arthritis.

Risk factors for the disease and its progression include older age, female gender, and obesity. In addition, certain occupations (e.g., those requiring laborious tasks); engaging in sport activities; and a history of previous injuries, muscle weakness, genetic predisposition, and certain diseases can also place patients at risk for joint destruction. The most prominent modifiable risk factor for OA is obesity. In fact, both quality and quantity of life are reduced with OA, especially when obesity and OA are combined. A program of diet and exercise can help minimize symptoms of OA in patients who are obese (CDC, 2015).

Clinical Manifestations

The main clinical manifestations of OA are pain, stiffness, and functional impairment. The joint pain is usually aggravated by movement or exercise and relieved by rest. If morning stiffness is present, it is usually brief, lasting less than 30 minutes. The onset is routinely insidious, progressing over multiple years.

On physical examination, the affected joint may be enlarged with a decreased range of motion. Although OA occurs most often in weight-bearing joints (hips, knees, cervical and lumbar spine), the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are also often involved causing bony enlargements of the DIP (Heberden's nodes) and PIP (Bouchard's nodes) joints. Crepitus may be palpated, especially over the knee. Joint effusion, a sign of inflammation, is usually mild. No systemic manifestations are found.

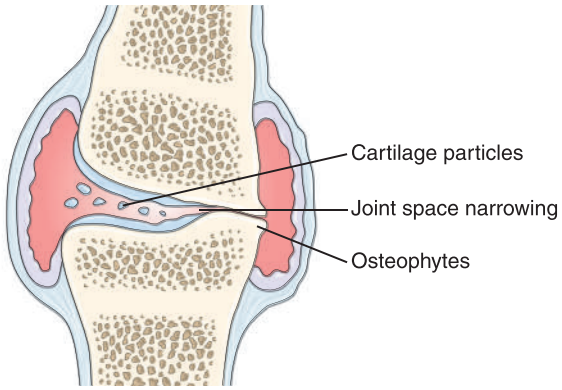

Figure 57-3 • Joint space narrowing and osteophytes (bone spurs) are characteristic of degenerative changes in joints.

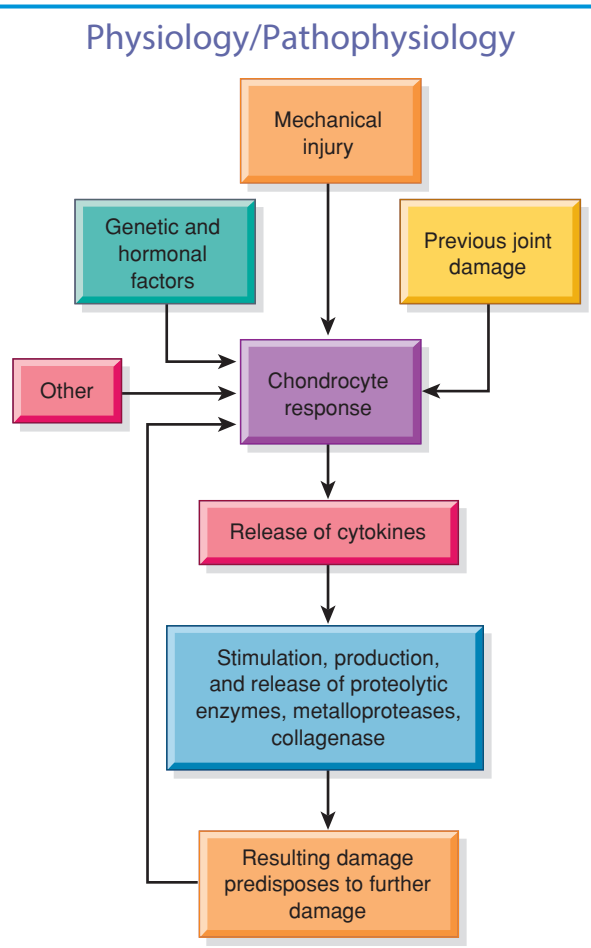

Figure 57-4 • Pathophysiology of osteoarthritis.

Assessment and Diagnostic Findings

Blood tests and examination of joint fluid are not useful in the diagnosis of OA but are occasionally indicated to rule out an autoimmune cause for the joint pain, such as RA. X-rays may show a narrowing of the joint space; osteophyte formation; and dense, thickened subchondral bone (Papadakis et al., 2015).

Medical Management

The goals of management are to decrease pain and stiffness and to maintain or, when possible, improve joint mobility. Exercise, especially in the form of cardiovascular aerobic exercise and lower extremity strength training, has been found to prevent OA progression and decrease symptoms of OA. Along with exercise, weight loss, which in turn decreases excess load on the joint, can also be extremely beneficial. Occupational and physical therapy can help the patient adopt self-management strategies (Kalunian, 2015a).

Wedged insoles, knee braces, and other modalities are being evaluated as possible therapies aimed at treating the abnormalities in biomechanics found in OA. The use of orthotic devices (e.g., splints, braces) and walking aids (e.g., canes) can improve pain and function by decreasing force on the affected joint (Kalunian, 2015a).

Patients with arthritis often use complementary, alternative, and integrative health therapies, such as massage, yoga, pulsed electromagnetic fields, TENS, and music therapy. These may also include herbal and dietary supplements, other special diets, acupuncture, acupressure, wearing copper bracelets or magnets, and participation in Tai chi. Research is under way to determine the effectiveness of many of these treatments. To date, no definitive evidence has been found regarding their efficacy (Kalunian, 2015a).

Pharmacologic Therapy

Pharmacologic management of OA is directed toward symptom management and pain control. Selection of medication is based on the patient's needs, the stage of disease, and the risk of side effects. Medications are used in conjunction with nonpharmacologic strategies. In most patients with OA, the initial analgesic therapy is acetaminophen/paracetamol. Some patients respond to the nonselective NSAIDs, and patients who are at increased risk for gastrointestinal complications, especially gastrointestinal bleeding, have been managed effectively with COX-2 enzyme blockers. However, COX-2 enzyme blockers must be used with caution because of the associated risk of cardiovascular disease. Other medications that may be considered are the opioids and intra-articular corticosteroids. Topical analgesic agents such as capsaicin (Capsin, Zostrix) and methyl salicylate are also used (Carter et al., 2015). Topical diclofenac sodium gel (Voltaren gel) has been FDA approved for the use of osteoarthritic joint pain in the hands and knees.

Other therapeutic approaches include glucosamine and chondroitin. Although it has been suggested that these substances modify cartilage structure, studies have not shown them to be effective (Martin, Van Sell, & Danter, 2012). Viscosupplementation, the injection of gel-like substances (hyaluronates) into a joint (intra-articular), is thought to supplement the viscous properties of synovial fluid. These viscosupplements aim to prevent the loss of cartilage and repair chondral defects (Kalunian, 2015b).

Surgical Management

In moderate to severe OA, when pain is severe or because of loss of function, surgical intervention may be used. The procedures most commonly used are osteotomy (to alter the distribution of weight within the joint) and arthroplasty. In arthroplasty, diseased joint components are replaced (see Chapter 36). Rehabilitation with physical therapy that is initiated within the first 24 hours is associated with decreased hospital length of stay and improved balance and gait function (Martin, Thornhill, & Katz, 2015).

Nursing Management

Pain management and optimal functional ability are major goals of nursing intervention. With those goals in mind, nursing management of the patient with OA includes pharmacologic and nonpharmacologic approaches as well as education. The patient's understanding of the disease process and symptom pattern is critical to the plan of care. Because patients with OA usually are older, they may have other health problems. Commonly they are overweight, and they may have a sedentary lifestyle. Weight loss and exercise are important approaches to lessen pain and disability. Canes or other assistive devices for ambulation should be considered, and any stigma about the use of these devices should be explored. Exercises such as walking should be begun in moderation and increased gradually. Patients should plan their daily exercise for a time when the pain is least severe or plan to use an analgesic agent, if appropriate, before exercising. Adequate pain management is important for the success of an exercise program. Open discussion regarding the use of complementary, alternative, and integrative health therapies is important to maintain safe and effective practices for patients looking for relief.

Spondyloarthropathies

The spondyloarthropathies are another category of systemic inflammatory disorders of the skeleton. The spondyloarthropathies include ankylosing spondylitis (AS), reactive arthritis (formerly known as Reiter's syndrome), and psoriatic arthritis. Spondyloarthritis is also associated with inflammatory bowel diseases such as Crohn's disease (regional enteritis) and ulcerative colitis (Grossman & Porth, 2014).

These rheumatic diseases share several clinical features. The inflammation tends to occur peripherally at the sites of attachment—at tendons, joint capsules, and ligaments. Periosteal inflammation may be present. Many patients have arthritis of the sacroiliac joints. The onset tends to occur during young adulthood, with the disease affecting men more often than women. There is a strong tendency for these conditions to occur in families. Frequently, the HLA-B27 genetic marker is found. In addition, more than one of these conditions can be found simultaneously in the same person or another family member (Carter et al., 2015).

As with other inflammatory conditions, patients with spondyloarthropathies have an increased risk for cardiovascular disease. These findings may be related to a state of chronic systemic inflammation and an increase in traditional cardiac risk factors, such as lack of exercise due to increased pain (Carter et al., 2015).

Ankylosing Spondylitis

AS is a chronic and inflammatory disease of the spine. It is more prevalent in males than in females and is usually diagnosed in the second or third decade of life. The disease is also more severe in males, and significant systemic involvement is likely.

AS affects the cartilaginous joints of the spine and surrounding tissues, making them rigid, decreasing mobility, and leading to kyphosis (a stooped position). This kyphosis can, in turn, lead to decreased stability and balance. Back pain is the characteristic feature. The back pain can be so severe that it may mask symptoms of a cervical fracture, which can lead to neurologic problems if left untreated. Occasionally, the large synovial joints, such as the hips, knees, or shoulders, may be involved (Carter et al., 2015).

AS also exhibits systemic effects. Uveitis occurs in 20% to 25% of patients with AS and may be a presenting feature (Smith, 2013). Another potential complication of AS is the risk of osteoporosis, which appears to be related to the inflammatory process as well as bone turnover and low vitamin D levels. Other complications involve atrioventricular conduction defects, aortic insufficiency, and pulmonary fibrosis (Papadakis et al., 2015). As the disease progresses, ankylosis of the entire spine may occur, leading to respiratory compromise and further complications.

Reactive Arthritis (Reiter's Syndrome)

The disease process involved in reactive arthritis is called *reactive* because the arthritis occurs after an infection, primarily gastrointestinal or genitourinary (Carter et al., 2015). It mostly

affects young adult males and is characterized primarily by urethritis, arthritis, and conjunctivitis. Dermatitis and ulcerations of the mouth and penis may also be present. Low back pain is common.

Psoriatic Arthritis

Psoriatic arthritis is an inflammatory arthritis associated with the skin disease psoriasis. In fact, research has suggested that between 10% and 20% of people with psoriasis will eventually develop psoriatic arthritis (Carter et al., 2015); (Dewing, 2015). Psoriasis is the most common autoimmune disease in India, affecting 1.2% to 2.8% of the population (Dogra & Yadav, 2010). Psoriatic arthritis onset occurs between 30 and 50 years of age and affects equal numbers of men and women (Dewing, 2015). Age and sex adjusted psoriatic arthritis prevalence is 0.01% among Indians (Chopra, 2015).

Pathogenesis of the disease process is hypothesized to start in the skin with an exaggerated immune response to environmental factors and then spreads to the joints in genetically susceptible individuals. Genetics is found to be a strong predictor. Many men and women diagnosed with psoriatic arthritis usually have a first-degree relative with psoriasis. Research shows that the HLAs are also present in up to 50% of patients diagnosed with psoriatic arthritis testing positive for the HLA-B27 antigen (Dewing, 2015). Although these patients test negative for rheumatoid factor, levels of TNF-α and other cytokines are elevated (Dewing, 2015). The body is triggered to activate the T cells of the immune system, producing inflammatory cytokines and mediators that cause changes and inflammation in the body, which also may result in erosions and joint destruction. In addition to joint damage, this cascade may also damage the ligaments, tendons, skin, and nails. Nail psoriasis occurs in approximately 90% of patients (Dewing, 2015).

Psoriatic arthritis is characterized by synovitis, polyarthritis, and spondylitis. Inflammatory back pain is a common symptom, which is differentiated from other back pain by symptoms of back pain presenting at a young age, pain improving with activity, and pain occurring at night. Radiographic evidence of asymmetrical sacroiliitis or spondylitis may also assist with diagnosing psoriatic arthritis (Dewing, 2015). Other sites of pain commonly seen in these patients are the Achilles tendon, plantar fascia, or tibial tuberosity areas. Pain in these areas is common from the inflammation that occurs at the entheses, where tendons and ligaments attach to the bone.

In addition to pain, infections can also occur since this is a systemic disease. Uveitis occurs in approximately 1.5% to 25% of patients diagnosed with psoriatic arthritis. Uveitis should be quickly diagnosed and treated by the ophthalmologist to prevent vision loss (Dewing, 2015).

Medical Management

Medical management of spondyloarthropathies focuses on treating pain and maintaining mobility by suppressing inflammation. For the patient with AS, good body positioning and posture are essential so that if ankylosis (fixation) does occur, the patient is in the most functional position. Maintaining range of motion with regular exercise and a muscle-strengthening program is especially important and has been linked with higher quality of life for the patient (Carter et al., 2015).

Pharmacologic Management

The European League Against Rheumatism guidelines recommend NSAIDs as the first-line therapy for treating all spondylarthropathies. All chronic conditions (cardiac, renal, and gastrointestinal) should be taken into consideration when prescribing long-term NSAIDS. Methotrexate, sulfasalazine, and leflunomide may also be used; these drugs may help with skin and peripheral joint disease but may not prevent spinal changes. Corticosteroid injections may be used for periodic flares; however, oral and long-term use of steroids is not recommended due to the possibility of psoriatic skin flare when discontinuing use. More recently, anti-TNF therapy has been approved by the FDA for psoriatic arthritis. Anti-TNF medications that have been used effectively include etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), golimumab (Simponi), and certolizumab pegol (Cimzia). Two additional agents include apremilast (Otezla), which is a PDE4 inhibitor, and ustekinumab (Stelara), an anti-IL12/anti-IL23 agent (Carter et al., 2015); (Dewing, 2015).

Surgical Management

With advanced AS and subsequent debilitating kyphosis, an osteotomy of the spine can be done. One study showed that an average correction of 45 degrees in the cervical spine was obtained and that quality of life also improved. Surgical management may also include total joint replacement (see Chapter 36) (Carter et al., 2015).

Nursing Management

Major nursing interventions in the spondyloarthropathies are related to symptom management and maintenance of optimal functioning. Affected patients are primarily young men. Their major concerns are often related to prognosis and job modification, especially among those who perform physical work. Patients may also express concerns about leisure and recreational activities. Focusing on physical activity and staying active and maintaining good posture will help to prevent chronic changes that may lead to deformities. It is important to address psychological changes, such as depression and emotional stress, that can occur with the diagnosis and chronicity of the disease (Carter et al., 2015). If symptoms are present, the primary provider should assess for emotional stress and treat as appropriate.

Metabolic and Endocrine Diseases Associated with Rheumatic Disorders

Metabolic and endocrine diseases may be associated with rheumatic disorders. These include biochemical abnormalities (amyloidosis and scurvy), endocrine diseases (diabetes and acromegaly), immune deficiency diseases (human immune deficiency virus infection, acquired immune deficiency syndrome), and some inherited disorders (hypermobility syndromes). However, the most common conditions are the crystal-induced arthropathies, in which crystals such as monosodium urate (gout) or calcium pyrophosphate (calcium pyrophosphate dihydrate disease or pseudogout) are deposited within joints and other tissues (Papadakis et al., 2015).

Gout

Gout is the most common form of inflammatory arthritis. More than 8.3 million Americans self-report the diagnosis of gout (CDC, 2015b). The prevalence is reported to be about 3.9% and appears to be on the rise. Men are three to four times more likely to be diagnosed with gout than women. The prevalence of gouty arthritis is less in Indians (0.05%) compared to the western

population (Chopra, 2015). The incidence of gout increases with age, body mass index, alcohol consumption, hypertension, and diuretic use (CDC, 2015b). Evidence links the consumption of fructose-rich beverages with the risk of gout for both men and women (CDC, 2015b). Patients with gout have an increased risk of cardiovascular disease. Comorbid conditions such as hypertension, dyslipidemia, diabetes, OA, and kidney disease may be present in patients with gout (Papadakis et al., 2015).

Given that the incidence of gout increases with age, its management can be complicated by other medical conditions, medications, and age-related changes (Carter et al., 2015).

Pathophysiology

Gout is caused by hyperuricemia (increased serum uric acid). Uric acid is a by-product of purine metabolism; purines are basic chemical compounds found in high concentrations in meat products. Urate levels are affected by diet, medications, overproduction in the body, and inadequate excretion by the kidneys. Hyperuricemia (serum concentration greater than 6.8 mg/dL) can, but does not always, cause urate crystal deposition. However, as uric acid levels increase, the risk becomes greater. The initial cause for the gout attack occurs when macrophages in the joint space phagocytize urate crystals. Through a series of immunologic steps, interleukin 1 beta is secreted, increasing the inflammation. This process is exacerbated by the presence of free fatty acids. Both alcohol and consumption of a large meal, especially with red meat, can lead to increases in free fatty acid concentrations; they also are implicated as triggers to acute gout attacks (Carter et al., 2015).

With repeated attacks, accumulations of sodium urate crystals, called tophi, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear. Renal urate lithiasis (kidney stones), with chronic kidney disease secondary to urate deposition, may develop.

Primary hyperuricemia may be caused by severe dieting or starvation, excessive intake of foods that are high in purines (shellfish, organ meats), or heredity. In secondary hyperuricemia, gout is a clinical feature secondary to any of a number of genetic or acquired processes, including conditions in which there is an increase in cell turnover (leukemia, multiple myeloma, some types of anemias, psoriasis) and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (e.g., diuretics such as thiazides and furosemide), low-dose salicylates, or ethanol can contribute to uric acid underexcretion (Klippel et al., 2008). The finding of urate crystals in the synovial fluid of asymptomatic joints suggests that factors other than crystals may be related to the inflammatory reaction. Recovered monosodium urate crystals are coated with immunoglobulins that are mainly IgG. IgG enhances crystal phagocytosis, thereby demonstrating immunologic activity (Klippel et al., 2008).

Clinical Manifestations

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), tophi (crystalline deposits accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four stages of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout (Neoai, Jansen, Dalbeth, et al., 2015). The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout.

For hyperuricemic people who are going to develop gout, acute arthritis is the most common early clinical manifestation. The metatarsophalangeal joint of the big toe is a commonly affected joint. The tarsal area, ankle, or knee may also be affected. Less commonly, the wrists, fingers, and elbows may be affected. Trauma, alcohol ingestion, dieting, medications, surgical stress, or illness may trigger the acute attack. The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days even without treatment. The attack is followed by a symptom-free period (the intercritical stage) until the next attack, which may not come for months or years. However, with time, attacks tend to occur more frequently, involve more joints, and last longer (Becker, 2015).

Tophi (seen in chronic tophaceous gout) are generally associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid are also associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, subchondral bone, infrapatellar and Achilles tendons, and subcutaneous tissue on the extensor surface of the forearms and overlying joints. They have also been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclera. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause renal stones and kidney damage.

Medical Management

A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint. Uric acid crystals are seen within the polymorphonuclear leukocytes in the fluid.

Acute attacks are managed with colchicine (Colcrys) (oral or parenteral), an NSAID such as indomethacin (Indocin), or a corticosteroid. Management of hyperuricemia, tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Once the acute attack has subsided, uric acid lowering therapy should be considered. Xanthine oxidase inhibitors, such as allopurinol (Zyloprim) and febuxostat (Uloric), are the agents of choice. Given the role of IL-1 in the pathogenesis of gout, some experts suggest that there may be a role for anakinra (Kineret), an IL-1 receptor antagonist in the management of acute gout (Papadakis et al., 2015).

Management between gout attacks needs to include lifestyle changes such as avoiding purine-rich foods, weight loss, decreasing alcohol consumption, and avoiding certain medications. Uricosuric agents, such as probenecid (Benemid), may be indicated in patients with frequent acute attacks. Uricosuric medications correct hyperuricemia and dissolve deposited urate. Corticosteroids may also be used in patients who have no response to other therapy. In patients with refractory chronic gout who are not controlled with the regimens mentioned earlier, pegloticase (Krystexxa), a newer agent, has been shown to be effective in lowering uric acid levels (Becker, 2016). Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function (see Table 57-5) (Carter et al., 2015).

Nursing Management

Severe dietary restriction is not necessary; however, the nurse encourages the patient to restrict consumption of foods high in purines, especially organ meats, and to limit alcohol intake.

TABLE 57-5 Common Medications Used to Treat Gout

Medication	Actions and Use	Nursing Implications
Colchicine (Colcrys)	Lowers the deposition of uric acid and interferes with leukocyte infiltration, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	*Acute management*: Administer when attack begins; dosage increased until pain is relieved or diarrhea develops, then stop medication *Chronic management*: Causes gastrointestinal upset in most patients.
Probenecid (Benemid)	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Be alert for nausea and rash.
Allopurinol (Zyloprim), febuxostat (Uloric)	Xanthine oxidase inhibitors; interrupt the breakdown of purines before uric acid is formed; inhibit xanthine oxidase because uric acid formation is blocked	Monitor for side effects, including bone marrow depression, vomiting, and abdominal pain. Avoid starting medication or increasing dose if active flare present.

Adapted from Karch, A. (2014). Lippincott's nursing drug guide. Philadelphia, PA: Lippincott Williams & Wilkins.

Maintenance of normal body weight should be encouraged. In an acute episode of gouty arthritis, pain management with prescribed medications is essential, along with avoidance of factors that increase pain and inflammation, such as trauma, stress, and alcohol. Medication adherence is critical; therefore, counseling needs to be initiated by the nurse when appropriate. Between acute episodes, the patient feels well and may abandon preventive behaviors, which may result in an acute attack. Acute attacks are most effectively treated if therapy is begun early (Carter et al., 2015).

Fibromyalgia

Fibromyalgia is a chronic pain syndrome that involves chronic fatigue, generalized muscle aching, stiffness, sleep disturbances, and functional impairment. It is estimated to affect more than 5 million Americans, representing 2% to 5% of the general population, with women affected more than men. Between 25% and 65% of patients with fibromyalgia have other rheumatologic conditions such as RA, SLE, and AS (CDC, 2015c). Fibromyalgia is reported to be 3.8% in urban areas and 4.5% in rural localities in India (Chopra, 2015).

Pathophysiology

The amplified pain experienced by patients with fibromyalgia is neurogenic in origin (Carter et al., 2015). Specifically, the central nervous system's ascending and descending pathways (that regulate and moderate pain processing) function abnormally, causing amplification of pain signals. Some scientists describe this as if the "volume control setting" for pain were abnormally high (Carter et al., 2015). Therefore, stimulation that may not normally elicit pain, such as touch, may do so. In addition, there are a number of predisposing factors to pain, including anxiety, depression, physical trauma, emotional stress, sleep disorder, and viral infection (Carter et al., 2015).

Assessment and Diagnostic Findings

The American College of Rheumatology established preliminary diagnostic criteria and symptom severity indices for fibromyalgia (Carter et al., 2015). These criteria emphasize the regions of pain, rather than specific points, and take into account the fatigue, cognitive symptoms, and unrefreshed sleep that patients with fibromyalgia also tend to experience (Carter et al., 2015).

Medical Management

Treatment consists of attention to the specific symptoms reported by the patient. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tricyclic antidepressants such as amitriptyline (Elavil) and nortriptyline (Pamelor) as well as sleep hygiene measures are used to improve or restore normal sleep patterns (Cash & Glass, 2015). Muscle relaxants such as cyclobenzaprine (Amrix) may also be used to help with relaxation and pain. Cognitive behavioral therapy is also useful in improving sleep and attentional dysfunction. In addition, serotonin norepinephrine reuptake inhibitors, such as duloxetine (Cymbalta), venlafaxine (Effexor), and milnacipran (Savella); selective serotonin reuptake inhibitors, including fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft); as well as anticonvulsants such as gabapentin (Neurontin) and pregabalin (Lyrica) have been reported to be effective (Carter et al., 2015). Individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in affected patients. There has also been some promising research in complementary, alternative, and integrative health therapies, such as acupuncture, massage, homeopathy, hydrotherapy, craniosacral therapy, and myofascial therapy (Carter et al., 2015).

Nursing Management

Typically, patients with fibromyalgia have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to pay special attention to supporting these patients and providing encouragement as they begin their program of therapy. Careful listening to patients' descriptions of their concerns and symptoms is essential to help them make the changes that are necessary to improve their quality of life (Carter et al., 2015).

Miscellaneous Disorders

The last category in the classification of the rheumatic diseases is aptly labeled miscellaneous disorders because it contains a mix of disorders that are frequently associated with arthritis and other conditions. These include the direct consequences of trauma (including internal derangement and loose bodies of joints), pancreatic disease (related to avascular necrosis or osteonecrosis), sarcoidosis (a multisystem disorder particularly of the lymph nodes and lungs), and palindromic rheumatism (an uncommon variety of recurring and acute arthritis and periarthritis that in some may progress to RA but is characterized by symptom-free periods of days to months). Other conditions include villonodular synovitis, chronic active hepatitis, and drug-related rheumatic syndromes. The nursing interventions related to these varied conditions are specific

to the multisystemic problems experienced by the patient. However, the musculoskeletal components should not be neglected or overlooked. Further information about these rare disorders can be found in specialty references.

CRITICAL THINKING EXERCISES

1. A 62-year-old patient who was recently diagnosed with osteoarthritis (OA) comes in for her follow-up appointment. She wants to know why she is not being prescribed "stronger medications" for her arthritis like her friend is taking. Her friend has RA and her pain improved significantly after starting adalimumab injections. Describe your teaching plan to explain the physiologic differences between OA and RA, medications commonly used for OA and the difference between treatment regimens for OA and RA.
2. Your patient is a 52-year-old male patient with a history of hypertension, stage 3 kidney disease, diabetes, and hyperlipidemia. He smokes 1 pack of cigarettes a day and drinks alcohol on occasion. He is 6'2" and weighs 110 kg. Today he presents with complaints of severe pain in his right great toe that started Sunday morning. He spent a long weekend with friends, drank a lot of alcohol, and ate a lot of rich food. He woke Sunday morning with pain in his foot that has progressively gotten worse. He has been diagnosed with gout. Identify the priorities, approach, and techniques you would use to provide nursing care to this patient. How would you prioritize the physical examination and techniques performed since his pain scale is 8/10? What lifestyle modifications are a priority for this patient?
3. You are the nurse taking care of a woman with Sjögren's syndrome. What is the evidence for symptom management for this patient? What criteria would you use to assess the strength of the evidence? What is the evidence for treatment options to improve her symptoms?

UNIT

XVIII Oncologic Nursing

Chapter 58 Management of Patients with Oncologic Disorders 1849

Chapter 59 Palliative Care and End-of-Life Care 1949

CHAPTER 58

Management of Patients with Oncologic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1 Compare the function and behavior of normal and cancer cells.
2 Differentiate between the different malignant processes that occur in oncologic disorders.
3 Identify agents and factors that are carcinogenic.
4 Describe the role of nurses in health education and prevention of oncologic disorders.
5 Differentiate among the goals of cancer care: prevention, diagnosis, cure, control, and palliation.
6 Describe the roles of surgery, radiation therapy, chemotherapy, hematopoietic stem cell transplantation, hyperthermia, targeted therapy, and symptom management in treating cancer.
7 Use the nursing process as a framework for the care of patients with cancer.
8 Describe the etiopathophysiology, clinical manifestations, and collaborative management of selected cancers in females
9 Identify assessment parameters and nursing management of patients with oncologic emergencies.
10 Discuss the role of nurses in cancer survivorship care.

GLOSSARY

alopecia: hair loss
anaplasia: pattern of growth in which cells lack normal characteristics and differ in shape and organization with respect to their cells of origin; usually, anaplastic cells are malignant
angiogenesis: growth of new blood vessels that allow cancer cells to grow
apoptosis: a normal cell mechanism of programmed cell death
benign: not cancerous; benign tumors may grow but are unable to spread to other organs or body parts
brachytherapy: delivery of radiation therapy through internal implants placed inside or adjacent to the tumor
cancer: a group of disorders characterized by abnormal cell proliferation, in which cells ignore growth-regulating signals in the surrounding environment
carcinogenesis: process of transforming normal cells into malignant cells
carcinogens: chemicals, physical factors, and other agents that cause cancer
chemotherapy: the use of medications to kill tumor cells by interfering with cellular functions and reproduction
cytokines: substances produced primarily by cells of the immune system to enhance production and functioning of components of the immune system
extravasation: leakage of intravenous medication from the veins into the subcutaneous tissues
grading: identification of the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and structural characteristics of the tissue of origin
graft-versus-host disease (GVHD): an immune response initiated by T lymphocytes of donor tissue against the recipient's tissues (skin, gastrointestinal tract, liver); an undesirable response
graft-versus-tumor effect: the donor immune cell response against the malignancy; a desirable response
malignant: having cells or processes that are characteristic of cancer
mammogram: screening test performed to identify breast cancer early in those who are at risk of developing breast cancer
metastasis: spread of cancer cells from the primary tumor to distant sites
mucositis: inflammation of the lining of the mouth, throat, and gastrointestinal tract often associated with cancer therapies
myelosuppression: suppression of the blood cell–producing function of the bone marrow
nadir: lowest point of white blood cell depression after therapy that has toxic effects on the bone marrow
neoplasia: uncontrolled cell growth that follows no physiologic demand; cancer
neutropenia: abnormally low absolute neutrophil count
oncology: field or study of cancer
palliation: relief of symptoms and promotion of comfort and quality of life regardless of the disease stage
PAP smear test: Papanicolaou smear test, a screening test to identify the cancer cervix at early stage
precision medicine: using advances in research, technology, and policies to develop individualized plans of care to prevent and treat disease
radiation therapy: the use of ionizing radiation to kill malignant cells
staging: process of determining the extent of disease, including tumor size and spread or metastasis to distant sites
stomatitis: inflammation of the oral tissues, often associated with some chemotherapeutic agents and radiation therapy to the head and neck region
targeted therapies: cancer treatments that seek to minimize the negative effects on healthy tissues by disrupting specific cancer cell functions (such as malignant transformation), metabolism, communication pathways, processes for growth and metastasis, and genetic coding
thrombocytopenia: decrease in the number of circulating platelets; associated with the potential for bleeding
vesicant: substance that can cause inflammation, damage, and necrosis with extravasation from blood vessels and contact with tissues

Introduction

Cancer is a large group of disorders with different causes, manifestations, treatments, and prognoses. Because cancer can involve any organ system and treatment approaches have the potential for multisystem effects, cancer nursing practice overlaps with numerous nursing specialties. Cancer nursing practice covers all age groups and is carried out in various settings, including acute care institutions, outpatient centers, physician offices, rehabilitation facilities, the home, and long-term care facilities. The scope, responsibilities, and goals of cancer nursing, also called oncology nursing, are as diverse and complex as those of any nursing specialty. Nursing management of the patient with oncologic disorders includes care of patients throughout the cancer trajectory from prevention through end-of-life care (see Fig. 58-1).

Precision medicine is now possible because of the recent development of biologic databases (e.g., human genome sequencing), technological advances that can identify unique characteristics of individual persons (e.g., genomics, cellular assay tests), and computer-driven systems that can mine and analyze datasets. This is an exciting time for oncology as the immediate goal of the precision medicine initiative is to focus on preventing and curing cancers (Collins & Varmus, 2015).

Epidemiology

In 2015, nearly 700,000 new cancer cases were diagnosed. In the same year, nearly 600,000 Americans died as a result of cancer. Despite significant advances in science and technology, cancer is the second leading cause of death in the United States (Siegel, Miller, & Jemal, 2015). Currently, one in four deaths is caused by cancer. The leading causes of cancer death in the United States in order of frequency and location are lung, prostate, and colorectal cancer in men and lung, breast, and colorectal cancer in women. Most cancer occurs in older adults; according to the American Cancer Society (ACS), 78% of all cancer diagnoses are in people 55 years of age or older (2015a). Overall, the incidence of cancer is higher in men than in women.

Although the overall rate of cancer deaths has declined, cancer death rates in African American men remain substantially higher than those among Caucasian men and two times those of Hispanic men (Siegel et al., 2015). While African American women have a lower risk of cancer overall than white women, they have 14% higher death rates for all cancers compared with white women and women in general (ACS, 2016a). Racial disparities may be attributed to the burdens of comorbid conditions, such as cardiovascular disease, and poverty experienced more often in the African American population than in others (ACS, 2016a); (DeNavas-Walt, Proctor, & Smith, 2013).

Cancer incidence and death rates also vary by geography. In states where the prevalence of tobacco use is high, the incidence of lung cancer tends to be greater than in states where smoking is not as common. In locations where there is greater socioeconomic disparity, the incidence of advanced cancer and overall cancer death rates are higher than in regions where there is not such disparity (Kohler, Sherman, Howlader, et al., 2015).

According to the Indian Council of Medical Research (ICMR), India is likely to have 17.3 lakh new cases of cancer and over 8.8 lakh deaths due to cancer by 2020 with cancers of breast, lungs, and cervix topping the list.

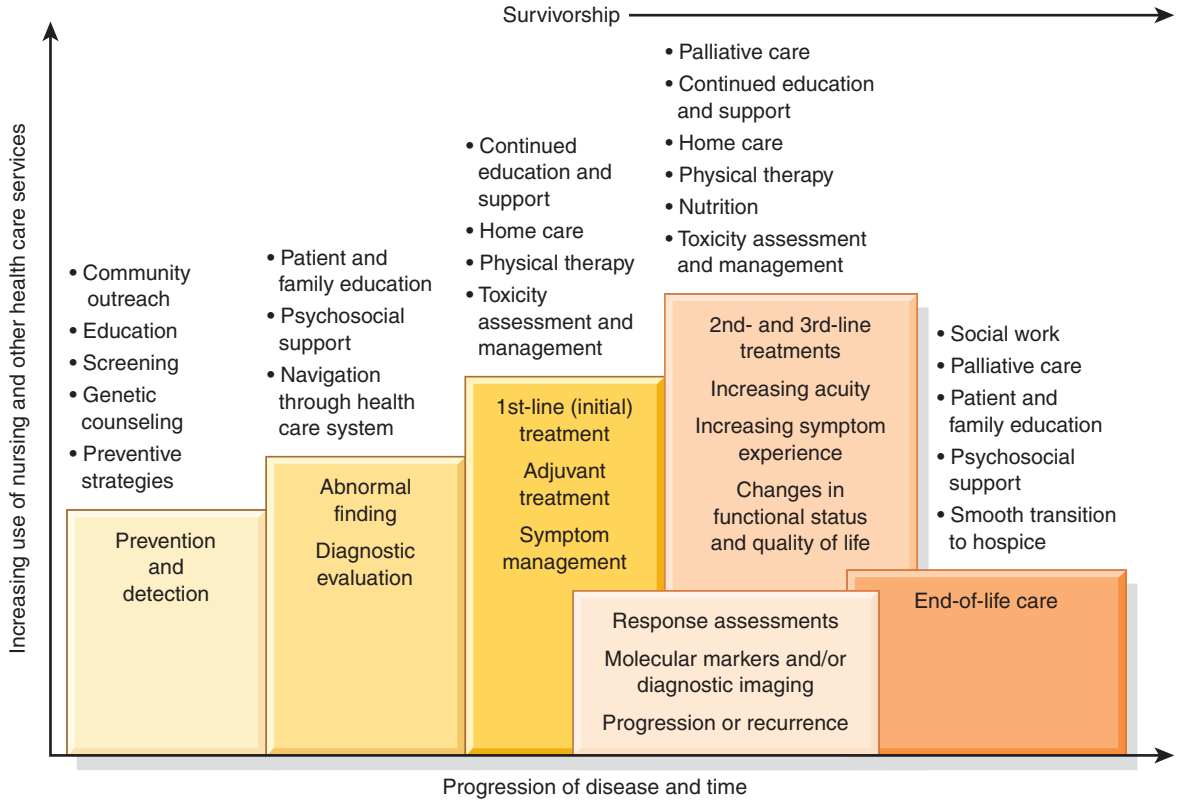

Figure 58-1 • Cancer care trajectory. The cancer care trajectory reflects the phases and care required during the continuum of the cancer experience from prevention and early detection through end-of-life care. Specialized nursing care is provided throughout the entire trajectory.

TABLE 58-1 Regional Distribution and Causes of Cancer in India

Region	Type of Cancer	Possible Cause
Northeast region (highest cancer rate)	Esophagus cancer	Tobacco, household burning of firewood
West Bengal	Lung, urinary bladder cancer	Air and water pollution
South and coastal India	Stomach cancer	Diet rich in spices and salt
Goa	Colon cancer	Red meat, alcohol, and tobacco
Gujarat and Rajasthan	Head and neck cancer	Tobacco and pan masala
Punjab (Malwa Belt)	All cancers higher than average, especially, kidney, urinary bladder, and breast cancer	Pollution, pesticides, and toxins in food

Adopted from National Registry Cancer Program, ICMR report, 2015.

According to the World Health Organization cancer report, the number of cancer cases in India is increasing every year. Cancer can affect almost any part of the body. National Cancer Registry reported that the cancer of lungs, oral cavity, lip, throat, and neck in males and cancer of breast, cervix, and ovary in females account for over 50% of all cancer deaths in India.

The Northeast region in India reported the highest number of cancer cases in both males and females. Aizawl district in Mizoram reported the highest number of cases among males while Papum Pare district in Arunachal Pradesh recorded the highest number of cases among females (ICMR, 2016).

Geographical Distribution of Cancer in India

There are various internal and external factors affecting regional variation in cancer incidence and mortality. Internal factors include genetic, hormonal, and poor immune conditions while external or environmental factors include food habits, industrialization, pollution, and lifestyle. India's most populous state, Uttar Pradesh, is estimated to have the maximum number of cancer cases and cancer mortality rates followed by Maharashtra and Bihar (Parihar, 2015).

Table 58-1 lists cancer-affected geographical regions in India with their possible causes.

Pathophysiology of the Malignant Process

Cancer is a disease process that begins when a cell is transformed by genetic mutations of the cellular deoxyribonucleic acid (DNA). Genetic mutations may be inherited and/or acquired, leading to abnormal cell behavior (Grossman & Porth, 2014). The initial genetically altered cell forms a clone and begins to proliferate abnormally, evading normal intracellular and extracellular growth-regulating processes or signals as well as the immune system defense mechanisms of the body. Genetic mutations may lead to abnormalities in cell signaling transduction processes (signals from outside and within cells that turn cell activities either on or off) that can in turn lead to cancer development. Ultimately cells acquire a variety of capabilities that allow them to invade surrounding tissues and/or gain access to lymph and blood vessels, which carry the cells to other areas of the body resulting in metastasis or spread of the cancer (Acharyya, Matrisian, Welch, et al., 2015). Pathophysiology of a malignant process is presented in Figure 58-2.

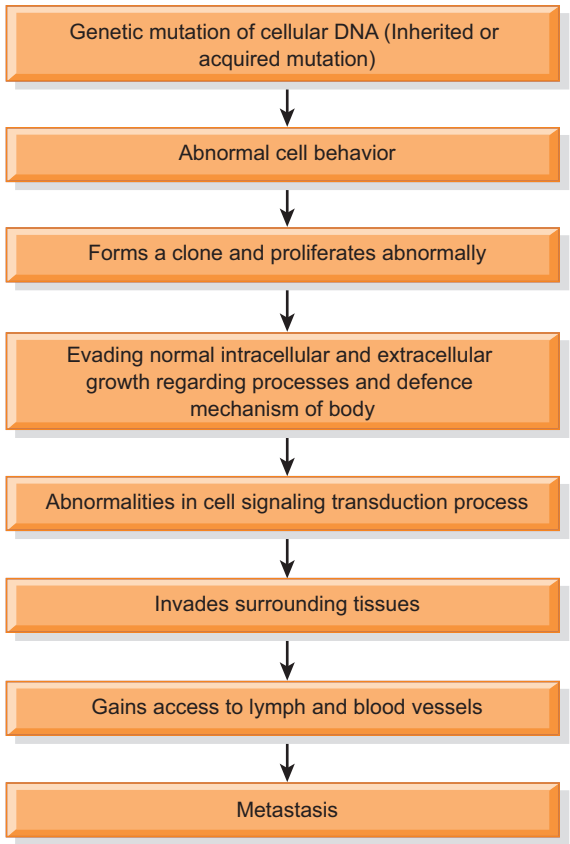

Figure 58-2 • Pathophysiology of a malignant process. *Signaling transduction process*: It is by which a cell converts an extracellular signal into a response. It plays an important role in activity, cellular function, cellular differentiation, and cell proliferation.

Characteristics of Malignant Cells

Benign and malignant cells differ in many cellular growth characteristics, including the method and rate of growth, ability to metastasize or spread, destruction of tissue, and ability to cause death. These differences are summarized in Table 58-2. The degree of anaplasia (a pattern of growth in which cells lack normal characteristics and differ in shape and organization with respect to their cells of origin) is associated with increased malignant potential.

Carcinogenesis

Molecular Process

Malignant transformation, or **carcinogenesis,** is thought to be at least a three-step cellular process, involving initiation, promotion, and progression. Agents that initiate or promote malignant transformation are referred to as **carcinogens**.

During *initiation,* carcinogens (substances that can cause cancer), such as chemicals, physical factors, or biologic agents,

TABLE 58-2 Characteristics of Benign and Malignant Tumors

Characteristics	Benign	Malignant
Cell	Well-differentiated cells resemble normal cells of the tissue from which the tumor originated.	Cells are undifferentiated and may bear little resemblance to the normal cells of the tissue from which they arose.
Mode of growth	Tumor grows by expansion and does not infiltrate the surrounding tissues; usually encapsulated.	Grows at the periphery and overcomes contact inhibition to invade and infiltrate surrounding tissues
Rate of growth	Rate of growth is usually slow.	Rate of growth is variable and depends on level of differentiation; the more anaplastic the tumor, the faster its growth.
Metastasis	Does not spread by metastasis	Gains access to the blood and lymphatic channels and metastasizes to other areas of the body or grows across body cavities such as the peritoneum
General effects	Is usually a localized phenomenon that does not cause generalized effects unless its location interferes with vital functions	Often causes generalized effects, such as anemia, weakness, systemic inflammation, weight loss, and CACS
Tissue destruction	Does not usually cause tissue damage unless its location interferes with blood flow	Often causes extensive tissue damage as the tumor outgrows its blood supply or encroaches on blood flow to the area; may also produce substances that cause cell damage
Ability to cause death	Does not usually cause death unless its location interferes with vital functions	Eventually causes death unless growth can be controlled

CACS, cancer-related anorexia-cachexia syndrome.

Adapted from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

cause mutations in the cellular DNA. Normally, these alterations are reversed by DNA repair mechanisms or the changes initiate programmed cellular death (apoptosis) or cell senescence. Cells can escape these protective mechanisms with permanent cellular mutations occurring, but these mutations usually are not significant to cells until the second step of carcinogenesis.

During *promotion,* repeated exposure to promoting agents (co-carcinogens) causes proliferation and expansion of initiated cells with increased expression or manifestations of abnormal genetic information, even after long latency periods. Promoting agents are not mutagenic and do not need to interact with the DNA. Latency periods for the promotion of cellular mutations vary with the type of agent, the dosage of the promoter, and the innate characteristics and genetic stability of the target cell. The promotion phase generally leads to the formation of a preneoplastic or benign (noncancerous) lesion.

During *progression,* the altered cells exhibit increasingly malignant behavior. These cells acquire the ability to stimulate angiogenesis (growth of new blood vessels that allow cancer cells to grow), to invade adjacent tissues, and to metastasize. Cellular oncogenes are responsible for vital cell functions, including proliferation and differentiation. Cellular proto-oncogenes, such as those for the epidermal growth factor receptor (EGFR), transcription factors such as *c-Myc,* or cell signaling proteins such as *Kirsten ras* (*KRAS*), act as "on switches" for cellular growth. Amplification of proto-oncogenes or overexpression of growth factors, such as epidermal growth factor (EGF), can lead to uncontrolled cell proliferation. Mutations that increase the activity of oncogenes also deregulate cell proliferation. Genetic alterations in the gene for *KRAS* have been associated with pancreatic, lung, and colorectal cancers (http://www.mycancergenome.org/content/disease/lung-cancer/kras/ (Lovly, Horn, & Pao, 2015). Just as proto-oncogenes "turn on" cellular growth, cancer suppressor genes "turn off," or regulate, unneeded cellular proliferation. When suppressor genes are mutated, resulting in loss of function or expression, the cells begin to produce mutant cell populations that are different from their original cellular ancestors. See Chart 58-1 for further discussion of genetics concepts and cancer. A schematic representation of carcinogenesis may be perused from Figure 58-3.

Proliferative Patterns

During the lifespan, various body tissues normally undergo periods of rapid or proliferative growth that must be distinguished from malignant growth activity. Several patterns of cell growth exist: hyperplasia, dysplasia, and metaplasia. Cancerous cells, described as malignant neoplasms, demonstrate uncontrolled cell growth that follows no physiologic demand (neoplasia). Although both benign and malignant growths are classified and named by tissue of origin, the *International Classification of Diseases for Oncology* (Fritz, Percy, Jack, et al., 2013) is used by scientists and clinicians around the world as the nomenclature for malignant disease (see Table 58-3).

Etiology

Factors implicated or known to induce carcinogenesis include viruses and bacteria, physical agents, chemicals, genetic or familial factors, lifestyle factors, and hormones. Additional research is needed for a better understanding of the relationships between etiologic factors and cancer.

Viruses and Bacteria

It is estimated that about 11% of all cancers worldwide are linked to viral infections (Schiller & Lowy, 2014). After infecting individuals, DNA viruses insert a part of their own DNA near the infected cell genes causing cell division. The newly formed cells that now carry viral DNA lack normal controls on growth. Examples of these viruses that are known to cause cancer include human papillomavirus (HPV) (cervical and head and neck cancers), hepatitis B virus (HBV) (liver cancer), and Epstein-Barr virus (EBV) (Burkitt lymphoma and nasopharyngeal cancer) (Chen, Hsu, Yang, et al., 2014).

There is little evidence to support the link of most bacteria to cancer, although chronic inflammatory reactions to bacteria and the production of carcinogenic metabolites are possible mechanisms that continue to be investigated.

Chart 58-1 GENETICS IN NURSING PRACTICE

Genetics Concepts and Oncologic Disorders

Cancer is a genetic disease. Every phase of carcinogenesis is affected by multiple gene mutations. Some of these mutations are inherited (present in germ-line cells) and present a greater risk for a person to develop oncologic disorders; however, most (90%) are somatic mutations that are acquired mutations in specific cells. Examples of cancers influenced by genetics include:

Autosomal dominant:
- Breast and ovarian cancer
- Colorectal cancer
- Familial adenomatous polyposis
- Cowden syndrome
- Li-Fraumeni syndrome
- Lynch Syndrome (Hereditary nonpolyposis colon cancer)
- Multiple endocrine neoplasia types 1 and 2
- Neurofibromatosis types 1 and 2
- Prostate cancer
- Retinoblastoma
- Von Hippel–Lindau syndrome
- Wilm's tumor

Autosomal recessive:
- Ataxia telangiectasis
- Endometrial cancer
- Gastrointestinal stromal tumor
- Familial melanoma syndrome
- Xeroderma pigmentosum

Nursing Assessments

Refer to Chart 3-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Oncologic Disorders
- Obtain information about both maternal and paternal sides of family for three generations.
- Obtain cancer history for at least three generations.
- Look for clustering of cancers that occur at young ages, multiple primary cancers in one individual, cancer in paired organs, and two or more close relatives with the same type of cancer suggestive of hereditary cancer syndromes.

Patient Assessment
- Assess for the following:
  - Physical findings that may predispose the patient to cancer, such as multiple colon polyps or the presence of more than one tumor. If a tumor was previously diagnosed, inquire about the age of the patient when the first tumor was noted.
  - Skin findings, such as atypical moles, that may be related to familial melanoma syndrome.
  - Multiple *café-au-lait* spots, axillary freckling, and two or more neurofibromas associated with neurofibromatosis type 1.
  - Facial trichilemmomas, mucosal papillomatosis, multinodular thyroid goiter or thyroid adenomas, macrocephaly, fibrocystic breasts, and other fibromas or lipomas related to Cowden syndrome.
- Assess for lifestyle risks (e.g., smoking, obesity, alcohol use).
- Determine potential occupational or environmental hazards that may generate exposure to inhaled chemicals, gases, or other irritants (e.g., toxic metals, asbestos, radon).

Management Issues Specific to Oncologic Disorders
- Assess patient's understanding of genetics factors related to their cancer.
- Offer appropriate genetics information and resources.
- Refer for cancer risk assessment when a hereditary cancer syndrome is suspected so that patient and family can discuss inheritance risk with other family members and availability of genetic testing.
- Provide support to patients and families with known genetic test results for hereditary cancer syndromes. Refer to support groups as appropriate.
- Participate in the management and coordination of risk reduction measures for those with known gene mutations.

Genetics Resources Specific to Oncologic Disorders

American Cancer Society: www.cancer.org
National Cancer Institute: www.cancer.gov
Indian Cancer Society, www.indiancancersociety.org

Helicobacter pylori is one bacterium identified as a significant cause of gastric cancer (Bessede, Dubus, Megraud, et al., 2014).

Physical Agents

Physical factors associated with carcinogenesis include exposure to sunlight, radiation, chronic irritation or inflammation, tobacco carcinogens, industrial chemicals and asbestos.

Excessive exposure to the ultraviolet rays of the sun, especially in fair-skinned people, increases the risk of skin cancers. Factors such as clothing styles (sleeveless shirts or shorts), the use of sunscreens, occupation, recreational habits, and environmental variables, including humidity, altitude, and latitude, all play a role in the amount of exposure to ultraviolet light.

Exposure to ionizing radiation can occur with repeated diagnostic x-ray procedures or with radiation therapy used to treat disease. Improved x-ray equipment minimizes the risk of extensive radiation exposure. Radiation therapy used in cancer treatment and exposure to radioactive materials at nuclear weapon manufacturing sites or nuclear power plants in the past have been associated with a higher incidence of leukemia, multiple myeloma, and cancers of the lung, bone, breast, thyroid, and other tissues. Background radiation from the natural decay processes that produce radon has also been associated with lung cancer. Ventilation is advised in homes with high levels of trapped radon to allow the gas to disperse into the atmosphere.

Chemical Agents

Many cancers are thought to be related to environmental factors (ACS, 2015a). Most hazardous chemicals produce their toxic effects by altering DNA structure. This can occur in body sites distant from that of initial chemical exposure.

Tobacco smoke, thought to be the single most lethal chemical carcinogen, accounts for about one third of cancer deaths (ACS, 2015a). Smoking is strongly associated with cancers of the lung, head and neck, esophagus, stomach, pancreas, cervix, kidney, and bladder and with acute myeloblastic leukemia (U.S. Department of Health and Human Services [HHS], 2014).

Passive smoke (i.e., secondhand smoke) has been linked to lung cancer; nonsmokers who live with a smoker have about a 20% to 30% greater risk of developing lung cancer (HHS, 2014). There is evidence that passive smoke may be linked with childhood leukemia and cancers of the larynx, pharynx, brain, bladder, rectum, stomach, and breast (HHS, 2014).

Other combustible forms of tobacco such as cigars, pipes, roll-your-own products, and water pipes (or hookah) are also associated with increased cancer risk (ACS, 2015a). Electronic

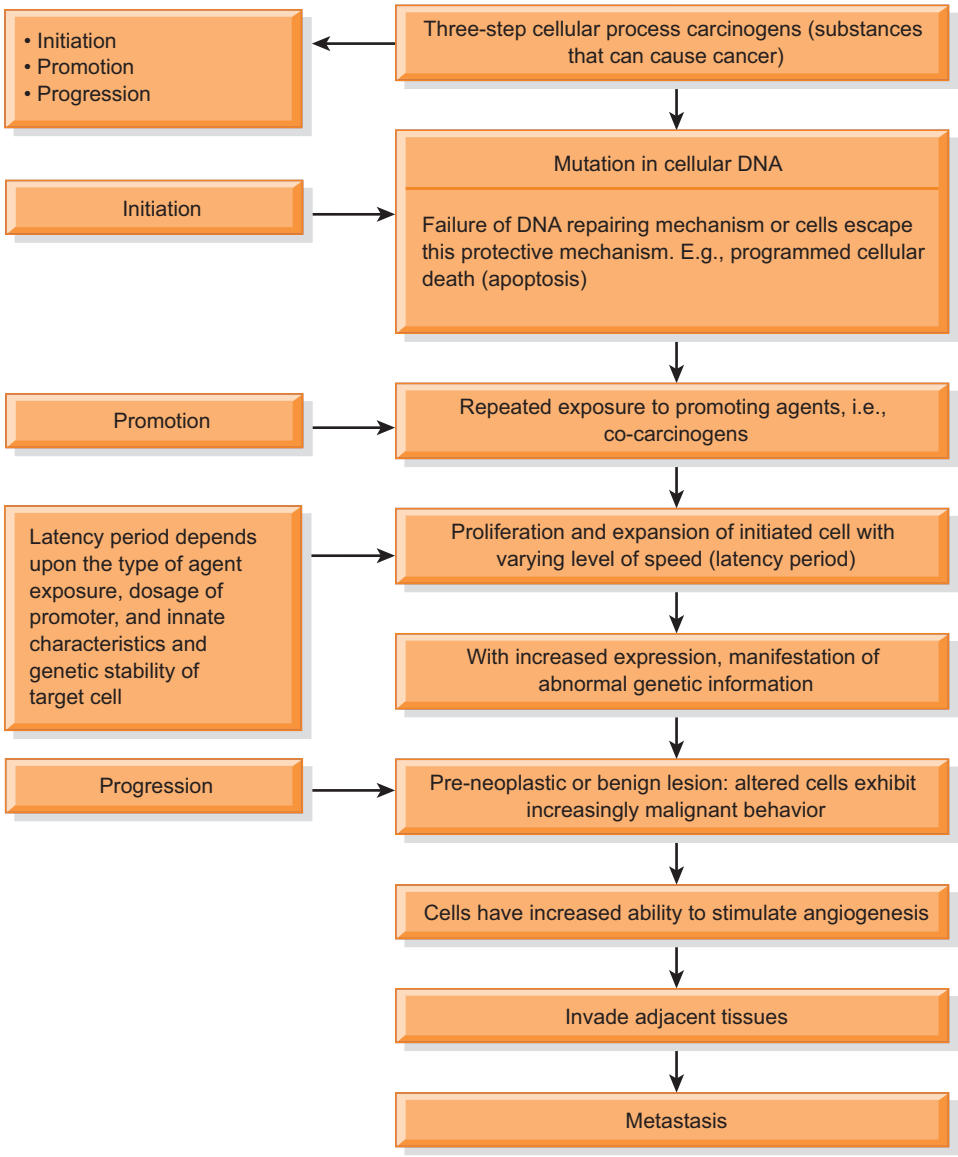

Figure 58-3 • Schematic presentation of carcinogenesis.

nicotine delivery systems referred to as electronic cigarettes have gained increased popularity as an alternative to tobacco. Although there are no data regarding the safety of these products, there is great concern about potential negative health effects.

Smokeless tobacco products, such as chewing tobacco and snuff, used most often by young adults aged 18 to 24 years, are associated with an increased risk of oral, pancreatic, and esophageal cancer (ACS, 2015a).

Many chemical substances found in the workplace are carcinogens or co-carcinogens. In the United States, carcinogens are classified by two federal agencies: the National Toxicology Program of the Department of Health and Human Services (HHS) and the Environmental Protection Agency's (EPA) Integrated Risk Information System (IRIS). The Centers for Disease Control and Prevention (CDC) established the National Institute for Occupational Safety and Health (NIOSH) to provide occupational exposure limits and guidelines for protection of the workforce as regulated by the Occupational Safety and Health Act of 1970. The extensive list of suspected chemical substances continues to grow and includes aromatic amines and aniline dyes; pesticides and formaldehydes; arsenic, soot, and tars; asbestos; benzene; cadmium; chromium compounds; nickel and zinc ores; wood dust; beryllium compounds; and polyvinyl chloride. Betel nut and lime, which are chewed as stimulants in some cultures, are also included.

Genetics and Familial Factors

Almost every cancer type has been shown to run in families. This may be due to genetics, shared environments, cultural or lifestyle factors. Genetic factors play a fundamental role in cancer cell development. Cancer has been associated with extra chromosomes, too few chromosomes, or translocated chromosomes. Cancers with these underlying genetic abnormalities include chronic myelogenous leukemia, meningiomas, acute leukemia, retinoblastomas, and Wilms tumor. In addition, certain syndromes represent a cluster of cancers identified by a specific genetic alteration that is inherited across generations. In these families, the associated genetic mutation is found in all cells (it is germline and somatic) and represents an inherited susceptibility to cancer for all family members who carry the mutation.

TABLE 58-3 Classification of Cancer by Tissue of Origin

Classification	Tissue of Origin	Characteristics	Term	Examples
Carcinoma	Epithelial	Account for 80–90% of all cancers		
	• Glandular epithelium	Organs or glands capable of secretion	Adenocarcinoma	Adenocarcinoma of the breast, lung, prostate
	• Squamous epithelium	Covers or lines all external and internal body surfaces	Squamous cell carcinoma	Squamous cell cancer of the skin, lung, esophagus
Sarcoma	Connective or Supportive			
	• Bone	Most common form of cancer of the bone	Osteosarcoma	Osteosarcoma of the femur, humerus
	• Cartilage	Rare, arises from within bones	Chondrosarcoma	Chondrosarcoma of the femur, pelvis
	• Adipose	Arises from deep soft tissue	Liposarcoma	Liposarcoma of the retroperitoneum, thigh
	• Smooth muscle	Very rare	Leiomyosarcoma	Leiomyosarcoma of the uterus, intestines, stomach
	• Skeletal muscle	Most common in young children	Rhabdosarcoma	Rhabdosarcoma of the head and neck, limbs
	• Fibrous tissue	Often involves long or flat bones	Fibrosarcoma	Fibrosarcoma of the femur, tibia, mandible
	• Membranes lining body cavities	Most often related to asbestos exposure	Mesothelial sarcoma or mesothelioma	Mesothelioma of the pleura or peritoneum
	• Blood vessels	With liver involvement may be related to occupational exposure to vinyl chloride monomer	Angiosarcoma	Angiosarcoma of the liver, heart
Myeloma	Plasma cells	Produced by B-cell lymphocytes; plasma cells produce antibodies	Not applicable (N/A)	N/A
Lymphoma	Lymphocytes	Two main classifications; may involve lymph nodes and/or body organs	Non-Hodgkin lymphoma	B-cell lymphoma, T-cell lymphoma
			Hodgkin lymphoma	N/A
Leukemia	Hematopoietic cells in the bone marrow	May involve various cell lines produced in the bone marrow		
	• White blood cells (WBCs)	N/A	Myelogenous	Acute myelogenous leukemia
	• Lymphocytes	N/A	Lymphocytic	Acute lymphocytic leukemia
	• Red blood cells (RBCs)	Involves overproduction of RBCs and is associated with increased levels of WBCs and platelets; also risk of additional bone marrow disease	Erythremia	Polycythemia vera

Adapted from Fritz, A., Percy, C., Jack, A., et al. (2013). World Health Organization. (2013). International classification of diseases for oncology (ICD-O)–3rd edition, 1st revision. Retrieved on 2/25/2016 at: apps.who.int/iris/bitstream/10665/96612/1/9789241548496_eng.pdf?ua=1

Approximately 5% to 10% of cancers in adults display a pattern of cancers suggestive of a familial predisposition (NCI, 2016). The hallmarks of families with a hereditary cancer syndrome include cancer in two or more first-degree relatives (the parent, sibling, or child of an individual), onset of cancer in family members younger than 50 years, the same type of cancer in several family members, individual family members with more than one type of cancer, and a rare cancer in one or more family members (NCI, 2016). There is also evidence of an autosomal dominant inheritance pattern of cancers affecting several generations of a family.

There have been considerable advances in the recognition of inherited cancer susceptibility syndromes and in the ability to isolate and identify the inherited genetic mutations responsible for cancer. These advances have enabled the appropriate identification of families at risk for certain syndromes. Examples include hereditary breast and ovarian cancer syndrome (*BRCA1* and *BRCA2*) and multiple endocrine neoplasia syndrome (*MEN1* and *MEN2*) (see Chart 58-1). Other cancers associated with familial inheritance syndromes include nephroblastomas, pheochromocytomas, and colorectal, stomach, thyroid, renal, prostate, and lung cancers (NCI, 2016).

Life Style Factors

Around one-third of the cancer deaths are due to the 5 leading behavioral and dietary risks: high body mass index, low fruit and vegetable intake, lack of physical activity, tobacco use, and alcohol use. These factors are second only to tobacco use as major risk factors associated with cancer development (ACS, 2015a).

The risk of cancer increases with long-term ingestion of carcinogens or co-carcinogens or the absence of protective substances in the diet. Dietary substances that appear to

increase the risk of cancer include fats, alcohol, salt-cured or smoked meats, nitrate- and nitrite-containing foods, and red and processed meats. Heavy alcohol use increases the risk of cancers of the mouth, pharynx, larynx, esophagus, liver, colon, rectum, and breast (ACS, 2015a).

Poor diet and obesity have been identified as contributing factors to the development of cancers of the breast (in postmenopausal women), colon, endometrium, esophagus, and kidney. Obesity is also associated with an increased risk for cancers of the pancreas, gallbladder, thyroid, ovary, and cervix, and for multiple myeloma, Hodgkin lymphoma, and an aggressive form of prostate cancer. Multiple studies have long linked sedentary lifestyles and lack of regular exercise to cancer development (Lu, Clague, & Bernstein, 2015); (Thomson, McCullough, Wertheim, et al., 2014).

Hormonal Agents

Tumor growth may be promoted by disturbances in hormonal balance, either by the body's own (endogenous) hormone production or by administration of exogenous hormones. Cancers of the breast, prostate, and uterus are thought to depend on endogenous hormonal levels for growth. Prenatal exposure to diethylstilbestrol (a synthetic form of the female hormone estrogen) has long been recognized as a risk factor for clear cell adenocarcinoma of the lower genital tract.

Hormonal changes related to the female reproductive cycle are also associated with cancer incidence. Early onset of menses before age 12 and delayed onset of menopause after age 55, null parity (never giving birth), and delayed childbirth after age 30 are all associated with an increased risk of breast cancer. Increased numbers of pregnancies are associated with a decreased incidence of breast, endometrial, and ovarian cancers.

Women who take estrogen after menopause appear to have an increased risk of ovarian cancer. Combination estrogen and progesterone therapy is linked to a higher risk of breast cancer. The longer the combined therapy is used, the higher the risk. However, within 3 years of stopping the hormones, the risk returns to that of a woman who never used this therapy. Women who have taken hormonal therapy appear to have a lower risk of getting colorectal cancer, but when cancers are found it may be more advanced (more likely to have spread to lymph nodes or distant sites) than the cancers found in women not taking hormones (ACS, 2015b).

Role of the Immune System

In humans, transformed cells arise on a regular basis, but are recognized by surveillance cells of the immune system that destroy them before cell growth becomes uncontrolled (immune surveillance). When the immune system fails to identify and stop the growth of transformed cells, a tumor can develop and progress.

Patients who are immunocompromised have an increased incidence of cancer. Transplant recipients who receive immunosuppressive therapy to prevent rejection of the transplanted organ have an increased incidence of cancer (Grossman & Porth, 2014). Patients with acquired immune deficiency syndrome (AIDS) have an increased incidence of Kaposi sarcoma and other cancers. Patients who were previously treated for one cancer are at increased risk for secondary cancers (Grossman & Porth, 2014).

Normal Immune Responses

Through the process of immune surveillance, an intact immune system usually has the ability to recognize and combat cancer cells through multiple, interacting cells and actions of the innate, humoral, and cellular components of the immune system. Tumor-associated antigens (TAAs; also called *tumor cell antigens*) are found on the membranes of many cancer cells. TAAs are processed by antigen-presenting cells (APCs) (e.g., macrophages and dendritic cells [very specialized cells of the immune system] that present antigens to both T- and B lymphocytes) and are presented to T lymphocytes that recognize the antigen-bearing cells as foreign. Multiple TAAs have been identified—some are found in many types of cancer, some exist in the normal tissues of origin as well as the cancer cells, some exist in both normal and cancer cells but are overexpressed (exist in higher concentrations) in cancer cells, and others are very specific to certain cancer types (Kasper, Fauci, Hauser, et al., 2015).

In response to recognizing TAAs as foreign, T-cell lymphocytes release several cytokines that elicit various immune system actions, including (1) proliferation of cytotoxic (cell-killing) T lymphocytes capable of direct destruction of cancer cells, (2) induction of cancer cell apoptosis, and (3) recruitment of additional immune system cells (B-cell lymphocytes that produce antibodies, natural killer cells, and macrophages) that contribute to the destruction and degradation of cancer cells.

Immune System Evasion

Several theories postulate how malignant cells survive and proliferate, evading the elaborate immune system defense mechanisms (Grossman & Porth, 2014). If the body fails to recognize the TAAs on cancer cells or the function of the APCs is impaired, the immune response is not stimulated. Some cancer cells have been found to have altered cell membranes that interfere with APC binding and presentation to T lymphocytes. Tumors can also express molecules that induce T-lymphocyte anergy or tolerance such as PD-1 ligand. These molecules bind to PD-1 proteins on T lymphocytes and either block the killing of the tumor or induce cell death in the lymphocyte. In addition, cancer cells have been found to release cytokines that inhibit APCs as well as other cells of the immune system. When tumors do not possess TAAs that label them as foreign, the immune response is not alerted. This allows the tumor to grow too large to be managed by normal immune mechanisms.

The immunogenicity (immunologic appearance) of cancer cells can be altered through genetic mutations, allowing the cells to evade immune cell recognition. Conversely, mutations are the source for some TAAs. Tumor antigens may combine with the antibodies produced by the immune system and hide or disguise themselves from normal immune defense mechanisms. The tumor antigen–antibody complexes that evade recognition lead to a false message to decrease further production of antibodies as well as other immune system components.

Overexpression (abnormally high concentrations) of host suppressor T lymphocytes induced through the release of cytokines by malignant cells is thought to down-regulate the immune response, thus permitting uncontrolled cell growth (Kasper et al., 2015). Suppressor T lymphocytes normally assist in regulating lymphocyte production and diminishing immune responses (i.e., antibody production) when they are no longer required. Low levels of antibodies and high levels of suppressor cells have been found in patients with multiple myeloma, which is a cancer associated with hypogammaglobulinemia (low amounts of serum antibodies). Conversely, there is evidence that proliferation of helper T lymphocytes, which promote the immune response, is impaired by cytokines produced by cancer cells (Kasper et al., 2015). Without helper T lymphocytes,

the immune system response is limited and the cancer cells continue to proliferate. Understanding the role of the immune system and identification of the ways in which cancer evades the body's natural defenses provide the foundation for therapeutic approaches that seek to support and enhance the immune system's role in combating cancer (see Chapter 54).

Detection and Prevention of Cancer

Nurses in all settings play a key role in cancer detection and prevention. Primary, secondary, and tertiary prevention of cancer are all important.

Primary Prevention

Primary prevention is about reducing the risks of disease through health promotion and risk reduction strategies. Guidelines on nutrition and physical activity for cancer prevention can be found in Chart 58-2.

An example of primary prevention is the use of immunization to reduce the risk of cancer through prevention of infections associated with cancer. The HPV vaccine is recommended to prevent cervical and head and neck cancers (Chen et al., 2014). The vaccine to prevent HBV infection is recommended by the CDC (2015) to reduce the risk of hepatitis and subsequent development of liver cancer.

Secondary Prevention

Secondary prevention involves screening and early detection activities that seek to identify precancerous lesions and early-stage cancer in individuals who lack signs and symptoms of cancer. ACS screening is advocated for many types of cancer (See Table 58-4) (ACS, 2016b). Detection of cancer at an early stage may reduce costs, use of resources, and the morbidity associated with advanced stages of cancer and their associated complex treatment approaches. Many screening and detection programs target people who do not regularly practice health-promoting behaviors or lack access to health care. Nurses continue to develop community-based screening and detection programs that address barriers to health care or reflect the socioeconomic and cultural beliefs of the target population (Benito, Binefa, Lluch, et al., 2014); (Brittain & Murphy, 2015); (Shackelford, Weyhenmeyer, & Mabus, 2015).

The evolving understanding of the role of genetics in cancer cell development has contributed to prevention and screening efforts. Many centers offer cancer risk evaluation programs that provide interdisciplinary in-depth assessment, screening, education, and counseling as well as follow-up monitoring for people at high risk for cancer (National Comprehensive Cancer Network [NCCN] 2015a); (NCCN 2015b). The NCI provides guidance for cancer risk assessment, counseling, education, and genetic testing (NCI, 2016).

Tertiary Prevention

Tertiary prevention efforts focus on monitoring for and preventing recurrence of the primary cancer as well as screening for the development of second malignancies in cancer survivors. Survivors are assessed for the development of second malignancies such as lymphoma and leukemia, which have been associated with certain chemotherapy agents and the use of radiation therapy (ACS, 2014). Survivors may also develop second malignancies not related to treatment but genetic mutations related to inherited cancer syndromes, environmental exposures, and lifestyle factors.

Diagnosis of Cancer

A cancer diagnosis is based on assessment of physiologic and functional changes and results of the diagnostic evaluation.

Chart 58-2 HEALTH PROMOTION

American Cancer Society Guidelines on Nutrition and Physical Activity for Cancer Prevention

Individual Choices

Achieve and Maintain a Healthy Weight Throughout Life

- Be as lean as possible throughout life without being underweight.
- Avoid excessive weight gain at all ages. For those who are currently overweight or obese, losing even a small amount of weight has health benefits and is a good place to start.
- Engage in regular physical activity and limit consumption of high-calorie foods and beverages as key strategies for maintaining a healthy weight.

Adopt a Physically Active Lifestyle

- Adults should engage in at least 150 minutes of moderate-intensity or 75 minutes of vigorous-intensity physical activity each week, or an equivalent combination, preferably spread throughout the week.
- Children and adolescents should engage in at least 1 hour of moderate- or vigorous-intensity physical activity each day, with vigorous-intensity activity at least 3 days each week.
- Limit sedentary behavior such as sitting, lying down and watching television, and other forms of screen-based entertainment.
- Doing any intentional physical activity above usual activities, no matter what one's level of activity, can have many health benefits.

Consume a Healthy Diet, With an Emphasis on Plant Sources

- Choose foods and beverages in amounts that help achieve and maintain a healthy weight.
- Limit consumption of processed meat and red meats.
- Eat at least $2\frac{1}{2}$ cups of vegetables and fruits each day.
- Choose whole grains in preference to processed (refined) grains.

If You Drink Alcoholic Beverages, Limit Consumption

- Drink no more than one drink per day for women or two per day for men.

Community Action

Public, private, and community organizations should work collaboratively at national, state, and local levels to implement policy environmental changes that:

- Increase access to affordable, healthy foods in communities, worksites, and schools, and decrease access to and marketing of foods and beverages of low nutritional value, particularly to youth.
- Provide safe, enjoyable, and accessible environments for physical activity in schools and worksites, and for transportation and recreation in communities.

TABLE 58-4 American Cancer Society Screening Guidelines for the Early Detection of Cancer in Average-Risk Asymptomatic People[a]

Cancer Site	Population	Test or Procedure	Recommendation
Breast	Women, ages 40–54	Mammography	Women should undergo regular screening mammography starting at age 45 years. Women ages 45–54 should be screened annually. Women should have the opportunity to begin annual screening between the ages of 40 and 44.
	Women age 55 and over	Mammography	Transition to biennial screening, or have the opportunity to continue annual screening. Continue screening as long as overall health is good and life expectancy is 10+ years.
Cervix	Women, ages 21–29	Pap test	Screening should be done every 3 years with conventional or liquid-based Pap tests. Screening should be done every 5 years with both the HPV test and the Pap test (preferred), or every 3 years with the Pap test alone (acceptable).
	Women ages 30–65	Pap test & HPV DNA test	Women ages 66+ who have had ≥3 consecutive negative Pap tests or ≥2 consecutive negative HPV and Pap tests within the past 10 years, with the most recent test occurring in the past 5 years should stop cervical cancer screening. Women who have had a total hysterectomy should stop cervical cancer screening.
	Women ages 66+	Pap test & HPV DNA test	
Colorectal[b]	Men and women, ages 50+	Guaiac-based fecal occult blood test (gFOBT) with at least 50% sensitivity or fecal immunochemical test (FIT) with at least 50% sensitivity, or	Annual testing of spontaneously passed stool specimens. Single stool testing during a clinician office visit is not recommended, nor are "throw in the toilet bowl" tests. In comparison with guaiac-based tests for the detection of occult blood, immunochemical tests are more patient-friendly and are likely to be equal or better in sensitivity and specificity. There is no justification for repeating FOBT in response to an initial positive finding.
		Stool DNA test, or	Every 3 years
		Flexible sigmoidoscopy (FSIG), or	Every 5 years. FSIG can be performed alone, or consideration can be given to combining FSIG performed every 5 years with a highly sensitive guaiac-based gFOBT or FIT performed annually.
		Double-contrast barium enema (DCBE), or	Every 5 years
		Colonoscopy, or	Every 10 years
		CT Colonography	Every 5 years
Endometrial	Women, at menopause	At the time of menopause, women at average risk should be informed about risks and symptoms of endometrial cancer and encouraged to report any unexpected bleeding or spotting to their physicians.	N/A
Lung	Current or former smokers (quit within past 15 years) ages 55–74 in good health with at least a 30 pack-year history	Low-dose helical CT (LDCT)	Clinicians with access to high-volume, high-quality lung cancer screening and treatment centers should initiate a discussion about lung cancer screening with apparently healthy patients aged 55–74 who have at least a 30 pack-year smoking history, and who currently smoke or have quit within the past 15 years. A process of informed and shared decision making with a clinician related to the potential benefits, limitations, and harms associated with screening for lung cancer with LDCT should occur before any decision is made to initiate lung cancer screening. Smoking cessation counseling remains a high priority for clinical attention in discussions with current smokers, who should be informed of their continuing risk of lung cancer. Screening should not be viewed as an alternative to smoking cessation.

(Continued)

(Continued)

Prostate	Men, age 50+	Digital rectal examination (DRE) and prostate-specific antigen (PSA) test	Men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about whether to be screened for prostate cancer, after receiving information about the potential benefits, risks, and uncertainties associated with prostate cancer screening. Prostate cancer screening should not occur without an informed decision-making process.
Cancer-related checkup	Men and women, age 20+	On the occasion of a periodic health examination, the cancer-related checkup should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures.	N/A

HPV, human papillomavirus; DNA, deoxyribonucleic acid; CT, computed tomography.

[a]All individuals should become familiar with the potential benefits, limitations, and harms associated with cancer screening.

[b]All positive tests (other than colonoscopy) should be followed up with colonoscopy.

Adapted with permission from American Cancer Society. Cancer Facts and Figures 2016. Atlanta: American Cancer Society, Inc.

Patients with suspected cancer undergo extensive testing to (1) determine the presence and extent of cancer, (2) identify possible disease metastasis, (3) evaluate the function of involved and uninvolved body systems and organs, and (4) obtain tissue and cells for analysis, including evaluation of tumor stage and grade. The diagnostic evaluation includes a review of systems; physical examination; imaging studies; laboratory tests of blood, urine, and other body fluids; procedures; and pathologic analysis. A selection of diagnostic tests is found in Table 58-5.

Patients undergoing extensive testing may be fearful of the procedures and anxious about possible test results. Nurses help address the patient's fear and anxiety by explaining the tests to be performed, the sensations likely to be experienced, and the patient's role in the test procedures. The nurse encourages the patient and family to voice their fears about the test results, supports the patient and family throughout the diagnostic evaluation, and reinforces and clarifies information conveyed by the physician. The nurse also encourages the patient and family to communicate, share their concerns, and discuss their questions and concerns with one another.

Tumor Staging and Grading

A complete diagnostic evaluation includes identifying the stage and grade of the tumor. This is accomplished prior to treatment to provide baseline data for evaluating outcomes of therapy and to maintain a systematic and consistent approach to ongoing diagnosis and treatment. Treatment options and prognosis are based on tumor stage and grade.

Staging provides a common language used by health care providers and scientists to accurately communicate about cancer across clinical settings and in research. These systems also provide a convenient shorthand notation that condenses lengthy descriptions into manageable terms for comparisons of treatments and prognoses.

Staging determines the size of the tumor, the existence of local invasion, lymph node involvement, and distant metastasis. Several systems exist for classifying the anatomic extent of disease. The tumor, nodes, and metastasis (TNM) system (see Chart 58-3) is one system used to describe many solid tumors (Acharyya et al., 2015); (ACS, 2015a).

Chart 58-3

TNM Classification System

T The extent of the primary tumor
N The absence or presence and extent of regional lymph node metastasis
M The absence or presence of distant metastasis
The use of numerical subsets of the TNM components indicates the progressive extent of the malignant disease.

Primary Tumor (T)

Tx Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma in situ
T1, T2, T3, T4 Increasing size and/or local extent of the primary tumor

Regional Lymph Nodes (N)

Nx Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1, N2, N3 Increasing involvement of regional lymph nodes

Distant Metastasis (M)

Mx Distant metastasis cannot be assessed
M0 No distant metastasis
M1 Distant metastasis

Grading is the pathologic classification of tumor cells. Grading systems seek to define the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and histologic characteristics of the tissue of origin (differentiation). Samples of cells used to establish the tumor grade may be obtained from tissue scrapings, body fluids, secretions, washings, biopsy, or surgical excision. This information helps providers predict the behavior and prognosis of various tumors. The grade corresponds with a numeric value ranging from I to IV. Grade I tumors, also known as well-differentiated tumors, closely resemble the tissue of origin

TABLE 58-5 Selected Diagnostic Tests Used to Detect Cancer

Test	Description	Examples of Diagnostic Uses
Tumor marker identification	Analysis of substances found in tumor tissue, blood, or other body fluids that are indicative of cancer cells or specific characteristics of cancer cells. These substances may also be found in some normal body tissues	Breast, colon, lung, ovarian, testicular, prostate cancers
Genetic tumor markers (Also called prognostic indicators)	Analysis for the presence of mutations (alterations) in genes found in tumors or body tissues. Assists in diagnosis, selection of treatment, prediction of response to therapy, and risk of progression or recurrence	Breast, lung, kidney, ovarian, brain cancers; leukemia; and lymphoma. Many uses of genetic profiling are considered investigational
Mammography	Use of x-ray images of the breast	Breast cancer
Magnetic resonance imaging (MRI)	Use of magnetic fields and radiofrequency signals to create sectioned images of various body structures	Neurologic, pelvic, abdominal, thoracic, breast cancers
Computed tomography (CT) scan	Use of narrow-beam x-ray to scan successive layers of tissue for a cross-sectional view	Neurologic, pelvic, skeletal, abdominal, thoracic cancers
Fluoroscopy	Use of x-rays that identify contrasts in body tissue densities; may involve the use of contrast agents	Skeletal, lung, gastrointestinal cancers
Ultrasonography (ultrasound)	High-frequency sound waves echoing off body tissues are converted electronically into images; used to assess tissues deep within the body	Abdominal and pelvic cancers
Endoscopy	Direct visualization of a body cavity or passageway by insertion of an endoscope into a body cavity or opening; allows tissue biopsy, fluid aspiration, and excision of small tumors. Used for diagnostic and therapeutic purposes	Bronchial, gastrointestinal cancers
Nuclear medicine imaging	Uses IV injection or ingestion of radioisotope substances followed by imaging of tissues that have concentrated the radioisotopes	Bone, liver, kidney, spleen, brain, thyroid cancers
Positron emission tomography (PET)	Through the use of a tracer, provides black-and-white or color-coded images of the biologic activity of a particular area, rather than its structure. Used in detection of cancer or its response to treatment	Lung, colon, liver, pancreatic, head and neck cancers; Hodgkin and non-Hodgkin lymphoma and melanoma
PET fusion	Use of a PET scanner and a CT scanner in one machine to provide an image combining anatomic detail, spatial resolution, and functional metabolic abnormalities	See PET
Radioimmunoconjugates	Monoclonal antibodies are labeled with a radioisotope and injected IV into the patient; the antibodies that aggregate at the tumor site are visualized with scanners	Colorectal, breast, ovarian, head and neck cancers; lymphoma and melanoma
Vascular imaging	Use of contrast agents that are injected into veins or arteries and monitored by fluoroscopy, CT, or MRI imaging in order to assess tumor vasculature. Used to assess tumor vascularity prior to surgical procedures. Use in assessing the efficacy of antiangiogenesis (preventing new blood vessel formation) drugs is largely investigational	Liver and brain cancers

in structure and function. Tumors that do not clearly resemble the tissue of origin in structure or function are described as poorly differentiated or undifferentiated and are assigned grade IV. These tumors tend to be more aggressive, less responsive to treatment, and associated with a poorer prognosis as compared to well-differentiated, grade I tumors. Various staging and grading systems are used to characterize cancers.

Anatomic Stage Group

Once the diagnosis, clinical stage, and histologic grade have been determined, the anatomic stage group, designated by I through IV (representing increasing severity of disease), is assigned to facilitate communication, treatment decisions, and estimation of prognosis. The anatomic stage group is also useful for comparing clinical outcomes.

Management of Cancer

Treatment options offered to patients with cancer are based on treatment goals for each specific type, stage, and grade of cancer. The range of possible treatment goals includes complete eradication of malignant disease (cure), prolonged survival and containment of cancer cell growth (control), or relief of symptoms associated with the disease and improvement of quality of life (palliation). Treatment approaches are not initiated until the diagnosis of cancer has been confirmed and staging and grading have been completed.

The health care team and the patient and family must have a clear understanding of the treatment options and goals. Open communication and support are vital as those involved periodically reassess treatment plans and goals when complications of therapy develop or disease progresses.

Multiple modalities are commonly used in cancer treatment. Various approaches, including surgery, radiation therapy, chemotherapy, hematopoietic stem cell transplantation (HSCT), hyperthermia, and targeted therapy, may be used together or at different times throughout treatment. Understanding the principles of each and how they interrelate is important in understanding the rationale and goals of treatment.

Surgery

Surgical removal of the entire cancer remains the ideal and most frequently used treatment method. However, the specific surgical approach may vary for several reasons. Diagnostic surgery is the definitive method for obtaining tissue to identify the cellular characteristics that influence all treatment decisions. Surgery may be the primary method of treatment, or it may be prophylactic, palliative, or reconstructive.

Diagnostic Surgery

Diagnostic surgery, or biopsy, is performed to obtain a tissue sample for histologic analysis of cells suspected to be malignant. In most instances, the biopsy is taken from the actual tumor; however, in some situations, it is necessary to take a sample of lymph nodes near a suspicious tumor. Many cancers can metastasize from the primary site to other areas of the body through the lymphatic circulation. Knowing whether adjacent lymph nodes contain tumor cells helps the health care team plan the best therapeutic approach to combat cancer that has spread beyond the primary tumor site. The use of injectable dyes and nuclear medicine imaging can help identify the sentinel lymph node or the initial lymph node to which the primary tumor and surrounding tissue drain. Sentinel lymph node biopsy (SLNB), also known as sentinel lymph node mapping, is a minimally invasive surgical approach that in many instances has replaced more invasive lymph node dissections (lymphadenectomy) and the associated complications such as lymphedema and delayed healing. SLNB has been widely adopted for regional lymph node staging in selected cases of melanoma and breast cancer (NCCN, 2015c).

Biopsy Types

Biopsy methods include excisional, incisional, and needle biopsy. The biopsy type is determined by the size and location of the tumor, the type of treatment anticipated if the cancer diagnosis is confirmed, and the need for surgery and general anesthesia. The biopsy method that allows for the least invasive approach while permitting the most representative tissue sample is chosen. Diagnostic imaging techniques can be used to assist in locating the suspicious lesion and to facilitate accurate tissue sampling. The patient and family are provided the opportunity and time to discuss the options before definitive plans are made.

Excisional biopsy is used for small, easily accessible tumors of the skin, upper or lower gastrointestinal and upper respiratory tracts. In many cases, the surgeon can remove the entire tumor as well as the surrounding marginal tissues. The removal of normal tissue beyond the tumor area decreases the possibility that residual microscopic malignant cells may lead to a recurrence of the tumor. This approach not only provides the pathologist with the entire tissue specimen for the determination of stage and grade but also decreases the chance of seeding tumor cells (disseminating cancer cells throughout surrounding tissues).

Incisional biopsy is performed if the tumor mass is too large to be removed. In this case, a wedge of tissue from the tumor is removed for analysis. The cells of the tissue wedge must be representative of the tumor mass so that the pathologist can provide an accurate diagnosis. If the specimen does not contain representative tissue and cells, negative biopsy results do not guarantee the absence of cancer.

Excisional and incisional approaches are often performed through endoscopy. However, a surgical procedure may be required to determine the anatomic extent or stage of the tumor. For example, a diagnostic or staging laparotomy (the surgical opening of the abdomen to assess malignant abdominal disease) may be necessary to assess malignancies such as gastric or colon cancer.

Needle biopsy is performed to sample suspicious masses that are easily and safely accessible, such as some masses in the breasts, thyroid, lung, liver, and kidney. Needle biopsies are most often performed on an outpatient basis. They are fast, relatively inexpensive, easy to perform, and may require only local anesthesia. In general, the patient experiences slight and temporary physical discomfort. In addition, the surrounding tissues are minimally disturbed, thus decreasing the likelihood of seeding cancer cells (disseminating cancer cells to adjacent tissue). Fine-needle aspiration (FNA) biopsy involves aspirating cells rather than intact tissue through a needle that is guided into a suspected diseased area. This type of specimen can only be analyzed by cytological examination (viewing only cells, not tissue). Often, x-ray, computed tomography (CT) scanning, ultrasonography, or magnetic resonance imaging (MRI) is used to help locate the suspicious area and guide placement of the needle. FNA does not always yield enough material to permit accurate diagnosis, necessitating additional biopsy procedures. A core needle biopsy uses a specially designed needle to obtain a small core of tissue that permits histologic analysis. Most often, this specimen is sufficient to permit accurate diagnosis.

Surgery as Primary Treatment

When surgery is the primary approach in treating cancer, the goal is to remove the entire tumor or as much as is feasible (a procedure sometimes called *debulking*) as well as any involved surrounding tissue, including regional lymph nodes.

Two common surgical approaches used for treating primary tumors are local and wide excisions. Local excision, often performed on an outpatient basis, is warranted when the mass is small. It includes removal of the mass and a small margin of normal tissue that is easily accessible. Wide or radical excisions (en bloc dissections) include removal of the primary tumor, lymph nodes, adjacent involved structures, and surrounding tissues that may be at high risk for tumor spread. This surgical method may result in disfigurement and altered functioning, necessitating rehabilitation, reconstructive procedures, or both. However, wide excisions are considered if the tumor can be removed completely and the chances of cure or control are good.

Minimally invasive surgical techniques are increasingly replacing traditional surgery associated with large incisions for a variety of cancers. The advantages of minimally invasive approaches include minimization of surgical trauma, decreased blood loss, decreased incidence of wound infection and other complications associated with surgery, decreased surgical time and requirement for anesthesia, decreased postoperative pain and limited mobility, and shorter periods of recovery (Nguyen, Summers, & Finkelstein, 2015).

Video-assisted endoscopic surgery, an example of minimally invasive surgery, uses an endoscope with intense lighting and an attached multichip mini-camera that is inserted into the

body through a small incision. The surgical instruments are inserted into the surgical field through one or two additional small incisions, each about 3 cm in length. The camera transmits the image of the involved area to a monitor so that the surgeon can manipulate the instruments to perform the necessary procedure. Such surgery is used for many thoracic and abdominal procedures. The use of robotics during laparoscopic procedures permits the removal of tumors with more precision and dexterity than could be accomplished by laparoscopic surgery alone (Niklas, Saar, Berg, et al., 2016). Laparoscopic robotic-assisted surgery has been used for prostate and gynecologic cancers. Transoral robotic-assisted surgery is being used for certain types of oral and laryngeal cancers (Chung, Rosenthal, Magnuson, et al., 2015).

Salvage surgery is an additional treatment option that uses an extensive surgical approach to treat the local recurrence of cancer after the use of a less extensive primary approach. Mastectomy to treat recurrent breast cancer after primary lumpectomy and radiation is an example of salvage surgery.

Surgery may completely excise limited areas of metastatic disease (referred to as oligometastatic disease) as well. An example would be colon cancer with one to three small areas of liver metastasis and no evidence of cancer elsewhere. In the past, patients with recurrent or metastatic disease were treated with palliation only as their disease was considered incurable. However, evidence suggests possible cure or prolonged disease-free survival for patients with controlled or completely removed primary cancer and completely removed, limited, metastatic disease (Corbin, Hellman, & Weichselbaum, 2013); (Di Lascio, & Pagani, 2014).

In addition to surgery that uses surgical blades or scalpels to excise the mass and surrounding tissues, several other types of techniques are available. Table 58-6 provides examples of these techniques.

A multidisciplinary approach to patient care is essential for the patient undergoing cancer-related surgery. The effects of surgery on the patient's body image, self-esteem, and functional abilities are addressed. If necessary, a plan for postoperative rehabilitation is made before the surgery is performed. The growth and dissemination of cancer cells may have produced distant micrometastases by the time the patient seeks treatment. Therefore, attempting to remove wide margins of tissue in the hope of "getting all the cancer" may not be feasible. This reality substantiates the need for a coordinated multidisciplinary approach to cancer therapy.

Once the surgery has been completed, one or more additional (or adjuvant) modalities may be chosen to increase the likelihood of eradicating the remaining microscopic cancer cells that are undetectable by available diagnostic procedures. However, some cancers that are treated surgically in the very early stages (e.g., skin and testicular cancers) are considered to be curable without additional therapy.

Prophylactic Surgery

Prophylactic or risk reduction surgery involves removing non-vital tissues or organs that are at increased risk of developing cancer. The following factors are considered when discussing possible prophylactic surgery:

- Family history and genetic predisposition
- Presence or absence of signs and symptoms
- Potential risks and benefits
- Ability to detect cancer at an early stage
- Alternative options for managing increased risk
- The patient's acceptance of the postoperative outcome

Colectomy, mastectomy, and oophorectomy are examples of prophylactic surgeries. Identification of genetic markers indicative of inherited cancer syndromes or a predisposition to develop some types of cancer plays a role in decisions concerning prophylactic surgeries. However, what is adequate justification for prophylactic surgery remains controversial. For example, several factors are considered when deciding to proceed with a prophylactic mastectomy, including a strong family history of breast cancer; positive *BRCA1* or *BRCA2* findings; an abnormal physical finding on breast examination, such as progressive nodularity and cystic disease; a proven history of breast cancer in the opposite breast; abnormal mammography findings; abnormal biopsy results; and individual factors that may influence the patient's decision-making process (Mahon, 2014). Prophylactic surgery is discussed with patients and families along with other approaches for managing increased risk of cancer development. Preoperative education and counseling, as well as long-term follow-up, are provided.

Palliative Surgery

When surgical cure is not possible, the goals of surgical interventions are to relieve symptoms, make the patient as

TABLE 58-6 Selected Techniques Used for Localized Destruction of Tumor Tissue

Type of Procedure	Description	Examples of Use
Chemosurgery	Use of chemicals or chemotherapy applied directly to tissue to cause destruction	Intraperitoneal chemotherapy for ovarian cancer involving the abdomen and peritoneum
Cryoablation	Use of liquid nitrogen or a very cold probe to freeze tissue and cause cell destruction	Cervical, prostate, and rectal cancers
Electrosurgery	Use of an electric current to destroy tumor cells	Basal and squamous cell skin cancers
Laser surgery	Use of light and energy aimed at an exact tissue location and depth to vaporize cancer cells (also referred to as photocoagulation or photoablation)	Dyspnea associated with endobronchial obstructions
Photodynamic therapy	IV administration of a light-sensitizing agent (hematoporphyrin derivative [HPD]) that is taken up by cancer cells, followed by exposure to laser light within 24–48 hours; causes cancer cell death	Palliative treatment of dysphagia associated with esophageal and dyspnea associated with endobronchial obstructions
Radiofrequency ablation (RFA)	Uses localized application of thermal energy that destroys cancer cells through heat: temperatures exceed 50°C (122°F)	Nonresectable liver tumors, pain control with bone metastasis

TABLE 58-7 Types of Palliative Surgery and Interventions

Procedure	Indications
Abdominal shunt placement	Ascites
Biliary stent placement	Biliary obstruction
Bone stabilization	Displaced bone fracture related to metastatic disease
Colostomy or ileostomy	Bowel obstruction
Cordotomy	Pain
Epidural catheter placement (for administering epidural analgesics)	Pain
Excision of solitary metastatic lesion	Metastatic lung, liver, or brain lesion
Gastrostomy, jejunostomy tube placement	Upper gastrointestinal tract obstruction
Hormone manipulation (removal of ovaries, testes, adrenals, pituitary)	Tumors that depend on hormones for growth
Nerve block	Pain
Percutaneous enteral gastrostomy (PEG) tube placement	Enteral nutrition
Pericardial drainage tube placement	Pericardial effusion
Peritoneal drainage tube placement	Ascites
Pleural drainage tube placement	Pleural effusion
Ureteral stent placement	Ureteral obstruction
Venous access device placement (for administering parenteral analgesics)	Pain

comfortable as possible, and promote quality of life as defined by the patient and family. Palliative surgery is performed in an attempt to relieve symptoms, such as ulceration, obstruction, hemorrhage, pain, and malignant effusions (see Table 58-7). Honest and informative communication with the patient and family about the goal of surgery is essential to avoid false hope and disappointment.

Reconstructive Surgery

Reconstructive surgery may follow curative or extensive surgery in an attempt to improve function or obtain a more desirable cosmetic effect. It may be performed in one operation or in stages. The surgeon who will perform the surgery discusses possible reconstructive surgical options with the patient before the primary surgery is performed. Reconstructive surgery may be indicated for breast, head and neck, and skin cancers.

The nurse assesses the patient's needs and the impact that altered functioning and body image may have on quality of life. Nurses provide patients and families with opportunities to discuss these issues. The individual needs of the patient undergoing reconstructive surgery and their families must be accurately recognized and addressed.

Nursing Management

Patients undergoing surgery for cancer require general perioperative nursing care (see Chapter 5). Surgical care is individualized according to age, organ impairment, specific deficits, comorbidities, cultural implications, and altered immunity. Combining other treatment methods, such as radiation and chemotherapy, with surgery also contributes to postoperative complications, such as infection, impaired wound healing, altered pulmonary or renal function, and the development of venous thromboembolism (VTE). The nurse completes a thorough preoperative assessment for factors that may affect the patient undergoing the surgical procedure.

Preoperatively, the nurse provides the patient and family with verbal and written information about the surgical procedure as well as other interventions that may take place intraoperatively (i.e., radiation implants). Instructions concerning prophylactic antibiotic requirements, diet, and bowel preparation are also provided.

Patients who are undergoing surgery for the diagnosis or treatment of cancer may be anxious about the surgical procedure, possible findings, postoperative limitations, changes in normal body functions, and prognosis. The patient and family require time and assistance to process this information, possible changes, and expected outcomes resulting from the surgery.

The nurse serves as the patient advocate and liaison and encourages the patient and family to take an active role in decision making when possible. If the patient or family asks about the results of diagnostic testing and surgical procedures, the nurse's response is guided by the information that was conveyed previously. The nurse may be asked to explain and clarify information for patients and families that was provided initially but was not grasped because of intense anxiety. It is important that the nurse, as well as other members of the health care team, provide information that is consistent.

Postoperatively, the nurse assesses patient responses to surgery and monitors the patient for possible complications, such as infection, bleeding, thrombophlebitis, wound dehiscence, fluid and electrolyte imbalance, and organ dysfunction. The nurse also provides for the patient's comfort. Postoperative education addresses wound care, pain management, activity, nutrition, and medication information.

Plans for discharge, follow-up, home care, and subsequent treatment and rehabilitation are initiated as early as possible to ensure continuity of care from hospital to home or from a cancer referral center to the patient's local hospital and health care provider. Patients and families are encouraged to use community resources such as the ACS for support and information (see the Resources section at the end of this chapter).

Radiation Therapy

Approximately 60% of patients with cancer receive radiation therapy at some point during treatment (Halperin, Wazer, Perez, et al., 2013). Radiation may be used to cure cancer, as in thyroid carcinomas, localized cancers of the head and neck, and cancers of the cervix. Radiation therapy may also be used to control cancer when a tumor cannot be removed surgically or when local nodal metastasis is present. Neoadjuvant (prior to local definitive treatment) radiation therapy, with or without chemotherapy, is used to reduce tumor size in order to facilitate surgical resection. Radiation therapy may be given prophylactically to prevent local recurrence or spread of microscopic cells from the primary tumor to a distant area (e.g., irradiating the breast and axilla following lumpectomy or mastectomy for breast cancer). Palliative radiation therapy is used to relieve the symptoms of locally advanced or metastatic disease, especially when the cancer has spread to the brain, bone, or soft tissue, or to treat oncologic emergencies, such as superior vena cava syndrome, bronchial airway obstruction, or spinal cord compression.

Two types of ionizing radiation—electromagnetic radiation (x-rays and gamma rays) and particulate radiation (electrons, beta particles, protons, neutrons, and alpha particles)—can be used to kill cells. The most lethal damage is the direct alteration of the DNA molecule within the cells of both malignant and normal tissues. Ionizing radiation can directly break the strands of the DNA helix, leading to cell death. It can also indirectly damage DNA through the formation of free radicals. If the DNA cannot be repaired, the cell may die immediately or may initiate apoptosis (Datta, Kundu, Ghosh, et al., 2014); (Montezano, Dulak-Lis, Tsiropoulou, et al., 2015).

Replicating cells are most vulnerable to the disruptive effects of radiation (during DNA synthesis and mitosis, i.e., early S, G_2, and M phases of the cell cycle; see Fig. 58-4). Therefore, those body tissues that undergo frequent cell division are most sensitive to radiation therapy. These tissues include bone marrow, lymphatic tissue, epithelium of the gastrointestinal tract, hair follicles, and gonads. Slower-growing tissues and tissues at rest (e.g., muscle, cartilage, nervous system, and connective tissues) are relatively radioresistant (less sensitive to the effects of radiation). However, it is important to remember that radiation therapy is localized treatment, and only the tissues that are within the treatment field are affected.

A radiosensitive tumor is one that can be destroyed by a dose of radiation that still allows for cell repair and regeneration in the surrounding normal tissue. If the radiation is delivered when most tumor cells are cycling through the cell cycle, the number of cancer cells destroyed (cell kill) is maximal. Radiation sensitivity is enhanced in tumors that are smaller in size and that contain cells that are rapidly dividing (highly proliferative) and poorly differentiated (no longer resembling the tissue of origin).

Radiation Dosage

The radiation dosage depends on the sensitivity of the target tissues to radiation, the size of the tumor, radiation tolerance of the surrounding normal tissues, and critical structures adjacent to the tumor target. The lethal tumor dose is defined as the dose that will eradicate 95% of the tumor yet preserve normal tissue. In external-beam radiation therapy (EBRT), the total radiation dose is delivered over several weeks in daily doses called *fractions*. This allows healthy tissue to repair and achieves greater cell kill by exposing more cells to the radiation as they begin active cell division. Repeated radiation treatments over time (fractionated doses) also allow for the periphery of the tumor to be reoxygenated repeatedly, because tumors shrink from the outside inward. This increases the radiosensitivity of the tumor, thereby increasing tumor cell death (Morgan, Ten Haken, & Lawrence, 2015). Newer approaches take advantage of increased radiation beam conformality (better tumor targeting) to administer radiation in fewer doses with larger fractions sizes (hypo-fractionation and stereotactic body radiotherapy [SBRT]).

Administration of Radiation

Radiation therapy can be given in various ways depending on the source of radiation used, the location of the tumor, and the type of cancer. The primary radiotherapy modalities include EBRT, brachytherapy (a form of internal radiation), systemic (radioisotopes), and contact or surface molds.

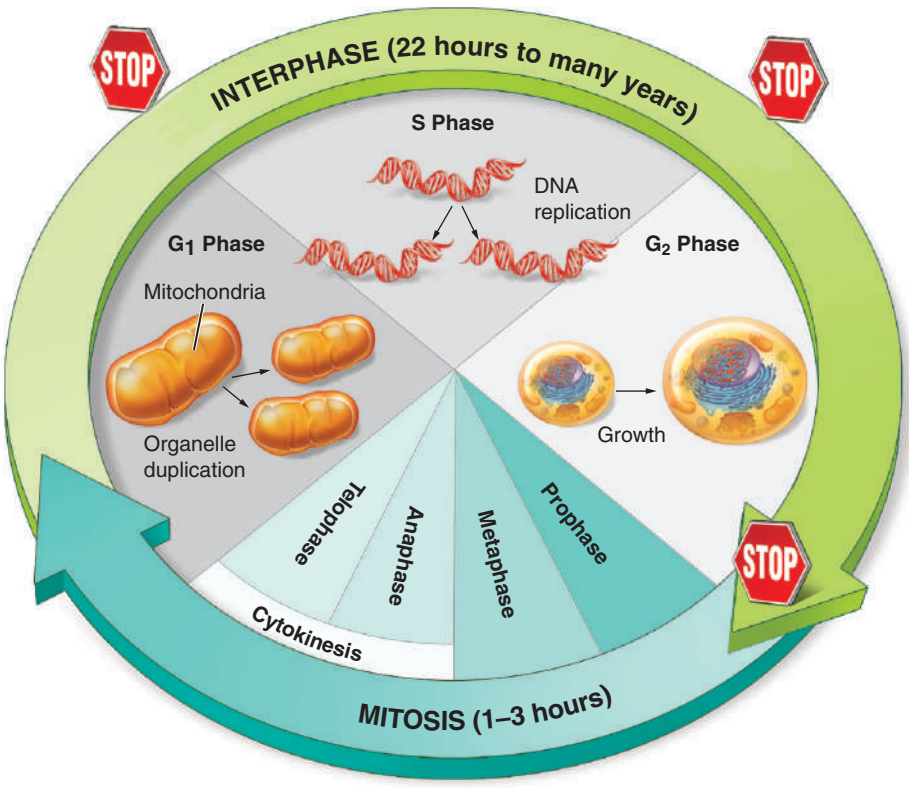

Figure 58-4 • Cell cycle. The cell cycle's four steps are illustrated beginning with G_1 and proceeding to M. The first growth phase (G_1), DNA synthesis phase (S), second growth phase (G_2), and mitosis (M) are illustrated. Reprinted with permission from Grossman, S. G., & Porth, C.M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

External Radiation

EBRT is the most commonly used form of radiation therapy. The energy utilized in EBRT is generated either from a linear accelerator or from a unit that generates energy directly from a core source of radioactive material such as a GammaKnife™ unit. Through computerized software programs, both approaches are able to shape an invisible beam of highly charged photons or gamma rays to penetrate the body and target the tumor with pinpoint accuracy.

Advances in computer technology allow multiple imaging modalities (CT, MRI, and PET scans) to be used to provide three-dimensional images of the tumor, neighboring tissues at risk for microscopic spread, and surrounding normal tissues or organs at risk for radiation-induced toxicity. These images, referred to as volumetric images, allow the radiation oncologist to plan for multiple radiation beams directed from different angles and different planes so that the beams conform precisely around the tumor (referred to as conformal radiation). The dose of radiation that reaches the surrounding normal tissues is reduced, leading to much less toxicity than in older forms of radiation therapy (Halperin et al., 2013). Treatment enhancements in EBRT include the ability to control different intensity or energy levels of radiation beams at different angles directed at the tumor, a process known as intensity-modulated radiation therapy (IMRT), which enables higher doses to be delivered to the tumor while sparing the important healthy structures surrounding the tumor (Halperin et al., 2013). IMRT can be given as standard daily fractions or as "hyperfractionated" twice-daily fractions, which shortens the duration of the patient's treatment schedule. Image-guided radiation therapy (IGRT) uses continuous monitoring of the tumor with ultrasound, x-ray, or CT scans during the treatment to allow for automatic adjustment of the beams as the tumor changes shape or position in an effort to spare the healthy surrounding tissue and reduce side effects. Additional treatment enhancements include respiratory gating, where the treatment delivery is actually synchronized with the patient's respiratory cycle, enabling the beam to be adjusted as the tumor or organ moves. These treatment advancements improve tumor destruction while reducing acute and long-term toxicities (Halperin et al., 2013).

Gamma rays generated from the spontaneous decay of naturally occurring solid source of radioactivity, such as cobalt-60, are one of the oldest forms of EBRT. With the advent of modern linear accelerators, the use of solid radioactive elements is confined primarily to the GammaKnife™ stereotactic radiosurgery unit, which is used as a one-time, high-dose delivery of EBRT for treatment of both benign and malignant intracranial lesions.

Stereotactic body radiotherapy (SBRT) is another form of EBRT that uses higher doses of radiation to penetrate very deeply into the body to control deep-seated tumors that cannot be treated by other approaches such as surgery. SBRT is delivered with considerably higher treatment fraction doses over a short span of time, usually 1 to 5 treatment days, in contrast to daily treatments for 5 days per week for 6 to 8 weeks for conventional EBRT. Specialized linear accelerators with the capability of robotically moving around the patient are used to deliver SBRT, such as the CyberKnife®, Trilogy™, and TomoTherapy® delivery systems, which are now more commonly available.

Proton therapy is another approach to EBRT. Proton therapy utilizes high linear energy transfer (LET) in the form of charged protons generated by a large magnetic unit called a *cyclotron*. The advantage of proton therapy is that it is capable of delivering its high-energy dose to a deep-seated tumor, with decreased doses of radiation to the tissues in front of the tumor while virtually no energy exits through the patient's healthy tissue behind the tumor (Halperin et al., 2013). Proton therapy permits treatment of deep tumors in close proximity to critical structures, such as the heart or major blood vessels.

Internal Radiation

Internal radiation includes localized implantation or systemic radionuclide administration. Brachytherapy delivers the dose of radiation to a localized area while systemic radiotherapy relies on strategies for getting the radionuclides closer to the tumor. The specific radioisotope used is selected on the basis of its half-life, which is the time it takes for half of its radioactivity to decay, and the depth of penetration of the radiation.

Brachytherapy

Brachytherapy is the placement of radioactive sources within or immediately next to the cancer site in order to provide a highly targeted, intense dose of radiation beyond a dose that is usually provided by EBRT. In addition, this form of radiation delivery helps to spare exposure to normal surrounding tissue. The radiation source can be implanted by means of needles or rods, seeds, beads, ribbons, or catheters placed into body cavities (vagina, abdomen, pleura), lumens within organs, or interstitial tissue compartments (breast, prostate). Multiple imaging techniques such as ultrasound, CT, or MRI are used to guide placement of radiation sources. Patients may have many fears or concerns about internal radiation, and the nurse explains the various approaches and safety precautions that will be used to protect the patient, family, and health care staff.

Brachytherapy may be delivered as a temporary or a permanent implant. Temporary applications are delivered as high-dose radiation (HDR) for short periods of time, while low-dose radiation (LDR) is delivered over a more extended period of time. The primary advantage of HDR brachytherapy is that treatment time is shorter, there is reduced exposure to personnel, and the procedure can be performed on an outpatient basis over several days. HDR brachytherapy can be used for intraluminal, surface, interstitial, and intra-cavitary lesions. Intraluminal HDR brachytherapy involves the insertion of catheters or hollow tubes into the lumens of organs so that the radioisotope can be delivered as close to the tumor bed as possible. Lesions in the bronchus, esophagus, rectum, or bile duct can be treated with this approach. Contact or surface application is used for treatment of tumors of the eye, such as retinoblastoma in children or ocular melanoma in adults.

Interstitial HDR implants, used in treating such malignancies as prostate, pancreatic, or breast cancer, may be temporary or permanent, depending on the site and radioisotope used. Based on the dose to be delivered (LDR or HDR), the implants may consist of seeds, needles, wires, strands, or small catheters positioned to provide a local radiation source. Prostate HDR therapy is one form of interstitial brachytherapy, in which radioactive strands or wires are placed, while the patient is under anesthesia, into hollow catheters that have been inserted in the perineum close to the prostate gland (Halperin et al., 2013).

Intracavitary radioisotopes are used to treat gynecologic cancers. In these malignancies, the radioisotopes are inserted into specially positioned applicators within the vagina. The applicator placement is verified by x-ray. Treatment can be achieved with either HDR or LDR brachytherapy sources, depending on the

extent of disease. LDR therapy requires hospitalization because the patient is treated over several days. HDR intraoperative radiotherapy (IORT) has been used as a treatment approach for advanced gynecologic cancer that has spread to the para-aortic area or pelvic wall (Lukens, Gamez, Hu, et al., 2014).

Systemic radiotherapy (radiopharmaceutical therapy) involves the intravenous (IV) administration of a therapeutic radioactive isotope targeted to a specific tumor. Radioactive iodine (I-131) is a widely used form of systemic brachytherapy that is the primary treatment for thyroid cancer (Beck, 2015). Radium-223 dichloride selectively targets prostate cancer bone metastases with high-energy, short-range alpha particles and is approved for the treatment of patients with symptomatic bone metastases and no known visceral metastatic disease (NCCN, 2015d). Radioisotopes are also used as a form of radioimmunotherapy for the treatment of refractory non-Hodgkin lymphoma. (See Chapter 28 for more information on lymphoma.)

Toxicity

Toxicities associated with radiation therapy are most often localized in the region being irradiated and may be increased if concomitant chemotherapy is given. Acute or early toxicities most often begin within 2 weeks of the initiation of treatment occur when normal cells within the treatment area are damaged and cellular death exceeds regeneration. Body tissues most affected are those that normally proliferate rapidly, such as the skin, the epithelial lining of the gastrointestinal tract, and the bone marrow.

Altered skin integrity is common and can include alopecia (hair loss) associated with whole brain radiation. Other skin reactions, referred to as radiation dermatitis, occur along a continuum ranging from erythema and dry desquamation (flaking of skin) to moist or wet desquamation (dermis exposed, skin oozing serous fluid) to, potentially, ulceration. Factors that contribute to the severity of radiation dermatitis include the dose and form of radiation, inclusion of skin folds in the irradiated area, increased age and the presence of medical comorbidities (Fogh & Yom, 2014). Symptoms of radiation dermatitis may necessitate treatment interruption, delays, or cessation of therapy. Re-epithelialization occurs after treatments have been completed. Hyperpigmentation, a less severe radiation-associated skin reaction, may develop about 2 to 4 weeks after the initiation of treatment.

Alterations in oral mucosa secondary to radiation therapy in the head and neck region include stomatitis (inflammation of the oral tissues), decreased salivation and xerostomia (dryness of the mouth), and change in or loss of taste. Depending on the targeted region, any portion of the gastrointestinal mucosa may be involved, causing mucositis (inflammation of the lining of the mouth, throat, and gastrointestinal tract). For example, patients receiving thoracic irradiation for lung cancer may experience acute esophageal irritation—associated chest pain and dysphagia. Anorexia, nausea, vomiting, and diarrhea may occur if the stomach or colon is in the radiation field. Symptoms subside and gastrointestinal re-epithelialization occurs after treatments have been completed. Bone marrow cells proliferate rapidly, and if sites containing bone marrow (e.g., the iliac crest or sternum) are included in the radiation field, anemia, leukopenia (decreased white blood cells [WBCs]), and thrombocytopenia (a decrease in platelets) may result. The patient is then at increased risk for infection and bleeding until blood cell counts return to normal. One medication, amifostine (Ethyol), is occasionally used in patients with head and neck cancers to reduce acute and chronic xerostomia while preserving antitumor efficacy of the necessary radiation doses (Citrin & Mitchell, 2014).

Systemic side effects are commonly experienced by patients receiving radiation therapy. These include fatigue, malaise, and anorexia that may be secondary to substances released when tumor cells are destroyed. Early effects tend to be temporary and most often subside within 6 months of the cessation of treatment.

Late effects (approximately 6 months to years after treatment) of radiation therapy may occur in body tissues that were in the field of radiation. These effects are chronic, usually a result of permanent damage to tissues, loss of elasticity, and changes secondary to a decreased vascular supply. Severe late effects include fibrosis, atrophy, ulceration, and necrosis and may affect the lungs, heart, central nervous system, and bladder. With advances in treatment planning and the accuracy of treatment delivery, the occurrence of late toxicities has diminished. However, late or chronic symptoms, such as dysphagia, incontinence, cognitive impairment, and sexual dysfunction, may persist for several years with implications for survivors' overall health and quality of life (Oeffinger, 2013).

Nursing Management

Nurses anticipate, prevent, and work collaboratively with other providers to manage symptoms associated with radiation therapy in order to promote healing, patient comfort, and quality of life. Symptoms that are not appropriately managed may lead to poor outcomes as a result of interruptions, decreased doses, or early cessation of treatment (Fogh & Yom, 2014). Ideally, nurses consider factors that may be predictive of radiation toxicities or radiosensitivity of tissues. In particular, diminished body mass index (BMI) and elevated radiation doses have been associated with greater toxicity and symptoms (O'Gorman, Sasiadek, Denieffe, et al., 2015). The area of the body being irradiated partially guides the focus of nursing assessments.

In patients receiving EBRT, the nurse assesses the patient's skin regularly throughout the course of treatment. In addition, nutritional status and general feelings of well-being are assessed throughout the course of treatment. Evidence-based protocols for nursing management of the toxicities associated with radiation therapy are used. If systemic symptoms, such as weakness and fatigue, occur, the nurse explains that these symptoms are a result of the treatment and do not represent deterioration or progression of the disease.

Protecting Caregivers

When the patient has a radioactive implant in place, the nurse and other health care providers need to protect themselves, as well as the patient, from the effects of radiation. Patients receiving internal radiation emit radiation while the implant is in place; therefore, contact with the health care team is guided by principles of time, distance, and shielding to minimize exposure of personnel to radiation. Specific instructions are provided by the radiation safety officer from the radiology department and specify the maximum time that can be spent safely in the patient's room, the shielding equipment to be used, and special precautions and actions to be taken if the implant is dislodged (Halperin et al., 2013). Safety precautions used in caring for a patient receiving brachytherapy include assigning the patient to a private room, posting appropriate notices about radiation safety precautions, having staff members wear dosimeter badges, making sure that pregnant staff members are not assigned to the patient's care, prohibiting visits by children or pregnant visitors, limiting visits from others to 30 minutes daily, and seeing that visitors maintain a 6-foot distance from the radiation source.

Patients with seed implants typically are able to return home; radiation exposure to others is minimal. Information about any precautions, if needed, is provided to the patient and family members to ensure safety. Depending on the dose and energy emitted by a systemic radionuclide, patients may or may not require special precautions or hospitalization (Halperin et al., 2013). The nurse should explain the rationale for these precautions to keep the patient from feeling unduly isolated.

Chemotherapy

Chemotherapy involves the use of antineoplastic drugs in an attempt to destroy cancer cells by interfering with cellular functions, including replication and DNA repair (Grossman & Porth, 2014). Chemotherapy is used primarily to treat systemic disease rather than localized lesions that are amenable to surgery or radiation. Chemotherapy may be combined with surgery, radiation therapy, or both to reduce tumor size preoperatively (neoadjuvant), to destroy any remaining tumor cells postoperatively (adjuvant), or to treat some forms of leukemia or lymphoma (primary). The goals of chemotherapy (cure, control, or palliation) must be realistic because they will determine the medications that are used and the aggressiveness of the treatment plan.

Cell Kill and the Cell Cycle

Each time a tumor is exposed to chemotherapy, a percentage of the tumor cells (20% to 99%, depending on dosage and agent) are destroyed. Repeated doses of chemotherapy are necessary over a prolonged period to achieve regression of the tumor. Eradication of 100% of the tumor is almost impossible; the goal of treatment is eradication of enough of the tumor so that the remaining malignant cells can be destroyed by the body's immune system (Grossman & Porth, 2014)

Actively proliferating cells within a tumor are the most sensitive to chemotherapy (the ratio of dividing cells to resting cells is referred to as the growth fraction). Non-dividing cells capable of future proliferation are the least sensitive to antineoplastic medications and consequently are potentially dangerous. However, the non-dividing cells must be destroyed to eradicate the disease. Repeated cycles of chemotherapy or sequencing of multiple chemotherapeutic agents is used to achieve more tumor cell destruction by destroying the non-dividing tumor cells as they begin active cell division.

Reproduction of both healthy and malignant cells follows the cell cycle pattern (see Fig. 58-4). The cell cycle time is the time required for one cell to divide and reproduce two identical daughter cells. The cell cycle of any cell has four distinct phases, each with a vital underlying function (Grossman & Porth, 2014):

- G_1 phase—RNA and protein synthesis occurs
- S phase—DNA synthesis occurs
- G_2 phase—premitotic phase; DNA synthesis is complete, mitotic spindle forms
- Mitosis—duplicated chromosomes separate and cell division occurs

Classification of Chemotherapeutic Agents

Chemotherapeutic agents may be classified by their mechanism of action in relation to the cell cycle. Agents that exert their maximal effect during specific phases of the cell cycle are termed *cell cycle–specific agents.* These agents destroy cells that are actively reproducing by means of the cell cycle; most affect cells in the S phase by interfering with DNA and RNA synthesis. Other agents, such as plant alkaloids, are specific to the M phase, where they halt mitotic spindle formation. Chemotherapeutic agents that act independently of the cell cycle phases are termed *cell cycle–nonspecific agents.* These agents usually have a prolonged effect on cells, leading to cellular damage or death. Many treatment plans combine cell cycle–specific and cell cycle–nonspecific agents to increase the number of vulnerable tumor cells killed during a treatment period (Neuss, Polovich, McNiff, et al., 2013).

Chemotherapeutic agents are also classified by chemical group, each with a different mechanism of action. These include the alkylating agents, nitrosoureas, antimetabolites, antitumor antibiotics, topoisomerase inhibitors, plant alkaloids (also referred to as mitotic inhibitors), hormonal agents, and miscellaneous agents. The classification, mechanism of action, cell cycle specificity, and common side effects of selected antineoplastic agents are listed in Table 58-8.

Chemotherapeutic agents from multiple categories may be used together to maximize cell destruction. Combination chemotherapy

TABLE 58-8 Select Antineoplastic Agents

Drug Class and Examples	Mechanism of Action	Cell Cycle Specificity	Common Side Effects
Alkylating Agents			
Busulfan (Busulfex, Myleran), carboplatin (Paraplatin), chlorambucil (Leukeran), cisplatin (Platinol-AQ), cyclophosphamide (Cytoxan), dacarbazine (DTIC-Dome), altretamine (Hexalen), ifosfamide (Ifex), melphalan (Alkeran), nitrogen mustard (Mustargen), oxaliplatin (Eloxatin), thiotepa (Thioplex)	Bond with DNA, RNA, and protein molecules leading to impaired DNA replication, RNA transcription, and cell functioning; all resulting in cell death	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, cystitis (cyclophosphamide, ifosfamide), stomatitis, alopecia, gonadal suppression, renal toxicity (cisplatin), and development of secondary malignancies
Nitrosoureas			
Carmustine (BCNU [BiCNU, Gliadel]), lomustine or CCNU (CeeNU), semustine (methyl-CCNU [MeCCNU]), streptozocin (Zanosar)	Similar to alkylating agents; cross the blood–brain barrier	Cell cycle—nonspecific	Delayed and cumulative myelosuppression, especially thrombocytopenia; nausea, vomiting, pulmonary, hepatic and renal damage

(Continued)

(Continued)

Topoisomerase I Inhibitors			
Irinotecan (Camptosar) Topotecan (Hycamtin) ***Topoisomerase II Inhibitors*** Etoposide (Etopophos, VePesid) Teniposide (Vumon, VM-26)	Induce breaks in the DNA strand by binding to enzyme topoisomerase, preventing cells from dividing	Cell cycle—specific (S phase)	Bone marrow suppression, diarrhea, nausea, vomiting, flulike symptoms (topotecan), rash (etoposide), hepatotoxicity (teniposide)
Antimetabolites			
5-Azacytidine (Vidaza), capecitabine (Xeloda), cytarabine (DepoCyt, Tarabine), edatrexate fludarabine (Fludara), 5-fluorouracil (5-FU), gemcitabine (Gemzar), hydroxyurea (Droxia, Hydrea), cladribine (Leustatin), 6-mercaptopurine (Purinethol), methotrexate (Trexall, Rheumatrex), pentostatin (Nipent), 6-thioguanine (Tabloid)	Interferes with the biosynthesis of metabolites or nucleic acids necessary for RNA and DNA synthesis; inhibits DNA replication and repair	Cell cycle—specific (S phase)	Nausea, vomiting, diarrhea, bone marrow suppression, stomatitis, renal toxicity (methotrexate), hepatotoxicity (6-thioguanine), hand-foot syndrome (capecitibine)
Antitumor Antibiotics			
Bleomycin (BLM, Blenoxane), dactinomycin (Cosmegen), daunorubicin (DaunoXome), doxorubicin (Adriamycin), epirubicin, idarubicin (Idamycin), mitomycin (Mutamycin), mitoxantrone (Novantrone), plicamycin (Mithracin)	Interfere with DNA synthesis by binding DNA; prevent RNA synthesis	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, alopecia, anorexia, cardiac toxicity (daunorubicin, doxorubicin), red urine (doxorubicin, idarubicin, epirubicin), pulmonary fibrosis (bleomycin)
Mitotic Spindle Inhibitors			
Plant alkaloids: Vinblastine (Velban), vincristine (VCR [Oncovin]), vinorelbine (Navelbine)	Arrest metaphase by inhibiting mitotic tubular formation (spindle); inhibit DNA and protein synthesis	Cell cycle—specific (M phase)	Bone marrow suppression (mild with VCR), peripheral neuropathies, nausea and vomiting
Taxanes: Paclitaxel (Taxol), docetaxel (Taxotere)	Arrest metaphase by inhibiting tubulin depolymerization	Cell cycle—specific (M phase)	Hypersensitivity reactions, bone marrow suppression, alopecia, peripheral neuropathies, **mucositis**
Epothilones: Ixabepilone (Ixempra)	Alters microtubules and inhibits mitosis	Cell cycle—specific (M phase)	Peripheral neuropathies, bone marrow suppression, hypersensitivity reactions, hepatic impairment
Hormonal Agents			
Androgens and antiandrogens, estrogens and antiestrogens, progestins and antiprogestins, aromatase inhibitors, luteinizing hormone-releasing hormone analogues, steroids	Bind to hormone receptor sites that alter cellular growth; block binding of estrogens to receptor sites (antiestrogens); inhibit RNA synthesis; suppress cytochrome P450 system	Cell cycle—nonspecific	Hypercalcemia, jaundice, increased appetite, masculinization, feminization, sodium and fluid retention, nausea, vomiting, hot flashes, vaginal estrogen dryness
Miscellaneous Agents			
Asparaginase (Elspar), procarbazine (Matulane)	Inhibits protein, DNA, and RNA synthesis	Varies	Anorexia, nausea, vomiting, bone marrow suppression, hepatotoxicity, hypersensitivity reaction, pancreatitis
Arsenic trioxide (Trisenox)	Causes fragmentation of DNA resulting in cell death; in acute promyelocytic leukemia, it corrects protein changes and changes malignant cells into normal white blood cells.		Nausea, vomiting, electrolyte imbalances, fever, headache, cough, dyspnea, electrocardiogram abnormalities

DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

(2013). 2013 Updated American Society of Clinical Oncology/Oncology Nursing Society chemotherapy administration safety standards including standards for the safe administration and management of oral chemotherapy. Oncology Nursing Forum, 40(3), 225–233.

relies on agents with varying mechanisms, potential synergistic actions, and differing toxicities. The use of combination therapy also helps prevent the development of drug-resistant cells.

Adjunct Chemotherapeutic Agents

In certain regimens, additional medications are given with chemotherapy agents to enhance activity or protect normal cells from injury. For example, leucovorin (Wellcovorin) is often given with fluorouracil (5-FU) to treat colorectal cancer. Leucovorin, a compound similar to folic acid, helps fluorouracil bind with an enzyme inside of cancer cells and enhances the ability of fluorouracil to remain in the intracellular environment. Leucovorin also rescues normal cells from the toxic effects of high doses of methotrexate (Trexall). When given at certain doses for the treatment of some forms of leukemia or lymphoma, methotrexate causes a folic acid deficiency in cells, resulting in cell death. Significant toxicity, including severe bone marrow suppression, mucositis, diarrhea and liver, and lung and kidney damage, can occur. Leucovorin helps to prevent or lessen these toxicities.

Administration of Chemotherapeutic Agents

Chemotherapy may be given in the hospital, outpatient center, or home setting by multiple routes. The route of administration depends on the type of agent; the required dose; and the type, location, and extent of malignant disease being treated. Standards for the safe administration of chemotherapy have been developed by the Oncology Nursing Society (ONS) and the American Society of Clinical Oncology (ASCO) (Neuss et al., 2013). Patient education is essential to maximize safety when chemotherapy is given in the home.

Dosage

The dosage of chemotherapeutic agents is based primarily on the patient's total body surface area, weight, previous exposure and response to chemotherapy or radiation therapy, and function of major organ systems. Dosages are determined to maximize cell kill while minimizing impact on healthy tissues and subsequent toxicities. The therapeutic effect may be compromised if modified and inadequate dosing is required due to toxicities. Modification of dosage is often required if critical laboratory values or the patient's symptoms indicate unacceptable or dangerous toxicities. Chemotherapy treatment regimens include standard-dose therapy, dose-dense regimens (giving chemotherapy more frequently than standard treatment regimens), and myeloablative therapy for HSCT. For certain chemotherapeutic agents, there is a maximum lifetime dose limit that must be adhered to because of the danger of long-term irreversible organ complications (e.g., because of the risk of cardiomyopathy, doxorubicin [Adriamycin] has a cumulative lifetime dose limit of 550 mg/m^2).

Extravasation

Intravenously given chemotherapy agents are additionally classified by their potential to damage tissue if they inadvertently leak from a vein into surrounding tissue (extravasation). The consequences of extravasation range from mild discomfort to severe tissue destruction, depending on whether the agent is classified as a nonvesicant, irritant, or vesicant. The pH levels of irritant agents (<5 or >9) induce inflammatory reactions but usually cause no permanent tissue damage (Schulmeister, 2014).

Vesicants are those agents that, if deposited into the subcutaneous or surrounding tissues (extravasation), cause inflammation; tissue damage; and possibly necrosis of tendons, muscles, nerves, and blood vessels. Although the mechanism of vesicant actions varies with each drug, some agents bind to cell DNA and cause cell death that progresses to involve neighboring cells, whereas other agents are metabolized into cells and cause a localized, painful reaction that usually improves over time (Schulmeister, 2014). Sloughing and ulceration of the tissue may progress to tissue necrosis that is so severe that skin grafting becomes necessary. The full extent of tissue damage may take several weeks to become apparent. Examples of commonly used agents classified as vesicants include dactinomycin (Cosmegen), daunorubicin (DaunoXome), doxorubicin (Adriamycin), nitrogen mustard (Mustargen), mitomycin (Mutamycin), vinblastine (Velban), and vincristine (Oncovin). Chemotherapy administration safety standards require the availability of defined extravasation management procedures, including antidote order sets and accessibility of antidotes in all settings where vesicant chemotherapy is given (Neuss et al., 2013); (Schulmeister, 2014).

Chemotherapy is given only by those who have the knowledge and established competencies for vesicant and extravasation management (Schulmeister, 2014). Prevention and management of extravasation are essential. Vesicant chemotherapy should never be given in peripheral veins involving the hand or wrist. Peripheral administration is permitted for short-duration infusions only, and placement of the venipuncture site should be on the forearm area using a soft, plastic catheter. For any frequent or prolonged administration of antineoplastic vesicants, right atrial silastic catheters, implanted venous access devices, or peripherally inserted central catheters (PICCs) should be inserted to promote safety during medication administration and reduce problems with access to the circulatory system (Figs. 58-5 and 58-6).

Hypersensitivity Reactions

Although hypersensitivity reactions (HSRs) can occur with any medication, many chemotherapy agents pose a high risk and

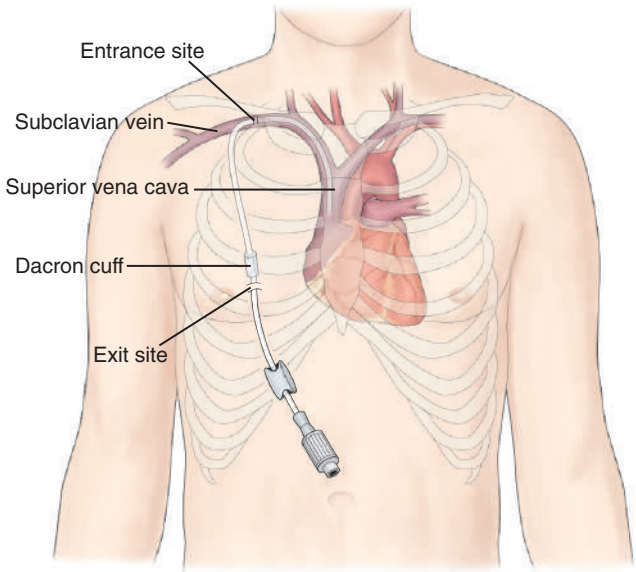

Figure 58-5 • Right atrial catheter. The right atrial catheter is inserted into the subclavian vein and advanced until its tip lies in the superior vena cava just above the right atrium. The proximal end is then tunneled from the entry site through the subcutaneous tissue of the chest wall and brought out through an exit site on the chest. The Dacron cuff anchors the catheter in place and serves as a barrier to infection.

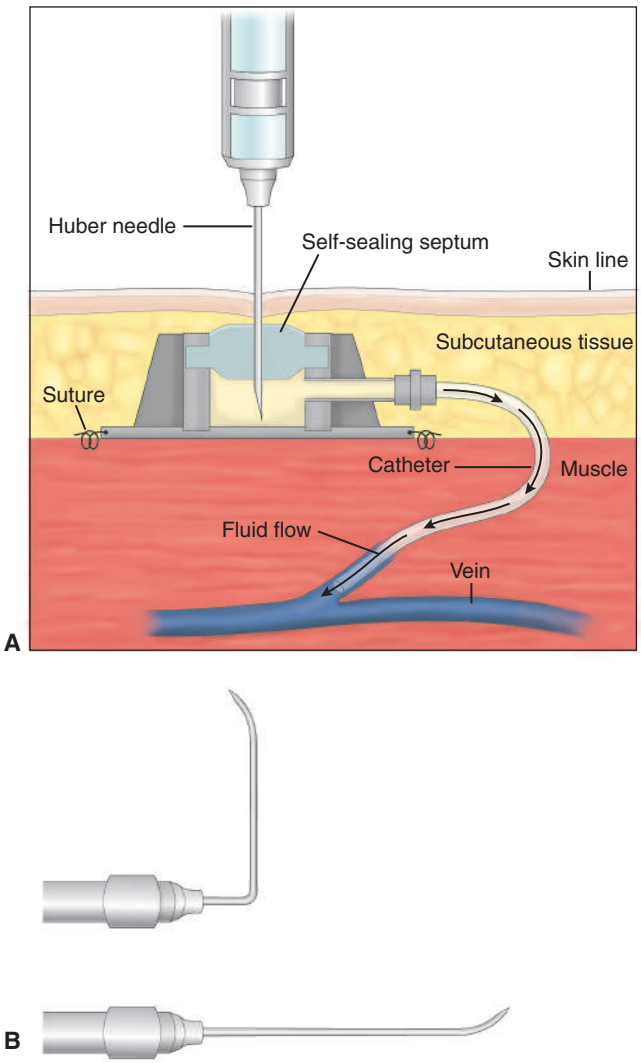

Figure 58-6 • Implanted vascular access device. **A.** A schematic diagram of an implanted vascular access device used for administration of medications, fluids, blood products, and nutrition. The self-sealing septum permits repeated puncture by Huber needles without damage or leakage. **B.** Two Huber needles used to enter the implanted vascular port. The 90-degree needle is used for top-entry ports for continuous infusions.

have been associated with life-threatening outcomes. HSRs are a subgroup of adverse drug reactions that are unexpected and associated with mild or progressively worsening signs and symptoms, such as rash, urticaria, fever, hypotension, cardiac instability, dyspnea, wheezing, throat tightness, and syncope (Braskett & Cohen, 2014). Immediate HSRs appear within 1 hour of an infusion, while delayed HSRs may occur hours afterward. Although patients may or may not react to the first infusion of a chemotherapy agent, repeated exposure increases the likelihood of a reaction.

Most immediate HSRs are immunoglobulin E (IgE)-mediated reaction—an allergic reaction. Examples of agents that may cause an allergic, IgE-mediated response include carboplatin, oxaliplatin (Eloxatin), and L-asparaginase. However, some HSRs, such as anaphylactoid reactions, are non–IgE-mediated (nonallergic) and a result of cytokine release syndrome (Braskett & Cohen, 2014); (Castells, 2015). Rituximab and cetuximab are examples of agents associated with non-IgE-mediated (nonallergic) HSRs. When signs and symptoms of HSR occur, the medication should be discontinued immediately and emergency procedures initiated. Many institutions have developed specific protocols for responding to HSRs, including standing orders for administration of emergency medications (Castells, 2015). (Chapter 56 presents further discussion of allergic reactions.)

For some chemotherapeutic agents, especially if they are essential in the treatment plan, desensitization procedures may be possible, and the patient is retreated with the agent at reduced dosages or slower infusion rates. Premedication regimens are used for certain chemotherapy agents to prevent or minimize reactions.

Toxicity

Toxicity associated with chemotherapy can be acute or chronic. Cells with rapid growth rates (e.g., epithelium, bone marrow, hair follicles, sperm) are very susceptible to damage, and the effects may manifest in virtually any body system.

Gastrointestinal System

The most common side effects of chemotherapy are nausea and vomiting, which may persist for 24 to 48 hours; delayed nausea and vomiting may occur up to 1 week after administration. The experience of chemotherapy-induced nausea and vomiting (CINV) may affect quality of life, psychological status, nutrition, fluid and electrolyte status, functional ability, compliance with treatment, and utilization of health care resources (Gonella & Di Giulio, 2015). Comorbidities, the underlying malignancy, other treatment approaches, and medications, as well as symptoms (i.e., pain), may contribute to CINV. Acute CINV is experienced in the first 24 hours after chemotherapy with a maximal intensity after 5–6 hours; delayed CINV occurs 24 hours posttreatment and may last as many as 7 days with a maximal intensity 48–72 hours after drug administration (Gonella & Di Giulio, 2015). Anticipatory nausea and vomiting, occurring prior to administration of chemotherapy, may be a conditioned response triggered by a stimulus such as the smell of the infusion setting, the sight of the nurse, or the outpatient center waiting room.

Several mechanisms are responsible for the occurrence of nausea and vomiting, including activation of multiple receptors found in the vomiting center of the medulla, the chemoreceptor trigger zone, the gastrointestinal tract, the pharynx, and the cerebral cortex. Activation of neurotransmitter receptors in these areas is thought to induce CINV. Stimulation may originate through peripheral, autonomic, vestibular, or cognitive pathways. The primary neuroreceptors known to be implicated in CINV are 5-hydroxytryptamine (5-HT or serotonin) and dopamine receptors (NCCN, 2015e).

The approach for managing CINV is based on the knowledge of the probability of emesis of the chemotherapy agents used. Algorithms are used to prevent and treat CINV based on national guidelines that consider this classification of chemotherapy agents (NCCN, 2015e).

Corticosteroids, phenothiazines, sedatives, and histamines are helpful, especially when used in combination with serotonin blockers to provide antiemetic protection (NCCN, 2015e). In order to manage delayed nausea and vomiting, antiemetic medications may be combined and are given for the first week at home after chemotherapy. Nonpharmacologic approaches such as relaxation techniques, imagery, acupressure, or acupuncture can help decrease stimuli contributing to symptoms and may be

most helpful for patients with anticipatory nausea and vomiting. Small, frequent meals, bland foods, and comfort foods may reduce the frequency or severity of symptoms.

Stomatitis is commonly associated with some chemotherapy agents because of the rapid turnover of epithelium that lines the oral cavity. The entire gastrointestinal tract is susceptible to mucositis (inflammation of the mouth, throat, and gastrointestinal tract) with diarrhea. Antimetabolites and antitumor antibiotics are the major culprits in mucositis and other gastrointestinal symptoms, which can be severe in some patients.

Hematopoietic System

Many chemotherapy agents cause some degree of myelosuppression (depression of bone marrow function), resulting in decreased WBCs (leukopenia), granulocytes (neutropenia), red blood cells (RBCs) (anemia), and platelets (thrombocytopenia) and increased risk of infection and bleeding. Depression of these cells is the usual reason for limiting the dose of the chemotherapy. Myelosuppression is predictable; for most agents, patients usually reach the point at which blood counts are lowest 7 to 14 days after chemotherapy has been given. During these 2 weeks, nurses anticipate associated toxicities, especially a fever associated with neutrophil count less than 1,500 cells/mm^3. Frequent monitoring of blood cell counts is essential, and patients are educated about strategies to protect against infection, injury, and blood loss, particularly while counts are low (Manea, 2014).

Other agents—colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF] and granulocyte-macrophage colony-stimulating factor [GM-CSF])—can be given after chemotherapy to stimulate the bone marrow to produce WBCs, especially neutrophils, at an accelerated rate, thus decreasing the duration of neutropenia. G-CSF and GM-CSF decrease the episodes of infection and the need for antibiotics and allow for more timely treatment cycles of chemotherapy with less need to reduce the dosage. Erythropoietin (EPO) stimulates RBC production, thus decreasing the symptoms of treatment-induced chronic anemia and reducing the need for blood transfusions. Interleukin 11 (IL-11) (oprelvekin [Neumega]) stimulates the production of megakaryocytes (precursors to platelets) and can be used to prevent and treat severe thrombocytopenia but has had limited use because of toxicities, such as HSR; capillary leak syndrome; pulmonary edema; atrial dysrhythmias; and nausea, vomiting, and diarrhea (Kuter, 2015).

Renal System

Some chemotherapy agents damage the kidneys because they impair water secretion, leading to syndrome of inappropriate secretion of antidiuretic hormone (SIADH), decrease renal perfusion, precipitate end products after cell lysis, and cause interstitial nephritis (Comerford, 2015). Cisplatin (Platinol), methotrexate, and mitomycin (Mutamycin) are particularly toxic to the kidneys. Rapid tumor cell lysis after chemotherapy results in increased urinary excretion of uric acid, which can cause renal damage. In addition, intracellular contents are released into the circulation, resulting in hyperkalemia, hyperphosphatemia, and hypocalcemia and obstructive nephropathy. (See later discussion of tumor lysis syndrome.)

Monitoring laboratory values of blood urea nitrogen (BUN), serum creatinine, creatinine clearance, and serum electrolytes is essential (Comerford, 2015). Adequate hydration, diuresis, alkalinization of the urine to prevent formation of uric acid crystals, and administration of allopurinol (Zyloprim) may be used to prevent renal toxicity. Amifostine has demonstrated an ability to minimize renal toxicities associated with cisplatin, cyclophosphamide (Cytoxan), and ifosfamide (Ifex) therapy.

Hemorrhagic cystitis is a bladder toxicity that can result from cyclophosphamide and ifosfamide therapy. Hematuria can range from microscopic to frank bleeding with symptoms ranging from transient irritation during urination, dysuria, and suprapubic pain to life-threatening hemorrhage. Protection of the bladder focuses on aggressive IV hydration, frequent voiding, and diuresis. Mesna (Mesnex) is a cytoprotectant agent that binds with the toxic metabolites of cyclophosphamide or ifosfamide in the kidneys to prevent hemorrhagic cystitis.

Cardiopulmonary System

Several agents are associated with cardiac toxicity. Anthracyclines (e.g., daunorubicin, doxorubicin) are known to cause irreversible cumulative cardiac toxicities, especially when total dosage reaches 300 mg/m^2 and 550 mg/m^2, respectively (Comerford, 2015). If these agents are given in the presence of thoracic radiation therapy or other agents with cardiotoxicity potential, the cumulative dose limit is lower. Patients at increased risk for the development of cardiopulmonary toxicities include those older than 70 years, those with a history of preexisting cardiac disease, hypertension, tobacco use, renal or hepatic dysfunction, and longer survival time. Dexrazoxane (Zinecard) has been used on a limited basis as a cardioprotectant when doxorubicin is needed in individuals who have already received a cumulative dose limit and continuation of therapy is deemed beneficial. Patients with known cardiac disease (e.g., heart failure) are treated with lower doses or agents not known to be associated with cardiac toxicity. Cardiac ejection fraction (volume of blood ejected from the heart with each beat) and other signs of heart failure must be monitored closely.

Bleomycin (Blenoxane), carmustine (BCNU), busulfan (Busulfex, Myleran), mitomycin, and paclitaxel/docetaxel, among other agents, have toxic effects on lung function, such as alveolar damage, bronchospasm, pneumonitis, and pulmonary fibrosis. Therefore, patients are monitored closely for changes in pulmonary function, including pulmonary function test results. Patients with known lung disease are treated with alternative agents not known to cause pulmonary toxicity. When pulmonary toxicity occurs, the agent is stopped and patients are treated with steroids and other supportive therapies (Schulmeister, 2014).

Capillary leak syndrome with resultant pulmonary edema is an effect of cytarabine (DepoCyt, Tarabine, Ara-C), mitomycin C, cyclophosphamide, and carmustine. Subtle onset of dyspnea and cough may progress rapidly to acute respiratory distress and subsequent respiratory failure. Patients who are at significant risk for capillary leak syndrome are monitored closely.

Reproductive System

Testicular and ovarian function can be affected by chemotherapeutic agents, resulting in possible sterility. Women may develop problems with ovulation or early menopause, whereas men may develop temporary or permanent azoospermia (absence of spermatozoa). Because treatment may damage reproductive cells, banking of sperm is often recommended for men before treatment is initiated (Frankel Kelvin, 2015). Options available for women prior to initiation of chemotherapy include freezing (cryopreservation) of oocytes, embryos, or ovarian tissue (Frankel Kelvin, 2015). Patients and their partners are informed

about potential changes in reproductive function resulting from chemotherapy. In addition, many chemotherapy agents are known or thought to be teratogenic. Therefore, patients are advised to use reliable methods of birth control while receiving chemotherapy and not to assume that sterility has resulted.

Neurologic System

Chemotherapy-induced neurotoxicity, a potentially dose-limiting toxicity, can affect the central nervous system, peripheral nervous system, and/or the cranial nerves. Neurotoxicity characterized by metabolic encephalopathy can occur with ifosfamide, high-dose methotrexate, and cytarabine. With repeated doses, the taxanes and plant alkaloids, especially vincristine, can cause cumulative peripheral nervous system damage with sensory alterations in the feet and hands. These sensations can be described as tingling, pricking, or numbness of the extremities; burning or freezing pain; sharp, stabbing, or electric shock–like pain; and extreme sensitivity to touch. If unreported by patients or undetected, progressive motor axon damage can lead to loss of deep tendon reflexes, with muscle weakness, loss of balance and coordination, and paralytic ileus.

Severe peripheral neuropathies may lead to diminished quality of life and functional abilities and result in dose reductions, a change in chemotherapy regimen, or early cessation of treatment (Tofthagen, Visovsky, & Hopgood, 2013). Although often reversible, these side effects may take many months to resolve or persist indefinitely. Along with the usual paresthesias of the hands and feet, oxaliplatin has a unique and frightening neurotoxicity presentation that is often precipitated by exposure to cold and is characterized by pharyngolaryngeal dysesthesia consisting of lip paresthesia, discomfort or tightness in the back of the throat, inability to breathe, and jaw pain.

Nursing Alert: Patients receiving oxaliplatin must be instructed to avoid drinking cold fluids or going outside with hands and feet exposed to cold temperatures to avoid exacerbation of these symptoms. Cisplatin may cause peripheral neuropathies and hearing loss due to damage to the acoustic nerve.

Cognitive Impairment

Many patients with cancer experience difficulty with remembering dates, multitasking, managing numbers and finances, organization, face or object recognition, inability to follow directions, feeling easily distracted, and motor and behavioral changes. Although not completely understood, these are viewed as symptoms of cognitive impairment, defined as a decline in the information-handling processes of attention and concentration, executive function, information processing speed, language, visual-spatial skill, psychomotor ability, learning, and memory (Von Ah, 2015). Commonly referred to by patients as "chemo brain," cognitive impairment has been associated with both cancer and cancer treatments, including surgery, radiation, chemotherapy, and targeted agents (Bender & Thelen, 2013). The symptoms may be subtle or profound with potential negative effects on functional abilities, employment, independence, quality of life, and psychosocial status. Comorbidities, age, medications, pain, impaired nutrition, anemia, fatigue, fluid and electrolyte disturbances, organ dysfunction, infection, and hormonal imbalances are factors that may contribute to the experience of cognitive impairment and make it difficult to fully understand. Underlying mechanisms of cognitive impairment in patients with cancer being explored include neurotoxic effects, oxidative stress, hormonal changes, immune dysregulation, cytokine release, clotting, genetic predisposition, and accelerated aging processes (Merriman, Von Ah, Miaskowski, et al., 2013); (Von Ah, 2015).

Fatigue

Cancer-related fatigue has been defined as an unusual, persistent, and subjective sense of tiredness that is not proportional to recent activity and interferes with usual functioning (NCCN, 2015f). Fatigue is a distressing side effect for most patients that greatly affects quality of life, during treatment and for months after treatment. The health care team works together to identify effective pharmacologic and nonpharmacologic approaches for fatigue management.

Nursing Management

Nurses play an important role in assessing and managing many of the problems experienced by patients receiving chemotherapy. Chemotherapy agents affect both normal and malignant cells; therefore, their effects are often widespread, affecting many body systems.

Laboratory and physical assessments of metabolic indices and the dermatologic, hematologic, hepatic, renal, cardiovascular, neurologic, and pulmonary systems are critical in evaluating the body's response to chemotherapy. These assessments are performed prior to, during, and after a course of chemotherapy to determine optimal treatment options, evaluate the patient's response, and monitor toxicity. Patients are monitored for long-term effects of chemotherapy after active treatment has been completed during the period of survivorship (see Chart 58-4).

Chart 58-4

Potential Long-Term Complications of Cancer Chemotherapy

- Abnormalities in senses of taste, smell, and touch
- Abnormal balance, tremors, or weakness
- Avascular necrosis
- Cardiovascular toxicity (coronary artery disease, myocardial infarction, congestive heart failure, valvular heart disease, peripheral arterial disease)
- Decreased libido
- Dental caries
- Dry mouth
- Dysphagia
- Dyspnea on exertion
- Growth retardation in children
- Herpes infections (zoster and varicella)
- Hypothyroidism
- Immune dysfunction
- Infertility
- Osteoporosis
- Pericarditis (acute or chronic)
- Pneumococcal sepsis
- Pneumonitis (acute or chronic)
- Secondary cancers:
  - Acute myeloid leukemia
  - Myelodysplastic syndromes
  - Non-Hodgkin lymphoma
  - Solid tumors (especially bone and soft tissue, lung, breast)
  - Thyroid cancer
  - Thymic hyperplasia

Assessing Fluid and Electrolyte Status

Anorexia, nausea, vomiting, altered taste, mucositis, and diarrhea put patients at risk for nutritional and fluid and electrolyte disturbances. Therefore, it is important for the nurse to assess the patient's nutritional and fluid and electrolyte status on an ongoing basis and to identify creative ways to encourage an adequate fluid and dietary intake.

Assessing Cognitive Status

Nurses should assess patients routinely for indications of cognitive impairment. Prior to the initiation of treatment, patients and families should be informed about the possibility of cognitive impairment. Nursing assessment plays an important role in determining the need for referral for neurocognitive evaluation and intervention (Jansen, 2013).

Modifying Risks for Infection and Bleeding

Suppression of the bone marrow and immune system is expected and frequently serves as a guide in determining appropriate chemotherapy dosage but increases the risk of anemia, infection, and bleeding disorders. Nursing assessment and care address factors that would further increase the patient's risk. The nurse's role in decreasing the risk of infection and bleeding is discussed further in the Nursing Care of Patients with Cancer section (see Chart 58-7).

Administering Chemotherapy

Nurses must be aware of chemotherapy and other agents most associated with HSRs, strategies for prevention, signs and symptoms characteristic of HSRs, and the appropriate early and time-sensitive interventions for preventing progression to anaphylaxis. Nurses provide patient and family education that emphasizes two key points: the importance of adhering to prescribed self-administered premedication before presenting to the infusion center, and recognizing and reporting the signs and symptoms to the nurse once the infusion has started. Patients and families are also educated about signs and symptoms that may occur at home following discharge from the infusion area that may warrant medication administration or immediate transport to the emergency department for further assessment and treatment.

The local effects of the chemotherapeutic agent are also of concern. The patient is observed closely during administration of the agent because of the risk and consequences of extravasation. Prevention of extravasation is essential and relies on vigilant nursing care (Neuss et al., 2013). Selection of peripheral veins, skilled venipuncture, and careful administration of medications are essential. Peripheral administration is limited to short duration (less than 1 hour; IV push or bolus) infusions using only a soft, plastic catheter placed in the forearm area. Continuous infusion of vesicants that takes longer than 1 hour or are given frequently are given only via a central line, such as a right atrial silastic catheter, implanted venous access device, or PICC. These long-term venous access devices promote safety during medication administration and reduce problems with repeated access to the circulatory system (see Figs. 58-5 and 58-6). Indwelling or subcutaneous venous access devices require consistent nursing care. Complications include infection and thrombosis (Cotogni, Barbero, Garrino, et al., 2015).

Indications of extravasation during administration of vesicant agents include the following:

- Absence of blood return from the IV catheter
- Resistance to flow of IV fluid
- Burning or pain, swelling, or redness at the site

Nursing Alert: If extravasation is suspected, the medication administration is stopped immediately.

An extravasation kit should be readily available with emergency equipment and antidote medications, as well as a quick reference for how to properly manage an extravasation of the specific vesicant agent used (although evidence-based data regarding effective antidotes are limited) (Gonzalez, 2013). Nurses should refer to their organization's policy and procedures for reporting, managing, and documenting extravasation. Safety standards require the availability of defined extravasation management procedures, including antidote order sets and accessibility of antidotes in all settings where vesicant chemotherapy is given (Neuss et al., 2013). Recommendations and guidelines for managing vesicant extravasation, which vary with each agent, have been issued by individual medication manufacturers, pharmacies, and the ONS (Neuss et al., 2013); (Schulmeister, 2014).

Difficulties or problems with administration of chemotherapeutic agents are brought to the attention of the primary provider promptly so that corrective measures can be taken to minimize local tissue damage.

The nurse evaluates the patient receiving neurotoxic chemotherapy, communicates findings with the medical oncologist, provides education to patients and families, and makes appropriate referrals for complete neurologic evaluation and occupational or rehabilitative therapies (Coyle, Griffie, & Czaplewski, 2014).

Preventing Nausea and Vomiting

Nurses are integral to the prevention and management of CINV. They collaborate with other members of the oncology care team to identify factors contributing to the experience of CINV and select effective antiemetic regimens that maximize currently available therapies. Nurses provide education for patients and families regarding antiemetic regimens and care for delayed CINV that may continue at home after the chemotherapy infusion has completed (NCCN, 2015e).

Managing Cognitive Changes

Although several approaches have been explored, no evidence-based guidelines for the prevention, treatment, or management of cognitive impairment have been established. Examples of nonpharmacologic approaches that nurses recommend to patients include exercise, natural restorative environmental intervention (walking in nature or gardening), and cognitive training programs (Merriman, et al., 2013); (Von Ah, 2015). Nurses should assist patients to address factors, such as fluid and electrolyte imbalances, nutrition deficits, fatigue, pain, and infection to minimize their contribution to cognitive impairment.

Managing Fatigue

Fatigue is a common side effect of chemotherapy. Nurses assist patients to explore the role that the underlying disease processes, combined treatments, other symptoms, and psychosocial distress play in the patient's experience of fatigue. In addition, nurses work with the patient and other team members to identify effective approaches for fatigue management (NCCN, 2015f).

Protecting Caregivers

Nurses involved in handling chemotherapeutic agents may be exposed to low doses of the agents by direct contact, inhalation, or ingestion. Studies suggest that nurses and others preparing chemotherapy agents or handling linens and other materials

that are contaminated with body fluids of patients receiving chemotherapy have been unknowingly exposed (Leduc-Souville, Bertrand, & Schlatter, 2013). Skin and eye irritation, nausea, vomiting, nasal mucosal ulcerations, infertility, low-birth-weight babies, congenital anomalies, spontaneous abortions, and mutagenic substances in urine have been reported in nurses preparing and handling chemotherapy agents (Leduc-Souville et al., 2013). The Occupational and Safety Health Administration (OSHA), the ONS, hospitals, and other health care agencies have developed specific precautions for health care providers involved in the preparation and administration of chemotherapy and for handling materials exposed to body fluids of those who have received these hazardous agents (see Chart 58-5) (Neuss et al., 2013); (Schulmeister, 2014). Nurses must be familiar with their institutional policies and procedures regarding personal protective equipment, handling and disposal of chemotherapy agents and supplies, and management of accidental spills or exposures. Emergency spill kits should be readily available in any treatment area where chemotherapy is prepared or given. Precautions must also be taken when handling any bodily fluids or excreta from the patient, as many agents are excreted unaltered in urine and feces. Nurses in all treatment settings have a responsibility to educate patients, families, caregivers, assistive personnel, and housekeepers concerning precautions.

Hematopoietic Stem Cell Transplantation

HSCT has been used to treat several malignant and nonmalignant diseases for many years. The use of HSCT for solid tumors is limited to clinical trials (Maziarz & Schubach-Slater, 2015). However, the use of HSCT in the treatment of certain adult hematologic malignancies (i.e., malignant myeloma, acute leukemia, and non-Hodgkin lymphoma) is considered standard of care.

The process of obtaining hematopoietic stem cells (HSCs) has evolved over the years. Historically, HSCs were obtained in the operating room by harvesting large amounts of bone marrow tissue from a donor under general anesthesia. However, peripheral blood stem cell collection using the process of apheresis has gained widespread use. The cells collected are specially processed and ultimately reinfused into the patient. This method of collecting HSCs is a safe and a more cost-effective means of collection than the process of harvesting of marrow (Maziarz & Schubach-Slater, 2015). Stem cells can also be collected from umbilical cord blood harvested from the placenta of newborns at birth.

Types

Types of HSCT are based on the source of donor cells and the treatment (conditioning) regimen used to prepare the patient for stem cell infusion and eradicate malignant cells. These include:

- *Allogeneic HSCT* (AlloHSCT): From a donor other than the patient (may be a related donor such as a family member or a matched unrelated donor from the National Bone Marrow Registry or Cord Blood Registry)
- *Autologous:* From the patient
- *Syngeneic:* From an identical twin
- *Myeloablative:* Consists of giving patients high-dose chemotherapy and, occasionally, total-body irradiation

Chart 58-5

Safety in Handling Chemotherapy for Health Care Providers

- When preparing (compounding, reconstituting) chemotherapy for administration, use the following safety equipment to prevent exposure through inhalation, direct contact, and ingestion:
  - Class II or III biological safety cabinet (BSC)
  - Closed system transfer devices
  - Puncture and leak-proof containers, IV bags
  - Needleless systems (i.e., IV tubing and syringes)
- If BSC is not available when preparing chemotherapy for administration, use the following safety equipment to minimize exposure:
  - Surgical N-95 respirator to provide respiratory and splash protection
  - Eye and face protection (both face shield and goggles) working at or above eye level or cleaning a spill
- When preparing or administering chemotherapy or handling linens and other materials contaminated with chemotherapy or blood and body fluids of patients receiving chemotherapy, wear the following for personal protection:
  - Double layer of powder-free gloves specifically designated for chemotherapy handling (the inner glove is worn under the gown cuff and the outer glove is worn over the cuff)
  - Long sleeve, disposable gowns (without seams or closures that can allow drugs to pass through) made of polyethylene-coated polypropylene or other laminate materials
- Linens contaminated with chemotherapy or blood and body fluids of patients receiving chemotherapy should be placed in the following:
  - Closed-system, puncture- and leak-proof containers labeled "hazardous: chemotherapy contaminated linens"
  - Above referenced container maintained in the infusion center soiled utility room for outpatient settings
  - Above referenced container maintained in the patient room and/or soiled utility room for inpatient settings
- Chemotherapy preparation equipment (i.e., syringes, tubing, empty vials, etc.), gowns, and gloves should be disposed of in:
  - Closed-system, puncture- and leak-proof containers labeled "hazardous: chemotherapy contaminated waste"
- Wash hands with soap and water after removing gloves used to prepare or administer chemotherapy or clean contaminated linens and other materials.
- "Spill kits" with the appropriate gowns, gloves, disposable absorbent materials for cleansing large areas, and hazard sign should be kept in all areas where chemotherapy is prepared and given.
- Implement a quality improvement program addressing safe chemotherapy handling that includes the following:
  - Standard operating policies and procedures for:
    - Chemotherapy handling, preparation, and disposal
    - Handling and disposal of chemotherapy spills
    - Handling and disposal of blood and body fluids and contaminated materials of patients receiving chemotherapy
  - Conduct competency-based education, training, and performance evaluations regarding chemotherapy safety procedures at orientation and at subsequent regular intervals.
  - Medical monitoring program to identify indicators of exposure
  - Root cause analysis for all chemotherapy spills and exposure incidents

Adapted from National Institute for Occupational Safety and Health. (2010). Personal protective equipment for health care workers who work with hazardous drugs. Available at: www.cdc.gov/niosh/docs/wp-solutions/2009–106/pdfs/2009–106.pdf

- *Nonmyeloablative:* Also called *mini-transplants;* does not completely destroy bone marrow cells

AlloHSCTs are used primarily for diseases of the bone marrow and are dependent on the availability of a human leukocyte antigen–matched donor, which greatly limits the number of possible transplants. An advantage of AlloHSCT is that the transplanted cells should not be immunologically tolerant of a patient's malignancy and should cause a lethal graft-versus-tumor effect in which the donor cells recognize the malignant cells and act to eliminate them.

AlloHSCT may involve either myeloablative (high-dose) or nonmyeloablative (mini-transplant) chemotherapy. In ablative AlloHSCT, the recipient receives high doses of chemotherapy and possibly total-body irradiation to completely eradicate (ablate) the bone marrow and any malignant cells and help prevent rejection of the donor stem cells. The collected HSCs that are infused IV into the recipients travel to sites in the body where they produce bone marrow and establish themselves through the process of engraftment. Once engraftment is complete (2 to 4 weeks, sometimes longer), the new bone marrow becomes functional and begins producing RBCs, WBCs, and platelets. In nonablative AlloHSCT, the chemotherapy doses are lower and are aimed at destroying malignant cells (without completely eradicating the bone marrow), thus suppressing the recipient's immune system to allow engraftment of donor stem cells. The lower doses of chemotherapy, associated with less organ toxicity and infection, can be used for older patients or those with underlying organ dysfunction for whom high-dose chemotherapy would be prohibitive. After engraftment, it is hoped that the donor cells will create a graft-versus-tumor effect. Before engraftment, patients are at high risk for infection, sepsis, and bleeding. Side effects of the high-dose chemotherapy and total-body irradiation can be acute and chronic. Acute side effects include alopecia, hemorrhagic cystitis, nausea, vomiting, diarrhea, encephalopathy, pulmonary edema, acute kidney injury, fluid and electrolyte imbalances, and severe mucositis (Maziarz & Schubach-Slater, 2015). Chronic side effects include sterility; pulmonary, cardiac, renal, neurologic, and hepatic dysfunction; osteoporosis; avascular bone necrosis; diabetes; and secondary malignancy (Maziarz & Schubach-Slater, 2015).

During the first 30 days after the conditioning regimen, AlloHSCT patients are at risk for developing hepatic sinusoidal obstructive syndrome (HSOS) (previously referred to as veno-occlusive disease) related to chemotherapy-induced inflammation of the sinusoidal epithelium. Inflammation causes embolization of RBCs, resulting in destruction, fibrosis, and occlusion of the sinusoids (Maziarz & Schubach-Slater, 2015). Signs and symptoms of HSOS may include weight gain, hepatomegaly, increased bilirubin, and ascites. Although various approaches have been used to treat HSOS, evidence-based strategies have not emerged. The use of peripheral stem cells, specific chemotherapy dosing, and nonmyeloablative regimens have been associated with a decreased incidence (Maziarz & Schubach-Slater, 2015).

Graft-versus-host disease (GVHD), a major cause of morbidity and mortality in 30% to 50% of the allogeneic transplant population, occurs when the donor lymphocytes initiate an immune response against the recipient's tissues (skin, gastrointestinal tract, liver) during the beginning of engraftment (Maziarz & Schubach-Slater, 2015). The donor cells view the recipient's tissues as foreign or immunologically different from what they recognize as "self" in the donor. To prevent GVHD, patients receive immunosuppressant drugs, such as cyclosporine (Sandimmune), methotrexate, tacrolimus (Prograf), or mycophenolate mofetil (MMF).

GVHD may be acute, occurring within the first 100 days, or chronic, occurring after 100 days (Barbarotta, 2015). Clinical manifestations of acute GVHD include diffuse rash progressing to blistering and desquamation similar to second-degree burns; mucosal inflammation of the eyes and the entire gastrointestinal tract with subsequent diarrhea that may exceed 2 L per day; and biliary stasis with abdominal pain, hepatomegaly, and elevated liver enzymes progressing to obstructive jaundice. The first 100 days or so after AlloHSCT is crucial for patients; the immune system and blood-making capacity (hematopoiesis) must recover sufficiently to prevent infection and hemorrhage. Most acute side effects, such as nausea, vomiting, and mucositis, resolve during this period of time. However, there are some complications that may occur, such as encephalopathy, hemolytic uremia syndrome, hemolytic anemia, and thrombotic thrombocytopenia purpura (Maziarz & Schubach-Slater, 2015).

Autologous HSCT (AuHSCT) is considered for patients with disease of the bone marrow who do not have a suitable donor for AlloHSCT or for patients who have healthy bone marrow but require bone marrow–ablative doses of chemotherapy to cure an aggressive malignancy. The most common malignancies treated with AuHSCT include lymphoma and multiple myeloma. However, the use of AuHSCT has gained increasing acceptance in treating neuroblastoma, Ewing sarcoma, and germ cell tumors (Maziarz & Schubach-Slater, 2015). Stem cells are collected from the patient and preserved for reinfusion; if necessary, they are treated to kill any malignant cells within the marrow, called *purging.* The patient is then treated with ablative chemotherapy and, possibly, total-body irradiation to eradicate any remaining tumor. Stem cells are then reinfused. Until engraftment occurs in the bone marrow sites of the body, there is a high risk of infection, sepsis, and bleeding. Acute and chronic toxicities from chemotherapy and radiation therapy may be severe. The risk of HSOS is also present after autologous transplantation. No immunosuppressant medications are necessary after AuHSCT, because the patient does not receive foreign tissue. A disadvantage of AuHSCT is the risk that tumor cells may remain in the bone marrow despite high-dose chemotherapy (conditioning regimens).

Syngeneic transplants result in less incidence of GVHD and graft rejection; however, there is also less graft-versus-tumor effect to fight the malignancy. Syngeneic transplant is associated with transmission of genetic defects (Maziarz & Schubach-Slater, 2015). For this reason, even when an identical twin is available for marrow donation, another matched sibling or even an unrelated donor may be the most suitable donor to combat an aggressive malignancy.

Nursing Management

Nursing care of patients undergoing HSCT is complex and demands a high level of skill. The success of HSCT is greatly influenced by nursing care throughout the transplantation process.

Implementing Care Before Treatment

All patients must undergo extensive evaluations before the transplant to assess the current clinical status of the disease. Nutritional assessments, extensive physical examinations, organ function tests, and psychological evaluations are conducted. Blood work includes assessing past infectious antigen exposure (e.g., hepatitis virus, cytomegalovirus, herpes simplex virus, human immunodeficiency virus, and syphilis). The patient's

social support systems and financial and insurance resources are also evaluated. Informed consent and patient education about the procedure and care before and after HSCT are vital.

Providing Care During Treatment

Skilled nursing care is required during the treatment phase of HSCT when high-dose chemotherapy (conditioning regimen) and total-body irradiation are given. The acute toxicities of nausea, diarrhea, mucositis, and hemorrhagic cystitis require close monitoring and symptom management by the nurse.

Nursing management during stem cell infusion consists of monitoring the patient's vital signs and blood oxygen saturation; assessing for adverse effects, such as fever, chills, shortness of breath, chest pain, cutaneous reactions, nausea, vomiting, hypotension or hypertension, tachycardia, anxiety, and taste changes; and providing strategies for symptom control, ongoing support, and patient education. During stem cell infusion, patients may experience adverse reactions to the cryoprotectant dimethyl sulfoxide (DMSO) used to preserve the harvested stem cells. These reactions may include nausea, vomiting, chills, dyspnea, cardiac dysrhythmias, and hypotension progressing to cardiac or respiratory arrest. Less common toxicities include neurologic and renal impairment (Maziarz & Schubach-Slater, 2015).

Nursing Alert: Until engraftment of the new marrow occurs, the patient is at high risk for death from sepsis and bleeding.

A cluster of symptoms referred to as engraftment syndrome may occur during the neutrophil recovery phase in both allogeneic and autologous transplants. Clinical features of this syndrome vary widely but may include noninfectious fever associated with skin rash, weight gain, diarrhea, and pulmonary infiltrates, with improvement noted after the initiation of corticosteroid therapy rather than antibiotic therapy (Maziarz & Schubach-Slater, 2015). Until engraftment is well established, the patient requires support with blood products and hematopoietic growth factors.

Potential infections may be bacterial, viral, fungal, or protozoan in origin. During the first 30 days following transplant, the patient is most at risk for developing reactivations of viral infections, including herpes simplex, EBV, cytomegalovirus, and varicella zoster. Mucosal denudement poses a risk for *Candida* (yeast) infection locally and systemically. Pulmonary toxicities offer the opportunity for fungal infections such as *Aspergillus.* Renal complications arise from the nephrotoxic chemotherapy agents used in the conditioning regimen or those used to treat infection (amphotericin B, aminoglycosides). A neutropenic diet is usually prescribed for patients to decrease the risk of exposure to foodborne infections from bacteria, yeast, molds, viruses, and parasites (Lassiter & Schneider, 2015). Whether a neutropenic diet decreases rates of infection is currently in question; see the nursing research profile in Chart 58-6.

Tumor lysis syndrome and acute tubular necrosis are also risks after HSCT. Nursing assessment for signs of these complications is essential for early identification and treatment. GVHD requires skillful nursing assessment to detect early effects on the skin, liver, and gastrointestinal tract. HSOS resulting from the conditioning regimens used can result in fluid retention, jaundice, abdominal pain, ascites, tender and enlarged liver, and encephalopathy. Pulmonary complications, such as pulmonary edema, interstitial pneumonia, and other pneumonias, often complicate recovery.

Providing Care After Treatment

Caring for Recipients

Ongoing nursing assessment during follow-up visits is essential to detect late effects of therapy after HSCT, which may occur 100 days or more after the procedure. Late effects include infections (e.g., varicella-zoster infection), restrictive pulmonary abnormalities, and recurrent pneumonias. Sterility often results due to total-body irradiation, chemotherapy, or both as components of the ablative regimen. Chronic GVHD can involve the skin, liver, intestine, esophagus, eyes, lungs, joints, and vaginal mucosa. Cataracts may also develop after total-body irradiation.

Chart 58-6 NURSING RESEARCH PROFILE

Do Neutropenic Diets Prevent Infection?

Lassiter, M., & Schneider, S. M. (2015). A pilot study comparing the neutropenic diet to a non-neutropenic diet in the allogeneic hematopoietic stem cell transplantation population. Oncology Nursing Forum, 19(3), 273–278.

Purpose

Despite years of implementation on oncology units, there is little evidence to support the use of a neutropenic diet. The purpose of this pilot study was to determine whether a neutropenic diet compared to a diet without restrictions made a difference in the incidence of infections and nutritional status of patients receiving myeloablative allogeneic hematopoietic stem cell transplantation (HSCT).

Design

This was a prospective randomized pilot study. A variety of laboratory measurements were collected for indications of infection (blood cultures) and to assess nutritional status. Laboratory measurements were compared between the control (neutropenic diet) and experimental (regular diet) arms using the two-sided Wilcoxon rank-sum test. Chi square was used to compare the percentage of patients with positive blood cultures in the two groups.

Findings

No significant differences between the control group (n = 21) and experimental group (n = 25) were found for demographic variables or patients who required total parenteral nutrition. Across all time points, no significant differences were found in any of the laboratory values with the exception of the total protein level. The median in the total protein level across all time points was 20% in the control arm and 16% in the experimental group, a significant difference (p = 0.023). Analysis of positive blood cultures failed to demonstrate any significant difference between the experimental and control groups.

Nursing Implications

Nurses should know that this pilot study provides beginning evidence that the neutropenic diet does not contribute to differences in infection rates or nutrition when compared to unrestricted diets in patients undergoing HSCT. Nurses need to conduct additional research with larger samples and multi-institutional involvement before the safety of changing this long-standing practice can be established.

The potential psychological impact of HSCT has been described as unique and unlike other experiences (Miceli, Lilleby, Noonan, et al., 2013). Psychosocial assessments by nursing staff must be ongoing and a priority. In addition to the multiple physical and psychological stressors affecting patients at each phase of the transplantation experience, the nature of the treatment and patient experience can place extreme emotional, social, financial, and physical demands on family, friends, and donors. Nurses assess the family and other caregivers' needs and provide education, support, and information about resources.

Caring for Donors

Like HSCT recipients, donors also require nursing care. They may experience mood alterations, decreased self-esteem, and guilt from feelings of failure if the transplantation fails. Family members must be educated and supported to reduce anxiety and promote coping during this difficult time. In addition, they must also be assisted to maintain realistic expectations of themselves as well as of the patient.

Hyperthermia

The use of hyperthermia (thermal therapy), which is the generation of temperatures greater than physiologic fever range (greater than 41.5°C [106.7°F]), has been used for many years to destroy cancerous tumors. Hyperthermia is most effective when combined with radiation therapy, chemotherapy, or biologic therapy. Hyperthermia and radiation therapy are thought to work well together because hypoxic tumor cells and cells in the S phase of the cell cycle are more sensitive to heat than radiation, and the addition of heat damages tumor cells so that they cannot repair themselves after radiation therapy. Hyperthermia preferentially damages tumor blood vessels, partly because these vessels are of inadequate size to dissipate the heat generated by hyperthermia.

Hyperthermia is thought to alter cellular membrane permeability when used with chemotherapy, allowing for an increased uptake of the chemotherapeutic agent. Hyperthermia may enhance the function of immune system cells, such as macrophages and T cells, to assist in combating malignant cells. Resistance to hyperthermia may develop during the treatment because cells adapt to repeated thermal insult.

Heat can be produced by using radio waves, ultrasound, microwaves, magnetic waves, hot-water baths, or even hot-wax immersions. Hyperthermia may be local or regional, or it may include the whole body. Local or regional hyperthermia may be delivered into a tumor, on the skin, into a body orifice, or by regional perfusion (i.e., an extremity affected by melanoma). Heated intraperitoneal chemotherapy has been used (in combination with surgery) to treat abdominal malignancies (Damsky-Dell, Held-Warmkessel, Jakubek, et al., 2014). Side effects of hyperthermia treatments include burns, fatigue, hypotension, peripheral neuropathies, thrombophlebitis, nausea, vomiting, diarrhea, and electrolyte imbalances. Cardiovascular stress may develop in patients receiving hyperthermia to a large area or whole body due to changes in pulse and blood pressure.

Nursing Management

Although hyperthermia has been used for years, patients and their families may be unfamiliar with this cancer treatment. Consequently, they need explanations about the procedure, its goals, and its effects. The nurse assesses the patient for adverse effects. Local skin care at the site of the implanted probes is necessary.

Targeted Therapies

Normal cell growth is regulated by well-defined communication pathways between the environment surrounding the cell and the internal cell environment, the nucleus, and the intracellular cytoplasm. The cell membrane contains important protein receptors that respond to signals transmitted from the external cell environment and transmit that signal to the internal cell environment using enzymatic pathways called *signal transduction pathways*. Although normal cells have transduction pathways, scientific advances have led to the recognition that cancer, at the cellular level, is characterized by deregulated cell signaling transduction pathways (both intra- and extracellular pathways), and receptors and proteins as well as altered cell membrane receptors and proteins play an important role in tumor initiation, growth, and spread (Caruana, Diaconu, & Dottia, 2014). This improved understanding of cancer cell behavior has allowed scientists to develop molecular-based therapies, called targeted therapies. These specifically target (like a lock and key mechanism) receptors, proteins, signal transduction pathways, and other processes to prevent the continued growth of cancer cells. Targeted therapies seek to work against cancer cell capabilities, such as malignant transformation, uncontrolled reproduction, growth and metastasis, blocking apoptosis, and altered genetic coding. Examples of targeted therapies include biologic response modifiers (BRMs) (such as monoclonal antibodies [MoAbs], growth factors and cytokines) and some types of gene therapy (Caruana et al., 2014).

Biologic Response Modifiers

BRM therapy involves the use of naturally occurring or recombinant (reproduced through genetic engineering) agents or treatment methods that can alter the immunologic relationship between the tumor and the patient with cancer (host) to provide a therapeutic benefit. Although the mechanisms of action vary with each type of BRM, the goal is to destroy or stop the malignant growth. The basis of BRM treatment lies in the restoration, modification, stimulation, or augmentation of the body's natural immune defenses against cancer (Blix, 2014).

Nonspecific Biologic Response Modifiers

Early investigations of the stimulation of the immune system involved nonspecific agents, such as bacille Calmette–Guérin (BCG) and *Corynebacterium parvum*. When injected into the patient, these agents serve as antigens that stimulate an immune response. The hope is that the stimulated immune system will then eradicate malignant cells. Extensive animal and human investigations with BCG have shown promising results, especially in treating localized malignant melanoma. In addition, BCG bladder instillation is a standard form of treatment for localized bladder cancer (Blix, 2014). However, the use of nonspecific agents in advanced cancer remains limited, and research is ongoing to identify other uses and agents.

Monoclonal Antibodies (MoAbs)

MoAbs, another type of BRM, have become available through technologic advances, enabling investigators to grow and produce targeted antibodies for specific malignant cells. Theoretically, this type of specificity allows MoAbs to destroy the cancer cells and spare normal cells. The specificity of MoAbs is dependent on identifying key antigen proteins on the surface of tumors that are not present on normal tissues. When the MoAb attaches to the cell surface antigen, an important

signal transduction pathway for communication between the malignant cells and the extracellular environment is blocked. The results may include an inability to initiate apoptosis, reproduce, or invade surrounding tissues.

The production of MoAbs involves injecting tumor cells that act as antigens into mice. B-cell lymphocytes in the spleen of the mouse produce immunoglobulin (antibodies) made in response to the injected antigens. Antibody-producing B cells are combined with a cancer cell that has the ability to grow indefinitely in culture medium and continue producing more antibodies.

The combination of spleen cells and the cancer cells is referred to as a hybridoma. From hybridomas that continue to grow in the culture medium, the desired antibodies are harvested, purified, and prepared for diagnostic or therapeutic use (see Fig. 58-7). Advances in genetic engineering have led to the production of MoAbs with combinations of mouse and human components (*chimeric MoAbs*) or all-human components (*human MoAbs*). MoAbs made with human genes have greater immunologic properties and are less likely to cause allergic reactions (Grossman & Porth, 2014).

Several MoAbs are used for treatment in cancer using various extracellular (on the cell membrane) and intracellular targets. Trastuzumab (Herceptin) has the ability to target the HER2 protein, an error of gene overexpression found in breast and other cancers (Comerford, 2015). Rituximab (Rituxan) is a MoAb that binds specifically with the CD20 antigen expressed by non-Hodgkin lymphoma and B-cell chronic lymphocytic leukemia (Comerford, 2015).

Some MoAbs are used alone, whereas others are used in combination with agents that facilitate their antitumor actions. Ibritumomab tiuxetan (Zevalin), a MoAb conjugated with a radioactive isotope, is used in the treatment of certain types of lymphoma (Mack, Ritchie, & Sapra, 2014). MoAbs are also used as aids in diagnostic evaluation of both primary and metastatic tumors through radiologic imaging and laboratory techniques. For example, the process of immunohistochemistry uses a MoAb tagged with a stain that binds with the protein of interest, providing a visual stain for the presence or absence of the protein (Mack et al., 2014). This type of test is used to identify the presence of estrogen and progesterone receptors on breast cancer cells to see if the cells will be responsive to hormonal agents. Immunohistochemistry testing is also used to detect several proteins associated with hereditary nonpolyposis colon cancer (Mack et al., 2014). MoAbs are used to assist in the diagnosis of ovarian, colorectal, breast, and prostate cancers and some types of leukemia and lymphoma. MoAbs are also used in purging residual tumor cells from peripheral stem cell collections for patients who are undergoing HSCT after high-dose cytotoxic therapy. Researchers continue to explore the development and use of MoAbs, either alone or in combination with other substances such as radioactive materials, chemotherapy agents, toxins, hormones, or other BRMs.

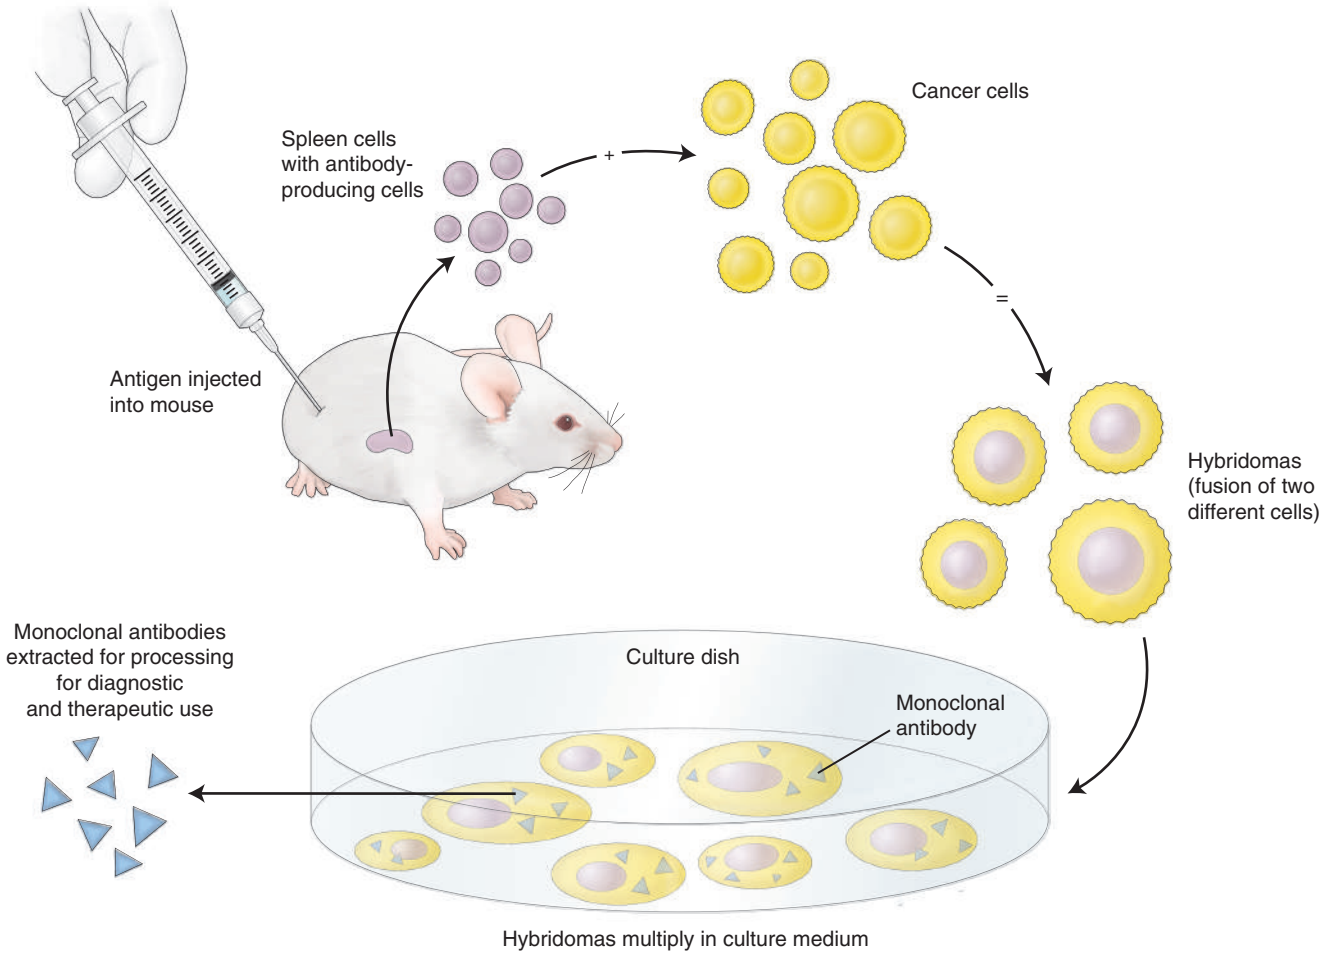

Figure 58-7 • Antibody-producing spleen cells are fused with cancer cells. This process produces cells called *hybridomas*. These cells, which can grow indefinitely in a culture medium, produce antibodies that are harvested, purified, and prepared for diagnostic or treatment purposes.

Cytokines

Cytokines, substances produced primarily by cells of the immune system to enhance or suppress the production and functioning of components of the immune system, are used to treat cancer or the adverse effects of some cancer treatments. Cytokines are grouped into families, such as interferons (IFNs), interleukins (ILs), and colony-stimulating factors. Colony-stimulating factors were described earlier in this chapter for their supportive role in myelosuppressive treatment modalities. (Refer to Chapter 54 for more detailed discussion of the immune system.)

Interferons (IFNs)

IFNs are cytokines with antiviral, antitumor, and immunomodulatory (inhibition or stimulation of the immune system) properties. Multiple antitumor effects of IFNs include antiangiogenesis, direct destruction of tumor cells, inhibition of growth factors, and disruption of the cell cycle (Weber, 2014). IFNs are used on a limited basis for the treatment of some solid and hematologic cancers. IFNs have been associated with significant toxicities, which have restricted their use and prompted clinicians to seek alternative therapies (Weber, 2014).

Interleukins (ILs)

ILs are cytokines produced by subsets of T-cell lymphocytes, natural killer cells, and dendritic cells (cells that present antigens to the immune system). Similar to IFNs, ILs have immunomodulatory effects on other components of the immune response. IL-2 has been approved by the U.S. Food and Drug Administration (FDA) as a treatment option for renal cell cancer and metastatic melanoma in adults. However, because toxicities may be severe and life life-threatening, the role of ILs as cancer treatment has been limited (Weber, 2014).

Cancer Vaccines

Cancer vaccines mobilize the body's immune response to prevent or treat cancer. These vaccines contain either portions of cancer cells alone or portions of cells in combination with other substances (adjuvants) that can augment or boost immune responses. *Autologous* vaccines are made from the patient's own cancer cells, which are taken from tumor tissue obtained during biopsy or surgical intervention. The cancer cells are killed and prepared for injection back into the patient. *Allogeneic* vaccines are made from cancer cell lines that are immortalized cells that were originally obtained from other people who had a specific type of cancer. These cancer cells are grown in a laboratory and eventually killed and prepared for injection.

Prophylactic vaccines prevent disease. Three vaccines have been approved by the FDA for the prevention of HPV. HPV2 (Cervarix), recommended for use in females only, protects against HPV types 16 and 18 that are responsible for about 70% of all cervical cancers (ACS, 2015a). HPV4 (Gardasil) provides protection against four HPV types (6, 11, 16, and 18) and is recommended for use in both males and females. HPV9 (Gardasil-9), recommended for both males and females, protects against nine HPV types associated with cervical, anal, vaginal, and vulvar cancers. HPV9 also protects against genital warts. All of the HPV vaccines are given as a series of three doses over 6 months. Although the role of HPV vaccines in prevention of oropharyngeal cancers related to HPV 16 has not been fully established, there are preliminary data to suggest effectiveness (Herrero, Quint, Hildesheim, et al., 2015).

Therapeutic vaccines kill existing cancer cells and inhibit further cancer development. Sipuleucel-T is indicated for men with metastatic prostate cancer that is no longer responding to hormone therapy. It is the only therapeutic vaccine currently FDA approved. Therapeutic vaccines do not cure cancer but are associated with improved patient survival (Kannan, Madden, & Andrews, 2014).

Gene Therapy

Gene therapy includes approaches that correct genetic defects, manipulate genes to induce tumor cell destruction, or assist the body's immune defenses in the hope of preventing or combating disease. One of the challenges confronting cancer gene therapy is the multiple somatic mutations involved in the development of cancer, making it difficult to identify the most effective gene therapy approach.

Considerable advances have been made in the identification of effective tumor cell targets and evaluation of the most appropriate vectors. Vectors serve as a vehicle or carrier to transport a gene into the target cell. With improved understanding of cell surface proteins and signaling pathways, many clinical trials are under way.

At this time, there are no FDA-approved gene therapies for cancer. Three approaches have been used in the development of gene therapies, with adenoviruses showing the most promise in each:

- *Tumor-directed therapy* is the introduction of a therapeutic gene (suicide gene) into tumor cells in an attempt to destroy them. This approach is challenging because it is difficult to identify the gene that would cause optimal tumor destruction, and patients with widespread disease would require multiple injections to treat every site of disease.
- *Active immunotherapy* is the administration of genes that will invoke the antitumor responses of the immune system.
- *Adoptive immunotherapy* is the administration of genetically altered lymphocytes that are programmed to cause tumor destruction.

Nursing Management

Patients receiving targeted therapies have many of the same needs as patients undergoing other cancer treatments. However, manipulation and stimulation of the immune system create unique challenges. Consequently, the nurse must assess the need for education, support, and additional resources for both the patient and the family and assist in planning and evaluating patient care. Patient education is important, as many of the toxicities associated with targeted therapies are not only a source of physical discomfort, but they also impact the quality of life, and potentially impact patient adherence to oral drug regimens (Vioral, Leslie, Best, et al., 2014); (Yagasaki & Komatsu, 2013).

Monitoring Therapeutic and Adverse Effects

The nurse must become familiar with each agent given and its potential effects. Adverse effects such as fever, myalgia, nausea, and vomiting, as seen with IFN therapy, may not be life-threatening. Other adverse effects (e.g., capillary leak syndrome, pulmonary edema, hypotension) that may become life-threatening can occur with BRM approaches such as high-dose IL-2 therapy. MoAbs are associated with both common and unique adverse effects. Although mild to moderate infusion reactions are more commonly associated with chimeric MoAbs, severe HSRs have been seen with MoAb infusions. Nurses must be aware of the adverse effects of BRMs and recognize the signs and symptoms of serious reactions to emergently institute

appropriate interventions and supportive care. Nurses monitor patients for the impact of adverse effects on performance status and quality of life so that appropriate measures can be implemented to improve patient outcomes.

Promoting Home, Community-Based, and Transitional Care

The nurse educates patients about self-care and assists in providing for continuing care. Some targeted therapies can be given subcutaneously by the patient or family members at home. As needed, the home care nurse educates the patient and family how to administer these agents and monitors the use of appropriate technique as well as safe disposal of sharps and contaminated materials. The nurse also provides instructions about side effects and helps the patient and family identify strategies to manage many of the common side effects of BRM therapy, such as fatigue, anorexia, and flulike symptoms.

The use of oral medications to treat cancer has risen greatly in the past several years, especially with advances in targeted therapies, many of which are given by mouth. It has been estimated that almost half of the new antineoplastic drugs are oral agents (IMS, 2014). Of over 700 drugs in development, 80% are based on targeted approaches and about 35% are oral agents. The rising use of oral therapies shifts the responsibility for delivery of treatment to patients and families in the home setting. Treatment approaches with newer mechanisms of action and associated toxicities, as well as the transition of responsibility to patients and families, increase the need for nurses to identify factors affecting adherence and develop strategies to address adherence barriers (see Table 58-9).

The nurse collaborates with physicians, social workers, third-party payers, and pharmaceutical companies to help the patient obtain reimbursement or support for the cost of oral targeted

TABLE 58-9 Strategies for Promoting Adherence to Oral Antineoplastic Agents

Assess for factors that may interfere with adherence to oral antineoplastic agents; develop plan of care that addresses specific assessment findings.

Barriers to Adherence	Strategies for Promoting Adherence
Sociodemographic Factors	
• Limited financial resources • Competing priorities for financial resources • Joblessness • Limited or no insurance • Racial or ethnic disparities • Lower level of education • Poor health literacy • Illiteracy • Non–English speaking • Lack of transportation • Lack of or limited social support • Rural residence	• Refer to financial counseling through health care facility, local nonprofit health/oncology support/advocacy, or other nonprofit community advocacy organizations. • Refer to social worker for referrals as described above and/or for disability applications through employer. • Explore patient assistance programs for costs of health care, copays, medications, household costs, transportation services (costs or availability), and home care available through nonprofit organizations, oncology support/advocacy or other nonprofit community advocacy organizations, religious institutions, philanthropic organizations, pharmaceutical industry–sponsored programs, health care institution–specific programs; assist with financial documentation and application procedures as needed. • Explore assistance programs for other priorities competing for financial resources (i.e., for utility costs, gas, child care, food). • Assist patient to identify family, friends, or other available supports to assist with activities of daily living, household responsibilities, errands, shopping, meals, transportation or other responsibilities; assist with delegation of needs and schedules of availability if needed. • Assess preferred method of learning (i.e., verbal, visual, written materials); tailor instructional materials to patient needs, including language. • Include family, significant other, and friends in education whenever feasible. • Use return demonstration of behaviors and devices used to support adherence. • Provide contact information that spans 24 hours for questions or problems. • Contact patient by phone or other means (e-mail) to assess for concerns in between follow-up visits to physician. • Encourage patient to use adherence reminders, such as pill boxes, medication calendars, checklists, medication diaries, alarms on cell phone or other devices/timers; explore availability of programmed telephone reminder services, text messages from family member, friend, or other caregiver; review diary at each visit. • Instruct patient to bring pill bottles to each follow-up visit; perform pill counts to monitor adherence. • Send postcard reminder to patient weekly (or less often) or 1 week prior to due date for medication refill. • Refer to home care for continued education, and follow up on adherence. • Identify local pharmacies that supply oral cancer therapies. Instruct patients to contact nurse if the pharmacy cannot fill the prescription within 24 hours. • Remind patients to anticipate need for adequate supply of medications prior to travel or vacation.
Age	
• Older adults; especially those >75 years	• Ensure that printed education materials and instructions are printed in black using at least 14-point sans serif font such as Arial or Calibri. • Use illustrated education materials. • Review and revise adherence strategies if patient status declines or changes. • Explore availability of alarmed medication box.
Beliefs	
• Oral medications less effective or important than IV treatments • Fatalism about disease outcomes	• Provide education regarding oral versus IV medications. • Discuss goals of care and ongoing assessment of response to treatment.

(Continued)

(Continued)

Comorbidities	
• Preexisting chronic disease • Vision or hearing impairments	• Communicate with primary care and other providers involved in care of patient regarding current cancer disease status and treatment; collaborate with other providers for ongoing management of nononcology issues or exacerbation of issues that may impact cancer treatment adherence. • Collaborate with appropriate resources to assist with special needs and assistive devices for vision or hearing impairments.
Polypharmacy	
• Multiple medications for comorbidities and/or cancer treatment and symptom management	• Review all medications prescribed by oncology physicians and other providers involved in care of patient for preexisting chronic disease. • Assess patient use of over-the-counter medications and other agents. • Consult with pharmacist to identify medications and other agents that may be contraindicated or that may interfere with antineoplastic regimen. • Collaborate with all providers prescribing medications in order to simplify and/or reduce number of required medications if possible. • Provide patient, family, or other caregiver education regarding specific instructions when multiple medications are required. • Provide written checklist for patient to utilize daily to check off each medication when taken. • Do not give patients prescriptions that allow for refills; prescriptions should be for a finite period of time that concludes with next scheduled visit.
Psychiatric, Psychological, or Cognitive Concerns	
• Psychiatric disease • Depression • Cognitive impairments • Anxiety	• Avoid initial education regarding oral medications at the same time of first physician visit; have patient and other learners return for another appointment to see nurse for education, and follow up with subsequent visit if deemed to be at high risk for adherence challenges. • Discuss with physician the necessity for referral to psychiatrist to evaluate need for psychotropic medications. • Refer patient for professional mental health counseling as needed. • Identify additional supports for care and education as discussed earlier.
Disease Factors	
• Symptoms such as pain, nausea, fatigue, skin rashes, etc. • Impaired mobility	• Proactively assess and manage symptoms related to underlying disease and/or treatments. • Provide patient, family, or other caregivers education about expected side effects and management strategies. • Instruct patient to premedicate with antiemetic as prescribed 30 minutes prior to taking oral antineoplastic agent if needed for nausea and/or vomiting. • Identify additional supports for care as discussed earlier. • Assess need for referral to home physical and/or occupational therapy to address impaired mobility and need for assistive devices.
Communication Issues	
• Patient–Clinician • Clinician—Clinician	• Establish rapport and allow patients, families, and other caregivers time and opportunity to ask questions. • Do not assume adherence to oral antineoplastic agents; assess potential barriers consistently throughout course of treatment at each follow-up visit. • Communicate with primary provider regarding current cancer disease status, treatment and information regarding antineoplastic agents, such as drug–drug interactions, expected toxicities, and toxicities requiring prompt intervention.

Adapted from Vioral, A., Leslie, M., Best, R., et al. (2014). Patient adherence with oral oncolytic therapies. Seminars in Oncology Nursing, 30(3), 190–199.

therapies and other required medications. The nurse also reminds the patient about the importance of keeping follow-up appointments with the physician and assesses the patient's need for symptom management related to the underlying diseases and/or adverse effects of treatment. Home care nurses maintain communication with the physician regarding patient adherence and tolerance of treatment so that changes in care can be implemented in a timely fashion.

Complementary, Alternative, and Integrative Health Therapies

Integrative healthcare is viewed as a comprehensive, interdisciplinary approach to preventing and treating illness and promoting health that brings together complementary, alternative, and conventional therapies. The use of an integrative approach to health wellness has grown within mainstream healthcare settings, particularly within oncology care (National Center for Complementary and Integrative Health [NCCIH], 2015).

Individuals use complementary approaches to prevent and treat cancer, although there are no data to support efficacy. Patients also use complementary approaches to manage symptoms related to cancer and associated treatments; some approaches are supported by clinical research while others are not. The NCCIH suggests that as many as 65% of people diagnosed with cancer have used some form of complementary medicine. The use of complementary strategies is influenced by age, race, ethnicity, and geography (Clarke, Black, Stussman, et al., 2015). However, patients do not routinely communicate complementary practices to their health care providers because they usually are not asked about its use; they withhold the information, fearing that their physicians would not approve,

or they feel that the use of these approaches will not affect the conventional treatment they are receiving

Although many complementary modalities can be a source of comfort and emotional support for patients, assessment of complementary therapy use is important for patient safety. Patients often perceive vitamins and dietary supplements as harmless, natural products that have no side effects or potential toxicities. In patients receiving any conventional therapies, the use of herbs or botanicals may interfere with drug metabolism, decrease or increase desired effects, or contain elements of uncertain pharmacologic capacities (NCCIH, 2015). Deep tissue massage and other manipulative therapies are contraindicated in patients with open wounds, radiation dermatitis, thrombocytopenia, VTE, and coagulation disorders, and in those taking anticoagulants.

Nursing Care of Patients with Cancer

The outlook for patients with cancer has greatly improved because of scientific and technologic advances. However, as a result of the underlying disease or various treatment modalities, patients with cancer may experience a variety of secondary problems such as reduced WBC counts, infection, bleeding, skin and nutritional problems, pain, fatigue, and psychological stress. Chart 58-7 provides a nursing care plan for patients with cancer.

Maintaining Tissue Integrity

Some of the most frequently encountered disturbances of tissue integrity include stomatitis, skin and tissue reactions to radiation therapy, cutaneous toxicities associated with targeted therapy, alopecia, and metastatic skin lesions.

Stomatitis

Mucositis, a common side effect of radiation and some types of chemotherapy, refers to an inflammatory process involving the mucous membranes of the oral cavity and the gastrointestinal tract. **Stomatitis,** a form of mucositis, is an inflammatory process of the mouth, including the mucosa and tissues surrounding the teeth. Stomatitis is characterized by changes in sensation, mild redness (erythema), and edema or, if severe, by painful ulcerations, bleeding, and secondary infection. Stomatitis commonly develops 5 to 14 days after patients receive certain chemotherapeutic agents, such as doxorubicin and 5-fluorouracil; immunotherapies, such as IL-2 and IFN; and molecular targeted drugs, such as temsirolimus and everolimus. Stomatitis affects up to 100% of patients undergoing high-dose chemotherapy with HSCT, 80% of patients with malignancies of the head and neck receiving radiotherapy, and up to 40% of patients receiving standard-dose chemotherapy (Gibson, Keefe, Lalla, et al., 2013). Stomatitis may be worse in patients with head and neck cancers who receive combined modality therapy of both radiation and chemotherapy. When severe, stomatitis can lead to interruptions, delays, and modifications in the course of treatment, all of which may contribute to less desirable patient outcomes. Severe oral pain can significantly affect swallowing, nutritional intake, speech, quality of life, coping abilities, and willingness to adhere to treatment regimens. In addition, stomatitis may lead to more frequent health care visits, hospitalizations, and increased health care costs (Eilers, Harris, Henry, et al., 2014). Stomatitis and mucositis are attributed to a cascade of molecular processes and submucosal endothelial cell destruction that begin almost immediately after the initiation of radiation and certain types of chemotherapy, prior to the development of signs and symptoms. Mucositis develops as a consequence of a sequence of related and interacting biologic events, culminating in injury and apoptosis of basal epithelial cells, leading to the loss of epithelial renewal, atrophy, and ulceration. Gram-positive and gram-negative organisms can invade the ulcerated tissue and result in infection.

Nursing assessment begins with an understanding of the patient's usual practices for oral hygiene and identification of individuals at risk for stomatitis. Oral cavity assessment is performed daily or at each patient visit (Tipian, 2014). Risk factors and comorbidities associated with stomatitis include poor oral hygiene, general debilitation, existing dental disease, prior irradiation to the head and neck region, impaired salivary gland function, the use of other medications that dry mucous membranes, myelosuppression (bone marrow depression), advanced age, tobacco use, previous stomatoxic chemotherapy, diminished renal function, and impaired nutritional status (Eilers et al., 2014). The patient is also assessed for dehydration, infection, pain, and nutritional impairment resulting from mucositis.

Optimal evidence-based prevention and treatment approaches for stomatitis remain limited but continue to be studied across disciplines (Eilers et al., 2014). Most clinicians agree that maintenance of good oral hygiene, including brushing, flossing, rinsing, and dental care, is necessary to minimize the risk of oral complications associated with cancer therapies.

Palifermin (Kepivance), an IV-administered synthetic form of human keratinocyte growth factor, is beneficial in the prevention of stomatitis in patients with hematologic malignancies who are preparing for HSCT (Vadhan-Raj, Goldberg, Perales, et al., 2013). Palifermin promotes epithelial cell repair and accelerated replacement of cells in the mouth and gastrointestinal tract. Careful timing of administration and monitoring are essential for effectiveness and to detect adverse effects. Other approaches recommended for practice include cryotherapy (topical application of oral ice during infusions), consistent oral hygiene, low-level laser therapy, and sodium bicarbonate mouth rinses (Eilers et al., 2014); (Tayyem, 2014). Additional aspects of care are discussed in Chart 58-7: Nursing care plan for patients with cancer.

Radiation-Associated Impairment of Skin Integrity

Although advances in radiation therapy have resulted in decreased incidence and severity of skin impairments, patients may still develop radiation dermatitis associated with pain, irritation, pruritus, burning, skin sloughing without drainage (dry desquamation) or with drainage (wet desquamation), and diminished quality of life. Nursing care for patients with radiation dermatitis includes maintenance of skin integrity, cleansing, promotion of comfort, pain reduction, prevention of additional trauma, prevention and management of infection, and promotion of a moist wound-healing environment (Fogh & Yom, 2014). In order to prevent impaired skin integrity, patients are advised to use moisturizer on the skin, avoid sun exposure to the area of treatment, and avoid tape or bandages and other sources of irritation or trauma. Although a variety of methods and products are used in clinical practice for patients with radiation-induced skin impairment, there is limited evidence to support their value. Patients with skin and tissue reactions to radiation therapy require careful skin care to prevent further skin irritation, drying, and damage, as discussed in the nursing care plan

Chart 58-7 PLAN OF NURSING CARE

The Patient with Cancer

Nursing Diagnosis: Risk for infection related to inadequate defenses related to myelosuppression secondary to radiation or antineoplastic agents

Goal: Prevention of infection

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient for evidence of infection. a. Check vital signs every 4 hours. b. Monitor white blood cell (WBC) count and differential each day. c. Inspect all sites that may serve as entry ports for pathogens (IV sites, wounds, skin folds, bony prominences, perineum, and oral cavity).	1. Signs and symptoms of infection may be diminished in the immunocompromised host. Prompt recognition of infection and subsequent initiation of therapy will reduce morbidity and mortality associated with infection.	• Demonstrates normal temperature and vital signs • Exhibits absence of signs of inflammation: local edema, erythema, pain, and warmth • Exhibits normal breath sounds on auscultation • Takes deep breaths and coughs every 2 hours to prevent respiratory dysfunction and infection.
2. Report fever (≥38.3°C [101°F] or ≥38°C [100.4°F] for >1 hour) (see Table 58-11), chills, diaphoresis, swelling, heat, pain, erythema, exudate on any body surfaces. Also report change in respiratory or mental status, urinary frequency or burning, malaise, myalgias, arthralgias, rash, or diarrhea.	2. Early detection of infection facilitates early intervention.	• Exhibits absence of pathogens on cultures • Avoids contact with others with infections • Avoids crowds • All personnel carry out hand hygiene after each voiding and bowel movement. • Excoriation and trauma of skin are avoided. • Trauma to mucous membranes is avoided (avoidance of rectal thermometers, suppositories, vaginal tampons, perianal trauma).
3. Obtain cultures and sensitivities as indicated before initiation of antimicrobial treatment (wound exudate, sputum, urine, stool, blood).	3. Tests identify the organism and indicate the most appropriate antimicrobial therapy. The use of inappropriate antibiotics enhances proliferation of additional flora and encourages growth of antibiotic-resistant organisms.	• Uses evidence-based procedures and techniques if participating in management of invasive lines or catheters • Uses electric razor • Is free of skin breakdown and stasis of secretions • Adheres to dietary and environmental precautions • Exhibits no signs of sepsis or septic shock • Exhibits normal vital signs, cardiac output, and arterial pressures when monitored • Demonstrates ability to administer colony-stimulating factor • Has bowel movements at regular intervals without constipation or straining • Patient hygiene is maintained. • Absence of IV catheter–related infection • Absence of skin abscesses • Absence of urinary catheter–related infection
4. Initiate measures to minimize infection. a. Discuss with patient and family: 1. Placing patient in private room if absolute WBC count <1000/mm^3. 2. Importance of patient avoiding contact with people who have known or recent infection or recent vaccination.	4. Exposure to infection is reduced. a. Preventing contact with pathogens helps prevent infection.	
b. Instruct all personnel in careful hand hygiene before and after entering room.	b. Hands are significant source of contamination.	
c. Avoid rectal or vaginal procedures (rectal temperatures, examinations, suppositories; vaginal tampons).	c. Incidence of rectal and perianal abscesses and subsequent systemic infection is high. Manipulation may cause disruption of membrane integrity and enhance progression of infection.	
d. Use stool softeners to prevent constipation and straining.	d. Minimizes trauma to tissues	
e. Assist patient in practice of meticulous personal hygiene.	e. Prevents skin irritation	
f. Instruct patient to use electric razor.	f. Minimizes skin trauma	
g. Encourage patient to ambulate in room unless contraindicated.	g. Minimizes chance of skin breakdown and stasis of pulmonary secretions	
h. Provide patient and family education on food hygiene and safe food handling.	h. No evidence supports dietary restrictions of avoiding raw or fresh fruit and vegetables for patients who are neutropenic. General precautions regarding food handling and storage are recommended.	

(Continued)

(Continued)

i. Each day, change water pitcher, denture cleaning fluids, and respiratory equipment containing water.	i. Stagnant water is a source of infection.
5. Assess IV sites every day for evidence of infection. a. Change peripheral short-term IV sites every other day. b. Cleanse skin with povidone–iodine before arterial puncture or venipuncture. c. Change central venous catheter dressings every 48 hours. d. Change all solutions and infusion sets every 72–96 hours. e. Follow Infusion Nursing Society guidelines for care of peripheral and central venous access devices.	5. Nosocomial staphylococcal septicemia is closely associated with IV catheters. a. Incidence of infection is increased when catheter is in place >72 hours. b. Povidone–iodine is effective against many gram-positive and gram-negative pathogens. c. Allows observation of site and removes source of contamination d. Once introduced into the system, microorganisms are capable of growing in infusion sets despite replacement of container and high flow rates. e. Infusion Nursing Society collaborates with other nursing subspecialties in determining guidelines for IV access care.
6. Avoid intramuscular injections.	6. Reduces risk for skin abscesses.
7. Avoid insertion of urinary catheters; if catheters are necessary, use aseptic technique.	7. Rates of infection greatly increase after urinary catheterization.
8. Educate patient or family member to administer granulocyte (or granulocyte-macrophage) colony-stimulating factor when prescribed.	8. Granulocyte colony-stimulating factor decreases the duration of neutropenia and the potential for infection.
9. Advise patient to avoid exposure to animal excreta, discuss dental procedures with primary provider, avoid vaginal douche, and avoid vaginal or rectal manipulation during sexual contact during the period of neutropenia.	9. Minimizes exposure to potential sources of infection and disruption of skin integrity.

Nursing Diagnosis: Risk for impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy
Goal: Maintenance of skin integrity

Nursing Intervention	Rationale	Expected Outcomes
1. In erythematous areas: a. Avoid the use of soaps, cosmetics, perfumes, powders, lotions, and ointments; non–aluminum-based deodorant may be used on intact skin. b. Use only lukewarm water to bathe the area. c. Avoid rubbing or scratching the area. d. Avoid shaving the area with a straight-edged razor.	1. Care to the affected areas must focus on preventing further skin irritation, drying, and damage. a. These substances may cause pain and additional skin irritation and damage. b. Avoiding water of extreme temperatures and soap minimizes additional skin damage, irritation, and pain. c. Rubbing, scratching, or both will lead to additional skin irritation, damage, and increased risk of infection. d. The use of razors may lead to additional irritation and disruption of skin integrity and increased risk of infection.	• Avoids use of soaps, powders, and other cosmetics on site of radiation therapy • States rationale for special care of skin • Exhibits minimal change in skin • Avoids trauma to affected skin region (avoids shaving, constricting and irritating clothing, extremes of temperature, and the use of adhesive tape) • Reports change in skin promptly • Demonstrates proper care of blistered or open areas • Exhibits absence of infection of blistered and opened areas. • Wound is free of development of eschar.

(Continued)

(Continued)

e. Avoid applying hot-water bottles, heating pads, ice, and adhesive tape to the area.	e. Avoiding extreme temperatures minimizes additional skin damage, irritation, burns, and pain.
f. Avoid exposing the area to sunlight or cold weather.	f. Sun exposure or extreme cold weather may lead to additional skin damage and pain.
g. Avoid tight clothing in the area. Use cotton clothing.	g. Allows air circulation to affected area
h. Topical agents such as Aquaphor, Radiacare gel, aloe vera, or Biafine (Valeant may be used, and low- or medium-potency corticosteroid cream may be given if pruritus is present.)	h. May aid healing; however, evidence supporting the benefits of topical agents is lacking.
2. If wet desquamation occurs:	2. Open weeping areas are susceptible to bacterial infection. Care must be taken to prevent introduction of pathogens.
a. Do not disrupt any blisters that have formed.	a. Disruption of skin blisters disrupts skin integrity and may lead to increased risk of infection.
b. Avoid frequent washing of the area.	b. Frequent washing may lead to increased irritation and skin damage, with increased risk of infection.
c. Report any blistering.	c. Blistering of skin represents progression of skin damage.
d. Use *prescribed* creams or ointments; topical antibacterial creams may help to dry a wet wound (e.g., Silvadene cream)	d. Anecdotally believed to decrease irritation and inflammation of the area and promote healing; although a variety of products are used in many settings, there are few randomized controlled trials with evidence to support one product or intervention over another.
e. If area weeps, apply a nonadhesive absorbent dressing.	e. Easier to remove and associated with less pain and trauma when drainage dries and adheres to dressing.
f. If the area is without drainage, moisture and vapor-permeable dressings, such as hydrocolloids and hydrogels on noninfected areas, have been used in many settings.	f. May promote healing; however, randomized controlled clinical trial support is lacking in the setting of moist desquamation. Hydrocolloid dressings may enhance comfort.
g. Consult with wound-ostomy-continence nurse (WOCN) and primary provider if eschar forms.	g. Eschar must be removed to promote healing and prevent infection. WOCNs have expertise in the care of wounds.

Nursing Diagnosis: Impaired oral mucous membrane: stomatitis
Goal: Maintenance of intact oral mucous membranes

Nursing Intervention	Rationale	Expected Outcomes
1. Assess oral cavity daily using the same assessment criteria or rating scale.	1. Provides baseline for later evaluation; maintains consistency in assessment findings	• States rationale for frequent oral assessment and hygiene
2. Identify individuals at increased risk for stomatitis and related complications.	2. Patient and treatment variables are associated with the incidence and severity of stomatitis as well as related complications such as delayed healing and infection.	• Factors associated with the incidence, severity, and complications are identified prior to initiation of cancer treatment • Oral mucosal assessment is conducted at baseline and on an ongoing basis. • Oral hygiene practices are initiated prior to development of stomatitis.

(Continued)

(Continued)

3. Instruct patient to report oral burning, pain, areas of redness, open lesions on oropharyngeal mucosa and lips, pain associated with swallowing, or decreased tolerance to temperature extremes of food.	3. Identification of initial stages of stomatitis will facilitate prompt interventions, including modification of treatment as prescribed by primary provider.	• Identifies signs and symptoms of stomatitis to report to nurse or primary provider • Participates in recommended oral hygiene regimen • Avoids mouthwashes with alcohol • Brushes teeth and mouth with soft toothbrush • Uses lubricant to keep lips soft and nonirritated • Avoids hard-to-chew, spicy, hot foods or other irritating foods • Maintains adequate hydration
4. Encourage and assist as needed in oral hygiene.	4. Patients who are having discomfort or pain, or other symptoms related to the disease and treatment, may require encouragement and assistance in performing oral hygiene. Oral hygiene is maintained to prevent complications of stomatitis, such as infection.	
Preventive		
1. Advise patient to avoid irritants such as commercial mouthwashes, alcoholic beverages, and tobacco.	1. Alcohol content of mouthwashes and tobacco smoke will dry oral tissues and potentiate breakdown.	• Exhibits clean, intact oral mucosa • Exhibits no ulcerations or infections of oral cavity • Exhibits no evidence of bleeding • Reports absent or decreased oral pain • Reports no difficulty swallowing • Exhibits healing (reepithelialization) of oral mucosa within 5–7 days (mild stomatitis)
2. Brush with soft toothbrush using nonabrasive toothpaste for 90 seconds after meals and at bedtime; allow toothbrush to air dry before storing; floss at least once daily or as advised by the clinician; patients who have not previously flossed regularly should not initiate flossing during stomatotoxic treatment; rinse mouth four times a day with a bland rinse (normal saline, sodium bicarbonate, or saline and sodium bicarbonate); avoid irritating foods (acidic, hot, rough, and spicy); use water-based moisturizers to protect lips.	2. Limits trauma and removes debris. Patients who have not previously flossed regularly do initiate flossing during stomatoxic treatment due to potential for injury to the oral mucosa and increased susceptibility to infection.	
3. Consider use of oral ice chips during stomatoxic chemotherapy infusions.	3. Oral cryotherapy has demonstrated reduced oral mucositis incidence, severity, and pain; improved quality of life; and minimizes chances of complications of oral mucositis	
4. Consider use of low level laser therapy.	4. Low energy level laser therapy has demonstrated decreased severity, duration, and pain associated with stomatitis.	
5. Consider administration of Palifermin as prescribed for patients receiving high-dose chemotherapy.	5. Palifermin, a recombinant keratinocyte growth factor (KGF) that stimulates the growth of cells lining the mouth and intestinal tract, has been shown to decrease the severity and duration of stomatitis.	
6. Maintain adequate hydration.	6. Maintenance of hydration prevents mucosal drying and breakdown.	
7. Provide written instruction and education to patients on the above items.	7. Written information reinforces patient education and provides the patient and family with a source.	
Mild stomatitis (generalized erythema, limited ulcerations, small white patches: *Candida*)		
1. Use normal saline mouth rinses every 1–4 hours.	1. Assists in removing debris, thick secretions, and bacteria	• Exhibits healing of oral tissues within 10–14 days (severe stomatitis) • Exhibits no bleeding or oral ulceration • Consumes adequate fluid and food • Exhibits absence of dehydration and weight loss • Exhibits no evidence of infection
2. Use soft toothbrush or toothette.	2. Minimizes trauma	
3. Remove dentures except for meals; be certain that dentures fit well.	3. Minimizes friction and discomfort	
4. Apply water-soluble lip lubricant.	4. Promotes comfort	
5. Avoid foods that are spicy or hard to chew and those with extremes of temperature.	5. Prevents local trauma	

(Continued)

(Continued)

Severe stomatitis (confluent ulcerations with bleeding and white patches covering >25% of oral mucosa)		
1. Obtain tissue samples for culture and sensitivity tests of areas of infection.	1. Assists in identifying need for antimicrobial therapy	a. Adheres to oral care regimen b. Exhibits healing of oral tissues within 10–14 days (severe stomatitis) • Consumes adequate fluid and food • Exhibits absence of dehydration and weight loss • Exhibits no evidence of infection • Reports absent or decreased discomfort or pain
2. Assess ability to chew and swallow; assess gag reflex.	2. Patient may be in danger of aspiration	
3. Use oral rinses (may combine in solution saline, anti-*Candida* agent, such as Mycostatin, and topical anesthetic agent [described later]) as prescribed, or place patient on side and irrigate mouth; have suction available.	3. Facilitates cleansing and provides for safety and comfort	
4. Remove dentures.	4. Prevents trauma from ill-fitting dentures	
5. Use toothette or gauze soaked with solution for cleansing.	5. Limits trauma and promotes comfort	
6. Use water-soluble lip lubricant.	6. Promotes comfort and minimizes loss of skin integrity	
7. Provide liquid or pureed diet.	7. Ensures intake of easily digestible foods without chewing	
8. Monitor for dehydration.	8. Decreased oral intake and ulcerations potentiate fluid deficits.	
9. Minimize discomfort.		
a. Consult primary provider for use of topical anesthetic, such as dyclonine and diphenhydramine, or viscous lidocaine.	a. Alleviates pain and increases sense of well-being; promotes participation in oral hygiene and nutritional intake	
b. Administer systemic analgesics as prescribed.	b. Adequate management of pain related to severe stomatitis can facilitate improved quality of life, participation in other aspects of activities of daily living, oral intake, and verbal communication.	
c. Perform mouth care as described.	c. Promotes removal of debris, healing, and comfort	

Nursing Diagnosis: Impairment of skin integrity related to rash
Goals: Maintenance of skin integrity

Nursing Intervention	Rationale	Expected Outcomes
Prevention		
1. Instruct patients to avoid sunlight through use of protective clothing, use of sun screen with SPF of 30 with physical blockers (zinc oxide, titanium dioxide), or avoidance of direct sun exposure.	1. Many agents are associated with photosensitivity; sunburn would intensify inflammation associated with rash and potentiate loss of skin integrity	• Sun exposure will be limited; no development of sun burn • Absence of dehydration • Participates in skin care regimen as instructed
2. Maintain adequate oral hydration.	2. Prevents skin dryness related to dehydration	• Absence of dryness, flaking
3. Avoid long hot showers or baths, harsh soaps and laundry detergents, perfumes, and non-hypoallergenic cosmetics.	3. Prevents skin irritation, dryness, flaking, and inflammation	
4. Apply emollients; apply hydrocortisone 1% cream with moisturizer at least twice daily; administer doxycycline 100 mg twice per day or minocycline, as prescribed	4. Minimizes dryness, flaking, and disruption of skin integrity.	
Treatment		
1. Apply topical treatment as prescribed: clindamycin 1%, fluocinonide 0.05% cream twice a day, or alclometasone 0.05% cream twice a day	1. Recommended as treatment to minimize skin disruption and prevent infection by Multinational Association of Supportive Care in Cancer (MSACC)	• Rash severity does not interfere with level of comfort and adherence to targeted therapy as prescribed; absence of local or systemic infection

(Continued)

(Continued)

2. For severe papulopustular rash: Administer systemic treatment as prescribed: doxycycline 100 mg twice per day; minocycline 100 mg daily; or isotretinoin at low doses of 20–30 mg per day	2. Recommended as treatment to minimize skin disruption and prevent infection by Multinational Association of Supportive Care in Cancer (MSACC)	• Rash severity does not interfere with level of comfort and adherence to targeted therapy as prescribed; absence of local or systemic infection • Local infection is controlled; absence of bacteremia and sepsis
3. Assess for development of infection: obtain cultures of pustules and administer appropriate antibiotics as prescribed by the physician	3. Prompt recognition and treatment of infection are necessary to prevent bacteremia, sepsis, and further patient compromise	

Nursing Diagnosis: Impaired tissue integrity: alopecia
Goal: Maintenance of tissue integrity; coping with hair loss

Nursing Intervention	Rationale	Expected Outcomes
1. Discuss potential hair loss and regrowth with patient and family; advise that hair loss may occur on body parts other than the head.	1. Provides information so that patient and family can begin to prepare cognitively and emotionally for loss	• Identifies alopecia as potential side effect of treatment • Identifies positive and negative feelings and threats to self-image • Verbalizes meaning that hair and possible hair loss have for him or her • States rationale for modifications in hair care and treatment • Uses mild shampoo and conditioner, and shampoos hair only when necessary • Avoids hair dryer, curlers, sprays, and other stresses on hair and scalp • Wears hat or scarf over hair when exposed to sun • Takes steps to deal with possible hair loss before it occurs; purchases wig or hairpiece if desired • Maintains hygiene and grooming • Interacts and socializes with others
2. Explore potential impact of hair loss on self-image, interpersonal relationships, and sexuality.	2. Facilitates coping and maintenance of interpersonal relationships	
3. Prevent or minimize hair loss through the following:	3. Retains hair as long as possible.	
a. Use scalp hypothermia and scalp tourniquets, if appropriate.	a. Decreases hair follicle uptake of chemotherapy (not used for patients with leukemia or lymphoma because tumor cells may be present in blood vessels or scalp tissue)	
b. Cut long hair before treatment.	b. Minimizes hair loss due to the weight and manipulation of hair	
c. Use mild shampoo and conditioner, gently pat dry, and avoid excessive shampooing.		
d. Avoid electric curlers, curling irons, dryers, clips, barrettes, hair sprays, hair dyes, and permanent waves.		
e. Avoid excessive combing or brushing; use wide-toothed comb.		
4. Prevent trauma to scalp.	4. Preserves tissue integrity	
a. Lubricate scalp with vitamin A and D ointment to decrease itching.	a. Assists in maintaining skin integrity	
b. Use sunscreen or wear hat when in the sun.	b. Prevents ultraviolet light exposure	
5. Suggest ways to assist in coping with hair loss.	5. Minimizes change in appearance	
a. Purchase wig or hairpiece before hair loss.	a. Wig that closely resembles hair color and style is more easily selected if hair loss has not begun.	
b. If hair loss has occurred, take photograph to wig shop to assist in selection.	b. Facilitates adjustment	
c. Begin to wear wig before hair loss.	c. Enables patient to be prepared for loss and facilitates adjustment	
d. Wear hat, scarf, or turban.	d. Conceals loss and protects scalp	
6. Encourage patient to wear own clothes and retain social contacts.	6. Assists in maintaining personal identity	

(Continued)

(Continued)

7. Explain that hair growth usually begins again once therapy is completed.	7. Reassures patient that hair loss is usually temporary

Nursing Diagnosis: Imbalanced nutrition: less than body requirements, related to nausea and vomiting
Goal: Patient experiences less nausea and vomiting associated with chemotherapy; weight loss is minimized

Nursing Intervention	Rationale	Expected Outcomes
1. Assess the patient's previous experiences and expectations of nausea and vomiting, including causes and interventions used.	1. Identifies patient concerns, misinformation, and potential strategies for intervention; also gives patient sense of empowerment and control	• Identifies previous triggers of nausea and vomiting • Exhibits decreased apprehension and anxiety • Identifies previously used successful interventions for nausea and vomiting • Reports decrease in nausea • Reports decrease in incidence of vomiting • Consumes adequate fluid and food when nausea subsides • Demonstrates use of distraction, relaxation, and imagery when indicated • Exhibits normal skin turgor and moist mucous membranes • No additional weight loss
2. Adjust diet before and after drug administration according to patient preference and tolerance.	2. Each patient responds differently to food after chemotherapy. A diet containing foods that relieve or prevent nausea or vomiting is most helpful.	
3. Prevent unpleasant sights, odors, and sounds in the environment.	3. Unpleasant sensations can stimulate the nausea and vomiting center.	
4. Use distraction, music therapy, biofeedback, self-hypnosis, relaxation techniques, and guided imagery before, during, and after chemotherapy.	4. Decreases anxiety, which can contribute to nausea and vomiting. Psychological conditioning may also be decreased.	
5. Administer prescribed antiemetics, sedatives, and corticosteroids before chemotherapy and afterward as needed.	5. Administration of antiemetic regimen before onset of nausea and vomiting limits the adverse experience and facilitates control. Combination drug therapy reduces nausea and vomiting through various triggering mechanisms.	
6. Ensure adequate fluid hydration before, during, and after drug administration; assess intake and output.	6. Adequate fluid volume dilutes drug levels, decreasing stimulation of vomiting receptors.	
7. Encourage frequent oral hygiene.	7. Reduces unpleasant taste sensations	
8. Provide pain-relief measures, if necessary.	8. Increased comfort increases physical tolerance of symptoms.	
9. Consult with dietician as needed.	9. Interdisciplinary collaboration is essential in addressing complex patient needs.	
10. Assess and address other contributing factors to nausea and vomiting, such as other symptoms, constipation, gastrointestinal irritation, electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.	10. Multiple factors may contribute to nausea and vomiting.	

Nursing Diagnosis: Imbalanced nutrition: less than body requirements, related to anorexia, cachexia, or malabsorption
Goal: Maintenance of nutritional status and of weight within 10% of pretreatment weight

Nursing Intervention	Rationale	Expected Outcomes
1. Assess and address factors that interfere with oral intake or are associated with increased risk of decreased nutritional status.	1. Multiple patient or treatment-related factors are associated with increased risk of impaired nutritional intake, such as radiation to the head, neck, and thorax; stomatoxic or emetogenic chemotherapy; prior oral, head, and neck surgery; mucositis; impaired swallowing or dysphagia; poor dentition; cough or shortness of breath.	• Factors associated with increased risk for impaired nutritional intake are identified. • Factors associated with increased risk of impaired nutritional intake are identified and addressed, whenever possible, through interdisciplinary collaboration. • Patient and family identify minimal nutritional requirements • Maintains or increases weight and body cell mass as per goals identified by nutritionist

(Continued)

(Continued)

2. Initiate appropriate referrals for interdisciplinary collaboration to manage factors that interfere with oral intake.	2. Other disciplines may be more appropriate for assessment and management of issues such as swallowing impairments (speech therapy), fatigue and decreased physical ability (physical and occupational therapy), nutritional assessment and determination of patient needs (nutritionist), cough and shortness of breath (respiratory therapy), poor dentition (dental medicine), depression/anxiety (social worker, psychologist, or psychiatrist).	• Reports decreasing anorexia and increased interest in eating • Demonstrates normal skin turgor • Identifies rationale for dietary modifications; patient and family verbalize strategies to minimize nutritional deficits • Participates in calorie counts and diet histories • Uses relaxation techniques and guided imagery before meals • Exhibits laboratory and clinical findings indicative of adequate nutritional intake: normal serum levels of protein, albumin, transferrin, iron, blood urea nitrogen (BUN), creatinine, vitamin D, electrolytes, hemoglobin, hematocrit, and lymphocytes; normal urinary creatinine levels • Consumes diet containing required nutrients • Carries out oral hygiene before meals • Reports decreased pain and/or other symptoms; symptoms do not interfere with oral intake • Reports decreasing episodes of nausea and vomiting • Participates in increasing levels of activity as measured by assessment of performance status • Family and friends do not focus efforts on encouraging food intake • States rationale for use of tube feedings or parenteral nutrition • Demonstrates ability to manage enteral feedings or parenteral nutrition, if prescribed • Maintains body position and alignment needed to facilitate chewing and swallowing
3. Educate patient to avoid unpleasant sights, odors, and sounds in the environment during mealtime.	3. Anorexia can be stimulated or increased with noxious stimuli.	
4. Suggest foods that are preferred and well tolerated by the patient, preferably high-calorie and high-protein foods. Respect ethnic and cultural food preferences.	4. Foods preferred, well tolerated, and high in calories and protein maintain nutritional status during periods of increased metabolic demand.	
5. Encourage adequate fluid intake, but limit fluids at mealtime.	5. Fluids are necessary to eliminate wastes and prevent dehydration. Increased fluids with meals can lead to early satiety.	
6. Suggest smaller, more frequent meals.	6. Smaller, more frequent meals are better tolerated because early satiety is less likely to occur.	
7. Promote relaxed, quiet environment during mealtime with increased social interaction as desired.	7. A quiet environment promotes relaxation. Social interaction at mealtime may foster appetite, divert focus on food, and promote enjoyment of eating.	
8. If patient desires, serve wine at mealtime with foods.	8. Wine may stimulate appetite and add calories.	
9. Consider cold foods, if desired.	9. Cold, high-protein foods are often more tolerable and less odorous than hot foods.	
10. Encourage nutritional supplements and high-protein foods between meals.	10. Supplements and snacks add protein and calories to meet nutritional requirements.	
11. Encourage frequent oral hygiene, particularly prior to meals.	11. Oral hygiene may stimulate appetite and increase saliva production.	
12. Address pain and other symptom management needs.	12. Pain and other symptoms impair appetite and nutritional intake.	
13. Increase activity level as tolerated.	13. Increased activity promotes appetite.	
14. Decrease anxiety by encouraging verbalization of fears and concerns; use relaxation techniques and guided imagery at mealtime.	14. Relief of anxiety may increase appetite.	
15. Instruct patient and family about body alignment and proper positioning at mealtime.	15. Proper body position and alignment are necessary to aid chewing and swallowing.	
16. Collaborate with dietician to provide nutritional counseling; instruct patient and family regarding enteral tube feedings of commercial liquid diets, elemental diets, or other foods as prescribed.	16. Nutritional counseling may improve outcomes. Tube feedings may be necessary in the severely debilitated patient who has a functioning gastrointestinal system but is unable to maintain adequate oral intake.	

(Continued)

(Continued)

17. Collaborate with dietician or nutrition support team to instruct patient and family regarding home parenteral nutrition with lipid supplements as prescribed.	17. Parenteral nutrition with supplemental fats supplies needed calories and proteins to meet nutritional demands, especially in the nonfunctional gastrointestinal system.	
18. Administer appetite stimulants as prescribed by primary provider.	18. Although the mechanism is unclear, medications such as megestrol acetate (Megace) have been noted to improve appetite in patients with cancer and human immunodeficiency virus infection.	
19. Encourage family and friends not to nag or cajole patient about eating.	19. Pressuring patient to eat may cause conflict and unnecessary stress.	
20. Assess and address other contributing factors to nausea, vomiting, and anorexia such as electrolyte imbalance, radiation therapy, medications, and central nervous system metastasis.	20. Multiple factors contribute to anorexia and nausea.	

Nursing Diagnosis: Fatigue
Goal: Decreased fatigue level

Nursing Intervention	Rationale	Expected Outcomes
1. Assess patient and treatment factors that are associated with or increase fatigue (e.g., anemia, fluid and electrolyte imbalances, pain, anxiety, etc.)	1. Multiple factors are associated with or contribute to cancer-related fatigue. Although fatigue is common in patients receiving chemotherapy or radiation therapy, there are several factors that can be modified or addressed, such as dehydration, electrolyte abnormalities, organ impairment, anemia, impaired nutrition, pain and other symptoms, depression, anxiety, impaired mobility, and shortness of breath.	• Factors contributing to fatigue are assessed and managed whenever possible. • Exhibits acceptable serum value levels for nutritional indices (See Imbalanced Nutrition) • Reports decreased pain and/or other symptoms • Consumes diet with recommended nutritional intake • Achieves or maintains appropriate weight and body mass • Maintains adequate hydration • Reports decreasing levels of fatigue • Adopts healthy lifestyle practices • Rests when fatigued • Reports adequate sleep • Requests assistance with activities appropriately • Uses relaxation exercises and imagery to decrease anxiety and promote rest • Reports no breathlessness during activities • Reports improved ability to relax and rest • Exhibits improved mobility and decreased fatigue Fatigue does not interfere with ability to participate in activities of daily living or pleasure
2. Institute interventions to address factors contributing to fatigue (e.g., correct electrolyte imbalance, manage pain, collaborative management of anemia, administer prescribed antidepressants, anxiolytics, hypnotics, or psychostimulants, as indicated)	2. Addressing factors contributing to fatigue assists in managing fatigue (i.e., lowered hemoglobin and hematocrit predispose patient to fatigue due to decreased oxygen availability especially in a setting of impaired mobility that requires increased energy expenditure).	
3. Encourage balance of rest and exercise; avoiding extended periods of inactivity. At minimum, promote patient's normal sleep habits.	3. Sleep helps to restore energy levels. Prolonged napping during the day may interfere with sleep habits.	
4. During active treatment, rearrange daily schedule and organize activities to conserve energy expenditure; encourage patient to ask for others' assistance with necessary chores, such as housework, child care, shopping, and cooking. During periods of profound fatigue, consider reduced job workload, if necessary and possible, by reducing number of hours worked per week.	4. Reorganization of activities can reduce energy losses and stressors.	
5. Encourage protein, fat, and calorie intake at least equal to that recommended for the general public.	5. Protein and calorie depletion decreases activity tolerance; preventing malnutrition, achieving and maintaining recommended weight and body mass assist in management of fatigue	

(Continued)

(Continued)

6. Encourage the use of relaxation techniques and guided imagery.	6. Promotion of relaxation and psychological rest limits contribution to physical fatigue.	
7. Encourage participation in planned exercise programs involving aerobic, resistance, and flexibility training based on individual limitations and safety measures. a. Minimum exercise for survivors depending on individual capabilities ranges from 10 minutes of light exercise, yoga, or stretching daily to 30 minutes of moderate to vigorous of activity	7. Various approaches to exercise programs have demonstrated increases in endurance and stamina and lower fatigue.	
8. Collaborate with other cancer providers to encourage them to give patients a prescription to exercise and explain role of exercise in cancer treatment.	8. Many providers fail to discuss the role of exercise and healthy lifestyle practices for patients during and after cancer treatment. Patients maybe more likely to utilize the benefits of exercise in addressing fatigue if they receive a formal prescription.	
9. Partner with community organizations (i.e., YMCA) to develop and offer cancer survivor specific rehab/exercise programs.	9. Creates community partnerships, a non-clinical environment of support, fosters increased awareness of survivorship needs, and provides referral sources that can reach more survivors.	
10. Collaborate with physical and occupational therapy; in addition, ensure safe and appropriate activities.	10. A CET designs and administers fitness assessments and exercise programs specific to an individual's cancer diagnosis, treatment, current recovery status; possesses basic understanding of cancer diagnoses, treatments, and potential adverse effects.	

Nursing Diagnosis: Chronic pain
Goal: Relief of pain and discomfort

Nursing Intervention	Rationale	Expected Outcomes
1. Use pain scale to assess pain and discomfort characteristics: location, quality, frequency, duration, etc., at baseline and on an ongoing basis.	1. Provides baseline for assessing changes in pain level and evaluation of interventions	• Reports decreased level of pain and discomfort on pain scale • Reports less disruption in activity and quality of life from pain and discomfort • Reports decrease in other symptoms and psychosocial distress • Adheres to analgesic regimen as prescribed • Barriers to adequately addressing pain do not interfere with strategies for managing pain. • Takes an active role in administration of analgesia • Identifies additional effective pain-relief strategies • Uses previously employed successful pain-relief strategies appropriately • Identifies and/or utilizes nonpharmacologic pain-relief strategies and reports successful decrease in pain • Reports that decreased level of pain permits participation in other activities and events and quality of life
2. Assure patient that you know the pain is real and will assist him or her in reducing it.	2. Fear that pain will not be considered real increases anxiety and reduces pain tolerance.	
3. Assess prior pain experiences and previous management strategies the patient found successful.	3. Helps to individualize pain management approaches and identify potential challenges or approaches that should not be utilized because of safety or other issues	
4. Assess other factors contributing to patient's pain: fear, fatigue, other symptoms, psychosocial distress, etc.	4. Provides data about factors that decrease the patient's ability to tolerate pain and increase pain level	
5. Provide education to patient and family about prescribed analgesic regimen.	5. Analgesics tend to be more effective when given early in pain cycle, around the clock at regular intervals, or when given in long-acting forms; breaks the pain cycle; premedication with analgesics is used for activities that cause increased pain or breakthrough pain.	

(Continued)

(Continued)

6. Address myths or misconceptions and lack of knowledge about the use of opioid analgesics.	6. Barriers to adequate pain management involve patients' fear of side effects, fatalism about the possibility of achieving pain control, fear of distracting providers from treating the cancer, belief that pain is indicative of progressive disease, and fears about addiction. Professional health providers also have demonstrated limited knowledge about evidence-based approaches to pain.	
7. Collaborate with patient, primary provider, and other health care team members when changes in pain management are necessary.	7. New methods of administering analgesia must be acceptable to patient, primary provider, and health care team to be effective; patient's participation decreases the sense of powerlessness.	
8. Consult with palliative care providers or team throughout the cancer continuum.	8. Palliative care specialists provide expertise and contribute to symptom management regardless of stage of disease or treatment within the cancer continuum, not only during end-stage disease. Palliative care can improve quality of life, length of survival, symptom burden, mood, and efficient utilization of health services.	
9. Explore nonpharmacologic and complementary strategies to relieve pain and discomfort: distraction, imagery, relaxation, cutaneous stimulation, acupuncture, etc.	9. Increases the number of options and strategies available to patient that serve as adjuncts to pharmacologic interventions.	

Nursing Diagnosis: Grieving related to loss; altered role functioning
Goal: Appropriate progression through grieving process

Nursing Intervention	Rationale	Expected Outcomes
1. Encourage verbalization of fears, concerns, and questions regarding disease, treatment, and future implications.	1. An increased and accurate knowledge base decreases anxiety and dispels misconceptions.	The patient and family: • Progress through the phases of grief as evidenced by increased verbalization and expression of grief. • Identify resources available to aid coping strategies during grieving. • Use resources and supports appropriately. • Discuss the future openly with each other. • Discuss concerns and feelings openly with each other. • Use nonverbal expressions of concern for each other. • Develop positive or adaptive coping mechanisms for processing of grief.
2. Explore previous successful coping strategies.	2. Provides frame of reference and examples of coping.	
3. Encourage active participation of patient or family in care and treatment decisions.	3. Active participation maintains patient independence and control.	
4. Visit family and friends to establish and maintain relationships and physical closeness.	4. Frequent contacts promote trust and security and reduce feelings of fear and isolation.	
5. Encourage ventilation of negative feelings, including projected anger and hostility, within acceptable limits.	5. This allows for emotional expression without loss of self-esteem.	
6. Allow for periods of crying and expression of sadness.	6. These feelings are necessary for separation and detachment to occur.	
7. Involve spiritual advisor as desired by the patient and family.	7. This facilitates the grief process and spiritual care.	
8. Refer patient and family to professional counseling as indicated to alleviate pathologic or nonadaptive grieving.	8. Goal is to facilitate the grief process or adaptive methods of coping.	
9. Allow for progression through the grieving process at the individual pace of the patient and family.	9. Grief work is variable. Not every person uses every phase of the grief process, and the time spent in dealing with each phase varies with every person. To complete grief work, this variability must be allowed.	

(Continued)

(Continued)

Nursing Diagnosis: Disturbed body image and situational low self-esteem related to changes in appearance, function, and roles
Goal: Improved body image and self-esteem

Nursing Intervention	Rationale	Expected Outcomes
1. Assess patient's feelings about body image and level of self-esteem.	1. Provides baseline assessment for evaluating changes and assessing effectiveness of interventions	• Identifies concerns of importance • Takes active role in activities • Maintains participation in decision making • Verbalizes feelings and reactions to losses or threatened losses • Participates in self-care activities • Permits others to assist in care when he or she is unable to be independent • Exhibits interest in appearance, maintains grooming, and uses aids (cosmetics, scarves, etc.) appropriately if desired • Participates with others in conversations and social events and activities • Verbalizes concern about sexual partner and/or significant others • Explores alternative ways of expressing concern and affection • The patient and significant other are able to maintain level of intimacy and express affection and acceptance.
2. Identify potential threats to patient's self-esteem (e.g., altered appearance, decreased sexual function, hair loss, decreased energy, role changes). Validate concerns with patient.	2. Anticipates changes and permits patient to identify importance of these areas to him or her	
3. Encourage continued participation in activities and decision making.	3. Encourages and permits continued control of events and self	
4. Encourage patient to verbalize concerns.	4. Identifying concerns is an important step in coping with them.	
5. Individualize care for the patient.	5. Prevents or reduces depersonalization and emphasizes patient's self-worth	
6. Assist patient in self-care when fatigue, lethargy, nausea, vomiting, and other symptoms prevent independence.	6. Physical well-being improves self-esteem.	
7. Assist patient in selecting and using cosmetics, scarves, hair pieces, hats, and clothing that increase their sense of attractiveness.	7. Promotes positive body image.	
8. Encourage patient and partner to share concerns about altered sexuality and sexual function and to explore alternatives to their usual sexual expression.	8. Provides opportunity for expressing concern, intimacy, affection, and acceptance.	
9. Refer to collaborating specialists as needed.	9. Interdisciplinary collaboration is essential in meeting patient needs.	

Collaborative Problem: Potential complication: risk for bleeding problems
Goal: Prevention of bleeding

Nursing Intervention	Rationale	Expected Outcomes
1. Monitor for factors increasing risk of bleeding (thrombocytopenia, elevated INR/PT/PTT, decreased fibrinogen or other clotting factors, use of medications affecting platelets or other clotting indices)	1. The underlying cancer, antineoplastic agents or other medications may interfere with normal mechanisms of clotting.	• Signs and symptoms of bleeding are identified. • Exhibits no blood in feces, urine, or emesis • Exhibits no bleeding of gums or injection/venipuncture sites • Exhibits no ecchymosis (bruising) or petechiae • Patient and family identify ways to prevent bleeding. • Uses recommended measures to reduce risk of bleeding (uses soft toothbrush, shaves with electric razor only) • Exhibits normal vital signs • Reports that environmental hazards have been reduced or removed • Maintains hydration • Reports absence of constipation • Avoids substances interfering with clotting • Absence of tissue destruction
2. Assess for and instruct patient/family about signs and symptoms of bleeding:	2. Early detection promotes early intervention.	
a. Petechiae or ecchymosis (bruising)	a. Petechiae and ecchymosis indicate injury to microcirculation and larger vessels.	
b. Decrease in hemoglobin or hematocrit	b. Decreased hemoglobin or hematocrit may indicate blood loss.	
c. Prolonged bleeding from invasive procedures, venipunctures, minor cuts or scratches	c. Prolonged bleeding may indicate abnormal clotting indices.	
d. Frank or occult blood in any body fluids	d. Occult blood in body fluids indicates bleeding.	
e. Bleeding from any body orifice	e. Indicates blood loss	
f. Altered mental status	f. Altered mental status may indicate decreased cerebral tissue oxygenation or bleeding.	
g. Hypotension; tachycardia	g. Hypotension or tachycardia may indicate blood loss.	

(Continued)

(Continued)

3. Instruct patient and family about ways to minimize risk of bleeding. a. Use soft toothbrush or toothette for mouth care. b. Avoid commercial mouthwashes. c. Use electric razor for shaving. d. Use emery board for nail care. e. Avoid foods that are difficult to chew. f. Keep lips moisturized with water-based lubricant g. Maintain fluid intake of at least 3 L per 24 hours unless contraindicated h. Use stool softeners or increase bulk in diet. i. Recommend use of water-based lubricant before sexual intercourse.	3. Patient can participate in self-protection. a. Prevents trauma to oral tissues b. Contain high alcohol content that will dry oral tissues c. Prevents trauma to skin d. Reduces risk of trauma to nail beds e. Prevents oral tissue trauma f. Prevents skin from drying g. Prevents skin and oral tissue membranes from drying h. Prevents trauma to rectal mucosa from straining i. Prevents friction and tissue trauma	• Exhibits normal mental status and absence of signs of intracranial bleeding • Avoids medications that interfere with clotting (e.g., aspirin) • Absence of epistaxis and cerebral bleeding
4. Initiate measures to minimize bleeding. Draw all blood for lab work with one daily venipuncture for hospitalized patients. a. Avoid taking temperature rectally or administering suppositories and enemas. b. Avoid intramuscular injections; use smallest needle possible. c. Apply direct pressure to injection and venipuncture sites for at least 5 minutes. d. Avoid bladder catheterizations; use smallest catheter if catheterization is necessary. e. Avoid medications that will interfere with clotting (e.g., aspirin). f. Recommend use of water-based lubricant before sexual intercourse. g. Platelet transfusions as prescribed; administer prescribed diphenhydramine hydrochloride (Benadryl) or hydrocortisone sodium succinate (Solu-Cortef) to prevent reaction to platelet transfusion. h. Supervise activity when out of bed. i. Caution against forceful nose blowing.	4. Measures are taken to minimize bleeding. a. Minimizes blood loss b. Bleeding may occur from intramuscular injection sites, particularly if large bore needles are used. c. Bleeding may occur if direct pressure is not applied for a long enough time period. d. Prevents trauma to urethra e. Minimizes risk of bleeding f. Helps prevent bleeding from small skin tears. g. Platelet count <20,000/mm_3 (0.02 × 1,012/L) is associated with increased risk of spontaneous bleeding. Allergic reactions to blood products are associated with antigen–antibody reaction that causes platelet destruction. h. Reduces risk of falls i. Prevents trauma to nasal mucosa and increased intracranial pressure

(see Chart 58-7, Risk for impaired skin integrity: erythematous and wet desquamation reactions to radiation therapy).

Alopecia

The temporary or permanent thinning or complete loss of hair is a potential adverse effect of whole brain radiation therapy, various chemotherapies and targeted agents. Alopecia usually begins 2 to 3 weeks after the initiation of chemotherapy and radiation therapy; regrowth most often begins within 8 weeks after the last treatment. Some patients who undergo radiation to the head may sustain permanent hair loss. The onset of gradually progressing alopecia and body hair loss associated with targeted therapies generally occurs 1 to 3 months after the start of treatment and may be patchy appearing as temporal or frontal

hair loss. This type of hair loss is usually reversible after the end of therapy and in some cases beginning sooner. Several targeted agents are associated with changes in hair growth rate, curliness, texture, and pigmentation. Although health care providers may view hair loss as a minor issue, for many patients it is a major assault on body image, challenging to self-esteem, and resulting in psychosocial distress and depression. Despite the significant psychosocial impact of alopecia, few studies have addressed methods to prevent or minimize the impact of alopecia. The use of cryotherapy to the head during the administration of chemotherapy has been explored but is not consistently used because of concern about later development of scalp metastasis. When cryotherapy is offered, its use avoided in patients with hematologic malignancies. Nurses provide information about hair loss and support the patient and family in coping with changes in body image. Patients are assisted to identify proactive choices that may empower them to improve responses to cancer and perceived lack of control as discussed in the nursing care plan (see Chart 58-7, Impaired tissue integrity: alopecia).

Malignant Skin Lesions

Skin lesions may occur with local extension or metastasis of the tumor into the epithelium and its surrounding lymph and blood vessels. Either locally invasive or metastatic cancer to the skin may result in redness (erythema), discolored nodules, or progression to wounds involving edema, exudates, and tissue necrosis. The most extensive lesions involve ulceration (referred to as fungating lesions) with an overgrowth of malodorous microorganisms. These lesions are a source of considerable pain, discomfort, and embarrassment. Although skin lesions occur in various malignancies, they are most commonly associated with breast cancer.

Ulcerating skin lesions usually indicate advanced or disseminated disease that is unlikely to be eradicated but may be controlled or palliated through systemic treatment (chemotherapy and targeted therapy) or radiation therapy. Local care of these lesions is a nursing priority. Nurses carefully assess malignant skin lesions for the size, appearance, condition of surrounding tissue, odor, bleeding, drainage, and associated pain or other symptoms, including evidence of infection. The potential for serious complications such as hemorrhage, vessel compression/obstruction, or airway obstruction, especially in head and neck cancer, should be noted so that the caregiver can be instructed in palliative measures to maintain patient comfort.

Nursing care (see Chart 58-7) also includes wound cleansing, reduction of superficial bacteria, control of bleeding, odor reduction, protection from further skin trauma, and pain management. The patient and family require emotional support, assistance, and guidance in providing wound care and addressing comfort measures at home.

Promoting Nutrition

Nutritional Impairment

Most patients with cancer experience some weight loss during their illness. Anorexia, malabsorption, and cancer-related anorexia-cachexia syndrome (CACS) are some common nutritional problems. Impaired nutritional status may contribute to both physical and psychosocial consequences (see Chart 58-8). Nutritional concerns include decreased protein and caloric intake, metabolic or mechanical effects of the cancer, systemic disease, side effects of the treatment, or the patient's emotional status.

Chart 58-8

Potential Consequences of Impaired Nutrition in Patients with Cancer

- Anemia
- Decreased survival
- Immune incompetence and increased incidence of infection
- Delayed tissue and wound healing
- Fatigue
- Diminished functional ability
- Decreased capacity to continue antineoplastic therapy
- Increased hospital admissions
- Increased length of hospital stay
- Impaired psychosocial functioning

Anorexia

Among the many causes of anorexia in patients with cancer are alterations in taste, manifested by increased salty, sour, and metallic taste sensations, and altered responses to sweet and bitter flavors. Taste changes contribute to decreased appetite and nutritional intake and subsequently protein–calorie malnutrition. Taste alterations may result from mineral (e.g., zinc) deficiencies, increases in circulating amino acids and cellular metabolites, or the administration of chemotherapeutic agents. Patients undergoing radiation therapy to the head and neck may experience "mouth blindness," which is a severe impairment of taste.

Anorexia may occur because patients develop early satiety after eating only a small amount of food. This sense of fullness occurs secondary to a decrease in digestive enzymes, abnormalities in the metabolism of glucose and triglycerides, and prolonged stimulation of gastric volume receptors, which convey the feeling of being full. Psychological distress (e.g., fear, pain, depression, and isolation) throughout illness may also have a negative impact on appetite. Patients may develop an aversion to food because of nausea and vomiting associated with treatment.

Malabsorption

Some patients with cancer are unable to absorb nutrients from the gastrointestinal system as a result of tumor activity, cancer treatments, or both. Malignancy can affect gastrointestinal activity in several ways (i.e., impaired enzyme production, interference with both protein and fat digestion) that can lead to increased gastrointestinal irritation, peptic ulcer disease, and fistula formation.

Chemotherapy and radiation associated with mucositis cause damage to mucosal cells of the bowel, resulting in impaired nutrient absorption. Abdominal irradiation has been associated with sclerosis of intestinal blood vessels and fibrotic changes in the gastrointestinal tissue, both impacting nutrient absorption. Surgical intervention may change peristaltic patterns, alter gastrointestinal secretions, and reduce the absorptive surfaces of gastrointestinal mucosa, all of which contribute to malabsorption.

Cancer-Related Anorexia-Cachexia Syndrome

CACS is a complex biologic process that results from a combination of increased energy expenditure and decreased intake (Alt-Epping & Nauck, 2015); (Bozzetti, 2013). This syndrome can occur in both the curative and palliative stages of treatment and care. Combined immunologic, neuroendocrine, and metabolic processes give rise to anorexia, unintentional weight loss, and increased metabolic demand with impaired

metabolism of glucose and lipids. As this syndrome continues, altered metabolic processes and tumor responses lead to cytokine release, causing generalized systemic inflammation. The patient experiences continued weight loss and malnutrition characterized by loss of adipose tissue, visceral protein, and skeletal muscle mass. Patients with CACS complain of loss of appetite, early satiety, and fatigue. As many as 80% of all patients with cancer experience some degree of cachexia (Alt-Epping & Nauck, 2015); (Bozzetti, 2013). Protein losses are associated with the development of anemia, peripheral edema, and progressive debilitation. The signs and symptoms of cancer cachexia and progressive debilitation appear to result in decreased quality of life, psychological distress, and anxiety for both patient and family as they respond to actual and perceived impending losses, fear, lack of control, and helplessness.

Nursing care is integral to an interdisciplinary approach that addresses the multiple factors contributing to impaired nutritional status in patients with cancer (see Chart 58-7).

General Nutrition Considerations

Assessment of the patient's nutritional status is conducted at diagnosis and monitored throughout the course of treatment and follow-up. Early identification of patients at risk for problems with intake, absorption, and cachexia, particularly during the early stages of disease, can facilitate timely implementation of specifically targeted interventions that attempt to improve quality of life, treatment outcomes, and survival (Bozzetti, 2013). Current weight, weight loss, diet and medication history, patterns of anorexia, nausea and vomiting, diarrhea, and situations and foods that aggravate or relieve symptoms are assessed and addressed.

The type of cancer, stage, and treatment approaches are considered so that proactive measures to support nutrition can be identified. For example, patients with head and neck cancers who are treated with radiation therapy, or some combination of surgery, radiation, chemotherapy and/or targeted agents, are at high risk for inadequate oral intake and nutritional deficits. In many centers, these patients have a percutaneous endoscopic gastrostomy (PEG) tube placed for enteral nutrition prior to initiation of treatment and the onset of mucositis, weight loss, and other consequences of impaired oral intake (Bozzetti, 2013). A speech therapy consult may be helpful for patients with oropharyngeal or laryngeal tumors or surgical interventions that are anticipated to effect swallowing, secretion management, speech, or respiratory function.

Whenever possible, every effort is made to maintain adequate nutrition through the oral route. Prokinetic agents such as metoclopramide (Reglan) are used to increase gastric emptying in patients with early satiety and delayed gastric emptying. Other pharmacologic interventions such as megestrol acetate (Megace) or corticosteroids (on a short term basis) may be used to improve appetite. Oral nutritional supplements are encouraged to meet nutritional needs and to maintain or improve weight gain and physical functioning. Supplements containing n-3 polyunsaturated fatty acids (omega-3), arginine, and nucleotides are suggested to decrease the inflammatory response and improve oxygen metabolism and intestinal function (Bozzetti, 2013). Approaches incorporate nutritional counseling, exercise, pharmacological interventions to combat anorexia, and symptom management when feasible (Alesi & del Fabbro, 2014). If adequate nutrition cannot be maintained by oral intake, nutritional support via the enteral route may be necessary as discussed previously. When needed, the patient and family are taught to administer enteral nutrition in the home.

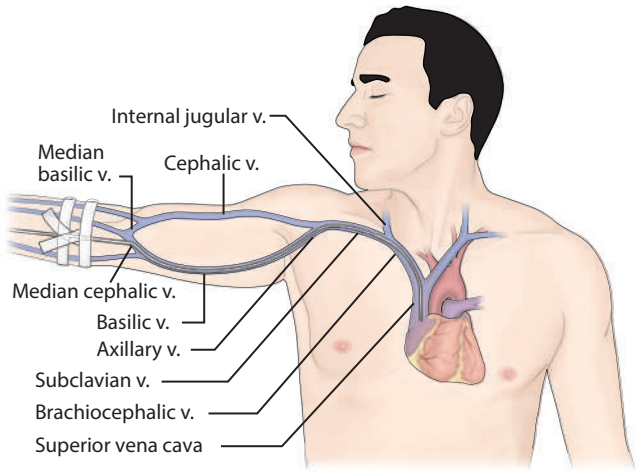

Figure 58-8 • A peripherally inserted central catheter is advanced through the cephalic or basilic vein to the axillary, subclavian, or brachiocephalic vein or the superior vena cava.

Home care nurses assist with patient education and monitor the patient's symptoms and response to enteral nutrition.

When malabsorption is a problem, enzyme and vitamin replacement may be instituted. Additional strategies include changing the feeding schedule, using simple diets, and relieving diarrhea. If malabsorption is severe, or the cancer involves the upper gastrointestinal tract, parenteral nutrition may be necessary. However, patients receiving parenteral nutrition are at increased risk for complications, including catheter-related and systemic infection. The use of parenteral nutrition in patients with advanced or end-stage cancer is seldom used and controversial (Bozzett, 2013). Parenteral nutrition can be given in several ways: by a long-term venous access device such as a right atrial catheter (see Fig. 58-5), implanted venous port (see Fig. 58-6), or PICC (see Fig. 58-8). The nurse educates the patient and family to care for the venous access device and to administer parenteral nutrition. Home care nurses provide education and assist with or supervise parenteral nutrition administration in the home.

Relieving Pain

More than half of patients with cancer experience pain throughout the cancer trajectory. Moderate to severe pain is reported by approximately 30% to 70% of patients with cancer during treatment and as many as 80% of those with advanced disease (Eaton, Mitchell, & Doorenbos, 2015). Although cancer pain may be acute, it is more frequently characterized as chronic. (See Chapter 9 for more information on pain.) As in other situations involving pain, the experience of cancer pain is influenced by physical, psychosocial, cultural, and spiritual factors.

Cancer can cause pain in various ways (see Table 58-10). Initially, pain is most often related to the underlying cancer process. Pain is also associated with various cancer treatments. Acute pain is linked with trauma from surgery. Occasionally, chronic pain syndromes, such as postsurgical neuropathies (pain related to nerve tissue injury), occur. Some chemotherapeutic agents cause tissue necrosis, peripheral neuropathies, and stomatitis—all potential sources of pain—whereas radiation therapy can cause pain secondary to skin, nervous tissue, or organ inflammation. Patients with cancer may have other sources of pain, such as arthritis or migraine headaches, that are unrelated to the underlying cancer or its treatment.

TABLE 58-10 Examples of Sources of Cancer Pain

Source	Descriptions	Underlying Cancer
Bone metastasis	Throbbing, aching	Breast, prostate, myeloma
Ischemia	Sharp, throbbing	Kaposi's sarcoma
Lymphatic or venous obstruction	Dull, aching, tightness	Lymphoma, breast, Kaposi's sarcoma
Nerve compression, infiltration	Burning, sharp, tingling	Breast, prostate, lymphoma
Organ obstruction	Dull, crampy, gnawing	Colon, gastric
Organ infiltration	Distention, crampy	Liver, pancreatic
Skin inflammation, ulceration, infection, necrosis	Burning, sharp	Breast, head and neck, Kaposi's sarcoma

The nurse assesses the patient for the source and site of pain as well as those factors that influence the patient's perception and experience of pain, such as fear and apprehension, fatigue, anger, and social isolation. Pain assessment scales (see Chapter 9) are useful for assessing the patient's pain before and after pain-relieving interventions are instituted to assess the effectiveness of interventions. Other symptoms that contribute to the pain experience, such as nausea and fatigue, are assessed and addressed as well.

In today's society, most people expect pain to disappear or resolve quickly. Although it is often controllable, advanced cancer pain is commonly irreversible and not quickly resolved. For many patients, pain is often seen as a signal that cancer is advancing and that death is approaching. As patients anticipate pain and anxiety increases, pain perception heightens, producing fear and further pain. Thus, chronic cancer pain can lead to a cycle progressing from pain to anxiety to fear and back to pain, especially when the pain is not adequately managed. Inadequate pain management is most often the result of misconceptions and insufficient knowledge about pain assessment and management on the part of patients, families, and health care providers (Eaton et al., 2015). Chapter 9 provides information regarding factors contributing to the pain experience, pain perception, and tolerance as well as pharmacologic and nonpharmacologic nursing interventions addressing pain. The nursing care plan (see Chart 58-7) also provides strategies for nursing assessment and management of chronic pain.

The World Health Organization advocates a three-step approach to treat cancer pain (see Fig. 58-9). Analgesics are given based on the patient's reported level of pain. A cancer pain algorithm, developed as a set of analgesic guiding principles, is given in Figure 58-10.

Pharmacologic and nonpharmacologic approaches, even those that may be invasive, are considered in managing cancer-related pain regardless of the patient's status along the cancer trajectory. The nurse assists the patient and family to take an active role in managing pain. The nurse provides education and support to correct fears and misconceptions about opioid use. Inadequate pain management leads to a diminished quality of life characterized by distress, suffering, anxiety, fear, immobility, isolation, and depression.

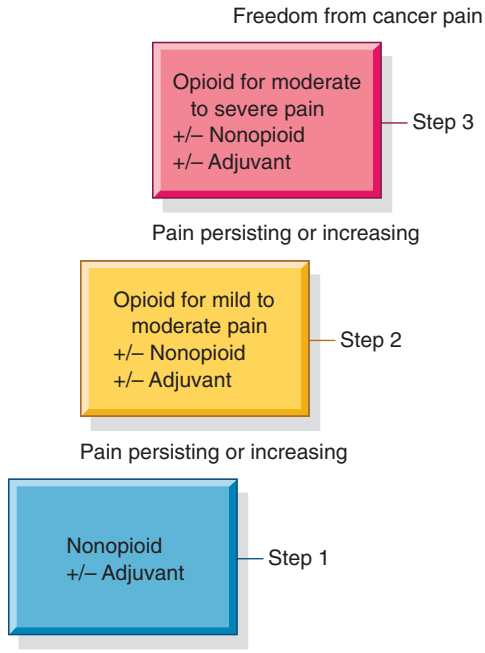

Figure 58-9 • Adapted from the World Health Organization three-step ladder approach to relieving cancer pain. Various opioid (narcotic) and nonopioid medications may be combined with other medications to control pain.

Decreasing Fatigue

Fatigue is one of the most frequent and distressing symptoms experienced by patients receiving cancer therapy. Patients report that fatigue persists and interferes with activities of daily living for months to years after the completion of treatment (Pachman, Price, & Carey, 2014). Fatigue rarely exists in isolation; patients typically experience other symptoms concurrently, such as pain, dyspnea, anemia, sleep disturbances, or depression.

In assessing fatigue, the nurse distinguishes between *acute fatigue,* which occurs after an energy-demanding experience, and *cancer-related fatigue,* which is defined as "a distressing persistent, subjective sense of physical, emotional and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning" (NCCN, 2015f). Acute fatigue serves a protective function, whereas cancer-related fatigue does not. The exact mechanisms of fatigue are not well understood and are multifactorial in nature.

Despite the commonly occurring experience of fatigue in patients with cancer, a reliable assessment tool has not been identified. The experience of fatigue is highly subjective, with patient descriptors varying greatly (NCCN, 2015f). The nurse assesses physiologic and psychological factors that can contribute to fatigue (see Chart 58-9).

Exercise and physical activity are effective approaches to the management of cancer-related fatigue (Pachman et al., 2014). Psychoeducational approaches, cognitive-behavioral therapy to address sleep, progressive muscle relaxation, yoga and mindfulness meditation maybe effective measures to facilitate fatigue management (Mitchell, Hoffman, Clark, et al., 2014). Nurses assist patients with strategies to minimize fatigue or help the patient cope with fatigue as described in the nursing care plan (see Chart 58-7). Occasionally, pharmacologic interventions are utilized, including antidepressants for patients

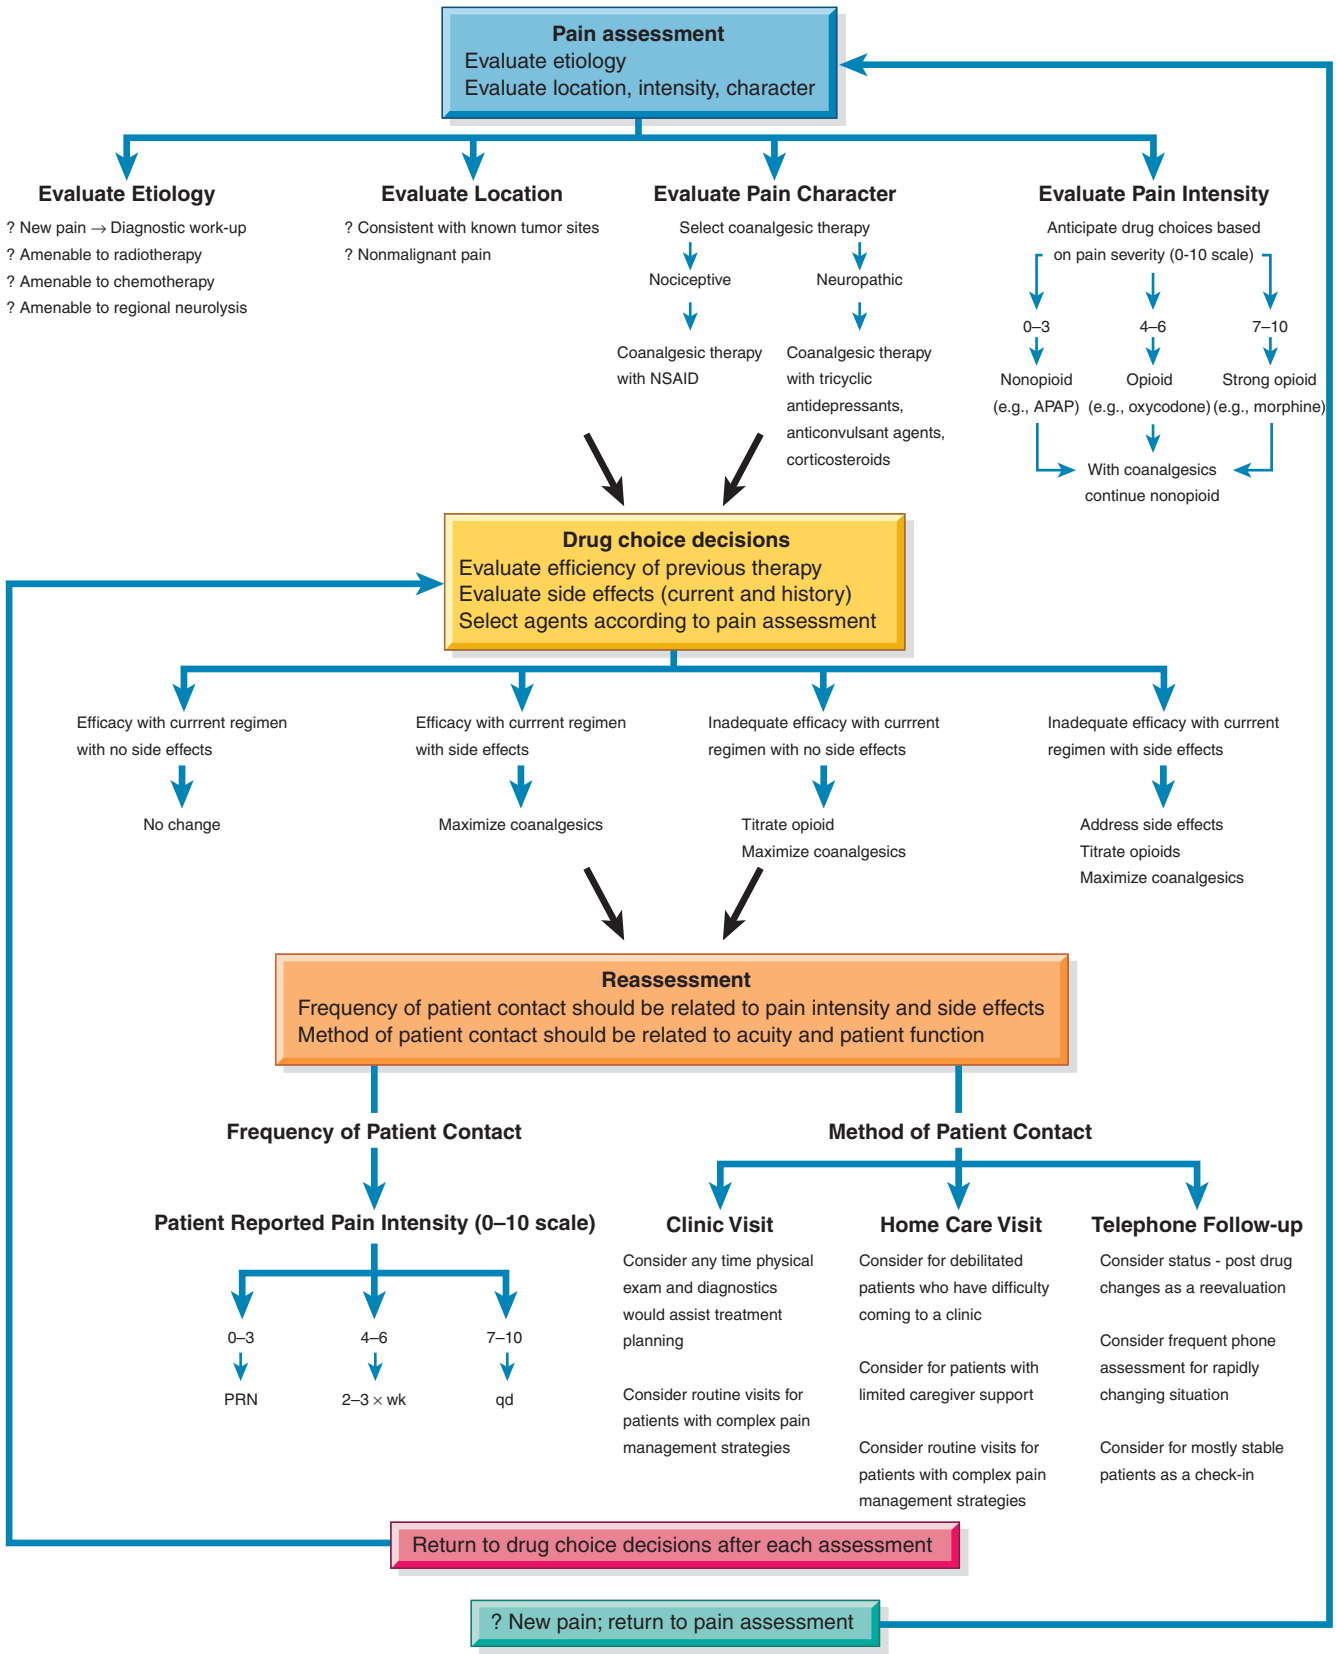

Figure 58-10 • The cancer pain algorithm (highest-level view) is a decision-tree model for pain treatment. Redrawn with permission from DuPen, A. R., DuPen, S., Hansberry, J., et al. (2000). An educational implementation of a cancer pain algorithm for ambulatory care. Pain Management Nursing, 1(4), 118.

Chart 58-9

Sources of Fatigue in Patients with Cancer

- Pain, pruritus
- Imbalanced nutrition related to nausea, vomiting, cancer-related anorexia-cachexia syndrome
- Electrolyte imbalance related to vomiting, diarrhea
- Ineffective protection related to neutropenia, thrombocytopenia, anemia
- Impaired tissue integrity related to stomatitis, mucositis
- Impaired physical mobility related to neurologic impairments, surgery, bone metastasis, pain, and analgesic use
- Uncertainty and deficient knowledge related to disease process, treatment
- Anxiety related to fear, diagnosis, role changes, uncertainty of future
- Ineffective breathing patterns related to cough, shortness of breath, and dyspnea
- Disturbed sleep pattern related to cancer therapies, anxiety, and pain

Adapted from Bryant, A. L., Walton, A. L., & Phillips, B. (2015). Cancer-related fatigue: Scientific progress has been made in 40 years. Clinical Journal of Oncology Nursing, 19(2), 137–139; National Comprehensive Cancer Network. (2015f). NCCN guidelines for supportive care: Cancer related fatigue. Retrieved on 3/24/2016 at: www.nccn.org/professionals/physician_gls/f_guidelines.asp#fatigue

with depression, anxiolytics for those with anxiety, hypnotics for patients with sleep disturbances, and psychostimulants for some patients with advanced cancer or fatigue that does not respond to other interventions (NCCN, 2015f).

Improving Body Image and Self-Esteem

The nurse identifies potential threats to the patient's body image and assesses the patient's ability to cope with the many bodily changes that may be experienced throughout the course of disease and treatment. Entry into the health care system is often accompanied by depersonalization. Threats to self-concept occur as the patient faces the realization of illness, disfigurement, possible disability, and death. To accommodate treatments or because of the disease, many patients with cancer are forced to alter their lifestyles. Priorities and values change when body image is threatened. Disfiguring surgery, hair loss, cachexia, skin changes, altered communication patterns, and sexual dysfunction can threaten the patient's self-esteem and body image.

A creative and positive approach is essential when caring for patients with altered body image. Nursing strategies for addressing issues related to body image and self-esteem are included in the nursing care plan (see Chart 58-7). The nurse serves as a listener and counselor to both the patient and the family. Possible influences of the patient's culture and age are considered when discussing concerns and potential interventions.

Addressing Sexuality

The physiologic processes associated with cancer; potential short- and long-term effects of cancer treatments; and psychosocial, emotional, and spiritual responses to the entire experience may lead patients to confront a variety of sexuality-based issues. Patients at the greatest risk of sexual dysfunction are those with tumors that involve the sexual or pelvic organs and those whose treatment affects the hormonal systems mediating sexual function (Goldfarb, Mulhall, Nelson, et al., 2013). Although sexuality is an important component of overall health, many nurses and other health professionals are hesitant to include sexuality in their discussions with patients (Kelvin, Steed, & Jarrett, 2014). Workshops have been developed to help nurses overcome barriers to discussing sexuality (Smith, 2015). In offering a holistic approach to the care of patients with cancer, nurses should initiate discussions about sexuality and assess sexual health.

Infertility, a common consequence of cancer and cancer treatments, can be of concern to patients and their partners. The potential for impaired fertility is discussed and options reviewed for fertility preservation (Frankel Kelvin, 2015). Fertility plans are discussed and determined prior to the initiation of any therapy that may compromise reproductive abilities.

Referrals are made as needed for specialized evaluation and interventions that are beyond the scope of nursing intervention.

Assisting in the Grieving Process

A cancer diagnosis need not indicate a fatal outcome. Many forms of cancer are curable, and others may be controlled for long periods of time similar to the course of other chronic diseases. Despite the tremendous advances in cancer, many patients and their families still view cancer as a fatal disease that is inevitably accompanied by pain, suffering, debilitation, and emaciation. Grieving is a normal response to these fears and to actual or potential losses: loss of health, normal sensations, body image, social interaction, intimacy, independence, and usual social roles. Patients, families, and friends may grieve for the loss of quality time to spend with others, the loss of future and unfulfilled plans, and the loss of control over the patient's body and emotional reactions. Nurses continue to assess the patient and family for positive or maladaptive coping behaviors, interpersonal communication, and evidence of the need for additional psychosocial support or interventions such as referral for professional counseling.

If the patient enters the terminal phase of disease, the nurse may assess that the patient and family members are at different stages of grief. In such cases, the nurse assists the patient and family to acknowledge and cope with their reactions and feelings. The nurse also empowers the patient and family to explore preferences for issues related to end-of-life care, such as withdrawal of active disease treatment, desire for the use of life-support measures, and symptom management approaches. Oncology nurses respectfully support the patient's spiritual or religious views. In addition, nurses consider the patient's cultural beliefs and practices when addressing issues related to grief. After the death of a patient with cancer, home care and/or hospice nurses follow up with surviving family members for bereavement counseling to facilitate expression and coping with feelings of loss and grief. (See Chapter 59 for further discussion of end-of-life issues.)

Management of Psychosocial Distress

Despite advances in cancer care, patients experience varying levels of psychosocial distress related to actual or potential losses, fear of the unknown, symptoms due to cancer or cancer treatments, changes in usual family and social roles, financial concerns, and a sense of loss of control. Psychosocial distress is defined as a multifactorial unpleasant emotional experience of a psychological (cognitive, behavioral, emotional), social, and/or spiritual nature

that may interfere with the ability to cope effectively with cancer, its physical symptoms and its treatment (NCCN, 2015g). Distress occurs along a continuum, ranging from common normal feelings of vulnerability, sadness, and fears to problems that can become disabling, such as depression, anxiety, panic, social isolation, and existential and spiritual crisis. Distress that is not addressed can have a significant impact on the overall well-being, interpersonal relationships, cognitive abilities, and adherence to treatment regimens, leading to poor outcomes.

Nurses need to screen patients for psychosocial distress during the course of the cancer experience. Patients are supported in managing various sources and levels of distress. Referral to mental health providers may be helpful to address specific concerns (Schilli, 2014).

Monitoring and Managing Potential Complications

Infection

For patients in all stages of cancer, the nurse assesses factors associated with the development of infection. Although infection-associated morbidity and mortality have greatly decreased, prevention and prompt treatment of infection are essential in patients with cancer. Often, more than one predisposing factor is present in patients with cancer. The nurse monitors laboratory studies to detect early changes in WBC counts. Common sites of infection, such as the pharynx, skin, perianal area, urinary, and respiratory tracts, are assessed on a regular basis. However, the typical signs of infection (swelling, redness, drainage, and pain) may not occur in myelosuppressed patients because of decreased circulating WBCs and a diminished local inflammatory response. Fever may be the only sign of infection (NCCN, 2015h). The nurse monitors the patient for sepsis, particularly if invasive catheters or long-term IV catheters are in place.

WBC function is often impaired in patients with cancer. Among the five types of WBCs, (neutrophils [granulocytes], lymphocytes, monocytes, basophils, and eosinophils), neutrophils serve as the body's primary initial defense against invading organisms. Comprising 60% to 70% of the body's WBCs, neutrophils act by engulfing and destroying infective organisms through phagocytosis. Both the total WBC count and the concentration of neutrophils are important in determining the patient's ability to fight infection. A decrease in circulating WBCs is referred to as leukopenia. Granulocytopenia is a decrease in neutrophils.

A differential WBC count identifies the relative numbers of WBCs and permits tabulation of polymorphonuclear neutrophils (PMNs) or segmented neutrophils (mature neutrophils, reported as "polys," PMNs, or "segs") and immature forms of neutrophils (reported as bands, metamyelocytes, and "stabs"). The absolute neutrophil count (ANC) is calculated by the following formula:

$$\text{ANC} = (\text{segmented neutrophils [\%]} + \text{bands [\%]}) \times \text{WBC count (cells/mm3)}$$

Example: $(25\% \text{ segs} + 25\% \text{ bands}) \times 6000 \text{ WBC cells/mm}^3 = 3000 \text{ ANC}$

Neutropenia, an abnormally low ANC, is associated with an increased risk of infection. The risk of infection rises as the ANC decreases. As the ANC declines below 1,500 cells/mm^3, the risk of infection rises. An ANC less than 500 cells/mm^3 reflects a severe risk of infection (NCCN, 2015h); (Segal, Walsh, Gea-Banacloche, et al., 2015). The ***nadir*** is the lowest ANC following chemotherapy, targeted therapy, or radiation therapy that suppresses bone marrow function. Severe neutropenia may necessitate delays in administration of myelosuppressive therapies or treatment dose adjustments, although the use of the hematopoietic growth factors (i.e., colony-stimulating factors; see previous discussion) has reduced the severity and duration of treatment-associated neutropenia as well as infection-related morbidity and early death (Smith, Bohlke, Lyman, et al., 2015). The administration of these growth factors assists in maintaining treatment schedules, drug dosages, treatment effectiveness, and quality of life.

Febrile patients who are neutropenic are assessed for factors that increase the risk of infection and for sources of infection through cultures of blood, sputum, urine, stool, IV and urinary or other catheters, and wounds, if appropriate (see Table 58-11). In addition, a chest x-ray is usually obtained to assess for pulmonary infection.

Defense against infection is compromised in many different ways. The integrity of the skin and mucous membranes is challenged by multiple invasive diagnostic procedures, by the adverse effects of all cancer treatment modalities, and by the detrimental effects of immobility. Impaired nutrition as a result of CACS, nausea, vomiting, diarrhea, and the underlying disease alters the body's ability to combat invading organisms. Medications such as antibiotics disturb the balance of normal flora, allowing the overgrowth of normal flora and pathogenic organisms. Other medications can also alter the immune response (see Chapter 54). Cancer itself may lead to defects in cellular and humoral immunity. Advanced cancer may cause obstruction of hollow viscera (e.g., intestines), blood, and lymphatic vessels, creating a favorable environment for proliferation of pathogenic organisms. In some patients, tumor cells infiltrate bone marrow and prevent normal production of WBCs.

Nurses are in a key position to assist in preventing and identifying symptoms of infection, as discussed in the nursing care plan (see Chart 58-7). Clinical practice guidelines developed by the ONS, the Infusion Nurses Society (INS), the NCCN, and the ASCO are used to guide prevention and management of infection. Interventions to prevent infection and alternative patient education formats for infection-related instruction are high nursing research priorities.

Gram-positive bacteria (*Streptococcus,* enterococci, and *Staphylococcus* species) and gram-negative organisms (*Escherichia coli, Klebsiella pneumoniae, Enterobacter,* and *Pseudomonas aeruginosa*) are the most frequently isolated causes of infection. Fungal organisms, such as *Candida albicans,* also contribute to the incidence of serious infection. Viral infections in immunocompromised patients are caused most often by herpes simplex, respiratory syncytial, parainfluenza, and influenza A and B viruses.

Fever is reported promptly as it is an important sign of infection in patients when associated with neutropenia. Patients with neutropenic fever (see Table 58-11) are assessed for infection and reported promptly (NCCN, 2015h). Antibiotics may be prescribed after cultures of wound drainage, exudates, sputum, urine, stool, or blood are obtained. Careful consideration is given to the underlying malignancy, prior antineoplastic treatment, ANC, comorbidities, and other patient-related factors prior to the identification of the most appropriate antibiotic therapy. Evidence-based guidelines are available for prevention and treatment of cancer-related infections (NCCN, 2015h). Patients with neutropenia are treated with broad-spectrum antibiotics before the infecting organism is identified because of the

TABLE 58-11 Assessment of Neutropenic Fever in Patients with Cancer

Fever Criteria	Neutropenia Criteria
• Any one-time temperature of 38.3°C (101°F) or • Any temperature of ≥38°C (100.4°F) or ≥1 h	• <500 neutrophils/mcL or • <1000 neutrophils/mcL and predicted to decline to ≤500 neutrophils/mcL over the next 48 hours

Assessment Targets for Neutropenic Fever Evaluation			
Infection Risk Factors	**Physical Assessment**	**Diagnostic Procedures**	**Microbiologic Cultures**
• Chronic comorbid illnesses • Underlying hematologic malignancies • Immunosuppression related to factors other than neutropenia (i.e., immunosuppressive therapy following allogeneic HSCT or hypogammaglobulinemia [decreased gammaglobulin production]) • Solid tumors causing obstructions of the bronchial tree, ureters, colon, or biliary ducts • Advanced or refractory underlying malignancy • Prolonged duration of neutropenia • Age ≥65 years • Limited mobility and/or debilitation • Medications (e.g., corticosteroids such as prednisone) • Antibiotic therapy or prophylaxis • Recent surgery for diagnosis or treatment • Chemotherapy or targeted therapy received within the last 7–10 days • Prior treatment with multiple types of chemotherapy regimens • Recent radiation therapy; especially to areas associated with bone marrow reserves • Prior documented infections • Impaired skin integrity • Invasive drainage or urinary catheters • Peripheral or central venous access devices • Exposures (travel, others with infection, blood administration, pets) • Diarrhea • Poor nutritional status • Recent lumbar puncture or indwelling Ommaya reservoir™ (long-term intraventricular catheter for administration of chemotherapy into CSF and ventricles)	• Skin, pressure points, wounds • Surgical or biopsy incision sites • IV access or reservoir sites • Drainage catheter sites • Tracheostomy site • Lungs and sinuses • Perivaginal and perirectal area • Alimentary canal, abdomen • Neurologic assessment • Vital signs	• Diagnostic imaging as appropriate to identify abscesses, fistulas, pneumonia, obstruction, etc. • Complete blood count/differential • Serum chemistries, liver function tests • Renal function tests • Pulse oximetry or arterial blood gases • Lumbar puncture for CSF analysis	• Blood (peripheral and central venous access if applicable) • Urine (especially with indwelling catheter) • Skin wounds, lesions, incision sites, catheter exit sites • Catheter tips when feasible • Drainage from catheters • Stool, diarrhea • Sputum • CSF

CSF, cerebrospinal fluid.

Available at: www.nccn.org/professionals/physician_gls/pdf/infections.pdf; Segal, B. H., Walsh, T. J., Gea-Banacloche, J. C., et al. (2015). Infections in the cancer patient. In V. T., DeVita, T. S., Lawrence, & S. A., Rosenberg, (Eds.). Cancer: Principles & practice of oncology. Philadelphia: Lippincott Williams & Wilkins.

increased risk of mortality associated with untreated infection. Broad-spectrum antibiotic therapy targets the most likely major pathogenic organisms. It is important for these medications to be given and taken promptly as scheduled to achieve adequate blood levels. Once the offending organism is identified, more specific antimicrobial therapy is prescribed as appropriate. Nurses provide education for patients and families regarding prevention of infection, signs and symptoms to report, and the importance of adherence to prescribed antimicrobial therapy.

Septic Shock

The nurse assesses the patient frequently for signs and symptoms of infection and inflammation throughout the trajectory of cancer care. Sepsis and septic shock are life-threatening complications that must be prevented or detected and treated promptly. Although all patients with cancer are at risk, patients who are neutropenic or who have hematologic malignancies are at the greatest risk. Patients with signs and symptoms of impending sepsis and septic shock require immediate hospitalization and aggressive treatment in the intensive care setting. (See Chapter 8 for discussion of sepsis and septic shock.)

Bleeding and Thrombocytopenia

Platelets are essential for normal blood clotting and coagulation (hemostasis). Thrombocytopenia, a decrease in the circulating platelet count, is the most common cause of bleeding in patients with cancer and is usually defined as a platelet count less than 100,000/mm^3 (0.1×10^{12}/L). The risk of bleeding increases when the platelet count decreases below 50,000/mm^3 (0.05×10^{12}/L). At platelet counts lower than 10,000/mm^3 (0.02×10^{12}/L), the risk for spontaneous bleeding is increased (Barbarotta, 2015).

Thrombocytopenia often results from bone marrow depression after certain types of chemotherapy and radiation therapy and with tumor infiltration of the bone marrow. In some cases, platelet destruction is associated with an enlarged spleen (hypersplenism) and abnormal antibody function, which occur with leukemia and lymphoma. Bacterial and viral infections may lead to early platelet destruction or impaired bone marrow production of platelets and subsequent thrombocytopenia. Some medications (i.e., heparin, vancomycin) may cause bone marrow toxicity leading to decreases in circulating platelets. Less commonly, posttransfusion complications may lead to antibody destruction of platelets causing profound

thrombocytopenia. Lastly, coagulopathies associated with infection or malignancies, such as gastric and pancreatic cancer, may result in thrombocytopenia (Kuter, 2015). The nursing care plan addresses nursing assessment parameters and interventions for patients at risk for bleeding (see Chart 58-7).

Nursing Alert: Although laboratory test results confirm the diagnosis of thrombocytopenia, the patient who is developing thrombocytopenia may display early signs and symptoms. Thus, nurses need to observe keenly for petechiae and ecchymoses, which are early indicators of decreasing platelet levels. Early detection promotes early intervention.

Additional medications may be prescribed to address bleeding or thrombocytopenia based on the underlying etiology. (Refer to Chapter 27 for further discussion of assessment and treatment of thrombocytopenia and coagulopathies.)

Venous thromboembolism (VTE), a common problem for patients with cancer, includes deep venous thrombosis (DVT), pulmonary embolism (PE), superficial venous thrombosis (SVT), and thrombosis in other abdominal or thoracic venous tributaries such as the mesenteric veins or the superior vena cava. The incidence of VTE has been linked to an increased likelihood of death in patients with cancer (NCCN, 2015i). Factors associated with risk for VTEs in cancer patients include pre-existing underlying or cancer-related coagulopathies, medications including chemotherapy, hospitalizations, surgical procedures, increased age, debilitation, immobility, infection, and peripheral and central venous catheters (NCCN, 2015i). Patients with cancer are monitored for associated risk factors and are assessed on an ongoing basis for VTE. Nurses provide patient and family education regarding symptoms of VTE to report to the provider. Recommendations for prophylaxis are based on national guidelines and patient risk factors. Nursing assessment findings associated with VTE are reported promptly so that VTE evaluation and treatment can be initiated expeditiously.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

Most commonly, patients with cancer are diagnosed and treated in the outpatient setting. Nurses in outpatient settings often have the responsibility for patient education and helping coordinate care in the home (see Chart 58-10). The shift of care from acute care facilities to the home or outpatient settings as well as the increasing use of oral antineoplastic agents places significant responsibility for care on the patient and family. In order to maintain optimal patient outcomes and quality of life, patients and families require support and information that will prepare them to engage in self-care. Education initially focuses on the most immediate care needs likely to be encountered at home.

Approaches to preparing patients for self-care responsibilities are chosen with consideration of the patient's preferred learning strategies, level of education, and health literacy. Knobf (2013) suggests that patient education is best achieved through a nurse–patient relationship that involves an exchange of information to support patient needs that can vary across time points of the cancer continuum. Easily understood, concrete, objective information that assists patients to understand what to expect and includes sensory and temporal components is important. Symptoms, side effects of treatment, and changes in the patient's status that should be reported are discussed and reinforced with printed materials that can be referred to in the home. Nurses help to empower patients by sharing strategies to manage side effects or other symptoms. Additional learning needs are based on the priorities conveyed by the patient and family as well as on the complexity of care required.

Technologic advances allow home administration of IV chemotherapy, blood products, and antibiotics; enteral or parenteral nutrition; and parenteral analgesics. Patients and families are taught to care for vascular access devices, infusion pumps, various types of drainage catheters, and on occasion complex wounds. The importance of patient safety and infection control is included in patient and family education. Although

Chart 58-10 HOME CARE CHECKLIST

The Patient Receiving Care for an Oncologic Disorder

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of cancer treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate how to administer the chemotherapy agent in the home:
  - Describe safe storage and handling of oral chemotherapy/targeted agents in the home.
  - Demonstrate safe disposal of needles, syringes, IV supplies, or unused chemotherapy medications.
  - List possible side effects of chemotherapeutic agents and suggested management approaches.
- List possible side effects of radiation therapy and suggested management approaches.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider.
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Locate list of names and telephone numbers of resource personnel involved in care (e.g., home care nurse, infusion services, IV vendor, equipment company, radiation therapy department).
- Explain treatment plan and importance of upcoming visits to the primary provider.
- State how to obtain medical supplies after discharge.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Demonstrate usage of adaptive equipment for ADLs.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community)
  - Identify phone numbers of support groups for people with cancer and their caregivers/families
  - State meeting locations and times
- Identify the need for health promotion, disease prevention, and screening activities

ADL, activities of daily living; IADL, independent activities of daily living.

TABLE 58-12 Age-Related Changes and their Effects on Patients with Cancer

Age-Related Changes	Implications
Impaired immune system	Use special precautions to avoid infection; monitor for atypical signs and symptoms of infection.
Altered drug absorption, distribution, metabolism, and elimination	Mandates careful calculation of chemotherapy and frequent assessment for drug response and side effects; dose adjustments may be necessary.
Increased prevalence of other chronic diseases	Monitor for effect of cancer or its treatment on patient's other chronic diseases; monitor patient's tolerance for cancer treatment; monitor for interactions with medications used to treat chronic diseases.
Diminished renal, respiratory, and cardiac reserve	Be proactive in prevention of decreased renal function, atelectasis, pneumonia, and cardiovascular compromise; monitor for side effects of cancer treatment.
Decreased skin and tissue integrity; reduction in body mass; delayed healing	Prevent pressure ulcers secondary to immobility; monitor skin and mucous membranes for changes related to radiation or chemotherapy; monitor nutritional status.
Decreased musculoskeletal strength	Prevent falls; assess support for performing activities of daily living in home setting; encourage safe use of assistive mobility devices.
Decreased neurosensory functioning: loss of vision, hearing, and distal extremity tactile senses	Provide instruction modified for patient's hearing and vision changes; provide instruction concerning safety and skin care for distal extremities; assess home for safety.
Altered social and economic resources	Assess for financial concerns, living conditions, and resources for support.
Potential changes in cognitive and emotional capacity	Provide education and support modified for patient's level of functioning and safety.

nurses are often available to provide some assistance with cancer care in the home, patients and families need information that will enable them to have a sense of comfort, decrease distress, improve coping, foster self-management, promote adherence, and enhance quality of life (Knobf, 2013).

Continuing and Transitional Care

Referral for home or transitional care is often indicated for patients with cancer. The responsibilities of the nurse include assessing the home environment and suggesting modifications in the home or in care to help address the patient's physical and safety needs. Home care nurses also assess the psychosocial impact of cancer on the patient and family so that appropriate interventions can be identified and/or referrals for support services are instituted.

Ongoing nursing visits and/or phone contact from the home or transitional care nurse assist in prevention, early identification, prompt reporting, and management of patient problems. Timely modifications in therapy to manage symptoms and adverse effects of treatment may decrease patient suffering and decrease emergency department visits or hospital admissions. Continued contact facilitates evaluation of the patient's progress, responses to treatment, and assessment of the ongoing needs of the patient and family. It is necessary to assess the patient's and family's understanding of the treatment plan and management strategies and to reinforce previous education. The nurse facilitates coordination of patient care by maintaining close communication with all involved health care providers. The nurse may make referrals and coordinate available community resources (e.g., home aides, community nurses, support groups) to assist patients and caregivers.

Gerontologic Considerations

Approximately 53% of cancer incidence and 69% of cancer deaths occur in persons aged 65 years or older (ACS, 2015a). The rising number of individuals over age 65 with cancer has led to the emergence of geriatric oncology, a multidimensional and multidisciplinary approach to treating growing numbers of older adults with cancer.

Nurses working with older adults must understand the normal physiologic changes that occur with aging and the implications for the patient with cancer (see Table 58-12). These changes that affect all body systems may ultimately influence older patients' responses to cancer treatment. In addition, many older patients have other chronic diseases requiring multiple medications. The existence of comorbidities and multiple medications may contribute to drug interactions and toxicities in older patients.

The understanding of the effects and tolerance of chemotherapy, targeted therapies, and radiation in the older adult is limited, as older adults have been underrepresented in oncology clinical trials. Potential chemotherapy-related toxicities, such as renal impairment, myelosuppression, fatigue, and cardiomyopathy, may increase as a result of declining organ function and diminished physiologic reserves. The recovery of normal tissues after radiation therapy may be delayed, and older adult patients may experience more severe adverse effects, such as mucositis, nausea and vomiting, and myelosuppression. Because of impaired healing and declining pulmonary and cardiovascular functioning, older patients are slower to recover from surgery. Older patients are also at increased risk for complications, such as atelectasis, pneumonia, and wound infections.

SELECTED MALIGNANT CONDITIONS

Breast Cancer

Breast cancer is a major health problem in the United States. Current statistics indicate that over a lifetime (birth to death), a woman's risk of developing breast cancer is about 12%, or one

in eight. Currently, about 231,840 new cases of invasive breast cancer are diagnosed in women each year. Risk of developing breast cancer increases with increasing age. About two of three invasive breast cancers are found in women 55 years or older. About 5% to 10% of breast cancer cases are thought to be hereditary, resulting directly from gene defects (cell mutations) inherited from a biologic parent (ACS, 2015).

Breast cancer has been ranked number one cancer among Indian women with age-adjusted rate as high as 25.8 per 100,000 women and mortality 12.7 per 100,000 women. Data reports from various latest national cancer registries were compared for incidence and mortality rates. The age-adjusted incidence rate of carcinoma of the breast was found as high as 41 per 100,000 women in Delhi, followed by Chennai (37.9), Bangalore (34.4), and Thiruvananthapuram District (33.7). A statistically significant increase in age-adjusted rate over time (1982–2014) in all the population-based cancer registries (PBCRs) namely Bangalore (annual percentage change: 2.84%), Barshi (1.87%), Bhopal (2.00%), Chennai (2.44%), Delhi (1.44%), and Mumbai (1.42%) was observed (Malvia, Bagadi, Dubey, et al., 2017).

Female breast cancer incidence rates vary substantially by race and ethnicity. Higher death rates in African Americans have been attributed to later stage at diagnosis and poorer stage-specific survival. Research suggests that racial disparities in cancer mortality are driven in large part by differences in socioeconomic status (ACS, 2013).

Types of Breast Cancer

Ductal Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is characterized by the proliferation of malignant cells inside the milk ducts without invasion into the surrounding tissue. Unlike invasive breast cancer, DCIS does not metastasize and a woman generally does not die of DCIS unless it develops into invasive breast cancer. DCIS can develop into invasive breast cancer if left untreated. The best estimates are that 14% to 53% of untreated DCIS progresses to invasive breast cancer over a period of 10 years or more. However, the natural history of DCIS is not well understood, and it is currently not possible to accurately predict which women with DCIS will go on to develop invasive breast cancer (ACS, 2015). DCIS is frequently manifested on a mammogram with the appearance of calcifications and is considered breast cancer stage 0.

Medical Management

Current management takes into account (1) assurance of an accurate diagnosis, (2) assessment of DCIS size and grade, and (3) careful margin evaluation. The pathologist analyzes the piece of breast tissue removed to determine the type and grade of the DCIS or how abnormal the cells look when compared with normal breast cells and how fast they are growing. Grade III (high-grade DCIS) cells tend to grow more quickly than grade I (low-grade) and grade II (moderate-grade) cells and look much different from normal breast cells. Accurate grading of DCIS is critical, because high nuclear grade and the presence of necrosis (the premature death of cells in living tissue) are highly predictive of the inability to achieve adequate margins or borders of healthy tissue around the cancer, of local recurrence, and of the probability of missed areas of invasion. The pros and cons of irradiating patients with DCIS who are treated conservatively should be carefully weighed on a case-by-case basis, considering recent trials have shown that radiation has a beneficial effect on distant recurrence, breast cancer–specific mortality, and overall survival. Breast conservation (treatment of a breast cancer without the loss of the breast) can be curative for well-defined subsets of women with DCIS (ACS, 2015).

Invasive Cancer

The NCCN (2015), a nonprofit group of the world's 21 leading cancer centers, disseminates estimates for various types of cancer.

Infiltrating Ductal Carcinoma

Infiltrating ductal carcinoma—the most common histologic type of breast cancer—accounts for 80% of all cases. The tumors arise from the duct system and invade the surrounding tissues. They often form a solid irregular mass in the breast.

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma accounts for 10% to 15% of breast cancers. The tumors arise from the lobular epithelium and typically occur as an area of ill-defined thickening in the breast. They are often multicentric and can be bilateral.

Medullary Carcinoma

Medullary carcinoma accounts for about 5% of breast cancers, and it tends to be diagnosed more often in women younger than 50 years. The tumors grow in a capsule inside a duct. They can become large and may be mistaken for a fibroadenoma. The prognosis is often favorable.

Mucinous Carcinoma

Mucinous carcinoma accounts for about 3% of breast cancers and often presents in women who are postmenopausal and are 75 years and older. A mucin producer, the tumor is also slow growing; thus, the prognosis is more favorable than in many other types.

Tubular Ductal Carcinoma

Tubular ductal carcinoma accounts for about 2% of breast cancers. Because axillary metastases are uncommon with this histology, prognosis is usually excellent. Micropapillary invasive ductal carcinoma is a rare type of aggressive ductal cancer characterized by a high rate of axillary node metastasis and skin involvement.

Inflammatory Carcinoma

Inflammatory carcinoma is a rare (1% to 3%) and aggressive type of breast cancer that has unique symptoms. The cancer is characterized by diffuse edema and erythema of the skin, often referred to as peau d'orange (resembling an orange peel). This is caused by malignant cells blocking the lymph channels in the skin. An associated mass may or may not be present; if there is a mass, it is often a large area of indiscrete thickening. Inflammatory carcinoma can be confused with an infection because of its presentation. The disease can spread to other parts of the body rapidly. Chemotherapy often plays an initial role in controlling disease progression, but radiation and surgery may also follow.

Paget Disease

Paget disease of the breast accounts for 1% of diagnosed cases of breast cancer (Grossman & Porth, 2014). Symptoms typically include a scaly, erythematous, pruritic lesion of the nipple. Paget disease often represents DCIS of the nipple but may have an invasive component. If no lump can be felt in the breast tissue and the biopsy shows DCIS without invasion, the prognosis is very favorable.

Risk Factors

There is no single, specific cause of breast cancer. A combination of genetic, hormonal, and possibly environmental factors may increase the risk of its development (see Table 58-13). More than 80% of all cases of breast cancer are sporadic, meaning that patients have no known family history of the disease. The remaining cases are either familial (there is a family history of breast cancer, but it is not passed on genetically) or genetically acquired. There is no evidence that smoking, silicone breast implants, the use of antiperspirants, underwire bras, or abortion (induced or spontaneous) increases the risk of the disease. There is some evidence that long-term smoking, starting before first pregnancy, and night shift work may increase the risk for breast cancer (ACS, 2015).

As stated previously, breast cancer can be genetically inherited, resulting in significant risk. Approximately 5% to 10% of breast cancer cases have been linked to specific genetic mutations. Factors that may indicate a genetic link include multiple first-degree relatives with early-onset breast cancer, breast and ovarian cancer in the same family, male breast cancer, and Ashkenazi Jewish background. *BRCA1* and *BRCA2* are tumor suppressor genes that normally function to identify damaged deoxyribonucleic acid (DNA) and thereby restrain abnormal cell growth (Yarbo, Wujcik, & Gobel, 2013). Mutations in these genes on chromosome 17 are responsible for the majority of hereditary breast cancer. *BRCA* mutations in women have been associated with an overall risk of breast cancer up to 65% (ACS, 2015). Currently, women who are *BRCA* positive are counseled to start screening, typically using mammography, once a year and then MRI 6 months after the yearly mammography by 25 years of age, or 5 to 10 years earlier than their youngest affected family member. Mutations in the PALB2 gene confer similar risk. Males who carry the *BRCA2* mutation may have a lifetime risk of 6% to 7% of developing breast cancer (Jain & Gradishar, 2014).

Protective Factors

Certain factors may be protective against the development of breast cancer. Breast feeding for at least 1 year, regular or moderate physical activity and maintaining a healthy body weight are cited as protective (ACS, 2015). Some research suggests that the use of extra virgin olive oil regularly in one's diet may be preventive (Toledo, Salas-Salvad, Donat-Vargas, et al., 2015).

Breast Cancer Prevention Strategies in the Patient who is at High Risk

Patients often over- or underestimate their risk of developing breast cancer. A consultation with a breast specialist is of

TABLE 58-13 Risk Factors for Breast Cancer

Risk Factor	Comments
Female gender	99% of cases occur in women.
Increasing age	Increasing age is associated with an increased risk.
Personal history of breast cancer	Once treated for breast cancer, the risk of developing breast cancer in same or opposite breast is significantly increased.
Family history of breast cancer	Having first-degree relative with breast cancer (mother, sister, daughter) increases the risk twofold; having two first-degree relatives increases the risk fivefold. The risk is higher if the relative was premenopausal at the time of diagnosis. The risk is increased if a father or brother had breast cancer (exact risk is unknown).
Genetic mutation	*BRCA1* and *BRCA2* mutations account for majority of inherited cases of breast cancer (see additional information in text).
Hormonal Factors	
• Early menarche	Before 12 years of age
• Late menopause	After 55 years of age
• Nulliparity	No full-term pregnancies
• Late age at first full-term pregnancy	After 30 years of age
• Hormone therapy (formerly referred to as hormone replacement therapy)	Current or recent use of combined postmenopausal hormone therapy (estrogen and progesterone) Long-term use (several years or more)
Exposure to ionizing radiation during adolescence and early adulthood	The risk is highest if breast tissue was exposed while still developing (during adolescence), such as women who received mantle radiation (to the chest area) for treatment of Hodgkin lymphoma in their younger years.
History of benign proliferative breast disease	Having had atypical ductal or lobular hyperplasia or lobular carcinoma in situ increases the risk.
Obesity	Obesity and weight gain during adulthood increases the risk of postmenopausal breast cancer. During menopause, estrogen is primarily produced in fat tissue. More fat tissue can increase estrogen levels, thereby increasing breast cancer risk.
High-fat diet	More research is needed.
Alcohol intake (beer, wine, or liquor)	Two to five drinks daily increases the risk about one and a half times.

Adapted from National Comprehensive Cancer Network (NCCN). (2015). Clinical practice guidelines: Breast. Retrieved on 3/7/2016 at: www.nccn.org/professionals/physician_gls/PDF/infections.pdf

paramount importance prior to embarking on any of the prevention strategies that follow. Once patients have an accurate assessment of their risk, along with the knowledge of the pros and cons of each prevention strategy, they can make a decision that is most appropriate for their situation.

Long-Term Surveillance

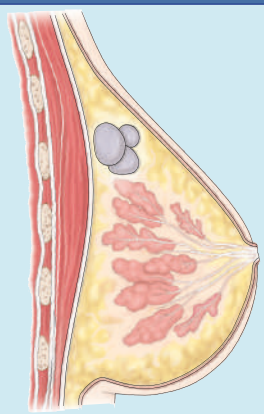
Long-term surveillance focuses on early detection. As recommended by the ACS (2012), women at high risk for breast cancer benefit from additional screening using MRI along with a yearly mammogram. Clinical breast examinations may be performed twice a year starting as early as 25 years of age. Mammograms may also be performed as early as 25 years of age. Data concerning the effectiveness of BSE are limited. In addition to yearly mammography and MRI, other screening tests, including ultrasonography, may be useful.

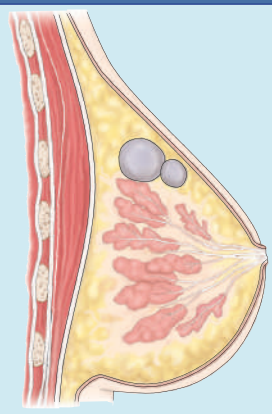
Chemoprevention

Chemoprevention is the main modality that aims to prevent the disease. Several national, randomized clinical trials in the past two decades have led to FDA approval of tamoxifen and raloxifene (Evista) as effective chemopreventive agents for use in women who are at high risk (Cummings, Eckert, Krueger, et al., 1999); (Fisher, Constantino, Wickerham, et al., 1998); (Vogel, Costantino, Wickerham, et al., 2006). In addition, anastrozole (Arimidex) and exemestane (Aromasin) are now used for chemoprevention (Comerford, 2015). Nurses can help women who are considering chemoprevention by providing them with information about the benefits, risks, and possible side effects of these medications.

Prophylactic Mastectomy

Prophylactic mastectomy is another primary prevention modality that can reduce the risk of breast cancer by 90% (National Cancer Institute [NCI], 2013) and is sometimes referred to as a "risk-reducing" mastectomy. The procedure consists of a total mastectomy (removal of breast tissue) and is usually accompanied by immediate breast reconstruction. Possible candidates include women with a strong family history of breast cancer, a diagnosis of LCIS or atypical hyperplasia, a mutation in a *BRCA* gene, and previous cancer in one breast. Because of physical and psychological ramifications including anxiety, depression, and altered body image, this procedure should be undertaken only after extensive counseling related to its risks and benefits. The procedure does not confer 100% protection against the development of breast cancer (NCI, 2013).





A multidisciplinary approach should be used to help the patient arrive at a decision that is best for her. Consultation with a genetic counselor, plastic surgeon, medical oncologist, and psychiatrist can be invaluable. The patient needs to understand that this surgery is elective and not emergent. The nurse can play a valuable role in providing the patient with information, clarification, and support during the decision-making process.

Clinical Manifestations

Breast cancers can occur anywhere in the breast but are usually found in the upper outer quadrant, where the most breast tissue is located. In general, the lesions are nontender, fixed rather than mobile, and hard with irregular borders. Complaints of diffuse breast pain and tenderness with menstruation are usually associated with benign breast disease. See Table 58-14 for comparison of benign and malignant breast tumors.

TABLE 58-14 Comparison of Various Breast Masses

The most common breast masses are due to cysts, fibroadenomas, or malignancy. Biopsy is usually needed for confirmation, but the following characteristics are diagnostic clues:

Characteristics	Cysts	Fibroadenomas	Malignancy
			
Age	30–55 years, regress after menopause except with use of estrogen therapy	Puberty to menopause	30–90 years; most common, 40–80 years
Number	Single or multiple	Usually single	Usually single
Shape	Round	Round, disc, or lobular	Irregular or stellate
Consistency	Soft to firm, usually elastic	Usually firm	Firm or hard
Mobility	Mobile	Mobile	May be fixed to skin or underlying tissues
Tenderness	Usually tender	Usually nontender	Usually nontender
Retraction signs	Absent	Absent	May be present

Adapted from Weber, J., & Kelley, J. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

With the increased use of mammography, more women are seeking treatment at earlier stages of the disease. These women often have no signs or symptoms other than a mammographic abnormality. Some women with advanced disease seek initial treatment after ignoring symptoms. Advanced signs may include skin dimpling, nipple retraction, or skin ulceration.

Assessment

Health History

When a patient presents with a breast problem, the nurse conducts a general health assessment, including history of medical disorders and previous surgery; family history of diseases, particularly cancer; gynecologic and obstetric history; present medications (including prescriptions, vitamins, and herbals); past and present use of hormonal contraceptives, hormone therapy (HT) (formerly referred to as hormone replacement therapy [HRT]), or fertility treatments; and social habits (e.g., smoking, drinking alcohol, illicit drug use). Psychosocial information, such as the patient's marital status, occupation, and availability of resources and support people, is obtained. Any recent x-rays or other diagnostic tests are noted. Focused questions pertaining to the breast disorder are asked concerning the onset of the disorder and the length of time it has been present. In addition, the patient is asked if any masses are palpable and if there is any associated pain, swelling, redness, nipple discharge, or change in the skin. Knowledge and comfort related to breast self-awareness, which can include breast self-examination (BSE), should also be ascertained from the patient.

Physical Assessment: Female Breast

A female breast examination can be conducted during any general physical or gynecologic examination or whenever the patient reports an abnormality. The American Cancer Society (ACS) screening guidelines for early detection of cancer (ACS, 2012) state that an annual clinical breast examination for women 40 years and older is preferable. A clinical breast examination every 1 to 3 years for women between the ages of 20 and 39 years is preferable as part of a periodic health examination (ACS, 2012). A thorough breast examination, including instruction in breast awareness and BSE, takes at least 10 minutes.

Inspection

Examination begins with inspection. The patient is asked to disrobe to the waist and sit in a comfortable position facing the examiner. The breasts are inspected for size and symmetry. A slight variation in the size of each breast is common and generally normal. The skin is inspected for color, venous pattern, thickening, or edema. Erythema (redness) may indicate benign local inflammation or superficial lymphatic invasion by a neoplasm. A prominent venous pattern can signal increased blood supply required by a tumor. Edema and pitting of the skin may result from a neoplasm blocking lymphatic drainage, giving the skin an orange peel appearance (peau d'orange)—a classic sign of advanced breast cancer. Nipple inversion of one or both breasts is not uncommon and is significant only when of recent origin. Ulceration, rashes, or spontaneous nipple discharge requires evaluation. Examples of abnormal breast findings on inspection can be found in Chart. 58-11

Palpation

The breasts are palpated with the patient sitting up (upright) and lying down (supine). In the supine position, the patient's shoulder is first elevated with a small pillow to help balance the breast on the chest wall. Failure to do this allows the breast tissue to slip laterally, and a breast mass may be missed. The entire surface of the breast and the axillary tail is systematically palpated using the flat part (pads) of the second, third, and fourth fingertips, held together, making dime-size circles. The examiner may choose to proceed in a clockwise direction, following imaginary concentric circles from the outer limits of the breast toward the nipple. Other acceptable methods are to palpate from each number on the face of the clock toward the nipple in a clockwise fashion or along imaginary vertical lines on the breast (see Fig. 58-11).

Palpation of the axillary and clavicular areas is easily performed with the patient seated (see Fig. 58-12). To examine the axillary lymph nodes, the examiner gently abducts the patient's arm from the thorax. With the left hand, the patient's right forearm is grasped and supported. The right hand is then free to palpate the axilla. Any lymph nodes that may be lying against the thoracic wall are noted. Normally, these lymph nodes are not palpable, but if they are enlarged, their location, size, mobility, and consistency are noted. During palpation, the examiner notes any patient-reported tenderness or masses. If a mass is detected, it is described by its location (e.g., right breast, 2 cm from the nipple at 2 o'clock position). Size, shape, consistency, border delineation, and mobility are included in the description (Morrow, 2014). The examiner then modifies these steps to use the right hand to grasp the patient's left forearm, and then uses the left hand to palpate the axilla of the left breast.

The breast tissue of the adolescent is usually firm and lobular, whereas that of the postmenopausal woman is more likely to feel thinner and fattier. During pregnancy and lactation, the breasts are firmer and larger with lobules that are more distinct. Hormonal changes cause the areola to darken.

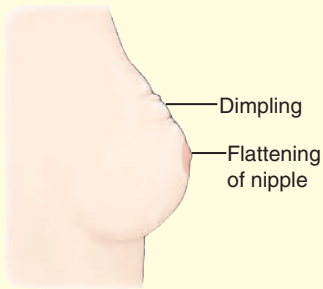
Obesity may have a proinflammatory effect on the breast that can contribute to increased rates of atypia. Atypia in breast ductal lavage and C-reactive protein levels in the nipple are significantly correlated with body mass index (BMI). Excessive body weight, as reflected by a BMI of 25 kg/m^2 or higher, is associated with postmenopausal breast cancer and increases the risk of dying of this disease (Gucalp, Morris, Hudis, et al., 2014).

Cysts are commonly found in women who are menstruating and are usually well defined and freely movable. In the premenstrual period, cysts may be larger and more tender. Malignant tumors, on the other hand, tend to be hard, poorly defined, and nontender. A clinician should further evaluate any abnormalities detected during inspection and palpation.

Diagnostic Evaluation

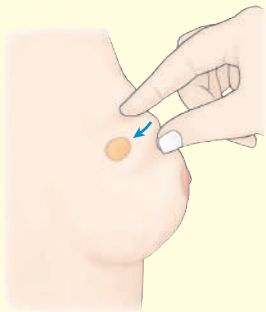
A wide range of diagnostic studies may be performed in patients with breast conditions. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should note trends in the patient's test results, because they often provide information about disease progression as well as the patient's response to therapy

Mammography



Mammography is a breast imaging technique used to visualize the breast to detect small abnormalities that could suggest malignant or benign disease (Fischbach & Dunning, 2015). The procedure takes about 15 minutes and can be performed in a

Chart 58-11 ASSESSMENT



Abnormal Assessment Findings During Inspection of the Breasts

Retraction Signs

- Signs include skin dimpling, creasing, or changes in the contour of the breast or nipple
- They may be secondary to contraction of fibrotic tissue that can occur with underlying malignancy
- They may be secondary to scar tissue formation after breast surgery
- Retraction signs may appear only with position changes

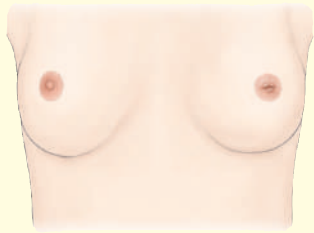
Retraction signs

Retraction with compression

Increased Venous Prominence

- Unilateral localized increase in venous pattern associated with malignant tumors
- Normal with bilateral and symmetrical breast enlargement associated with pregnancy and lactation

Increased venous prominence



Peau d'Orange (Edema)

- Associated with inflammatory breast cancer
- Caused by interference with lymphatic drainage
- Breast skin has orange peel appearance
- Skin pores enlarge
- May be noted on the areola
- Skin becomes thick, hard, and immobile

Peau d'orange

Nipple Inversion

- Considered normal if long-standing
- Associated with fibrosis and malignancy if recent development

Nipple inversion

Paget Disease (Malignancy of Mammary Ducts)

- Early signs—erythema of nipple and areola
- Late signs—thickening, scaling, and erosion of the nipple and areola

Paget's disease

hospital radiology department or independent imaging center. Two views are taken of each breast. The breast is mechanically compressed from top to bottom (craniocaudal view) and side to side (mediolateral oblique view) (see Fig. 58-13). Women may experience some discomfort because maximum compression is necessary for proper visualization. The new mammogram is compared with previous mammograms, and any changes may indicate a need for further investigation. Mammography may detect a breast tumor before it is clinically palpable (i.e., smaller than 1 cm); however, it has limitations (Fischbach & Dunning, 2015). The false-negative rate ranges between 5% and 10% (Helvie & Patterson, 2014). Younger women, or those taking HTs, may have dense breast tissue, making it more difficult to detect lesions with mammography.

Patients scheduled for a mammogram may voice concern about exposure to radiation. The radiation exposure is equivalent to about 1 hour of exposure to sunlight, so patients would have to have many mammograms in a year to increase their cancer risk. To ensure that a mammogram is reliable, it is important that a woman find a reputable facility.

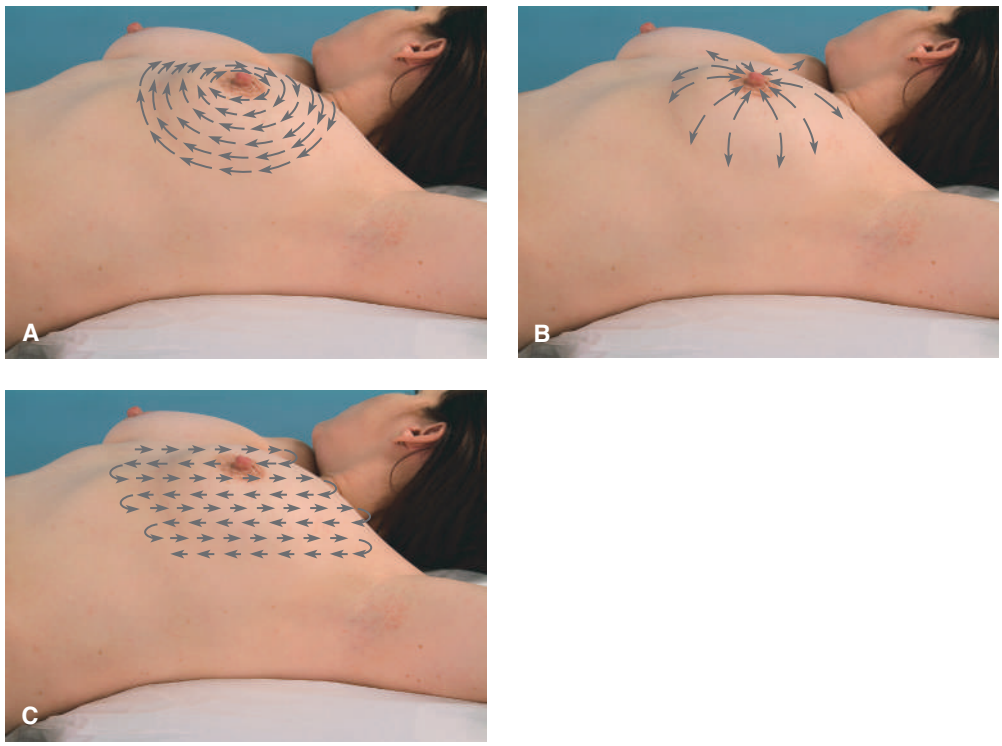


Figure 58-11 • Breast examination with the woman in a supine position. The entire surface of the breast is palpated from the outer edge of the breast to the nipple; palpation patterns are circular or clockwise **(A)**, wedge **(B)**, and vertical strip **(C)**.

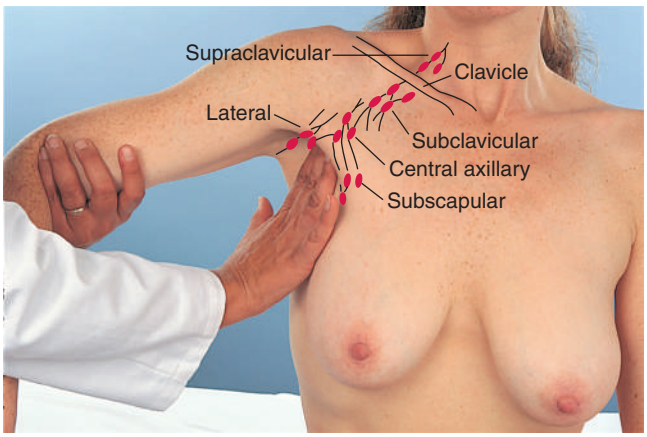

Figure 58-12 • Palpating axillary nodes in breast examination.

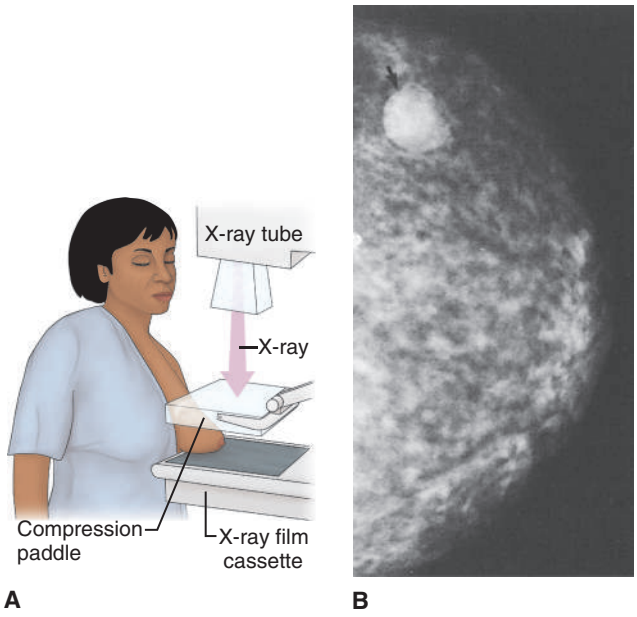

Figure 58-13 • The mammography procedure **(A)** relies on x-ray imaging to produce the mammogram **(B)**, which in this case reveals a breast lump.

In 2015, the ACS changed the mammography recommendations to state that healthy women should have mammography every year beginning at age 45 years (ACS, 2015). Women 55 and older may continue yearly screening or transition to every 2 years. This change was based on calculations that starting annual screening mammography later and getting it less often would cause less harm and be as safe as starting it earlier and getting it more often. Screening every other year may, however, result in a missed diagnosis and a small increase in the probability of being diagnosed with later-stage cancer (Kerlikowske, 2015).

The ACS, however, continues to recommend that women 45 years and older have a mammogram every year and that they continue to do so for as long as they do not have serious, chronic health problems such as congestive heart failure, end-stage kidney disease, chronic obstructive pulmonary disease, and moderate to severe dementia. Age alone should not be the reason to stop having regular mammograms (ACS, 2012).

Newer techniques for breast screening include digital mammography and 3D mammography. Digital mammography records x-ray images on a computer instead of on film, thus allowing radiologists to adjust the contrast and focus on an image without having to take additional x-rays. Although the accuracy of both film and digital screening mammography is

similar for most women, digital mammography has been shown to be better at detecting estrogen receptor–negative tumors and cancer in extremely dense breasts. Both of these subgroups are more common in younger women, who may therefore choose digital mammography if they wish to have screening mammography. The 3D mammography obtains multiple projections of the compressed breast and results in fewer call backs for additional imaging (Jochelson, 2014). Computer-aided detection (CAD) is an option for radiologists and can be helpful in finding abnormal areas that should be checked more closely for early cancers. Refinements and improvements have been made to CAD software with a focus on increasing sensitivity for masses and reducing false-positive rates.

Contrast Mammography

A contrast mammography (i.e., ductogram, galactogram) is a diagnostic procedure that involves injection of less than 1 mL of radiopaque material through a cannula inserted into a ductal opening on the areola, which is followed by a mammogram (Fischbach & Dunning, 2015). It is performed to evaluate an abnormality within the duct when the patient has bloody nipple discharge on expression, spontaneous nipple discharge, or a solitary dilated duct noted on mammography.

Ultrasonography

Ultrasonography (ultrasound) is used as a diagnostic adjunct to mammography to help distinguish fluid-filled cysts from other lesions. A thin coating of lubricating jelly is spread over the area to be imaged. A transducer is then placed on the breast. The transducer transmits high-frequency sound waves through the skin toward the area of concern. The sound waves that are reflected back form a two-dimensional image, which is then displayed on a computer screen. No radiation is emitted during the procedure. Ultrasound is also used as an adjunct to mammography in women with dense breast tissue.

Ultrasonography has advantages and disadvantages. Although it can diagnose cysts with great accuracy, it cannot definitively rule out malignant lesions. Microcalcifications, which are detectable on mammography, cannot be identified on ultrasonography. Finally, examination techniques and interpretation criteria are not standardized.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the breast is a highly sensitive test that has become a useful diagnostic adjunct to mammography. A magnet is linked to a computer that creates detailed images of the breast without exposure to radiation. An intravenous (IV) injection of gadolinium, a contrast dye, is given to improve visibility. The patient lies face down, and the breast is placed through a depression in the table. A coil is placed around the breast, and the patient is placed inside the MRI machine. The entire procedure takes about 30 to 40 minutes.

Breast MRI is useful for evaluation of contralateral disease, invasive lobular carcinoma, and assessment of chemotherapeutic response. The ACS recommends an annual MRI scan in addition to mammography in women at high risk for breast cancer (i.e., those with greater than 20% lifetime risk). Candidates include women who have a *BRCA1* or *BRCA2* mutation, a first-degree relative with either of these mutations, certain rare genetic syndromes, or radiation to the chest between 10 and 30 years of age (ACS, 2012). MRI should be used in addition to mammography, not instead of it.

Some disadvantages of MRI include high cost, variations in technique and interpretation, and the potential for patient claustrophobia. The procedure cannot always accurately distinguish between malignant and benign breast conditions, so false positive results may occur. MRI is contraindicated in patients with implantable metal devices (e.g., aneurysm clips, pacemakers, ports of tissue expanders) because of the metallic force. Foil-backed medication patches (e.g., nicotine, nitroglycerin, fentanyl) must be removed prior to MRI to avoid burns to the skin.

Procedures for Tissue Analysis

Percutaneous Biopsy

Percutaneous biopsy is performed on an outpatient basis to sample palpable and nonpalpable lesions. Less invasive than a surgical biopsy, percutaneous biopsy is a needle or core biopsy that obtains tissue by making a small puncture in the skin. Table 58-15 outlines the different types of biopsies that can be performed to obtain a tissue diagnosis.

Nursing Alert: It is important to understand the differences between common procedures used for patients with breast disorders. Mammography is used to detect breast abnormalities, whereas biopsy is performed to confirm a diagnosis of breast cancer.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is a biopsy technique that is generally well tolerated by most women. A local anesthetic may or may not be used. A small-gauge needle (25 or 22 gauge) attached to a syringe is inserted into the mass or area of nodularity. Suction is applied to the syringe, and multiple passes are made through the mass. A simple cyst often disappears on aspiration, and the fluid is usually discarded. If no fluid is obtained, any cellular material obtained in the hub of the needle is spread on a glass slide or placed in a preservative and sent to

TABLE 58-15 Types of Breast Biopsies

Procedure	Palpable Mass	Health Professional Who Performs Procedure	Nature of Breast Tissue Removed
Fine-needle aspiration	Yes	Surgeon	Cellular material
Core needle biopsy	Yes	Surgeon	Tissue core
Stereotactic core biopsy	No	Radiologist	Tissue core
Ultrasound-guided core biopsy	No	Radiologist	Tissue core
Magnetic resonance imaging (MRI)-guided core biopsy	No	Radiologist	Tissue core
Excisional biopsy	Yes	Surgeon	Entire mass
Incisional biopsy	Yes	Surgeon	Tissue core
Wire needle localization biopsy; may be guided by mammogram, ultrasound, or MRI	No	Radiologist inserts wire; surgeon performs biopsy	Entire mass

the laboratory for analysis (CancerQuest, 2015). For nonpalpable masses, the same procedure can be performed by a radiologist using ultrasound guidance (ultrasound-guided FNA).

FNA is less expensive than other diagnostic methods, and results are usually available quickly. However, false-negative or false-positive results are possible, and appropriate follow-up depends on the clinical judgment of the treating physician.

Core Needle Biopsy

Core needle biopsy is similar to FNA, except a larger-gauge needle is used (usually 14 gauge). A local anesthetic is applied, and tissue cores are removed via a spring-loaded device. This procedure allows for a more definitive diagnosis than FNA, because actual tissue, not just cells, is removed. It is often performed for relatively large tumors that are close to the skin surface, but is also utilized for smaller, deeper lesions that are visible on ultrasound.

Stereotactic Core Biopsy

Stereotactic core biopsy is performed on nonpalpable lesions detected by mammography. The patient lies prone on the stereotactic table. The breast is suspended through an opening in the table and compressed between two x-ray plates. Images are then obtained using digital mammography. The exact coordinates of the lesion to be sampled are located with the aid of a computer. Next, a local anesthetic is injected into the entry site on the breast. A small nick is made in the skin, a core needle is inserted, and samples of the tissue are taken for pathologic examination. Often, several passes are taken to ensure that the lesion is well sampled. Post-biopsy images are then taken to check that sampling has been adequate. A small titanium clip is almost always placed at the biopsy site so that the site can easily be located if further treatment is indicated.

Stereotactic biopsy is quite accurate and often allows the patient to avoid a surgical biopsy. However, there is a small false-negative rate. Appropriate follow-up depends on the final pathologic diagnosis and the clinical judgment of the primary provider. The use of a titanium clip does not preclude subsequent MRIs.

Ultrasound-Guided Core Biopsy

The principles for ultrasound-guided core biopsy are similar to those of stereotactic core biopsy, but by using ultrasound guidance, computer coordination and mammographic compression are not necessary. An ultrasound-guided core biopsy does not use radiation and is also usually faster and less expensive than stereotactic core biopsy.

Magnetic Resonance Imaging–Guided Core Biopsy

MRI-guided core biopsy can be performed by a radiologist and technologist when the abnormal area in the breast is too small to be felt but is visible on MRI.

Surgical Biopsy

Surgical biopsy is usually performed using local anesthesia and intravenous (IV) sedation. After an incision is made, the lesion is excised and sent to a laboratory for pathologic examination. Surgical biopsy is usually preceded by a core biopsy or stereotactic biopsy for pathologic determination.

Types of Surgical Breast Biopsy

Excisional Biopsy

Excisional biopsy is the standard procedure for complete pathologic assessment of a palpable breast mass. The entire mass, plus a margin of surrounding tissue, is removed. This type of biopsy may also be referred to as a lumpectomy. Depending on the clinical situation, a frozen-section analysis of the specimen may be performed at the time of the biopsy by the pathologist, who does an immediate reading intraoperatively and provides a provisional diagnosis. This can help confirm a diagnosis in a patient who has had no previous tissue analysis performed.

Incisional Biopsy

Incisional biopsy surgically removes a portion of a mass. This is performed to confirm a diagnosis and to conduct special studies (e.g., ER/PR, HER-2/neu [also referred to as ERBB2]; see later discussion for explanation of these terms) that will aid in determining treatment, which is discussed later in this chapter. Complete excision of the area may not be possible or immediately beneficial to the patient, depending on the clinical situation. This procedure is often performed on women with locally advanced breast cancer or on women with suspected cancer recurrence, whose treatment may depend on the results of these special studies. However, pathologic information may be easily obtained from core needle biopsy, and incisional biopsy is becoming less common.

Wire Needle Localization

Wire needle localization is a technique used to locate nonpalpable masses or suspicious calcium deposits detected on a mammogram, ultrasound, or MRI that require an excisional biopsy. The radiologist inserts a long, thin wire through a needle, which is then inserted into the area of abnormality using x-ray or ultrasound guidance (whichever imaging technique originally identified the abnormality). The wire remains in place after the needle is withdrawn to ensure the precise location. The patient is then taken to the operating room, where the surgeon follows the wire to the tip and excises the area.

Nursing Management

During the preoperative or preprocedure visit, the nurse assesses the patient for any specific educational, physical, or psychosocial needs. This can be accomplished by reviewing the medical and psychosocial history and encouraging the patient to verbalize fears, concerns, and questions. Patients are often worried not only about the procedure but also about the potential implications of the pathology results. Providing a thorough explanation about what to expect in a supportive manner can help alleviate anxiety. Patients often have difficulty absorbing all the information given to them; therefore, written materials to take home are often provided to reinforce and clarify education.

The nurse instructs the patient to discontinue any agents that can increase the risk of bleeding, including products containing aspirin, nonsteroidal anti-inflammatory drugs, vitamin E supplements, herbal substances (such as ginkgo biloba and garlic supplements). Patients on prescription anticoagulants may need to check with the prescriber prior to temporary cessation for the procedure, as biopsies done without cessation of these drugs can result in prolonged bleeding and hematomas. The patient may be instructed not to eat or drink for several hours prior to the procedure or after midnight the night before the procedure, depending on the type of biopsy and anesthesia planned. Most breast biopsy procedures are performed with the use of moderate sedation and local anesthesia.

Immediate assessment after the procedure includes monitoring the effects of the anesthesia and inspecting the surgical dressing for any signs of bleeding. Once the sedation

has worn off, the nurse reviews the care of the biopsy site, pain management, and activity restrictions with the patient. Prior to discharge from the ambulatory surgical center or the office, the patient must be able to tolerate fluids, ambulate, and void. The patient must be accompanied home. The dressing covering the incision is usually removed after 48 hours, but the Steri-Strips, which are applied directly over the incision, should remain in place for approximately 7 to 10 days or until they fall off. The use of a supportive bra following surgery is encouraged to limit movement of the breast and reduce discomfort. A follow-up telephone call from the nurse 24 to 48 hours after the procedure can provide the patient with the opportunity to ask any questions and can be a source of great comfort and reassurance.

Most women return to their usual activities the day after the procedure but are encouraged to avoid jarring or high-impact activities for 1 week to promote healing of the biopsy site. Discomfort is usually minimal, and most women find acetaminophen/paracetamol (Tylenol) sufficient for pain relief, although a mild opioid analgesic agent may be prescribed if needed.

Follow-up after the biopsy includes a return visit to the surgeon for discussion of the final pathology report and assessment of the healing of the biopsy site. Depending on the results of the biopsy, the nurse's role varies. If the pathology report is benign, the nurse reviews incision care and explains what the patient should expect as the biopsy site heals (i.e., changes in sensation may occur weeks or months after the biopsy due to nerve injury within the breast tissue). If a diagnosis of cancer is made, the nurse's role changes dramatically.

Staging

Staging involves classifying the cancer by the extent of the disease in the body. It is based on whether the cancer is invasive or noninvasive, the size of the tumor, how many lymph nodes are involved, and if it has spread to other parts of the body. The stage of a cancer is one of the most important factors in determining prognosis and treatment options. The most common system used to describe the stages of breast cancer is the American Joint Committee on Cancer (AJCC) TNM (tumor, nodes, metastasis) system (see Chart 58-3). Other factors considered in staging include hormone receptors and genetic mutations.

Prognosis

Several different factors must be taken into consideration when determining the prognosis of a patient with breast cancer. Two of the most important factors are tumor size and whether the tumor has spread to the lymph nodes under the arm (axilla).

In general, the smaller the tumor appears, the better the prognosis. A tumor starts with a genetic alteration in a single cell and takes time to divide and double in size. A carcinoma may double in size 30 times to become 1 cm or larger, at which point it becomes clinically apparent. Doubling time varies, but breast tumors are often present for several years before they become palpable. Nurses can reassure patients that once breast cancer is diagnosed, they have a safe period of several weeks to make decisions regarding treatment; however, a lengthy delay is not advisable.

Prognosis also depends on the extent of spread of the breast cancer. The 5-year survival rate is approximately 88% for a stage I breast cancer and 15% for a stage IV breast cancer (ACS, 2015). The most common route of regional spread is to the axillary lymph nodes. Other sites of lymphatic spread include the internal mammary and supraclavicular nodes (see Fig. 58-14). Distant metastasis can affect any organ, but the most common sites are bone, lung, liver, pleura, adrenals, skin, and brain (ACS, 2015).

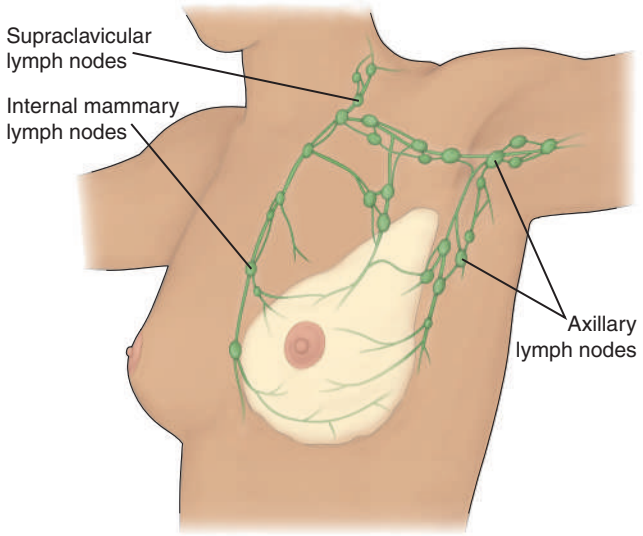

Figure 58-14 • Lymphatic drainage of the breast.

Chart 58-12

Pathologic Factors Associated with Favorable Prognosis for Breast Cancer

- Noninvasive tumors or invasive tumors <1 cm
- Negative axillary lymph nodes
- Estrogen receptor (ER) and progesterone receptor (PR) proteins
- Well-differentiated tumors
- Low expression of HER-2/neu oncogene (also known as ERBB2)
- No vascular or lymphatic invasion
- Diploid tumors with low S-phase fraction

Adapted from U.S. Department of Health and Human Services, Public Health Service. (2012). What you need to know about breast cancer. Bethesda, MD: National Institutes of Health.

In addition to the type of breast cancer and the stage, other factors may help determine prognosis (see Chart 58-12). Excessive number of copies of certain genes (amplification) or excessive amounts of their protein product (overexpression) may represent a poorer prognosis. The HER-2/neu (also known as ERBB2) oncogene is the classic example; approximately 25% of invasive breast cancers, which typically involve the more aggressive tumors, have amplification or overexpression of this gene (Press & Ma, 2015). The proliferative rate or rapidity in growth rate (S-phase fraction) and DNA content (ploidy) of a tumor are factors that are also associated with overall survival rate.

Surgical Management

The main goal of surgery is to gain local control of the disease. With breast cancer being diagnosed today at earlier stages, options for less invasive, breast conserving surgical procedures are available. Surgical treatment options for noninvasive and invasive breast cancer are summarized in Table 58-16.

Modified Radical Mastectomy

Modified radical mastectomy is performed to treat invasive breast cancer. The procedure involves removal of breast tissue,

TABLE 58-16 Surgical Treatment Options for Noninvasive and Invasive Breast Cancer

Noninvasive Breast Cancer	Invasive Breast Cancer
Breast conservation[a] alone	Breast conservation[a] with one of the following: Sentinel lymph node biopsy Axillary lymph node dissection
Total mastectomy alone	Total mastectomy with sentinel lymph node biopsy or Modified radical mastectomy

[a]Breast conservation treatment includes lumpectomy, wide excision, partial or segmental mastectomy, and quadrantectomy. These are relatively synonymous terms that describe removal of varying amounts of breast tissue.

including the nipple–areola complex. In addition, a portion of the axillary lymph nodes are also removed in axillary lymph node dissection (ALND). If immediate breast reconstruction is desired, the patient is referred to a plastic surgeon prior to the mastectomy so that she has the opportunity to explore all available options. In modified radical mastectomy, the pectoralis major and pectoralis minor muscles are left intact, unlike in radical mastectomy, in which the muscles are removed.

Total Mastectomy

Like modified radical mastectomy, total mastectomy (i.e., simple mastectomy) also involves removal of the breast and nipple–areola complex but does not include ALND. Total mastectomy may be performed in patients with noninvasive breast cancer (e.g., DCIS), which does not have a tendency to spread to the lymph nodes. It may also be performed prophylactically in patients who are at high risk for breast cancer (e.g., LCIS, *BRCA* mutation). A total mastectomy may also be performed in conjunction with sentinel lymph node biopsy (SLNB) for patients with invasive breast cancer.

Breast Conservation Treatment

The goal of breast conservation treatment (i.e., lumpectomy, wide excision, partial or segmental mastectomy, quadrantectomy) is to excise the tumor in the breast completely and obtain clear margins while achieving an acceptable cosmetic result. If the procedure is being performed to treat a noninvasive breast cancer, lymph node removal is not necessary. For an invasive breast cancer, lymph node removal (SLNB or ALND) is indicated. The lymph nodes are removed through a separate semicircular incision in the axilla.

Sentinel Lymph Node Biopsy

The status of the lymph nodes is the most important prognostic factor in breast cancer. The SLNB is a less invasive alternative to ALND and is considered a standard of care for the treatment of early-stage breast cancer. ALND is associated with potential morbidity, including lymphedema, cellulitis, decreased arm mobility, and sensory changes. Studies suggest that SLNB is highly accurate and is associated with a local recurrence rate similar to that of ALND (Chung & Giuliano, 2014). Table 58-17 compares SLNB and ALND.

The sentinel lymph node, which is the first node (or nodes) in the lymphatic basin that receives drainage from the primary tumor in the breast, is identified by injecting a radioisotope and/or blue dye into the breast; the radioisotope or dye then travels via the lymphatic pathways to the node. In SLNB, the surgeon uses a handheld probe to locate the sentinel lymph node, excises it, and sends it for pathologic analysis, which is often performed immediately during the surgery using frozen-section analysis. If the sentinel lymph node is positive, the surgeon can proceed with an immediate ALND, thus sparing the patient a return trip to the operating room and additional anesthesia. (The patient could also return for additional surgery at a later time.) If the sentinel lymph node is negative, a standard ALND is not needed, thus sparing the patient the possible complications of the procedure. After the procedure is complete, all specimens are sent to pathology for more thorough analysis.

Nursing Management

Patients who undergo SLNB in conjunction with breast conservation treatments are generally discharged the same day. Patients who undergo SLNB with total mastectomy usually stay in the hospital overnight, possibly longer if breast reconstruction is being performed. The patient must be informed that although frozen-section analysis is highly accurate, false-negative results can occur. A negative sentinel lymph node on frozen-section analysis may show metastatic disease on subsequent analysis, indicating that ALND is still necessary. The patient should also be reassured that the radioisotope and blue dye are generally safe. The nurse informs patients that they may notice a blue-green discoloration in the urine or stool for the first 24 hours as the blue dye is excreted. The incidence of lymphedema, decreased arm mobility, and seroma formation (collection of serous fluid) in the axilla is generally low, but the patient

TABLE 58-17 Comparison of Sentinel Lymph Node Biopsy and Axillary Lymph Node Dissection

Sentinel Lymph Node Biopsy	Axillary Lymph Node Dissection
Shorter operating room time (~15–30 minutes)	Longer operating room time (~60–90 minutes)
No surgical drain	Surgical drain
Local anesthesia with IV moderate sedation as outpatient surgery (unless being performed in conjunction with total mastectomy)	General anesthesia; usually overnight admission (sometimes done as outpatient surgery)
Lymphedema incidence approximately 0–7%	Lymphedema incidence approximately 0–20%
Presence of neuropathic sensations postoperatively (prevalence lower than after axillary lymph node dissection)	Presence of neuropathic sensations postoperatively
Decreased range of motion in affected arm unlikely postoperatively but may occur	Decreased range of motion likely postoperatively
Seroma (collection of serous fluid in the axilla) may occur postoperatively.	Seroma may occur postoperatively

should be prepared for these possibilities. Women who have SLNB alone have neuropathic sensations similar to those who undergo ALND, although the prevalence and severity of these sensations and the resulting distress are lower with SLNB (Chung & Giuliano, 2014).

The nurse must not overlook the psychosocial needs of the patient who has undergone SLNB. Although SLNB is a less invasive procedure than ALND and results in a shorter recovery period, a patient who has undergone SLNB also has many difficult issues surrounding her breast cancer diagnosis and treatment. The nurse must listen, provide emotional support, and refer the patient to appropriate specialists when indicated.

NURSING PROCESS

The Patient Undergoing Surgery for Breast Cancer

Assessment

The health history is a valuable tool to assess the patient's reaction to the diagnosis and her ability to cope with it. Pertinent questions include the following:

- How is the patient responding to the diagnosis?
- What coping mechanisms does she find most helpful?
- What psychological or emotional supports does she have and use?
- Is there a partner, family member, or friend available to assist her in making treatment choices?
- What are her educational needs?
- Is she experiencing any discomfort?

Diagnosis

Preoperative Nursing Diagnoses

Based on the assessment data, major preoperative nursing diagnoses may include the following:

- Deficient knowledge about the planned surgical treatments
- Anxiety related to the diagnosis of cancer
- Fear related to specific treatments and body image changes
- Risk for defensive or ineffective coping related to the diagnosis of breast cancer and related treatment options
- Decisional conflict related to treatment options

Postoperative Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Acute pain and discomfort related to surgical procedure
- Peripheral neurovascular dysfunction related to nerve irritation in affected arm, breast, or chest wall
- Disturbed body image related to loss or alteration of the breast
- Risk for ineffective coping related to the diagnosis of cancer and surgical treatment
- Self-care deficit related to partial immobility of upper extremity on operative side
- Risk for sexual dysfunction related to loss of body part, change in self-image, and fear of partner's responses
- Deficient knowledge: drain management after breast surgery, arm exercises to regain mobility of affected extremity, hand and arm care after ALND

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Lymphedema
- Hematoma/seroma formation
- Infection

Planning and Goals

The major goals may include increased knowledge about the disease and its treatment; reduction of preoperative and postoperative fear, anxiety, and emotional stress; improvement of decision-making ability; pain management; neurovascular function management; maintenance of a positive body image; improvement in coping abilities; increased self-care abilities; improvement in sexual function; and the absence of complications.

Preoperative Nursing Interventions

Providing Education and Preparation about Surgical Treatments

Patients with newly diagnosed breast cancer are expected to absorb an abundance of new information during a very emotionally difficult time, and this may lead to difficulty in making treatment decisions. The nurse plays a key role in reviewing treatment options by reinforcing information provided to the patient and answering any questions. The nurse fully prepares the patient for what to expect before, during, and after surgery. Patients undergoing breast conservation with ALND, or a total or modified radical mastectomy, generally remain in the hospital overnight (or longer if they have immediate reconstruction). Surgical drains will be inserted in the mastectomy incision and in the axilla if the patient undergoes ALND. A surgical drain is generally not needed after SLNB. The patient should be informed that she will go home with the drain(s) and that complete instructions about drain care will be provided prior to discharge. In addition, the patient should be informed that she will often have decreased arm and shoulder mobility after ALND and that she will be shown range-of-motion exercises prior to discharge. The patient should also be reassured that appropriate analgesia and comfort measures will be provided to alleviate any postoperative discomfort.

Reducing Fear and Anxiety and Improving Coping Ability

The nurse helps the patient cope with the physical and emotional effects of surgery. Many fears may emerge during the preoperative phase. These can include fear of pain, mutilation (after mastectomy), and loss of sexual attractiveness; concern about inability to care for oneself and one's family; concern about taking time off from work; and coping with an uncertain future. Providing the patient with realistic expectations about the healing process and expected recovery can help alleviate fears. Maintaining open communication and assuring the patient that she can contact the nurse at any time with questions or concerns can be a source of comfort. The patient should also be made aware of available resources at the treatment facility as well as in the breast cancer community such as social workers, psychiatrists, and support groups. Some women find it helpful and reassuring to talk to a survivor of breast cancer who has undergone similar treatments.

Promoting Decision-Making Ability

The patient may be eligible for more than one therapeutic approach; she may be presented with treatment options and then asked to make a choice. This can be very frightening for some patients, and they may prefer to have someone else make the decision for them (e.g., surgeon, family member). The nurse can be instrumental in ensuring that the patient and family

members truly understand their options. The nurse can then help the patient weigh the risks and benefits of each option. The patient may be presented with the option of having breast conservation treatment followed by radiation or a mastectomy. The nurse can explore the issues with the patient by asking questions such as the following:

- How do you think you might feel about losing your breast?
- Are you considering breast reconstruction?
- If you choose to retain your breast, would you consider undergoing radiation treatments 5 days a week for 5 to 6 weeks?

Questions such as these can help the patient focus. Once the patient's decision is made, it is very important to support it.

Postoperative Nursing Interventions

Relieving Pain and Discomfort

Many patients tolerate breast surgery well and have minimal pain during the postoperative period. This is particularly true of less invasive procedures such as breast conservation treatment with SLNB. However, all patients must be carefully assessed, because individual patients can have varying degrees of pain. Patients who have had more invasive procedures, such as a modified radical mastectomy with immediate reconstruction, may have considerably more pain. All patients are discharged home with analgesic medication (e.g., oxycodone and acetaminophen/paracetamol [Percocet]) and are encouraged to take it if needed. An over-the-counter analgesic agent such as acetaminophen/paracetamol may provide sufficient relief. Patients sometimes complain of a slight increase in pain after the first few days of surgery; this may occur as patients regain sensation around the surgical site and become more active. However, patients who report more than moderate pain must be evaluated to rule out any potential complications such as infection or hematoma. Postoperative pain may be more common in patients who have had axillary dissection and correlates with the number of nodes removed (Cherny & Truong, 2014). Alternative methods of pain management, such as taking warm showers (if permitted by the surgeon) and using distraction methods (e.g., guided imagery), may also be helpful. See Chapter 9 for further discussion of methods that relieve pain.

Managing Postoperative Sensations

Because nerves in the skin and axilla are often ligated or injured during breast surgery, patients experience a variety of sensations. Common sensations include tenderness, soreness, numbness, tightness, pulling, and twinges. These sensations may occur along the chest wall, in the axilla, and along the inside aspect of the upper arm. After mastectomy, some patients experience phantom sensations and report a feeling that the breast or nipple is still present. Overall, patients do not find these sensations severe or distressing. Sensations usually persist for several months and then begin to diminish, although some may persist for as long as 5 years and possibly longer. Patients should be reassured that this is a normal part of healing and that these sensations are not indicative of a problem.

Promoting Positive Body Image

Patients who have undergone mastectomy may find it difficult to view the surgical site for the first time. No matter how prepared the patient may think she is, the appearance of an absent breast can be very emotionally distressing. Ideally, the patient sees the incision for the first time when she is with the nurse or another health care provider who is available for support.

The nurse first assesses the patient's readiness and provides gentle encouragement. It is important to maintain the patient's privacy while assisting her as she views the incision; this allows her to express feelings safely to the nurse. Asking the patient what she perceives, acknowledging her feelings, and allowing her to express her emotions are important nursing actions. Reassuring the patient that her feelings are a normal response to breast cancer surgery may be comforting. If the patient has not had immediate reconstruction, providing her with a temporary breast form or soft padding to place in her bra on discharge can help alleviate feelings of embarrassment or self-consciousness.

Promoting Positive Adjustment and Coping

Providing ongoing assessment of how the patient is coping with her diagnosis of breast cancer and her surgical treatment is important in determining her overall adjustment. Assisting the patient in identifying and mobilizing her support systems can be beneficial to her well-being. The patient's spouse or partner may also need guidance, support, and education. Encouraging the patient to discuss issues and concerns with other patients who have had breast cancer may help her to understand that her feelings are normal and that other women who have had breast cancer can provide invaluable support and understanding.

The patient may also have considerable anxiety about the treatments that will follow surgery (i.e., chemotherapy and radiation) and their implications. Providing her with information about the plan of care and referring her to the appropriate members of the health care team also promote coping during recovery. Some women require additional support to adjust to their diagnosis and the changes that it brings. If a woman displays ineffective coping, consultation with a mental health provider may be indicated. Research suggests that nurse navigators can help those undergoing breast biopsy to cope (Harding, 2015) (see Chart 58-13).

Improving Sexual Function

Once discharged from the hospital and feeling well, most patients are physically allowed to engage in sexual activity, if interested. However, any change in the patient's body image, self-esteem, or the response of her partner may increase her anxiety level and affect sexual function. Some partners may have difficulty looking at the incision, whereas others may be completely unaffected. Encouraging the patient to openly discuss how she feels about herself and about possible reasons for a decrease in libido (e.g., fatigue, anxiety, self-consciousness) may help clarify issues for her. Helpful suggestions for the patient may include varying the time of day for sexual activity (when the patient is less tired), assuming positions that are more comfortable, and expressing affection using alternative measures (e.g., hugging, kissing, manual stimulation).

Most patients and their partners adjust with minimal difficulty if they openly discuss their concerns. However, if issues cannot be resolved, a referral for counseling (e.g., psychologist, psychiatrist, psychiatric clinical nurse specialist, social worker, sex therapist) may be helpful. The ambulatory care nurse in the outpatient clinic or hospital should inquire whether the patient who was sexually active prior to surgery has resumed activities, because many patients are reluctant or embarrassed to bring this topic up themselves.

Monitoring and Managing Potential Complications

Lymphedema. Lymphedema is a complication characterized by a chronic swelling of an extremity due to interrupted lymphatic circulation. The swelling is due to the accumulation

Chart 58-13 NURSING RESEARCH PROFILE

Nurse Navigators and Breast Biopsy

Harding, M. (2015). Effect of nurse navigation on patient care satisfaction and distress associated with breast biopsy. Clinical Journal Oncology Nursing, 19(1), E15–E20.

Purpose

This study was conducted to evaluate the impact of nurse navigation on satisfaction with care and level of stress in patients having a breast biopsy.

Design

This study used a descriptive cross sectional survey design. Two outpatient radiology sites were utilized including a community center and a breast center in Appalachia, following institutional review board (IRB) approval. The breast center used a multidisciplinary approach coordinated by a nurse navigator; the community center had no nurse navigator. Patients were invited to participate in the study prior to their biopsy. Study instruments included the Hospital Anxiety and Depression Scale (HADS), the State Trait Anxiety Inventory Scale (STAI-S), and the Patient Satisfaction Questionnaire (PSQ-18). Descriptive statistics were used to analyze demographic characteristics, *t* tests, chi square tests and Pearson correlations were used to examine variables.

Findings

One hundred and thirty seven women completed the study instruments at home following a core needle biopsy. The majority (68%) of the women were older than 50 years of age. Women who received navigation services ($N = 85$) had lower scores on all three distress measures (HAD-A [anxiety subscale], HAD-D [depression subscale], & STAI-S), with significantly lower anxiety levels on the HADS-A. There were no significant differences in patient satisfaction between the two groups. Sixty-six women (48%) sought outside information regarding an aspect of the diagnostic experience. Women not receiving navigation services were significantly more likely to seek outside information ($X^2 = 7.949$; $p < 0.01$), with a majority (67%) using the internet as an information source.

Nursing Implications

This study suggests that nurse navigators providing information and support can improve decision making and help prepare women for explanatory educational sessions with radiologists and surgeons. Nurses working with women having a breast biopsy should also keep in mind that this study reported women seeking additional information commonly used internet sources.

of protein-rich fluid in the interstitial space and is a somewhat common postoperative complication after ALND. It often affects both the breast and ipsilateral limb. It is associated with a painful swelling of the arm as well as weakness, shoulder pain, and tingling sensations in the arm and shoulder. Research results suggest that within 5 years of ALND, there is a 20% risk of lymphedema. Because sentinel lymph node dissection (SLND) involves more focused surgery and less disruption of the axilla, the risk is only up to 7% within 5 years. Risk factors for lymphedema in mixed-age groups include ALND, concomitant radiation therapy, increased age, presence of a concomitant infection, pre-existing cardiovascular conditions, and obesity (McLaughlin, 2014).

Lymphedema results if functioning lymphatic channels are inadequate to ensure a return flow of lymph fluid to the general circulation. After axillary lymph nodes are removed, collateral circulation must assume this function. Transient edema in the postoperative period occurs until collateral circulation has completely taken over this function, which generally occurs within a month. Performing prescribed exercises, elevating the arm above the heart several times a day, and gentle muscle pumping (making a fist and releasing) can help reduce the transient edema. The patient needs reassurance that this transient swelling is not lymphedema.

Once lymphedema develops, it tends to be chronic, so preventive strategies are vital. After ALND, the patient is taught hand and arm care to prevent injury or trauma to the affected extremity, thus decreasing the likelihood for development of lymphedema (see Chart 58-14). The patient is instructed to follow these guidelines for the rest of her life. She is also instructed to contact her primary provider immediately if she suspects that she has lymphedema, because early intervention provides the best chance for control. If allowed to progress without treatment, the swelling can become more difficult to manage. Treatment may consist of a course of antibiotic agents if an infection is present. A referral to a rehabilitation specialist

Chart 58-14 PATIENT EDUCATION

Hand and Arm Care After Axillary Lymph Node Dissection

The nurse instructs the patient to:

- Avoid blood pressures, injections, and blood draws in affected extremity.
- Use sunscreen (higher than 15 SPF) for extended exposure to sun.
- Apply insect repellent to avoid insect bites.
- Wear gloves for gardening.
- Use cooking mitt for removing objects from oven.
- Avoid cutting cuticles; push them back during manicures.
- Use electric razor for shaving armpit.
- Avoid lifting objects heavier than 2.3 – 4.5 kg.
- If a trauma or break in the skin occurs, wash the area with soap and water, and apply an over-the-counter antibacterial ointment (Bacitracin or Neosporin). Observe the area and extremity for 24 hours; if redness, swelling, or a fever occurs, call the surgeon or nurse.

(e.g., occupational or physical therapist) may be necessary for a compression sleeve or glove, exercises, manual lymph drainage, and a discussion of ways to modify daily activities to avoid worsening lymphedema. Ongoing research is seeking to identify which lymph nodes drain the arm before surgery so that they can be preserved when possible, helping to prevent the development of lymphedema

Hematoma or Seroma Formation. Hematoma formation (collection of blood inside a cavity) may occur after either mastectomy or breast conservation and usually develops within the first 12 hours after surgery. The nurse assesses for signs and symptoms of hematoma at the surgical site, which may include swelling, tightness, pain, and bruising of the skin. The surgeon should be notified immediately if there is gross swelling or increased bloody output from the drain. Depending on the surgeon's assessment, a compression wrap may be applied to the incision for approximately 12 hours, or the patient may be returned to the operating room so that the incision may be

reopened to identify the source of bleeding. Some hematomas are small, and the body absorbs the blood naturally. The patient may take warm showers (if permitted by the surgeon) or apply warm compresses to help increase the absorption. A hematoma usually resolves in 4 to 5 weeks.

A seroma, a collection of serous fluid, may accumulate under the breast incision after mastectomy or breast conservation or in the axilla. Signs and symptoms may include swelling, heaviness, discomfort, and a sloshing of fluid. Seromas may develop temporarily after the drain is removed or if the drain is in place and becomes obstructed. Seromas rarely pose a threat and may be treated by unclogging the drain or manually aspirating the fluid with a needle and syringe. Large, long-standing seromas that have not been aspirated may lead to infection. Small seromas that are not bothersome to the patient usually resolve on their own.

Infection. Although infection is rare, it is a risk after any surgical procedure. This risk may be higher in patients with conditions such as diabetes, immune disorders, and advanced age, as well as in those with poor hygiene. Patients are taught to monitor for signs and symptoms of infection (redness, warmth around incision, tenderness, foul-smelling drainage, temperature greater than 40°C [100.4°F], chills) and to contact the surgeon or nurse for evaluation. Treatment consists of oral or IV antibiotics (for more severe infections) for 1 or 2 weeks. Cultures are taken of any foul-smelling discharge.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Patients who undergo breast cancer surgery receive a tremendous amount of information both pre- and postoperatively. It is often difficult for the patient to absorb all of the information, partly because of the emotional distress that often accompanies the diagnosis and treatment. Prior to discharge, the nurse must assess the patient's readiness to assume self-care responsibilities and identify any gaps in knowledge. A review of education provided in written and oral forms, with reinforcement, may be required to ensure that the patient and family are prepared to manage the necessary care at home. The nurse reiterates symptoms that the patient should report, such as infection, seroma, hematoma, or arm swelling. All instruction should be reinforced during follow-up visits of the patients.

Most patients are discharged 1 or 2 days after ALND or mastectomy (possibly later if they have had immediate reconstruction) with surgical drains in place. Initially, the drainage fluid appears bloody, but it gradually changes to a serosanguineous and then a serous fluid over the next several days. The patient is given instructions about drainage management at home (see Chart 58-15). If the patient lives alone and drainage management is difficult, a referral for a home care nurse should be made. The drains are usually removed when the output is less than 30 mL in a 24-hour period (approximately 7 to 10 days). The home care nurse also reviews pain management and incision care.

In general, the patient may shower on the second postoperative day and wash the incision and drain site with soap and water to prevent infection. Some surgeons do not permit showers until 48 hours after drains are removed. If immediate reconstruction has been performed, showering may be contraindicated until the drain is removed. A dry dressing may be applied to the incision each day for 7 days. The patient should realize that sensation may be decreased in the operative area because the nerves were disrupted during surgery, and she should be informed that gentle care is needed to avoid injury. After the incision has completely healed (usually after 4 to 6 weeks), lotions or creams may be applied to the area to increase skin elasticity. The patient can begin to use deodorant on the affected side, although many women note that they no longer perspire as much as before the surgery.

Chart 58-15 HOME CARE CHECKLIST

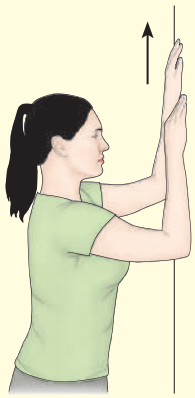
Patient with a Drainage Device Following Breast Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., prosthesis) used in adapting to any permanent changes in structure or function.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., when to shower, arm exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
  - Care for the drain site and incision as per surgeon's recommendation.
  - Demonstrate how to empty and measure fluid from the drainage device.
  - Demonstrate how to milk clots through the tubing of the drainage device.
  - Identify when the drain is ready for removal (usually when draining <30 mL for a 24-hour period).
- Describe signs and symptoms of complications.
  - State observations that require contacting the physician or nurse (e.g., sudden change in color of drainage, sudden cessation of drainage, signs or symptoms of an infection).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up appointments, therapy, and testing.
- Identify sources of support (e.g., friends, relatives, cancer support groups, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities (e.g. gynecologic examination, mammogram).

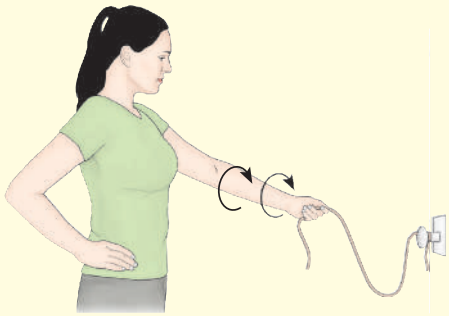
ADL, activities of daily living; IADL, independent activities of daily living.

After ALND, patients are taught arm exercises on the affected side to restore range of motion (see Chart 58-16). After SLNB, patients may also benefit from these exercises, although they are less likely to have decreased range of motion than those who have undergone ALND. Range-of-motion exercises are initiated on the second postoperative day; however, instruction often occurs on the first postoperative day. The goals of the exercise regimen are to increase circulation and muscle strength, prevent joint stiffness and contractures, and restore full range of motion. The patient is instructed to perform range-of-motion exercises at home three times a day for 20 minutes at a time until full range of motion is restored (generally 4 to 6 weeks). Most patients find that after the drain is removed, range of motion returns quickly if they have adhered to their exercise program.



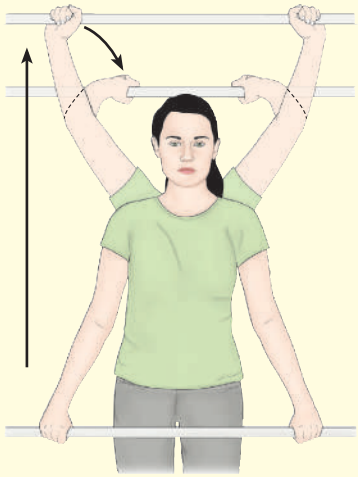
If the patient is having any discomfort, taking an analgesic agent 30 minutes before beginning the exercises can be helpful. Taking a warm shower before exercising can also loosen stiff

Chart 58-16 PATIENT EDUCATION

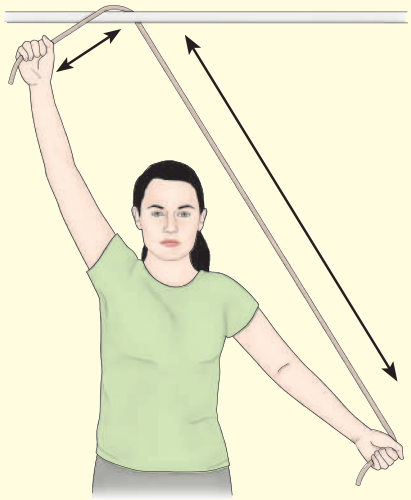


Exercise After Breast Surgery

The nurse instructs the patient to perform the following exercises:



1. *Wall handclimbing.* Stand facing the wall with feet apart and toes as close to the wall as possible. With elbows slightly bent, place the palms of the hand on the wall at shoulder level. By flexing the fingers, work the hands up the wall until arms are fully extended. Then reverse the process, working the hands down to the starting point.



2. *Rope turning.* Tie a light rope to a doorknob. Stand facing the door. Take the free end of the rope in the hand on the side of surgery. Place the other hand on the hip. With the rope-holding arm extended and held away from the body (nearly parallel with the floor), turn the rope, making as wide swings as possible. Begin slowly at first; speed up later.

3. *Rod or broomstick lifting.* Grasp a rod with both hands, held about 2 feet apart. Keeping the arms straight, raise the rod over the head. Bend elbows to lower the rod behind the head. Reverse maneuver, raising the rod above the head, then return to the starting position.

4. *Pulley tugging.* Toss a light rope over a shower curtain rod or doorway curtain rod. Stand as close to the rope as possible. Grasp an end in each hand. Extend the arms straight and away from the body. Pull the left arm up by tugging down with the right arm, then the right arm up and the left down in a see-sawing motion.

muscles and provide comfort. When exercising, the patient is encouraged to use the muscles in both arms and to maintain proper posture. Specific exercises may need to be prescribed and introduced gradually if the patient has had skin grafts; has a tense, tight surgical incision; or has had immediate reconstruction. Self-care activities, such as brushing the teeth, washing the face, and brushing the hair, are physically and emotionally therapeutic because they aid in restoring arm function and provide a sense of normalcy for the patient.

The patient is instructed about postoperative activity limitation. In general, heavy lifting (more than 2.3 to 5.4 kg is avoided for about 4 to 6 weeks, although normal household and work-related activities are promoted to maintain muscle tone. Brisk walking, the use of stationary bikes and stepping machines, and stretching exercises may begin as soon as the patient feels comfortable. Once the drain is removed, the patient may begin to drive if she has full arm range of motion and is no longer taking opioid analgesic agents. General guidelines for activity focus on the gradual introduction of previous activities (e.g., bowling, weight training) once fully healed.

Continuing and Transitional Care. Patients who have difficulty managing their postoperative care at home may benefit from a referral for home health, transitional, or community-based care. The nurse making a home visit assesses the patient's incision and surgical drain(s), adequacy of pain management, adherence to the exercise plan, and overall physical and psychological functioning. In addition, the home care nurse reinforces

previous education and communicates important physiologic findings and psychosocial issues to the patient's primary provider, nurse, or surgeon.

The frequency of follow-up visits after surgery may vary but generally should occur every 3 to 6 months for the first several years. The patient may alternate visits with the surgeon, medical oncologist, or radiation oncologist, depending on the treatment regimen. The ambulatory care nurse can also be a great source of education for the patient and family and should encourage them to telephone if they have any questions or concerns. It is common for people to ignore routine health care when a major health issue arises, so women who have been treated for breast cancer should be reminded of the importance of participating in routine health screening.

Evaluation

Expected preoperative patient outcomes may include:

1. Exhibits knowledge about diagnosis and surgical treatment options
   a. Asks relevant questions about diagnosis and available surgical treatments
   b. States rationale for surgery
   c. Describes advantages and disadvantages of treatment options
2. Verbalizes willingness to deal with anxiety and fears related to the diagnosis and the effects of surgery on self-image and sexual functioning
3. Demonstrates ability to cope with diagnosis and treatment
   a. Verbalizes feelings appropriately and recognizes normalcy of mood lability
   b. Proceeds with treatment in timely fashion
   c. Discusses impact of diagnosis and treatment on family and work
4. Makes decisions regarding treatment options in timely fashion

Expected postoperative patient outcomes may include:

1. Reports that pain has decreased and states pain and discomfort management strategies are effective
2. Identifies postoperative sensations and recognizes that they are a normal part of healing
3. Exhibits clean, dry, and intact surgical incisions without signs of inflammation or infection
4. Lists the signs and symptoms of infection to be reported to the nurse or surgeon
5. Verbalizes feelings regarding change in body image
6. Discusses meaning of the diagnosis, surgical treatment, and fears appropriately
7. Participates actively in self-care measures
   a. Performs exercises as prescribed
   b. Participates in self-care measures as prescribed
8. Discusses issues of sexuality and resumption of sexual relations
9. Demonstrates knowledge of post discharge recommendations and restrictions
   a. Describes follow-up care and activities
   b. Demonstrates appropriate care of incisions and drainage system
   c. Demonstrates arm exercises, and describes exercise regimen and activity limitations during postoperative period
   d. Describes care of affected arm and hand, and lists indications to contact the surgeon or nurse
10. Experiences no complications
    a. Identifies signs and symptoms of reportable complications (e.g., fever, redness, heat, pain, edema)
    b. Explains how to contact appropriate providers in case of complications

Radiation Therapy

Radiation therapy is used to decrease the chance of a local recurrence in the breast by eradicating residual microscopic cancer cells. Breast conservation treatment followed by radiation therapy for stages I and II breast cancer results in a survival rate equal to that of a modified radical mastectomy (NCCN, 2015). If radiation therapy, which is part of breast conservation treatment (see Chart 58-17), is contraindicated, a mastectomy would then be indicated.

External-beam radiation (the most common type) typically begins about 6 weeks after breast conservation to allow the surgical site to heal. If systemic chemotherapy is indicated, radiation therapy usually begins after its completion. Before radiation begins, the patient undergoes a planning session called a *simulation,* in which the anatomic areas to be treated are mapped out and then identified with small permanent ink markings. External-beam radiation, which delivers high-energy photons from a linear accelerator, is given to the entire breast region (whole breast radiation). Each treatment lasts only a few minutes and is generally given 5 days a week for 5 to 6 weeks. After completion of radiation to the entire breast, many patients receive a "boost"—a dose of radiation to the lumpectomy site where the cancer cells were located. The boost consists of the same dose of radiation but is less penetrating and directed to a smaller area. The treatments are not painful.

Because most breast cancer recurrences appear at or near the lumpectomy site, the need for whole breast radiation has been questioned. Partial breast radiation (radiation to the lumpectomy site alone) continues be evaluated at some institutions in patients who have been carefully selected. One approach is brachytherapy, in which radiation is delivered by an internal device that is placed close to the tumor within the breast. This technique can lead to an improved quality of life because the treatments are given over 4 to 5 days instead of 5 to 6 weeks. After mastectomy, postoperative radiation may be indicated for women at high risk for cancer recurrence (i.e.,

Chart 58-17

Contraindications to Breast Conservation Treatment

Note: Breast-conservation treatment includes both surgery and radiation.

Absolute Contraindications

- First or second trimester of pregnancy
- Presence of multicentric disease in the breast
- Prior radiation to the breast or chest region

Relative Contraindications

- History of collagen vascular disease
- Large tumor-to-breast ratio
- Tumor beneath nipple

Adapted from Harris, J., & Morrow, M. (2014). Breast-conserving therapy. In J. Harris, M. Lippman, M. Morrow, et al. (Eds.). Diseases of the breast (5th ed.). Philadelphia, PA: Wolters Kluwer.

chest wall involvement, four or more positive lymph nodes, tumors larger than 5 cm, positive surgical margins).

Side Effects

In general, radiation therapy is well tolerated. Acute side effects consist of mild to moderate erythema, breast edema, and fatigue. Occasionally, skin breakdown may occur in the inframammary fold or near the axilla toward the end of treatment. Fatigue can be depressing, as can the frequent trips to the radiation oncology unit for treatment. The patient needs to be reassured that the fatigue is normal and not a sign of recurrence. Side effects usually resolve within a few weeks to a few months after treatment is completed. Rare long-term effects of radiation therapy include pneumonitis, rib fracture, heart disease, breast fibrosis or necrosis (Harris & Morrow, 2014).

Nursing Management

Nurses play a significant role in supporting patients throughout their treatment with radiation therapy.

Self-care instructions for patients receiving radiation are provided to assist in the maintenance of skin integrity during the treatments and for several weeks after completion. They pertain only to the area being treated and not to the rest of the body. Instructions include:

- Use mild soap with minimal rubbing.
- Avoid perfumed soaps or deodorants.
- Use hydrophilic lotions (Lubriderm, Eucerin, Aquaphor) for dryness.
- Use a nondrying, antipruritic soap (Aveeno) if pruritus occurs.
- Avoid tight clothes, underwire bras, excessive temperatures, and ultraviolet light.

Follow-up care includes educating the patient to minimize sun exposure to the treated area (i.e., using sunblock with sun protection factor [SPF] of 15 or higher) and reassuring the patient that short-term minor twinges and pain in the breast are normal after radiation treatment.

Systemic Treatments

Chemotherapy

Adjuvant chemotherapy involves the use of anticancer agents in addition to other treatments (i.e., surgery, radiation) to delay or prevent a recurrence of breast cancer. It is recommended for patients who have positive lymph nodes or who have invasive tumors greater than 1 cm in size, regardless of nodal status. It is considered in patients with tumors that are 0.6 to 1 cm, are moderately to poorly differentiated, or have unfavorable features (NCCN, 2015). Table 58-18 outlines general indications for adjuvant chemotherapy. A survival benefit has been shown in both women who are pre- and postmenopausal and who have received chemotherapy, although data are limited in women older than 70 years. Chemotherapy is most commonly initiated after breast surgery and before radiation. Patients who delay initiation of chemotherapy beyond 90 days postsurgery have an increased risk of adverse outcomes (Chavez-McGregor, Clarke, Lichtensztajn, et al., 2016). Nurses encourage and assist in facilitating timely treatment to optimize outcomes.

Chemotherapy regimens for breast cancer combine several agents (polychemotherapy), generally given over a period of 3 to 6 months. Decisions regarding the optimal regimen are based on a variety of factors, including tumor characteristics

TABLE 58-18 General Indications for Adjuvant Chemotherapy for Breast Cancer

Nodal Status, Tumor Size	Adjuvant Chemotherapy
Node negative, ≤0.5 cm	None
Node negative 0.6–1 cm (well differentiated)	None
Node negative, 0.6–1 cm (moderately or poorly differentiated and/or unfavorable features)	Consider chemotherapy
Node negative, >1 cm	Chemotherapy
Node positive, any tumor size	Chemotherapy

- In addition to chemotherapy, patients with HER-2/neu-positive tumors will receive trastuzumab if they have node-positive disease; or node-negative disease with a tumor >1 cm. Trastuzumab is a monoclonal antibody that targets and inactivates the HER-2/neu protein. HER-2/neu is overproduced in 25–30% of tumors and is associated with rapid growth and poor prognosis.
- Following chemotherapy, patients with hormone receptor positive (ER+/PR+) tumors will receive hormonal therapy (tamoxifen or aromatase inhibitor) if they have either node-positive disease; node-negative disease with a tumor >1 cm; or node-negative disease with a tumor 0.6–1 cm and moderately or poorly differentiated and/or unfavorable features.

Note: These are only general guidelines. Recommendations may vary depending on factors such as prognostic variables, patient age, and comorbid conditions.

Adapted from National Comprehensive Cancer Network (NCCN). (2015). Clinical practice guidelines: Breast. Retrieved on 3/7/2016 at: www.nccn.org/professionals/physician_gls/PDF/infections.pdf

(i.e., tumor size, lymph node status, hormone receptor status, HER-2/neu status) and the patient's age, physical status, and existing comorbid conditions. A regimen that includes cyclophosphamide (Cytoxan), methotrexate (Trexall), and fluorouracil (Fluoroplex) (collectively referred to as CMF) has been the most widely used adjuvant therapy. It is usually well tolerated and may be considered for patients with a low risk of recurrence. CMF also may be considered for use in patients who have a high risk of cardiac toxicity or who have other limiting comorbidities. Anthracycline-based regimens (e.g., doxorubicin [Adriamycin], epirubicin [Ellence]) have shown longer survival in patients. However, the benefit relative to CMF is modest and is accompanied by increased toxicity (Meneses & Walker, 2014). Selection of patients most likely to benefit from anthracycline therapy would allow better use of current cytotoxic agents and reduce the risk of patients receiving toxicity with little or no effect. Identifying biomarkers that can accurately predict benefit from anthracyclines will also highlight key resistance/susceptibility pathways that can then be exploited clinically to further increase efficacy (Meneses & Walker, 2014). Cyclophosphamide, doxorubicin, and fluorouracil (CAF) and doxorubicin and cyclophosphamide (AC) are examples of combination regimens often given to patients who are at high risk.

The taxanes (paclitaxel [Taxol], docetaxel [Taxotere]) are generally incorporated into treatment regimens for patients with larger, node-negative cancers and for those with positive axillary lymph nodes. The addition of four cycles of paclitaxel after a standard course of AC (regimen known as ACT) has been found to increase the disease-free period and improve overall survival in patients with operable breast cancer and positive lymph nodes (Meneses & Walker, 2014).

Much attention has been focused on dose-dense chemotherapy, which is the administration of chemotherapeutic agents at standard doses with shorter time intervals between each cycle

of treatment. A systematic review and meta-analysis of existing data from randomized controlled trials that compared dose-dense chemotherapy with a standard chemotherapy schedule in women with nonmetastatic breast cancer demonstrated that dose-dense chemotherapy results in better overall and disease-free survival, particularly in women with hormone receptor–negative breast cancer (Bonilla, Ben-Aharon, Vidal, et al., 2010). However, additional data from randomized controlled trials are needed before dose-dense chemotherapy can be considered the standard of care (Bardia & Baselga, 2014).

Side Effects

Many of the side effects of adjuvant chemotherapy can be managed well, allowing patients to maintain their daily routines and work schedules. In large part, this is the a result of the meticulous educational and psychological preparation provided to patients and their families by oncology nurses, oncologists, social workers, and other members of the health care team. In addition, strides have been made in the effectiveness of antiemetic agents used to alleviate nausea and vomiting and the use of hematopoietic growth factors to treat neutropenia and anemia.

Common physical side effects of chemotherapy for breast cancer may include nausea, vomiting, bone marrow suppression, taste changes, alopecia (hair loss), mucositis, neuropathy, skin changes, and fatigue. A weight gain of more than 4.5 kg occurs in about half of all patients; the cause is unknown. Women who are premenopausal may also experience temporary or permanent amenorrhea.

Specific side effects vary with the type of chemotherapeutic agent used. In general, CMF and the taxanes are better tolerated than the anthracyclines. However, the taxanes can cause peripheral neuropathy, arthralgias, and myalgias, particularly at high doses. During taxane administration, hypersensitivity reactions may occur; therefore, the patient must be premedicated. Alopecia is also common. The side effects of the anthracyclines may be severe and include cardiotoxicity in addition to nausea and vomiting, bone marrow suppression, and alopecia. Their vesicant properties can lead to tissue necrosis if infiltration of the medication infusion occurs.

Nursing Management

Nurses play an important role in helping patients manage the physical and psychosocial sequelae of chemotherapy. (Earlier part of this chapter provides an in-depth discussion of side effect management.) Instructing the patient about the use of antiemetic agents and reviewing the optimal dosage schedule can help minimize nausea and vomiting. The different classes of antiemetic agents include serotonin (5-HT-3) receptor antagonists (palonosetron [Aloxi], granisetron [Kytril], ondansetron [Zofran]); neurokinin-1 receptor antagonists (aprepitant [Emend]); dopamine receptor antagonists (prochlorperazine [Compazine], metoclopramide [Reglan]); benzodiazepines (lorazepam [Ativan]); and corticosteroids (dexamethasone [Decadron]). Measures to ease the symptoms of mucositis may include rinsing with normal saline or sodium bicarbonate solution, avoiding hot and spicy foods, and using a soft toothbrush.

Some patients may require hematopoietic growth factors to minimize the effects of chemotherapy-induced neutropenia and anemia. Granulocyte colony-stimulating factors boost the white blood cell count, helping to reduce the incidence of neutropenic fever and infection. The short-acting form, filgrastim (Neupogen), is injected subcutaneously or IV for 7 to 10 days after chemotherapy administration. The long-acting form, pegfilgrastim (Neulasta), is injected once, no earlier than 24 hours after chemotherapy (Comerford, 2015). Erythropoietin growth factor increases the production of red blood cells, thus decreasing the symptoms of anemia. The short-acting form, epoetin alfa (Epogen) is usually given weekly. The long-acting form, darbepoetin alfa (Aranesp), can be given every 2 to 3 weeks. The nurse instructs the patient and family on proper injection technique of hematopoietic growth factors and about symptoms that require follow-up with a primary provider (see Chart 58-18).

Chart 58-18 HOME CARE CHECKLIST

Self-Administration of Hematopoietic Growth Factors

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Identify the benefits and expected outcome of hematopoietic growth factors.
- Locate list of names and telephone numbers of resource personnel involved in care (e.g., health care professionals, home care nurse, hematopoietic growth factor and supply vendor).
- Identify the equipment necessary for self-injection and how to obtain hematopoietic growth factor and supplies.
- Demonstrate how to give an injection properly, including:
  - How to draw up the solution in a syringe if indicated. (*Note:* Darbepoetin and pegfilgrastim come in prefilled syringes).
  - Identify appropriate body sites for self-injection.
  - Demonstrate correct disposal of sharps.
  - Describe proper storage of supplies.
- State what types of lifestyle and environmental changes are needed (if any) to maintain a clean home environment and prevent infection.
- State the name, dose, side effects, frequency, and schedule for all medications.
- List complications of medications/therapeutic regimen necessitating a call to the nurse or primary provider. (e.g., excessive pain, fever).
- List complications of medications/therapeutic regimen necessitating a visit to the emergency department.
- Explain treatment plan and importance of follow-up care to all health care providers.
  - State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify phone numbers of support groups for people with cancer and their caregivers/families.
  - State meeting locations and times.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

To prevent some of the emotional trauma associated with alopecia, it often helps to have a patient obtain a wig before hair loss begins to occur. The nurse may provide a list of wig suppliers in the patient's geographic region. Familiarity with creative ways to use scarves and turbans may also help minimize the patient's distress. The patient needs reassurance that new hair will grow back when treatment is completed, although the color and texture may be different. The ACS offers the Look Good Feel Better program, which provides useful tips for applying cosmetics during the period a patient is receiving chemotherapy (see Resources sections).

Chemotherapy may negatively affect the patient's self-esteem, sexuality, and sense of well-being. This, combined with the stress of a potentially life-threatening disease, can be acute. Providing support and promoting open communication are important aspects of nursing care. Referring the patient to the dietitian, social worker, psychiatrist, or spiritual advisor can provide additional support. Numerous community support and advocacy groups are available for patients and their families. Complementary therapies, such as guided imagery, meditation, and relaxation exercises, can also be used in conjunction with conventional treatments.

Hormonal Therapy

The use of adjuvant hormonal therapy, with or without the addition of chemotherapy, is considered in women who have hormone receptor–positive tumors. Its use can be determined by the results of an estrogen and progesterone receptor assay (a test to determine whether the breast tumor is nourished by hormones). About two thirds of breast cancers depend on estrogen for growth and express a nuclear receptor that binds to the estrogen; thus, they are estrogen receptor positive (ER+). Similarly, tumors that express the progesterone receptor are progesterone receptor positive (PR+). Hormonal therapy involves the use of synthetic hormones or other medications that compete with estrogen by binding to the receptor sites (SERMs), or the use of aromatase inhibitors, which block estrogen production by the adrenal glands. In general, tumors that are ER+/PR+ have the greatest likelihood of responding to hormonal therapy and have a more favorable prognosis than those that are ER–/PR–. Women who are pre- and perimenopausal are more likely to have non–hormone-dependent lesions, whereas women who are postmenopausal are more likely to have hormone-dependent lesions.

Traditionally, the SERM tamoxifen has been the main hormonal agent used in treatment of pre- and postmenopausal breast cancer and remains the mainstay in women who are premenopausal. As an SERM, tamoxifen has estrogen antagonistic (estrogen-blocking) and agonistic (estrogenlike) effects on certain tissues. Its antagonistic effects in the breast prevent estrogen from binding to the receptor sites, thus preventing tumor growth. Tamoxifen has positive agonistic effects on blood lipid profiles and bone mineral density in women who are postmenopausal. It also has agonistic effects on endometrial tissue and blood coagulation processes, leading to an increased incidence of endometrial cancer and thromboembolic events (e.g., deep vein thrombosis, superficial phlebitis, pulmonary embolism). Nevertheless, the benefits in most women with breast cancer outweigh the risks.

The aromatase inhibitors anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin) are important components in the hormonal management of women who are postmenopausal. Most of the circulating estrogens in women who are postmenopausal are derived from the conversion of the adrenal androgen androstenedione to estrone and the conversion of testosterone to estradiol. Aromatase inhibitors work by blocking the enzyme aromatase from performing the conversion, thereby decreasing the level of circulating estrogen in peripheral tissues. Clinical trials have demonstrated that the aromatase inhibitors are superior to tamoxifen in terms of overall response rate and clinical benefit and that inhibitors appear to be effective and feasible compared with tamoxifen as first-line hormonal therapy in women who are postmenopausal with advanced breast cancer (Rimawi & Osborne, 2014). These data ensure that aromatase inhibitors will play an increasingly central role in the long-term management of breast cancer. Trials are ongoing to determine the optimal treatment regimen and the timing of the treatment. Table 58-19 outlines the adverse effects of adjuvant hormonal therapy. Chart 58-19 outlines appropriate patient education to manage the adverse effects.

Targeted Therapy

An exciting area of research in the systemic treatment of breast cancer involves the use of targeted therapies. Trastuzumab (Herceptin) is a monoclonal antibody that binds specifically to the HER-2/neu protein. This protein, which regulates cell growth, is present in small amounts on the surface of normal breast cells and in most breast cancers. Approximately 25% to 30% of tumors overexpress (overproduce) the HER-2/neu protein and are associated with rapid growth and poor prognosis. Trastuzumab targets and inactivates the HER-2/neu protein, thus slowing tumor growth.

Unlike chemotherapy, trastuzumab spares the normal cells and has limited adverse reactions, which may include fever, chills, nausea, vomiting, diarrhea, and headache. However,

TABLE 58-19 Adverse Reactions Associated with Adjuvant Hormonal Therapy used to Treat Breast Cancer

Therapeutic Agent	Adverse Reactions/Side Effects
Selective Estrogen Receptor Modulator	
Tamoxifen (Soltamox)	Hot flashes, vaginal dryness/discharge/bleeding, irregular menses, nausea, mood disturbances, rashes; increased risk for endometrial cancer; increased risk for thromboembolic events (deep vein thrombosis, pulmonary embolism, superficial phlebitis)
Aromatase Inhibitors	
Anastrozole (Arimidex) Letrozole (Femara) Exemestane (Aromasin)	Musculoskeletal symptoms (arthritis, arthralgia, myalgia), increased risk of osteoporosis/fractures, nausea/vomiting, hot flashes, fatigue, mood disturbances, rashes

Chart 58-19 PATIENT EDUCATION

Managing Side Effects of Adjuvant Hormonal Therapy in Breast Cancer

The nurse instructs the patient in strategies to manage the following side effects:

Hot Flashes

- Wear breathable, layered clothing.
- Avoid caffeine and spicy foods.
- Perform breathing exercises (paced respirations).
- Consider medications (vitamin E, antidepressants) or acupuncture.

Vaginal Dryness

- Use vaginal moisturizers for everyday dryness (e.g., Replens, vitamin E suppository).
- Apply vaginal lubrication during intercourse (e.g., Astroglide, K-Y Jelly).

Nausea and Vomiting

- Consume a bland diet.
- Try to take medication in the evening.

Musculoskeletal Symptoms

- Take nonsteroidal analgesic agents as recommended.
- Take warm baths.

Risk of Endometrial Cancer

- Report any irregular bleeding to a gynecologist for evaluation.

Risk for Thromboembolic Events

- Report any redness, swelling, or tenderness in the lower extremities, or any unexplained shortness of breath.

Risk for Osteoporosis or Fractures

- Undergo a baseline bone density scan.
- Perform regular weight-bearing exercises.
- Take calcium supplements with vitamin D.
- Take bisphosphonates (e.g., alendronate) or calcitonin as prescribed.

when trastuzumab is given to patients who have previously been treated with an anthracycline, the risk of cardiac toxicity is increased. The medication has been shown to improve survival rates in women with HER-2/neu–positive metastatic breast cancer and is now regarded as standard therapy. It may be given as a single agent or in combination with chemotherapy. More recently, trastuzumab has been shown to be effective in treating early-stage breast cancer that is HER-2/neu positive. Assessing the benefits and risks of trastuzumab is complex, and medical oncologists often use a variety of aids in their decision making (Kimmick, Hughes, & Muss, 2014).

Treatment of Recurrent and Metastatic Breast Cancer

Despite the advances made in the treatment of breast cancer, it may recur locally (on the chest wall or in the conserved breast), regionally (in the remaining lymph nodes), or systemically (in distant organs). In metastatic disease, the bone, usually the hips, spine, ribs, skull, or pelvis, is the most common site of spread. Other sites of metastasis include the lungs, liver, pleura, and brain.

The overall prognosis and optimal treatment are determined by a variety of factors such as the site and extent of recurrence, the time to recurrence from the original diagnosis, history of prior treatments, the patient's performance status, and any existing comorbid conditions. Patients with bone metastases generally have a longer overall survival compared with metastases in visceral organs.

Local recurrence in the absence of systemic disease is treated aggressively with surgery, radiation, and hormonal therapy. Chemotherapy may also be used for tumors that are not hormonally sensitive. Local recurrence may be an indicator that systemic disease will develop in the future, particularly if it occurs within 2 years of the original diagnosis (NCCN, 2015).

Metastatic breast cancer involves control of the disease rather than cure (NCCN, 2015). Treatment includes hormonal therapy, chemotherapy, and targeted therapy. Surgery or radiation may be indicated in select situations. Women who are premenopausal and who have hormonally dependent tumors may eliminate the production of estrogen by the ovaries through oophorectomy (removal of the ovaries) or suppression of estrogen production by medications such as leuprolide (Lupron) or goserelin (Zoladex).

Patients with advanced breast cancer are monitored closely for signs of disease progression. Baseline studies are obtained at the time of recurrence. These may include complete blood count; comprehensive metabolic panel; tumor markers (i.e., carcinoembryonic antigen, cancer antigen 15-3); bone scan; CT of the chest, abdomen, and pelvis; and MRI of symptomatic areas. Additional x-rays may be performed to evaluate areas of pain or abnormal areas seen on bone scan (e.g., long bones, pelvis). These studies are repeated at regular intervals to assess for effectiveness of treatment and to monitor progression of disease.

Nursing Management

Nurses play an important role in not only educating patients and managing their symptoms but also in providing emotional support. Many patients find that recurrence of the disease is more distressing than the initial cancer diagnosis. They not only have to contend with another round of treatments but are also faced with a greater uncertainty about their future and long-term survival. The nurse can help the patient identify coping strategies and set priorities to optimize quality of life. Family members and significant others should be included in the treatment plan and follow-up care. Referrals to support groups, as well as psychiatry or psychiatric clinical nurse specialist, social work, and complementary medicine programs (e.g., guided imagery, meditation, yoga), should be made as indicated.

Nurses can also be instrumental in providing palliative care, if indicated. The highest priorities include alleviating pain and providing comfort measures. A frank discussion with the patient and family regarding their preferences for end-of-life care should occur before the need arises to ensure a smooth transition without disruption of care. Referrals to hospice and home health care should be initiated as necessary (see Chapter 59).

Reconstructive Procedures after Mastectomy

Breast reconstruction can provide a significant psychological benefit for women who are already struggling with the

emotional distress of losing a breast. A consultation with a plastic surgeon can help the patient understand procedures for which she is a candidate and the pros and cons of each. Factors to consider include body size and shape, comorbid conditions (e.g., hypertension, diabetes, obesity), personal habits such as smoking, and patient preference. The patient must be informed that although breast reconstruction can provide a good cosmetic result, it will never precisely duplicate the natural breast. Realistic preparation can help the patient avoid unrealistic expectations. Once reconstruction is complete, the opposite breast may require augmentation, reduction, or mastopexy to achieve symmetry on both sides. The patient must also be informed that breast reconstruction neither will interfere with breast cancer treatments nor affect the risk of cancer recurrence. Reconstruction is considered an integral component in the surgical treatment of breast cancer and is usually covered by insurance companies.

Many women elect immediate reconstruction at the time of the mastectomy operation. This can be beneficial in that it saves the woman from undergoing general anesthesia a second time and saves the cost and stress of future hospitalizations. However, it does increase the length of the surgical procedure. Delayed reconstruction is preferable in women who are having a difficult time deciding on the type of reconstruction that they desire. It may also be preferable in patients with advanced disease such as inflammatory breast cancer, where the breast cancer treatments should begin without delay. Any delays in healing after immediate reconstruction may interfere with the initiation of treatment.

Tissue Expander Followed by Permanent Implant

Breast reconstruction using a tissue expander followed by a permanent implant is the simplest and most common method used today (see Fig. 58-15). To accommodate an implant, the skin remaining after a mastectomy and the underlying muscle must gradually be stretched by a process called *tissue expansion.* The surgeon places a tissue expander (a balloonlike device) through the mastectomy incision underneath the pectoralis muscle. A small amount of saline is injected through a metal port intraoperatively to partially inflate the expander. Then, for about 6 to 8 weeks, at weekly intervals, the patient receives additional saline injections through the port until the expander is fully inflated. It remains fully expanded for about 6 weeks to allow the skin to loosen. The expander is then exchanged for a permanent implant. This is usually performed as an outpatient surgical procedure.

Advantages of the expansion procedure are a shorter operating time and a shorter recuperation period than for autologous reconstruction (see the Tissue Transfer Procedures section). A disadvantage is a tendency for the implant to feel firm and round, with little natural ptosis (sag). Women with a small to medium opposite breast with little ptosis are good candidates for this procedure. Women who have had radiation or who have connective tissue disease are not good candidates because of the decreased elasticity of the skin.

Nursing Alert: The patient must be cautioned not to have an MRI while the tissue expander is in place because the port contains metal. This is not an issue once the permanent implant is in place because it does not contain any metal.

The patient should be informed that for the rest of her life she should not engage in any exercises that will develop the pectoralis muscle, because this can result in distortion of the reconstructed breast.

Tissue Transfer Procedures

Autologous reconstruction is the use of the patient's own tissue to create a breast mound. A flap of skin, fat, and muscle with its attached blood supply is rotated to the mastectomy site to create a mound that simulates the breast. Donor sites may include the transverse rectus abdominal myocutaneous (TRAM) flap (abdominal muscle) (see Fig. 58-16), gluteal flap (buttock muscle), or the latissimus dorsi flap (back muscle) (see Fig. 58-17). The results more closely resemble a real breast because the skin and fat from the donor sites are similar in consistency to a natural breast. These procedures avoid the use of synthetic material. However, they involve longer recuperation than a tissue expander procedure. The risk of potential complications (e.g., infection, bleeding, flap necrosis) is also

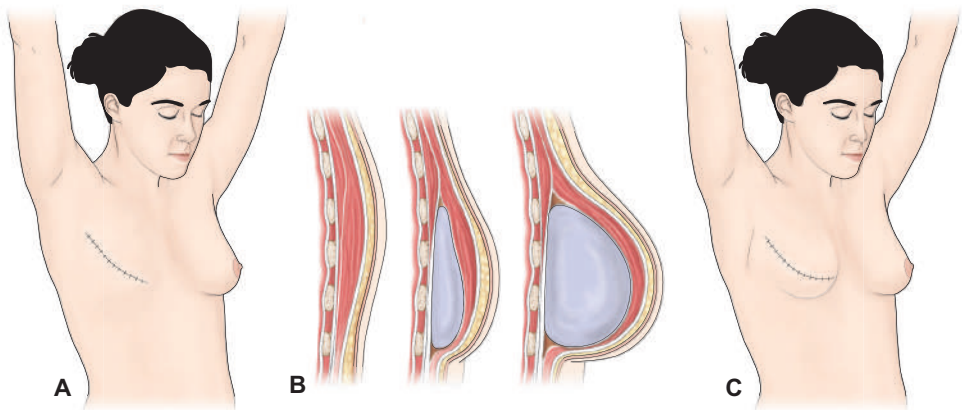

Figure 58-15 • Breast reconstruction with tissue expander. **A.** Mastectomy incision line prior to tissue expansion. **B.** The expander is placed under the pectoralis muscle and is gradually filled with saline solution through a port to stretch the skin enough to accept a permanent implant. **C.** The breast mound is restored. Although permanent, scars will fade with time. The nipple and areola are reconstructed later. Adapted from American Society of Plastic Surgeons.

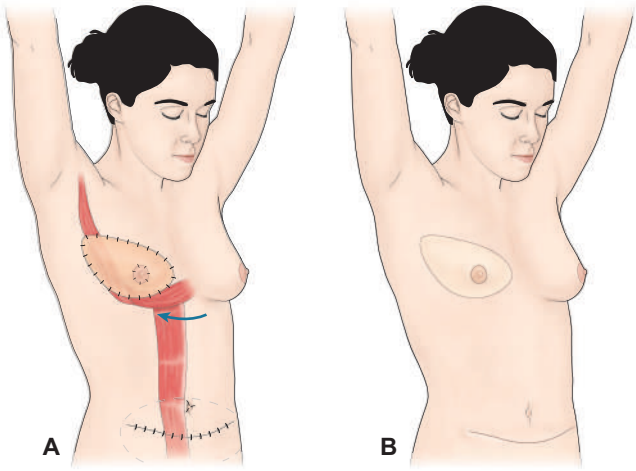

Figure 58-16 • Breast reconstruction: transverse rectus abdominal myocutaneous flap. **A.** A breast mound is created by tunneling abdominal skin, fat, and muscle to the mastectomy site. **B.** Final location of scars. Adapted from American Society of Plastic Surgeons.

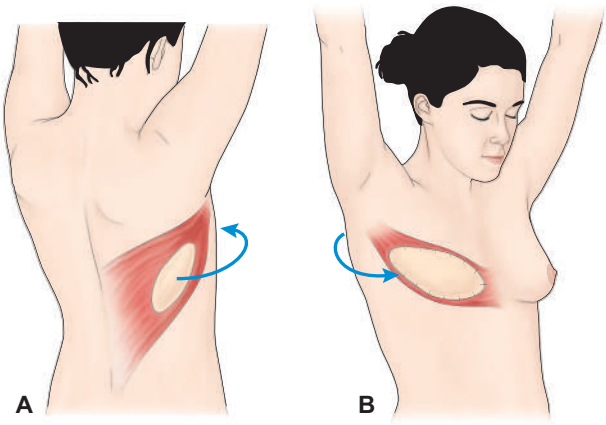

Figure 58-17 • Breast reconstruction: latissimus dorsi flap. **A.** The latissimus muscle with an ellipse of skin is rotated from the back to the mastectomy site. **B.** Because the flap is usually not bulky enough to provide an adequate breast mound, an implant is often also required. Adapted from American Society of Plastic Surgeons.

greater. Therefore, patients must be in relatively good health, and those with medical conditions (e.g., atherosclerosis, pulmonary disease, heart failure) that affect circulation or compromise oxygen delivery are not good candidates. Other candidates who are poor risks include those with poorly controlled diabetes or morbid obesity and those who smoke.

The TRAM flap is the most commonly performed tissue transfer procedure. A free TRAM procedure may also be performed; in this case, the skin, fat, muscle, and blood supply are completely detached from the body and then transplanted to the mastectomy site using microvascular surgery (the use of a microscope to reconnect the vessels). Postoperatively, patients who have undergone TRAM procedures often face a lengthy recovery (often 6 to 8 weeks) and have incisions both at the mastectomy site and at the donor site in the abdomen. Other free flap procedures include deep inferior epigastric perforator flap (DIEP) and superficial inferior epigastric artery flap (SIEA) depending on whether the superior gluteal artery perforator or the inferior one is utilized. Free flaps involve microsurgery for blood vessel transfer.

Deep breathing and leg exercises are essential because the patient is more limited in her activity and is at greater risk for respiratory complications and deep vein thrombosis. Measures to help the patient reduce tension on the abdominal incision during the first postoperative week include elevating the head of the bed 45 degrees and flexing the patient's knees.

Once the patient is able to ambulate, she can protect the surgical incision by splinting it and will gradually achieve a more upright position. The patient is instructed to avoid high-impact activities and lifting (more than 2.3 to 4.5 kg for 6 to 8 weeks after surgery) to prevent stress on the incision.

Nipple–Areola Reconstruction

After the breast mound has been created and the site has healed, some women choose to have nipple–areola reconstruction. This is a minor surgical procedure carried out either in the physician's office or at an outpatient surgical facility. The most common method of creating a nipple is with the use of local flaps (skin and fat from the center of the new breast mound), which are wrapped around each other to create a projecting nipple. The areola is created using a skin graft. The most common donor site is the upper inner thigh, because this skin has darker pigmentation than the skin on the reconstructed breast. After the nipple graft has healed, micropigmentation (tattooing) can be performed to achieve a more natural color. The surgeon can usually match the reconstructed nipple–areola complex with that of the contralateral breast for an acceptable cosmetic result.

Prosthetics

Not all patients desire or are candidates for reconstructive surgery. A breast prosthesis—an external form that simulates the breast—is another option. Prostheses are available in different shapes, sizes, colors, and materials, although they are most often made of silicone. They can be placed inside a pocket in a bra or can adhere directly to the chest wall. The nurse can provide the patient with the names of shops where she can be fitted for a prosthesis, or the patient can call the Reach to Recovery program of the ACS for appropriate referrals. The patient should be encouraged to find a shop with a comfortable, supportive atmosphere that employs a certified prosthetics consultant. In general, medical supply shops are not recommended because often they do not have the appropriate resources to ensure the proper fitting of a prosthesis.

Prior to discharge from the hospital, the nurse usually provides the patient with a temporary, lightweight, cotton-filled form that can be worn until the surgical incision is well healed (4 to 6 weeks). After that, the patient can be fitted for a prosthesis. A breast prosthesis can provide a psychological benefit and assist the woman in resuming proper posture because it helps balance the weight of the remaining breast.

Special Issues in Breast Cancer Management

Implications of Genetic Testing

The rapid advancement in genetics not only has brought new knowledge about inherited breast cancer, but it has also raised potential ethical and psychosocial issues. Although the actual

testing for the *BRCA1* and *BRCA2* and several other genes that increase risk involves a simple blood or saliva test, ethical and psychosocial issues must first be addressed. Before undergoing genetic testing, a person should meet either with a clinician who has expertise in this area or with a certified genetic counselor to discuss risk factors as well as the benefits, sequelae, and limitations of testing.

How people react when they receive their actual test results is not always easy to predict. A negative test in a person who comes from a family with a known mutation may lead to enormous relief. However, a negative test in a family with no known mutation may be a source of undue reassurance; the possibility of existing genes that cannot yet be detected remains. A negative test may also lead to feelings of guilt in a person whose family members did not receive favorable test results; this is known as survivor's guilt. A positive test could act as a motivator in a person to pursue appropriate screening or treatment, or it could cause tremendous anxiety, depression, and worry.

In addition, test results may be ambiguous, leading to feelings of confusion and uncertainty. People must be informed that not all gene carriers develop breast cancer (incomplete penetrance) and that not all noncarriers are protected or immune.

People must be well informed of all issues and potential implications prior to undergoing genetic testing. Nurses play a role in educating and counseling patients and their family members about the implications of genetic testing. Nurses provide support and clarification and make referrals to appropriate specialists when indicated.

Pregnancy and Breast Cancer

Breast cancer during pregnancy is defined as breast cancer diagnosed during gestation or within 1 year of childbirth and occurs in 1 in 3000 women (NCCN, 2015). Because of increased levels of hormones produced during pregnancy and subsequent lactation, the breast tissue becomes tender and swollen, making it more difficult to detect a mass. If a mass is found during pregnancy, ultrasound is the preferred diagnostic method because it involves no exposure to radiation. If indicated, mammography with appropriate shielding, FNA, and biopsy can be performed. Modified radical mastectomy remains the most common form of surgical treatment. SLNB is typically not performed because of the unknown effects of the radioisotope and the blue dye on the fetus. Breast conservation treatment may be considered if the breast cancer is diagnosed during the third trimester. Radiation can then be delayed until after delivery because it is contraindicated during pregnancy. If a woman is close to term, a cesarean section may be performed as soon as maturation of the fetus allows and then treatment is initiated. If aggressive disease is detected early in pregnancy and chemotherapy is advised, termination of the pregnancy may be considered. If a mass is found while a woman is breast-feeding, she is urged to stop to allow the breast to involute (return to its baseline state) before any type of surgery is performed (NCCN, 2015).

Fertility issues and the future desire for children are major concerns of young women who are survivors of breast cancer. Most cancer therapies have a substantial morbidity on reproductive function, not only because they increase the risk of early menopause but also because they are associated with a decreased ovarian reserve and a loss of fertility. It is estimated that physiologic age of the ovaries in a survivor of cancer may be 10 years older than the actual chronologic age.

Chemotherapy causes a progressive dose-related depletion of ovarian follicles and granulosa cells that translates into oligomenorrhea and subsequent premature ovarian failure, ultimately leading to what is known as chemotherapy-induced amenorrhea (CIA). Regardless of the beneficial effects that hormonal changes can have as part of the adjuvant endocrine strategy, CIA is an adverse event to consider when selecting the best adjuvant treatment. Patients with cancer need to be informed about their reproductive future and options to preserve fertility before treatment (Ruddy & Ginsburg, 2014).

Quality of Life and Survivorship

With increased early detection and improved treatment modalities, women with breast cancer have become the largest group of cancer survivors. However, the treatment or simply the diagnosis of breast cancer may have long-term effects that negatively affect the patient and her family. The patient should be prepared early on for the potential long-term effects of the disease so that she has realistic expectations and can make informed decisions.

Survivors of breast cancer may experience a variety of issues as a result of their diagnosis and treatment. Estrogen withdrawal from chemotherapy-induced menopause and hormonal treatments can lead to a variety of symptoms, including hot flashes, vaginal dryness, urinary tract infections, weight gain, decreased sex drive, and increased risk of osteoporosis. HT to alleviate symptoms is contraindicated in women with breast cancer. Certain chemotherapeutic agents can cause long-term cardiac effects and neuropathy. In addition, patients may experience impaired cognitive functioning, such as difficulty concentrating (often referred to as "chemo brain"). Rare long-term effects of radiation can include pneumonitis, rib fractures, heart disease, and breast fibrosis or necrosis (Harris & Morrow, 2014). Long-term sequelae after breast surgery may include lymphedema (mainly after ALND), pain, and sensory disturbances. Once lymphedema develops, it tends to be a chronic problem, so prevention strategies (discussed earlier) are vital. Weight gain and infections are risk factors for lymphedema (Ahn & Port, 2016). Nurses need to encourage patients to maintain an active lifestyle and avoid weight gain.

Long-term psychosocial sequelae may include fears of recurrence, mood changes (e.g., worry, sadness, anger, frustration), an increased sense of vulnerability, uncertainty, feelings of loss (e.g., fertility), concerns about body image, self-concept, and sexuality; emotional distress related to role adjustments and family response; and concerns about finances and employment. Depression and anxiety have been documented in 20% to 30% of women with breast cancer. Interventions should be targeted to meet informational needs, manage uncertainty, control symptoms, address cultural differences, and enhance social and emotional support (Heinz, & Williams, 2015); (Ligabel & Denlinger, 2013).

Gerontologic Considerations

Breast cancer reconstruction in older women with breast cancer is a feasible option that should be offered to patients. Most women tolerate the procedure well and have good cosmetic outcomes. Patients can be offered both implant-based reconstruction and autologous tissue transfer with minimal complications as long as appropriate preoperative selection criteria are used. The safety of reconstruction, together with increase in life expectancy and healthier lifestyles, makes breast reconstruction after mastectomy desirable at any age (NCCN, 2015).

A thorough assessment must be performed before any treatment is initiated, and careful monitoring must occur throughout the course of treatment to avoid complications. The physical and psychosocial assessment of the older woman should include general health, currently existing comorbidities, performance status, cognitive status, current medications, available resources, and support systems.

Breast Health of Women with Disabilities

Disparities in obtaining a mammogram at recommended screening intervals persist for many women, including those with disabilities. Prevalence of self-reported use of mammography is lower for women with a disability. Efforts to reduce disparities in breast cancer screening might be more effective if all segments of the population are targeted. Possible barriers to the use of mammography in women with disabilities include physical inaccessibility of office space and medical equipment; limited transportation and parking options; and time and assistance constraints associated with undressing, transferring, and positioning for medical examinations. Lesbian, gay, bisexual, transgender and those questioning their gender may also be uncomfortable with the health care system and avoid screening (Bosse, Nesteby, & Randall, 2015). To promote health and wellness, health agencies, providers, and health care plans must promote cancer prevention and educational programs that are inclusive and responsive to the special needs of women with disabilities (Swaine, Parish, Luken, et al., 2014).

An essential role of the nurse is to assist all women, including those with disabilities, to identify accessible health screening and to advocate for greater accessibility of imaging centers and other health care facilities. Reminding women of the need for recommended clinical breast examinations and mammograms is an important part of nursing care.

Male Breast Cancer

The lifetime risk of breast cancer in men is about 1 in 1000. The number of breast cancer cases in men relative to the population has been fairly stable over the past 30 years. Nearly 2350 new cases of invasive breast cancer were expected to be diagnosed in men in 2015 (ACS, 2015). Although breast carcinoma in both genders shares certain characteristics, notable differences have emerged. Familial cases in men usually have *BRCA2* rather than *BRCA1* mutations. Klinefelter syndrome, a chromosomal condition reflecting decreased testosterone levels, is the strongest risk factor for developing male breast carcinoma. Presentation is usually a painless lump, but is often late, with more than 40% of individuals having stage III or IV disease. When survival is adjusted for age at diagnosis and stage of disease, outcomes for male and female patients with breast cancer is similar (Jain & Gradishar, 2014).

Early detection is uncommon in male breast cancer because of the rare nature of the disease. Often, neither patient nor provider suspects male breast cancer early in its development. Treatment generally consists of a total mastectomy with either SLNB or ALND. As in women with breast cancer, prognosis depends on the stage of disease at presentation. Involvement of the axillary lymph nodes is the most important prognostic indicator. Male breast cancers are very likely to be ER+, and tamoxifen, although it has several side effects, is a mainstay of treatment.

Because breast cancer is primarily a disease of women, men may feel that a certain stigma is attached to their diagnosis. Health care professionals must be sensitive to their needs and provide information and support.

GYNECOLOGIC MALINANCIES

Gynecologic cancer is any cancer that starts in a woman's reproductive organs (CDC, 2014).

The projected incidence of female reproductive cancer in India includes about 75,000 new cases of breast cancer, 70,000 new cases of cervical uteri, 3–8% of ovarian cancer, 0.5–4.8% of carpus uteri, and 1–3% of vulvar and gestational trophoblastic tumors. Ovarian cancer is responsible for 58% (75,000 women annually) of all cancer deaths in women and is the leading cause of death in female reproductive cancers (Devi, 2009).

Although some cancers are difficult to detect or prevent, annual pelvic examination with a Pap smear is a painless and relatively inexpensive method of early detection (CDC, 2014). Primary providers can encourage women to follow this health practice by providing examinations that are educational and supportive and offer women an opportunity to ask questions and clarify misinformation.

Women diagnosed with gynecologic malignancies experience anxiety related to their prognosis. The occurrence of physical symptoms may cause more psychological distress. Intervention directed toward physical and psychological symptoms requires a multidisciplinary approach.

Cancer of the Cervix

Death from cervical cancer is less common due to early detection of cell changes by Pap smear (CDC, 2014). However, it is still the third most common female reproductive cancer and is estimated to affect nearly 13,000 women in the United States every year (CDC, 2014). Risk factors are presented in Chart 58-20.

In South Asia, India has highest age-standardized incidence rate of cervical cancer (22/100,000 women per year). As per the most recent available data, about 122,844 women are diagnosed with cervical cancer every year and 67,477 women die of the disease (ICO Information Centre on HPV and Cancer, 2014). The recent National Centre for Disease Informatics and Research (NCDIR) data show that between 2009 and 2011, Aizawl district in the northeastern part of India had the highest levels of cervical cancer at an age-adjusted rate of 24.3, followed by Barshi at 19.5 and Bangalore at 18.9 (NCRP, 2014). HPV prevalence among cervical cancer patients in India has varied from 87.8% to 96.67% (Sowjanya, Jain, Poli, et al., 2005) (Kulkarni, Kulkarni, Vastrad, et al., 2011) (Gheit, Vaccarella, Schmitt, et al., 2009) (Basu, Roychowdhury, Bafna, et al., 2009).

Preventive measures include regular pelvic examinations and Pap tests for all women, especially older women past childbearing age. Preventive counseling should encourage delaying first intercourse, avoiding HPV infection, engaging only in safer sex, ceasing smoking, and receiving HPV immunization.

There are several different types of cervical cancer. Most of these cancers are squamous cell carcinomas, and the rest are adenocarcinomas or mixed adenosquamous carcinomas. Adenocarcinomas begin in mucus-producing glands and are often due to HPV infection. Most cervical cancers, if not detected and treated, spread to regional pelvic lymph nodes, and local recurrence is not uncommon.

Chart 58-20 RISK FACTORS

Cervical Cancer

- Chronic cervical infection
- Early childbearing
- Exposure to diethylstilbestrol in utero
- Exposure to human papillomavirus, types 16 and 18
- Family history of cervical cancer
- HIV infection and other causes of immune deficiency
- Low socioeconomic status (may be related to early marriage and early childbearing)
- Nutritional deficiencies (folate, beta-carotene, and vitamin C levels are lower in women with cervical cancer than in women without it)
- Overweight status
- Prolonged use of oral contraceptives
- Sexual activity:
  - Multiple sex partners
  - Early age (<20 years) at first coitus (exposes the vulnerable young cervix to potential viruses from a partner)
- Sexual contact with men whose partners have had cervical cancer
- Sex with uncircumcised men
- Smoking and exposure to secondhand smoke

HIV, human immune deficiency virus.

Adapted from American Cancer Society. (2015b). Cervical Cancer. Retrieved on 11/27/2015 at www.cancer.org/acs/groups/cid/documents/webcontent/003094-pdf.pdf; Barakat, R. R., Berchuk, A., & Markman, M., et al. (Eds). (2013). Principles and practice of gynecologic oncology (6th ed). Philadelphia, PA: Lippincott Williams & Wilkins

Clinical Manifestations

Early cervical cancer rarely produces symptoms. If symptoms are present, they may go unnoticed as a thin, watery vaginal discharge often noticed after intercourse or douching. When symptoms such as discharge, irregular bleeding, or pain or bleeding after sexual intercourse occur, the disease may be advanced. Advanced disease should not occur if all women have access to gynecologic care and avail themselves to it. The nurse's role in access to care and its utilization is crucial.

In advanced cervical cancer, the vaginal discharge gradually increases and becomes watery and, finally, dark and foul smelling from necrosis and infection. The bleeding, which occurs at irregular intervals between periods (metrorrhagia) or after menopause, may be slight (just enough to spot the undergarments) and occurs usually after mild trauma or pressure (e.g., intercourse, douching, or bearing down during defecation). As the disease continues, the bleeding may persist and increase. Leg pain, dysuria, rectal bleeding, and edema of the extremities signal advanced disease.

As the cancer advances, it may invade the tissues outside the cervix, including the lymph glands anterior to the sacrum. In one third of patients with invasive cervical cancer, the disease involves the fundus. The nerves in this region may be affected, producing excruciating pain in the back and the legs that is relieved only by large doses of opioid analgesic agents. If the disease progresses, it often produces extreme emaciation and anemia that usually is accompanied by fever (due to secondary infection and abscesses in the ulcerating mass) and by fistula formation. Because the survival rate for in situ cancer is 100% and the rate for women with more advanced stages of cervical cancer decreases dramatically, early detection is essential.

Assessment and Diagnostic Findings

Diagnosis may be made on the basis of abnormal Pap smear results, followed by biopsy results identifying severe dysplasia (cervical intraepithelial neoplasia type III [CIN III], high-grade squamous intraepithelial lesions [HGSILs, also referred to as HSILs], or carcinoma in situ). HPV infections are usually implicated in these conditions. Carcinoma in situ is technically classified as severe dysplasia and is defined as cancer that has extended through the full thickness of the epithelium of the cervix, but not beyond. This is often referred to as preinvasive cancer.

In its very early stages, cervical cancer is found microscopically by Pap smear. In later stages, pelvic examination may reveal a large, reddish growth or a deep, ulcerating lesion. The patient may report spotting or bloody discharge.

When the patient has been diagnosed with invasive cervical cancer, clinical staging estimates the extent of the disease so that treatment can be planned more specifically and prognosis reasonably predicted. Staging is based on the International Federation of Gynecology and Obstetrics (FIGO) Staging Classification (Beckmann et al., 2014):

- Stage I, the carcinoma is strictly confined to the cervix.
- Stage II, the carcinoma invades beyond the uterus but not the pelvic wall or vagina.
- Stage III, the tumor spreads to the pelvic wall and/or the vagina, and/or causes hydronephrosis of the kidneys.
- Stage IV, the tumor has extended beyond the pelvis and involves the bladder or rectum.

Signs and symptoms are evaluated, and x-rays, laboratory tests, and special examinations, such as biopsy and colposcopy, are performed (Beckmann et al., 2014). Depending on the stage of the cancer, other tests and procedures may be performed to determine the extent of disease and appropriate treatment. These tests may include dilation and curettage (D&C), CT scan, MRI scan, IV urography, cystography, positron emission tomography (PET) scan, and barium x-ray studies. Treatment depends on the stage of the disease.

Medical Management

Precursor or Preinvasive Lesions

When precursor lesions, such as low-grade squamous intraepithelial lesions (LGSILs, also referred to as LSILs; CIN I and II or mild to moderate dysplasia), are found by colposcopy and biopsy, careful monitoring by frequent Pap smears or conservative treatment is possible. Conservative treatment may consist of monitoring, cryotherapy (freezing with liquid nitrogen), or laser therapy. A loop electrocautery excision procedure (LEEP) may also be used to remove abnormal cells. In this procedure, a thin wire loop with laser is used to cut away a thin layer of cervical tissue. LEEP is an outpatient procedure that usually is performed in a gynecologist's office; it takes only a few minutes. Analgesia is given before the procedure, and a local anesthetic agent is injected into the area. This procedure allows the pathologist to examine the removed tissue sample to determine if the borders of the tissue are disease free. Another procedure referred to as a cone biopsy or conization (removing a cone-shaped portion of the cervix) is performed when biopsy findings demonstrate CIN III or HGSIL (equivalent to severe dysplasia) and carcinoma in situ.

If preinvasive cervical cancer (carcinoma in situ) occurs when a woman has completed childbearing, a simple hysterectomy (removal of the uterus only) is usually recommended

(Beckmann et al., 2014). If a woman is pregnant or wishes to have children and invasion is less than 1 mm, conization may be sufficient. Frequent follow-up examinations are necessary to monitor for recurrence (Beckmann et al., 2014).

Patients who have precursor or premalignant lesions need reassurance that they do not have invasive cancer. However, the importance of close follow-up is emphasized because the condition, if untreated for a long time, may progress to cancer. Patients with cervical cancer in situ also need to know that this is usually a slow-growing and nonaggressive type of cancer that is not expected to recur after appropriate treatment.

Invasive Cancer

Treatment of invasive cervical cancer depends on the stage of the lesion, the patient's age and general health, and the judgment and experience of the provider. Surgery and radiation treatment (intracavitary and external) are most often used. Surgical procedures that may be used to treat cervical cancer are summarized in Chart 58-21. Robot-assisted technology for the treatment of cervical cancer is a rapidly growing alternative to more invasive surgical options with decreased length of stay, recovery time, decreased blood loss, and increase in total number of retrievable lymph nodes (ACOG, 2015c). Ethical issues often arise in the treatment of invasive cancers. These issues are summarized in Chart 58-22.

Frequent follow-up after surgery is imperative because the risk of recurrence is high and usually occurs within the first 2 years. Recurrences are often in the upper quarter of the vagina, and ureteral obstruction may be a sign. Weight loss, leg edema, and pelvic pain may be signs of lymphatic obstruction and metastasis.

Radiation, which is often part of treatment to reduce recurrent disease, may be delivered by an external beam or by brachytherapy (method by which the radiation source is placed near the tumor in a sealed source) or both. The field to be irradiated as well as the dose and method of radiation are determined by stage, volume of tumor, and lymph node involvement (Beckmann et al., 2014).

Chart 58-21

Surgical Procedures for Cervical Cancer

- Total hysterectomy—removal of the uterus, cervix, and ovaries
- Radical hysterectomy—removal of the uterus, ovaries, fallopian tubes, proximal vagina, and bilateral lymph nodes through an abdominal incision (*Note*: "Radical" indicates that an extensive area of the paravaginal, paracervical, parametrial, and uterosacral tissues is removed with the uterus.)
- Radical vaginal hysterectomy—vaginal removal of the uterus, ovaries, fallopian tubes, and proximal vagina
- Bilateral pelvic lymphadenectomy—removal of the common iliac, external iliac, hypogastric, and obturator lymphatic vessels and nodes
- Pelvic exenteration—removal of the pelvic organs, including the bladder or rectum and pelvic lymph nodes, and construction of diversional conduit, colostomy, and vagina
- Radical trachelectomy—removal of the cervix and selected nodes to preserve childbearing capacity in a woman of reproductive age with cervical cancer

Adapted from American Cancer Society. (2015b). *Cervical Cancer*. Retrieved on 11/27/2015 at www.cancer.org/acs/groups/cid/documents/webcontent/003094-pdf.pdf; Barakat, R. R., Berchuk, A., & Markman, M., et al. (Eds). (2013). Principles and practice of gynecologic oncology (6th ed). Philadelphia, PA: Lippincott Williams & Wilkins

A variety of chemotherapeutic approaches are used to treat advanced cervical cancer. They are often used in combination with surgery and radiation. Vaginal stenosis is a frequent side effect of radiation. Preventive therapy (i.e., vaginal dilator) can be used to avoid severe permanent vaginal stenosis.

Some patients with recurrences of cervical cancer are considered for pelvic exenteration, in which several pelvic organs are removed. This is a complex, extensive surgical procedure that is reserved for women with a high likelihood of cure. Unilateral leg edema, sciatica, and ureteral obstruction indicate likely disease progression. Patients with these symptoms have advanced disease and are not considered

Chart 58-22 ETHICAL DILEMMA

What if the Patient Refuses to Autonomously Make Decisions?

Case Scenario

You work on a gynecology-oncology unit in a small rural community hospital. The patient, a 60-year-old woman, has been admitted with a diagnosis of cancer of the vulva. She has been married to her husband since she was 16 years old. Both the patient and her husband are Mexican migrant workers. It has been determined that her disease is advanced and that she will need surgical removal of the vulva and radical node dissection. In addition, it is likely she will need chemotherapy and may be a candidate for enrollment in a clinical trial. After the treatment is explained using a medical translator, she asks her physician, "What would you do if it was your mother?" The physician reiterates the information about the surgery, and the patient states, "It is up to my husband to decide; he always makes our important decisions."

Discussion

Some cultures adhere to paternalistic tenets; the male "head of household" makes all major decisions, including health care decisions. The patient may be adhering to her cultural norms when she tells you that she will acquiesce to whatever decision her husband makes for her. Arguably, however, she may feel coerced or obligated to acquiesce to his decisions.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have preeminence as you proceed with your assessment of this patient?
- Describe any concerns you may have regarding beneficence and autonomy.
- Discuss any concerns that you may have about the patient's refusal to make a health care decision that will have a significant impact on her life. Assume that you have spoken in private with the patient and have verified that she understands that failure to have this surgery may put her life in jeopardy but she still refuses to make the decision. How can you professionally reconcile her decision to put her life at greater risk so that she may adhere to her cultural norms (i.e., decision-making done solely by the spouse)? Does this type of decision truly preserve her autonomy?
- What resources are available to help you, your professional colleagues, the patient, and her husband reach consensus on the best treatment or care in this situation?

candidates for this major surgical procedure. Surgery is complex because it is performed close to the bowel, bladder, ureters, and great vessels. Possible complications include pulmonary embolism (PE), pulmonary edema, myocardial infarction, cerebrovascular disease, hemorrhage, sepsis, small bowel obstruction, fistula formation, obstruction of the ileal conduit, bladder dysfunction, and pyelonephritis, most often in the first 18 months postoperatively. Vein constriction must be avoided postoperatively. Patients with varicose veins or a history of thromboembolic disease may be treated prophylactically with heparin. Antiembolism stockings are prescribed to reduce the risk of deep vein thrombosis (DVT). Nursing care of these patients is complex and requires coordination and care by experienced health care professionals.

Cancer of the Uterus (Endometrium)

Over the last decade there has been an increase in both the incidence and death rates of cancer of the uterine endometrium (fundus or corpus), possibly because of increased lifespan and coexisting comorbidities. Endometrial cancer is the most common gynecological malignancy in the West, but in India, the incidence rates are as low as 4.3 per 100,000 (Balasubramaniam, Sushma, Rasika, et al., 2013). Most of these cancers present at an early stage and are associated with a good prognosis (Maheshwari, Kumar, & Mahantshetty, 2016).

Many women with endometrial cancer have obesity, which increases the risk of morbidity and mortality from this disease. Cumulative exposure to estrogen is considered the major risk factor (see Chart 58-23). This exposure occurs with the use of estrogen therapy without the use of progestin, early menarche, late menopause, nulliparity, and anovulation. Other risk factors include infertility, diabetes, and the use of tamoxifen. Tamoxifen, which is taken for treatment or prevention of breast cancer, may cause proliferation of the uterine lining (ACOG, 2015d). Women who take tamoxifen should be monitored by their oncologists and/or gynecologic health care providers.

Pathophysiology

Most uterine cancers are endometrioid (i.e., originating in the lining of the uterus). There are two types. Type 1, which accounts for about 90% of cases, is estrogen dependent. It is usually low grade with a favorable prognosis. Type 2, which occurs in about 10% of cases, is high grade and usually serous cell or clear cell. Type 2 is considered to be estrogen independent. Older and African-American women are at higher risk for type 2 (ACOG, 2015d); (Beckmann et al., 2014).

Chart 58-23 RISK FACTORS

Uterine Cancer

- Age—usually >50 years; average age, 63 years
- Obesity that results in increased estrone levels (related to excess weight) resulting from conversion of androstenedione to estrone in body fat, which exposes the uterus to unopposed estrogen
- Unopposed estrogen therapy (estrogen used without progesterone, which offsets the risk of unopposed estrogen)
- Other—nulliparity, truncal obesity, early menarche, late menopause (after 52 years of age) and the use of tamoxifen

Adapted from American College of Obstetricians and Gynecologists. (2015d). Practice Bulletin No. 149: Endometrial cancer. Obstetrics and Gynecology, 125(4), 1006–10026.

Assessment and Diagnostic Findings

All women should be encouraged to have annual checkups, including a gynecologic examination. Any woman who is experiencing irregular bleeding should be evaluated promptly. If a menopausal woman experiences bleeding, an endometrial aspiration or biopsy is performed to rule out hyperplasia, which is a possible precursor of endometrial cancer. The procedure is quick and usually not painful. Transvaginal ultrasound can also be used to measure the thickness of the endometrium (ACOG, 2015d). (Women who are postmenopausal should have a very thin endometrium due to low levels of estrogen; a thicker lining warrants further investigation.) A biopsy or aspiration for tissue pathology is diagnostic.

Cytologic Test for Cancer (Pap Smear)

The Papanicolaou (Pap) smear is used to detect cervical cancer. Cervical secretions are gently removed from the cervical os and may be transferred to a glass slide and fixed immediately by spraying with a fixative or immersed in solution. If the Pap smear reveals atypical cells, the liquid method allows for HPV testing.

Terminology used to describe findings includes the following categories:

- No abnormal or atypical cells
- Atypical squamous cells of undetermined significance
- Inflammatory reactions and microbes identified
- Positive deoxyribonucleic acid (DNA) test for HPV
- Precancerous and cancerous lesions of the cervix identified

The patient may incorrectly assume that an abnormal Pap smear signifies cancer. If the Pap smear (liquid immersion method) shows atypical cells and no high-risk HPV types, the next Pap smear is performed in 1 year. If a specific infection is causing inflammation, it is treated appropriately, and the Pap smear is repeated. If the repeat Pap smear reveals atypical squamous cells with high-risk HPV types, colposcopy may be indicated. Pap smears that indicate precancerous lesions should be repeated in 4 to 6 months and colposcopy performed if the lesion has not resolved. Patients with Pap smears that indicate cancerous lesions require prompt colposcopy (Fischbach & Dunning, 2015).

If the Pap smear results are abnormal, prompt notification, evaluation, and treatment are crucial. Notification of patients is often the responsibility of nurses in a women's health care practice or clinic. Pap smear follow-up is essential because it can prevent cervical cancer. Interventions are tailored to meet the needs and health beliefs of the particular patient. Intensive telephone counseling, tracking systems, brochures, videos, and financial incentives have all been used to encourage follow-up. The nurse provides clear explanations and emotional support along with a carefully designed setting-specific follow-up protocol designed to meet the needs of the patient.

Colposcopy and Cervical Biopsy

If the cervical cytology screening result requires evaluation, a colposcopy is performed. The colposcope is an instrument with a magnifying lens that allows the examiner to visualize the cervix and obtain a sample of abnormal tissue for analysis (Fischbach & Dunning, 2015). Nurse practitioners and gynecologists require special training in this diagnostic technique.

After inserting a speculum and visualizing the cervix and vaginal walls, the examiner applies acetic acid to the cervix. Subsequent abnormal findings that indicate the need for biopsy

include leukoplakia (white plaque visible before applying acetic acid), acetowhite tissue (white epithelium after applying acetic acid), punctation (dilated capillaries occurring in a dotted or stippled pattern), mosaicism (a tilelike pattern), and atypical vascular patterns. If biopsy specimens show precancerous cells, the patient usually requires cryotherapy, laser therapy, or a cone biopsy (excision of an inverted tissue cone from the cervix).

Cryotherapy and Laser Therapy

Cryotherapy (freezing cervical tissue with nitrous oxide) and laser treatment are used in the outpatient setting. Cryotherapy may result in cramping and occasional feelings of faintness (vasovagal response). A watery discharge is normal for a few weeks after the procedure as the cervix heals; however, excessive bleeding, pain, or fever should be reported to the primary provider (Fischbach & Dunning, 2015).

Cone Biopsy and Loop Electrosurgical Excision Procedure

If endocervical curettage findings indicate abnormal changes or if the lesion extends into the canal, the patient may undergo a cone biopsy. This can be performed surgically or with a procedure called *loop electrosurgical excision procedure* (LEEP), which uses a laser beam (Fischbach & Dunning, 2015).

Usually performed in the outpatient setting, LEEP is associated with a high success rate in removal of abnormal cervical tissue. The gynecologist excises a small amount of cervical tissue, and the pathologist examines the borders of the specimen to determine if disease is present. A patient who has received anesthesia for a surgical cone biopsy is advised to rest for 24 hours after the procedure and to leave any vaginal packing in place until it is removed (usually the next day). The patient is instructed to report any excessive bleeding.

The nurse or primary provider provides guidelines regarding postoperative sexual activity, bathing, and other activities. Because open tissue may be potentially exposed to HIV and other pathogens, the patient is cautioned to avoid intercourse until healing is complete and verified at follow-up.

Endometrial (Aspiration) Biopsy

Endometrial biopsy, a method of obtaining endometrial tissue, is performed as an outpatient procedure. This procedure is usually indicated in cases of midlife irregular bleeding, postmenopausal bleeding, and irregular bleeding while taking hormone therapy (HT) or tamoxifen. A tissue sample obtained through biopsy permits diagnosis of cellular changes in the endometrium. The only absolute contraindication to an endometrial biopsy is the presence of a viable and desired pregnancy (Del Priore, 2015).

Women who undergo endometrial biopsy may experience slight discomfort. The examiner may apply a tenaculum (a clamplike instrument that stabilizes the uterus) after the pelvic examination and then inserts a thin, hollow, flexible suction tube (Pipelle or sampler) through the cervix into the uterus.

Findings on aspiration may include normal endometrial tissue, hyperplasia, or endometrial cancer. Simple hyperplasia is an overgrowth of the uterine lining and is usually treated with progesterone. Complex hyperplasia, which refers to overgrowth of cells with abnormal features, is a risk factor for uterine cancer and is treated with progesterone and careful follow-up. Women who are overweight, who are older than 45 years, who have a history of nulliparity and infertility, or who have a family history of colon cancer seem to be at higher risk for hyperplasia.

Dilation and Curettage

Dilation and curettage (D&C) may be diagnostic (identifies the cause of irregular bleeding) or therapeutic (often temporarily stops irregular bleeding). The cervical canal is widened with a dilator, and the uterine endometrium is scraped with a curette. The purpose of the procedure is to secure endometrial or endocervical tissue for cytologic examination, to control abnormal uterine bleeding, and as a therapeutic measure for incomplete abortion.

Because D&C is usually carried out under anesthesia and requires surgical asepsis, it is usually performed in the operating room. However, it may take place in the outpatient setting with the patient receiving a local anesthetic supplemented with diazepam (Valium) or midazolam (Versed).

The nurse explains the procedure, preparation, and expectations regarding postoperative discomfort and bleeding. The patient is instructed to void before the procedure. The patient is placed in the lithotomy position, the cervix is dilated with a dilating instrument, and endometrial scrapings are obtained by a curette. A perineal pad is placed over the perineum after the procedure, and excessive bleeding is reported. No restrictions are placed on dietary intake. If pelvic discomfort or low back pain occurs, mild analgesic medications usually provide relief. The primary provider indicates when sexual intercourse may be safely resumed. To reduce the risk of infection and bleeding, most gynecologists advise no vaginal penetration or use of tampons for 2 weeks.

Medical Management

Treatment for endometrial cancer consists of surgical staging, total or radical hysterectomy (discussed later in this chapter), and bilateral salpingo-oophorectomy and lymph node sampling. Laparoscopy or a robot-assisted laparoscopic surgery is less invasive than abdominal surgery (ACOG, 2015d). Lymph node sampling and visualization of the peritoneum can be accomplished in many women in this manner. Cancer antigen 125 (CA-125) levels must be monitored, because elevated levels are a significant predictor of extrauterine disease or metastasis. Depending on the stage, the therapeutic approach is individualized and is based on stage, type, differentiation, degree of invasion, and node involvement. Radiation may be used in the form of external-beam radiation or vaginal brachytherapy (ACOG, 2015d). Whole pelvis radiotherapy may be used if there is any spread beyond the uterus. Recurrent cancer usually occurs inside the vaginal vault or in the upper vagina, and metastasis usually occurs in lymph nodes or the ovary. Recurrent lesions in the vagina are treated with surgery and radiation. Recurrent lesions beyond the vagina are treated with hormonal therapy or chemotherapy. Progestin therapy is used frequently. Patients should be prepared for such side effects as nausea, depression, rash, or mild fluid retention with progestin therapy.

Cancer of the Vulva

Primary cancer of the vulva is rare, representing 5% of all gynecologic malignancies and 1% of cancer in women (Zweizig, Korets, & Cain, 2014). According to American Cancer Society (ACS, 2015a), more than 5150 new cases of vulvar carcinoma occur each year, with more than 1080 deaths. It is most common in women who are postmenopausal, although its incidence in younger women is increasing. Possible risk factors include smoking, HPV infection, HIV infection, and

immunosuppression. Squamous cell carcinoma accounts for most primary vulvar tumors. Less common are Bartholin gland cancer, vulvar sarcoma, and malignant melanoma. Little is known about what causes this disease; however, increased risk may be related to chronic vulvar irritation. In younger women, HPV infection may be implicated, especially types 16, 18, and 31. Prevention includes delaying onset of sexual activity to avoid early exposure to HPV, administration of the HPV vaccine, and avoidance of smoking. Regular pelvic examinations, Pap smears, and vulvar self-examination are helpful in early detection. Women with persistent irritation or itching should be encouraged to seek evaluation.

Clinical Manifestations

Vulvar cancers are rarely asymptomatic (Zweizig et al., 2014). Long-standing pruritus and soreness are the most common symptoms of vulvar cancer. Itching occurs in half of all patients with vulvar malignancy. Bleeding, dysuria, foul-smelling discharge, and pain may also be present and are usually signs of advanced disease. Cancerous lesions of the vulva are visible and accessible and grow relatively slowly. Early lesions appear as a chronic dermatitis; later, patients may note a lump that continues to grow and becomes a hard, ulcerated, cauliflower like growth. Biopsy should be performed on any vulvar lesion that persists, ulcerates, or fails to heal quickly with proper therapy. Vulvar malignancies may appear as a lump or mass, redness, or a lesion that fails to heal.

Medical Management

Vulvar intraepithelial lesions are preinvasive and are also called *vulvar carcinoma in situ.* They may be treated by local excision, laser ablation, application of chemotherapeutic creams, or cryosurgery.

When invasive vulvar carcinoma exists, treatment may include wide excision of the vulva and vulvectomy (removal of the vulva). An effort is made to individualize treatment, depending on the extent of the disease. A wide excision is performed only if lymph nodes are normal. More pervasive lesions require vulvectomy with deep pelvic node dissection. Vulvectomy is very effective at prolonging life but is frequently followed by complications (i.e., scarring, wound breakdown, leg swelling, vaginal stenosis, or rectocele). To reduce complications, only necessary tissue is removed. External-beam radiation may be used, resulting in sunburnlike irritation that usually resolves in 6 to 12 months. Laser therapy and chemotherapy are other possible treatment options.

If a widespread area is involved or the disease is advanced, a radical vulvectomy with bilateral groin dissection may be performed. Antibiotic and heparin prophylaxis may be prescribed preoperatively and continued postoperatively to prevent infection, DVT, and PE. Sequential compression devices (SCDs) are applied to reduce the risk of venous thromboembolism (VTE).

Although the role of systemic chemotherapy in the treatment of vulvar cancer remains to be determined, chemotherapy may be helpful when used in combination with radiation therapy in treatment for advanced disease. The combination of radiation and chemotherapy may reduce the size of the cancer, resulting in less extensive subsequent surgery (Zweizig et al., 2014).

Clinical trials to determine the most effective treatment are difficult to conduct because there are few patients with this condition. Morbidity with recurrence of the disease is high, and patterns of recurrence vary. Reconstruction after vulvectomy is performed by plastic surgeons when appropriate and desired.

Nursing Management

Obtaining the Health History

The health history is a valuable tool for establishing rapport with the patient. The reason the patient is seeking health care is apparent. What the nurse can tactfully elicit is the reason a delay, if any, occurred in seeking health care—for example, because of modesty, economics, denial, neglect, or fear (partners who are abusive sometimes prevent women from seeking health care). Factors involved in any delay in seeking health care and treatment may also affect recovery. The patient's health habits and lifestyle are assessed, and her receptivity to education is evaluated. Psychosocial factors are also assessed. Preoperative preparation and psychological support begin at this time.

Providing Preoperative Care

Relieving Anxiety

Prior to surgery, the patient must be allowed time to talk and ask questions. Fear often decreases when a woman who is to undergo wide excision of the vulva or vulvectomy learns that the possibility for subsequent sexual relations is good. The nurse reinforces the information the surgeon has given to the patient and addresses the patient's questions and concerns.

Preparing Skin for Surgery

Skin preparation may include cleansing the lower abdomen, inguinal areas, upper thighs, and vulva with chlorhexidine for several days before the surgical procedure. The patient may be instructed to do this at home.

Providing Postoperative Care

Relieving Pain

Because of the wide excision, the patient may experience severe pain and discomfort even with minimal movement. Therefore, analgesic agents are given preventively (i.e., around the clock at designated times) to relieve pain, increase the patient's comfort level, and allow mobility. Patient-controlled analgesia (see Chapter 9) may be used to relieve pain and promote patient comfort. Careful positioning using pillows usually increases comfort, as do soothing back rubs. A low Fowler position or, occasionally, a pillow placed under the knees reduces pain by relieving tension on the incision; however, efforts must be made to avoid pressure behind the knees, which increases the risk of DVT. Positioning the patient on her side, with pillows between her legs and against the lumbar region, provides comfort and reduces tension on the surgical wound.

Improving Skin Integrity

A pressure-reducing mattress may be used to prevent pressure ulcers. Moving from one position to another requires time and effort; the use of an overbed trapeze bar may help the patient move herself more easily. The extent of the surgical incision and the type of dressing are considered when choosing strategies to promote skin integrity. Intact skin needs to be protected from drainage and moisture. Dressings are changed as needed to ensure patient comfort, to perform wound care and irrigation (if prescribed), and to permit observation of the surgical site.

The wound is usually cleansed daily with warm, normal saline irrigations or other antiseptic solutions as prescribed, or a

transparent dressing may be in place over the wound to minimize exposure to the air and subsequent pain. The appearance of the surgical site and the characteristics of drainage are assessed and documented. After the dressings are removed, a bed cradle may be used to keep the bed linens away from the surgical site.

Supporting Positive Sexuality and Sexual Function

The patient who undergoes vulvar surgery usually experiences concerns about body image, sexual attractiveness, and functioning. Establishing a trusting nurse–patient relationship is important for the patient to feel comfortable with expressing her concerns and fears. The patient is encouraged to discuss her concerns with her sexual partner as well.

Because alterations in sexual sensation and functioning depend on the extent of surgery, the nurse needs to know about any structural and functional changes resulting from the surgery. Referral of the patient and her partner to a sex counselor may help them address these changes and resume satisfying sexual activity.

Monitoring and Managing Potential Complications

Location, extent, and exposure of the surgical site and incision put the patient at risk for contamination of the site, infection and sepsis. The patient is monitored closely for local and systemic signs and symptoms of infection: purulent drainage, redness, increased pain, fever, and increased white blood cell count. The nurse assists in obtaining specimens for culture if infection is suspected and administers antibiotic agents as prescribed. Hand hygiene—always a crucial infection-preventing measure—is of particular importance along with wearing masks whenever there is an extensive area of exposed tissue. Catheters, drains, and dressings are handled carefully with gloves on to avoid cross-contamination. A low-residue diet prevents straining on defecation and wound contamination.

The patient is at risk for complications of VTE, which include DVT and PE, because of the positioning required during surgery, postoperative edema, and the immobility needed to promote healing. SCDs are applied, and other prophylactic measures may be prescribed for patients at high risk. The patient is encouraged and reminded to perform ankle exercises to minimize venous pooling, which leads to VTE. The patient is encouraged and assisted in changing positions by using the overbed trapeze bar. Pressure behind the knees is avoided when positioning the patient, because this may increase venous pooling. The patient is assessed for signs and symptoms of DVT (leg pain, redness, warmth, edema) and PE (chest pain, tachycardia, dyspnea). Fluid intake is encouraged to prevent dehydration, which also increases the risk of DVT.

The extent of the surgical incision and possibly wide excision of tissue increase the risk of postoperative bleeding and hemorrhage. Pressure dressings are applied after surgery to minimize this risk.

Nursing Alert: The patient must be monitored closely for signs of hemorrhage and resulting hypovolemic shock. These signs may include decreased blood pressure; increased pulse rate; decreased urine output; decreased mental status; and cold, clammy skin.

If hemorrhage and shock occur, interventions include fluid replacement, blood component therapy, and vasopressor medications. Laboratory results (e.g., hematocrit and hemoglobin levels) and hemodynamic monitoring are used to assess the patient's response to treatment. Depending on the specific cause of hemorrhage, the patient may be returned to the operating room. See Chapter 8 for a detailed discussion of shock.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

Preparing the patient for hospital discharge begins before hospital admission. The patient and family are informed about what to expect during the immediate postoperative and recovery periods. Depending on the changes resulting from the surgery, the patient and her family may need instruction about wound care, urinary catheterization, and possible complications. The patient is encouraged to share her concerns and to assume increasing responsibility for her own care. She is encouraged and assisted in learning to care for the surgical site. A referral for transitional, home, or community-based care is made as indicated.

Nurses are in an ideal position to educate women about performing regular vulvar self-examinations. Using a mirror, patients can see what constitutes normal female anatomy and learn about changes that should be reported (e.g., lesions, ulcers, masses, and persistent itching). Nurses must urge women to seek health care if they notice anything abnormal, because vulvar cancer is one of the most curable of all malignant conditions.

Continuing and Transitional Care

Patients may be discharged early in their postoperative recovery to home or a subacute facility. During this phase, the patient's physical status and psychological responses to the surgery are assessed. In addition, the patient is assessed for complications and healing of the surgical site. During home visits, the nurse assesses the home to determine if modifications are needed to facilitate care. The home visit is used to reinforce previous education and to assess the patient's and the family's understanding of and adherence to the prescribed treatment strategies. Follow-up phone calls by the nurse to the patient between home visits are usually reassuring to the patient and family, who may be responsible for performing complex care procedures. Attention to the patient's psychological responses is important because the patient may become discouraged and depressed because of alterations in body image and a slow recovery. Communication between the nurse involved in the patient's immediate postoperative care and the home care nurse is essential to ensure continuity of care.

Cancer of the Vagina

Cancer of the vagina is uncommon, representing 1% to 3% of gynecologic cancers; it is usually squamous in origin (Beckmann et al., 2014). Malignant melanoma and sarcomas can occur. Most vaginal cancers are secondary and invasive at the time of diagnosis. Risk factors include previous cervical cancer, in utero exposure to diethylstilbestrol (DES), previous vaginal or vulvar cancer, previous radiation therapy, history of HPV, or pessary use. Any patient with previous cervical cancer should be examined regularly for vaginal lesions.

Vaginal pessaries, which are used to support prolapsed tissues, can be a source of chronic irritation. As such, they have been associated with vaginal cancer, but only when the devices were not cared for properly (i.e., the device was not cleaned regularly or the patient did not return to the primary provider regularly for vaginal examinations).

Patients often do not have symptoms but may report slight bleeding after intercourse, spontaneous bleeding, vaginal discharge, pain, and urinary or rectal symptoms (or both). Diagnosis is often by Pap smear. Encouraging close follow-up is the focus of nursing interventions with women who were exposed to DES in utero. Emotional support for mothers who received DES before its risks were discovered and their daughters who were exposed to DES in utero is essential.

Medical Management

Treatment of early lesions may include local excision, topical chemotherapy, or laser. Laser therapy is a common treatment option in early vaginal and vulvar cancer. Surgery for more advanced lesions depends on the size and the stage of the cancer. If radical vaginectomy is required, a vagina can be reconstructed with tissue from the intestine, muscle, or skin grafts. After vaginal reconstructive surgery and radiation, regular intercourse may be helpful in preventing vaginal stenosis. Water-soluble lubricants are helpful in reducing pain with intercourse (dyspareunia).

Following surgery, radiation therapy may be given by a variety of methods, including external-beam radiation, which is usually an outpatient procedure, or brachytherapy, which is internal radiation therapy. Internal radiation may be given with intracavitary radioactive material contained in a seed, wire, needle, or tube, which is placed into a cavity such as the uterus or vagina. Interstitial radiation is another type of internal radiation treatment in which the radioactive material is placed in or near the cancer but not into a body cavity and is used in cervical and ovarian malignancies. These treatments may be high dose for a short period or low dose, which may take longer. Treatment during hospitalization or during outpatient therapy depends on several factors, including the status of the patient and the mode of delivery.

Cancer of the Fallopian Tubes

Malignancies of the fallopian tube are the least common type of genital cancer (ACS, 2015a). Although this type of cancer can occur at any age, it is most common in women who are postmenopausal. Symptoms are often minimal, causing diagnosis to be made at an advanced stage (Beckmann et al., 2014). Symptoms include abdominal pain, abnormal bleeding, and vaginal discharge. An enlarged fallopian tube may be found on sonogram if dilated and fluid filled, or it may appear or be palpated as a mass. Surgery followed by radiation therapy is the usual treatment.

Cancer of the Ovary

Ovarian cancer is the leading cause of gynecologic cancer deaths worldwide including India. Despite careful physical examination, ovarian tumors are often difficult to detect because they are usually deep in the pelvis. No early screening mechanism exists at present. Tumor-associated antigens are helpful in determining follow-up care after diagnosis and treatment and to evaluate for recurrent disease but are not useful in early general screening (Beckmann et al., 2014).

Epidemiology

One in 70 women will develop ovarian cancer in her lifetime. The incidence of this type of cancer increases with age until 70 years, with most cases diagnosed by age 60 (Beckmann et al., 2014). The frequency of ovarian cancer is highest in industrialized countries and affects women of all races and ethnic backgrounds. Ovarian cancer has shown increased incidence rate in the recent years, and it is one of the most common malignancies affecting Indian women (Kaarthigeyan, 2012).

Family history is the most significant risk factor. Most cases are random, but 5% to 10% of ovarian cancers are familial (Beckmann et al., 2014). In most cases, the mutations are in the *BRCA1* gene and sometimes in the *BRCA2* gene. A family history in a first-degree relative (mother, daughter, or sister), older age, early menarche, late menopause, and obesity may increase the risk of ovarian cancer. However, most women who develop ovarian cancer have no known risk factors, and no definitive causative factors have been determined.

Patients with concerns about their family history should be referred to a cancer genetics center to obtain information and testing, if indicated. Women with inherited types of ovarian cancer tend to be younger when the diagnosis is made than the average age at the time of diagnosis. Hereditary nonpolyposis colorectal cancer (HNPCC, also known as Lynch syndrome) increases the risk of ovarian cancer 13-fold (Beckmann et al., 2014). Lifetime risk of developing ovarian cancer has been shown to be decreased by one half with long-term suppression (greater than 5 years) of ovulation through use of oral contraceptives (Beckmann et al., 2014).

Pathophysiology

Types of tumors include germ cell tumors, which arise from the cells that produce eggs and are the most common cause of ovarian cancer in women younger than 20 years (Beckmann et al., 2014); stromal cell tumors, which arise in connective tissue cells that produce hormones; and epithelial tumors, which originate from the outer surface of the ovary. Most ovarian cancers are epithelial in origin. Of the many different cell types in ovarian cancer, epithelial tumors constitute 90%. Germ cell and stromal tumors make up the other 10% (Beckmann et al., 2014).

Primary peritoneal carcinoma is closely related to ovarian cancer. Extraovarian primary peritoneal carcinoma (EOPPC) resembles ovarian cancer histologically and can occur in women with and without ovaries. Symptoms and treatment are similar. Because of the possibility of EOPPC, oophorectomy lessens the chance, but does not guarantee, that the patient will not develop carcinoma.

Clinical Manifestations

Symptoms of ovarian cancer are nonspecific and may include increased abdominal girth, pelvic pressure, bloating, back pain, constipation, abdominal pain, urinary urgency, indigestion, flatulence, increased waist size, leg pain, and pelvic pain. Symptoms are often vague, so many women tend to ignore them. Ovarian cancer is often silent, but enlargement of the abdomen from an accumulation of fluid is a common sign. All women with gastrointestinal symptoms without a known cause must be evaluated for potential ovarian cancer. Vague, undiagnosed, persistent gastrointestinal symptoms should alert the nurse to the possibility of an early ovarian malignancy. A palpable ovary in a woman who has gone through menopause is investigated immediately, because ovaries normally become smaller and less palpable after menopause.

Assessment and Diagnostic Findings

Any enlarged ovary must be investigated. Pelvic examination often does not detect early ovarian cancer, and pelvic imaging techniques are not always definitive. Ovarian tumors are classified as benign if there is no proliferation or invasion, borderline if there is proliferation but no invasion, and malignant if there is invasion. Of all new cases of ovarian tumors, 20% are classified as borderline and have low malignancy potential. However, by the time of diagnosis, most ovarian cancers are advanced (ACS, 2015a); (Beckmann et al., 2014).

Diagnostic test may include an MRI scan, transvaginal and pelvic ultrasound, chest x-rays, and a blood test for CA-125. An abdominal CT scan with and without contrast may be used to rule out metastasis (Beckmann et al., 2014).

Medical Management

Surgical Management

Surgical staging, exploration, and reduction of tumor mass are the basics of treatment. Surgical removal is the treatment of choice. Staging the tumor by the FIGO staging system is performed to guide treatment (see Chart 58-24). Likely treatment involves a total abdominal hysterectomy with removal of the fallopian tubes and ovaries and possibly the omentum (bilateral salpingo-oophorectomy and omentectomy), tumor debulking, para-aortic and pelvic lymph node sampling, diaphragmatic biopsies, random peritoneal biopsies, and cytologic washings. Postoperative management may include taxanes or platinum-based chemotherapy (discussed in the next section).

Borderline tumors resemble ovarian cancer but have much more favorable outcomes. Women diagnosed with this type of cancer tend to be younger (early 40s). A conservative surgical approach is used. The affected ovary is removed, but the uterus and the contralateral ovary may remain in place. Adjuvant therapy may not be warranted.

Pharmacologic Therapy

Chemotherapy is usually administered IV on an outpatient basis using a combination of platinum and taxane agents. Paclitaxel (Taxol) plus carboplatin (Paraplatin) are most often used because of their excellent clinical benefits and manageable toxicity. Leukopenia, neurotoxicity, and fever may occur.

Because paclitaxel often causes leukopenia, patients may need to take granulocyte colony-stimulating factor as well. Paclitaxel is contraindicated in patients with hypersensitivity to medications formulated in polyoxyethylated castor oil and in patients with baseline neutropenia. Because of possible adverse cardiac effects, paclitaxel is not used in patients with cardiac disorders. Hypotension, dyspnea, angioedema, and urticaria indicate severe reactions that usually occur soon after the first and second doses are given. Nurses who administer chemotherapy are prepared to assist in treating anaphylaxis. Patients should be prepared for inevitable hair loss.

Carboplatin may be used in the initial treatment and in patients with recurrence. It is used with caution in patients with renal impairment. Usually, six cycles are given. A positive clinical response is normalization of the tumor marker CA-125, negative CT results, and a normal physical and gynecologic examination.

Liposomal therapy, delivery of chemotherapy in a liposome, allows the highest possible dose of chemotherapy to the tumor target with a reduction in adverse effects. Liposomes are used as drug carriers because they are nontoxic, biodegradable, easily available, and relatively inexpensive. This encapsulated chemotherapy allows increased duration of action and better targeting. The encapsulation of doxorubicin (Doxil) lessens the incidence of nausea, vomiting, and alopecia. Patients must be monitored for bone marrow suppression and gastrointestinal and cardiac effects.

Combination IV and intraperitoneal chemotherapy is an option for some patients. However, this treatment is more toxic and side effects are more severe than regular chemotherapy (ACS, 2015c). Intraperitoneal chemotherapy is reserved for women with good kidney function (ACS, 2015c).

Genetic engineering and identification of cancer genes may make gene therapy a future possibility; gene therapy is under investigation. Emerging proteomic technologies (tissue-based protein analysis) look promising; they may allow earlier diagnosis and treatment decision making. New biomarkers need further validation, but protein signature patterns are now being tested. These technologies may result in individualized treatment strategies for epithelial ovarian cancer (ACS, 2015c).

Recurrence of ovarian cancer is common, and many patients may require treatment with multiple agents. Treatment is directed toward control of the cancer, maintenance of quality of life, and palliation. Liposomal preparations, intraperitoneal drug administration, anticancer vaccines, monoclonal antibodies directed against cancer antigens, gene therapy, and antiangiogenic treatments (to prevent formation of new blood vessels in an effort to halt growth of ovarian cancer) may be used in the treatment for recurrence.

Chart 58-24

Main Stages of Ovarian Cancer

I. Cancer is contained within the ovary (or ovaries).
II. Cancer is in one or both ovaries and has involved other organs (i.e., uterus, fallopian tubes, bladder, the sigmoid colon, or the rectum) within the pelvis.
III. Cancer involves one or both ovaries, and one or both of the following are present: (1) cancer has spread beyond the pelvis to the lining of the abdomen; (2) cancer has spread to lymph nodes.
IV. The most advanced stage of ovarian cancer. Cancer is in one or both ovaries. There is distant metastasis to the liver, lungs, or other organs outside the peritoneal cavity; ovarian cancer cells in the pleural cavity are evidence of stage IV disease.

Adapted from Beckmann, C. R., Ling, F. W., Herbert, W. N., et al. (Eds). (2014). Obstetrics and gynecology (7th ed.). Philadelphia, PA: Wolters Kluwer.

Nursing Management

Nursing measures involve those related to the patient's treatment plan, which may include surgery, chemotherapy, palliative care, or a combination of these. Nursing interventions after pelvic surgery to remove the tumor are similar to those after other abdominal surgeries. If ovarian cancer occurs in a young woman and the tumor is unilateral, it is removed. Childbearing, if desired, is encouraged in the near future. After childbirth, surgical reexploration may be performed, and the remaining ovary may be removed. If both ovaries are involved, bilateral oophorectomy is performed and chemotherapy follows.

Patients with advanced ovarian cancer may develop ascites and pleural effusion. Nursing care may include administering IV fluids prescribed to alleviate fluid and electrolyte imbalances, administering parenteral nutrition to provide adequate nutrition, providing postoperative care after intestinal bypass

to alleviate any obstruction, controlling pain, and managing drainage tubes. Comfort measures for women with ascites may include providing small frequent meals, decreasing fluid intake, administering diuretic agents, and providing rest. Patients with pleural effusion may experience shortness of breath, hypoxia, pleuritic chest pain, and cough. Thoracentesis is usually performed to relieve these symptoms. The patient with ovarian cancer often has complex needs and benefits from the assistance and support of an oncology clinical nurse specialist.

Hysterectomy

Hysterectomy is the surgical removal of the uterus to treat cancer, dysfunctional uterine bleeding, endometriosis, nonmalignant growths, persistent pain, pelvic relaxation and prolapse, and previous injury to the uterus. Hysterectomies have been steadily declining over the last decade as the number of other therapeutic options (i.e., laser therapy, endometrial ablation, UAE, and medications to shrink fibroid tumors) has increased (Wright, Herzog, Tsui, et al., 2013). Despite the decline in hysterectomies, it is still the most common gynecologic procedure affecting one in nine women in their lifetime; 90% of all hysterectomies are for benign causes (Clark-Pearson & Geller, 2013).

A total hysterectomy involves removal of the uterus and the cervix. Hysterectomy can be supracervical or subtotal, in which the uterus is removed but the cervix is spared. Radical hysterectomy involves removal of the uterus as well as the surrounding tissue, including the upper third of the vagina and pelvic lymph nodes. The procedure can be performed through the vagina, through an abdominal incision, or laparoscopically (in which the uterus is removed in sections through small incisions using a laparoscope). Malignant conditions usually require a total abdominal hysterectomy and bilateral salpingo-oophorectomy.

With advanced cancerwith extensive local spread pelvic exentration may be performed.Pelvic exentration is thesurgical procedure which involves removal of all the pelvic organs are removed including the genitourinary organs as well as rectum. Patients undergoing Pelvic exentration are at risk of pulmonary embolism (Grimes & Stattron, 2021). Patient may need Urinary or fecal diversion procedure. With advancement in diagnostic and preventice techniques pelvic exentration is rarely performed nowadays.

A laparoscopically assisted approach can also be used for vaginal hysterectomy. This procedure is performed as a short-stay procedure or ambulatory surgery in patients who are carefully selected. Robot-assisted hysterectomies are performed in more than 20% of cases, with similar outcomes compared to laparoscopic and vaginal methods at a higher cost (Ridgeway & Falcone, 2014).

Preoperative Management

Patients are advised to discontinue anticoagulant medications, NSAIDs such as aspirin, and vitamin E prior to surgery to reduce the risk of bleeding. Pregnancy is ruled out on the day of surgery. Prophylactic antibiotic agents may be given prior to surgery and discontinued the next day. Prevention of thromboembolic events is critical, and methods depend on the risk profile of the patient.

Postoperative Management

The principles of general postoperative care for abdominal surgery apply. Major risks are infection and hemorrhage. In addition, because the surgical site is close to the bladder, voiding problems may occur, particularly after a vaginal hysterectomy. Edema or nerve trauma may cause temporary loss of bladder tone (bladder atony), and an indwelling catheter may be inserted.

NURSING PROCESS

The Patient Undergoing a Hysterectomy

Assessment

The health history and the physical and pelvic examination are completed, and laboratory tests are performed. Additional assessment data include the patient's psychosocial responses, because the need for a hysterectomy may elicit strong emotional reactions. If the hysterectomy is performed to remove a malignant tumor, anxiety related to fear of cancer and its consequences adds to the stress of the patient and her family. Women who have had a hysterectomy may be at risk for psychological and physical symptoms. Alternatively, women may note improved physical and mental health after hysterectomy as troublesome symptoms may be alleviated.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety related to the diagnosis of cancer, fear of pain, possible perception of loss of femininity or childbearing potential
- Disturbed body image related to altered fertility and fears about sexuality and relationships with partner and family
- Acute pain related to surgery and other adjuvant therapy
- Deficient knowledge of the perioperative aspects of hysterectomy and postoperative self-care

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- VTE
- Bladder dysfunction
- Infection

Planning and Goals

The major goals may include relief of anxiety, acceptance of loss of the uterus, absence of pain or discomfort, increased knowledge of self-care requirements, and absence of complications.

Nursing Interventions

Relieving Anxiety

Anxiety stems from several factors: unfamiliar environment; the effects of surgery on body image and reproductive ability; fear of pain and other discomfort; and, possibly, feelings of embarrassment about exposure in the perioperative period. The nurse determines what the experience means to the patient and encourages her to verbalize her concerns. Throughout the preoperative, postoperative, and recovery periods, explanations are given about physical preparations and procedures that are performed.

Patient education addresses the outcomes of surgery, possible feelings of loss, and options for management of any symptoms that occur. Women vary in their preferences for

information and participation in decision making, including choice of treatment options, accurate and useful information at the appropriate time, support from their health care providers, and access to professional and lay support systems.

Improving Body Image

The patient may have strong emotional reactions to having a hysterectomy and personal feelings related to the diagnosis, views of significant others who may be involved (family, partner), religious beliefs, and fears about prognosis. Concerns such as the inability to have children and the effect on femininity may surface, as may questions about the effects of surgery on sexual relationships, function, and satisfaction. The patient needs reassurance that she will still have a vagina and that she can experience sexual activity after temporary postoperative abstinence while tissues heal. Information that sexual satisfaction and orgasm arise from clitoral stimulation rather than from the uterus reassures many women. Most women note some change in sexual feelings after hysterectomy, but they vary in intensity. In some cases, the vagina is shortened by surgery, and this may affect sensitivity or comfort.

When hormonal balance is upset, as often occurs with reproductive system disorders, the patient may experience depressed mood and heightened emotional sensitivity to people and situations. The nurse needs to approach and evaluate each patient individually in light of these factors. A nurse who exhibits interest, concern, and willingness to listen to the patient's fears will help the patient progress through the surgical experience.

Relieving Pain

Postoperative pain and discomfort are common. Therefore, the nurse assesses the intensity of the patient's pain and assists the patient with analgesia as prescribed. If the patient has abdominal distention or flatus, a rectal tube and application of heat to the abdomen may be prescribed. When abdominal auscultation reveals return of bowel sounds and peristalsis, additional fluids and a soft diet are permitted. Early ambulation facilitates the return of normal peristalsis.

Monitoring and Managing Potential Complications

Hemorrhage. Vaginal bleeding and hemorrhage may occur after hysterectomy. To detect these complications early, the nurse counts the perineal pads used or checks the incision site, assesses the extent of saturation with blood, and monitors vital signs. Abdominal dressings are monitored for drainage if an abdominal surgical approach has been used. In preparation for hospital discharge, the nurse gives prescribed guidelines for activity restrictions to promote healing and to prevent postoperative bleeding. Because many women may go home the day of surgery or within a day or two, they are instructed to contact the nurse or surgeon if bleeding is beyond what is expected, which should be minimal.

Venous Thromboembolism. Because of positioning during surgery, postoperative edema, and decreased activity postoperatively, the patient is at risk for DVT and PE. To minimize the risk, antiembolism stockings are applied. In addition, the patient is encouraged and assisted to change positions frequently, although pressure under the knees is avoided, and to exercise her legs and feet while in bed. The nurse helps the patient ambulate early in the postoperative period. The nurse also assesses for DVT (leg pain, redness, warmth, edema) and PE (chest pain, tachycardia, dyspnea). If the patient is being discharged home soon after surgery, she is instructed to avoid prolonged sitting in a chair with pressure at the knees, sitting with crossed legs, and inactivity. Furthermore, she is instructed to contact her primary provider if symptoms of DVT or PE occur.

Bladder Dysfunction. Because of possible difficulty in voiding postoperatively, occasionally an indwelling catheter may be inserted before or during surgery and is left in place in the immediate postoperative period. If a catheter is in place, it is usually removed shortly after the patient begins to ambulate. After the catheter is removed, urinary output is monitored; additionally, the abdomen is assessed for distention. If the patient does not void within a prescribed time, measures are initiated to encourage voiding (e.g., assisting the patient to the bathroom, pouring warm water over the perineum). If the patient cannot void, catheterization may be necessary. On rare occasions, the patient may be discharged home with the catheter in place and is instructed in its management.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The information provided to the patient is tailored to her needs. She must know what limitations or restrictions, if any, to expect. She is instructed to check the surgical incision daily and to contact her primary provider if redness or purulent drainage or discharge occurs. She is informed that her periods are now over but that she may have a slightly bloody discharge for a few days; if bleeding recurs after this time, it should be reported immediately. The patient is instructed about the importance of an adequate oral intake and of maintaining bowel and urinary tract function. The patient is informed that she is likely to recover quickly but that postoperative fatigue is not unusual.

The patient should resume activities gradually. This does not mean sitting for long periods, because doing so may cause blood to pool in the pelvis, increasing the risk of VTE. The nurse explains that showers are preferable to tub baths to reduce the possibility of infection and to avoid the dangers of injury that may occur when getting in and out of the bathtub. The patient is instructed to avoid straining, lifting, having sexual intercourse, or driving until permitted. Vaginal discharge, foul odor, excessive bleeding, any leg redness or pain, or an elevated temperature should be reported, and the nurse reinforces education regarding activities and restrictions.

Continuing and Transitional Care. Follow-up telephone contact provides the nurse with the opportunity to determine whether the patient is recovering without problems and to answer any questions that may have arisen. The patient is reminded about postoperative follow-up appointments. If the patient's ovaries were removed and she finds vasomotor symptoms troublesome, hormone therapy may be considered at a low dose for a short amount of time. The patient is reminded to discuss risks and benefits of hormone therapy and alternative therapies with her primary provider and gynecologic care provider. Decisions about use of hormone therapy need to be made individually in consultation with these providers.

Evaluation

Expected patient outcomes may include:

1. Experiences decreased anxiety
2. Has improved body image
   a. Discusses changes resulting from surgery with her partner
   b. Verbalizes understanding of her disorder and the treatment plan

c. Displays minimal depression or anxiety
3. Experiences minimal pain and discomfort
   a. Reports relief of abdominal pain and discomfort
   b. Ambulates without pain
4. Verbalizes knowledge and understanding of self-care
   a. Practices deep-breathing, turning, and leg exercises as instructed
   b. Increases activity and ambulation daily
   c. Reports adequate fluid intake and adequate urinary output
   d. Identifies reportable symptoms
   e. Schedules and keeps follow-up appointments
5. Absence of complications
   a. Has minimal vaginal bleeding and exhibits normal vital signs
   b. Ambulates early
   c. Notes no chest or calf pain and no redness, tenderness, or swelling in the extremities
   d. Reports no urinary problems or abdominal distention

Radiation Therapy

Radiation may be used in the treatment of cervical, uterine, and less frequently in ovarian cancers either alone or in combination with surgery and chemotherapy. Several approaches are used to deliver radiation to the female reproductive system: external radiation, intraoperative radiation therapy (IORT), and internal (intracavitary) irradiation or brachytherapy (Halperin, Wazer, Perez, et al. 2013). The cervix and uterus can serve as a receptacle for radioactive sources for internal radiation therapy.

Methods of Radiation Therapy

External Radiation Therapy

This method of delivering radiation destroys cancerous cells at the skin surface or deeper in the body. Other methods of delivering radiation therapy are more commonly used to treat cancer of the female reproductive system than this method.

Intraoperative Radiation Therapy

IORT allows radiation to be applied directly to the affected area during surgery. An electron beam is directed at the disease site. This direct-view irradiation may be used when para-aortic nodes are involved or for unresectable (inoperable) or partially resectable neoplasms. Benefits include accurate beam direction (which precisely limits the radiation to the tumor) and the ability during treatment to block sensitive organs from radiation. IORT is usually combined with external-beam irradiation pre- or postoperatively.

Internal (Intracavitary) Irradiation

After the patient receives an anesthetic agent and an examination, specially prepared applicators are inserted into the endometrial cavity and vagina. These devices are not loaded with radioactive material until the patient returns to her room. X-rays are obtained to verify the precise relationship of the applicator to the normal pelvic anatomy and to the tumor. When this step is completed, the radiation oncologist loads the applicators with predetermined amounts of radioactive material. This procedure, called *afterloading*, allows for precise control of the radiation exposure received by the patient, with minimal exposure of physicians, nurses, and other health care personnel. A patient undergoing internal radiation treatment remains isolated in a private room until the application is completed. Adjacent rooms may need to be evacuated and a lead shield placed at the doorway to the patient's room.

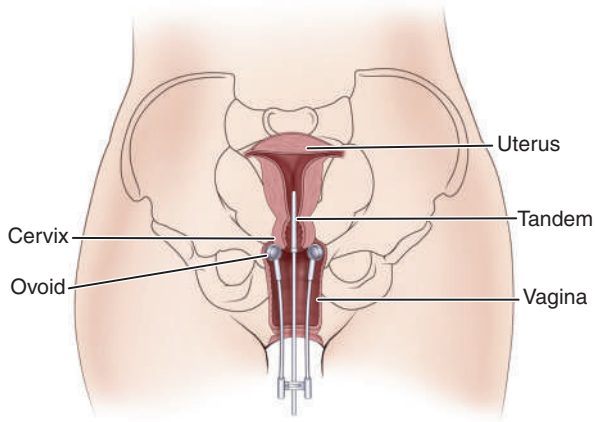

Figure 58-18 • Placement of tandem and ovoids for internal radiation therapy.

Of the various applicators developed for intracavitary treatment, some are inserted into the endometrial cavity and endocervical canal as multiple small irradiators (e.g., Heyman capsules). Others consist of a central tube (a tandem or intrauterine "stem") placed through the dilated endocervical canal into the uterine cavity, which remains in a fixed relationship with the irradiators placed in the upper vagina on each side of the cervix (vaginal ovoids) (see Fig. 58-18).

When the applicator is inserted, an indwelling urinary catheter is also inserted. Vaginal packing is inserted to keep the applicator in place and to keep other organs, such as the bladder and rectum, as far from the radioactive source as possible. The objective of the internal treatment is to maintain the distribution of internal radiation at a fixed dosage throughout the application, which may last 24 to 72 hours, depending on dose calculations made by the radiation physicist.

Automated high-dose rate intracavitary brachytherapy systems have been developed that allow outpatient radiation therapy. Treatment time is shorter, thereby decreasing patient discomfort. Staff exposure to radiation is also avoided. Isotopes of radium and cesium are used for intracavitary irradiation.

Nursing Considerations for Radiation Safety

Special precautions for the safety of the patient and the nurse are important considerations when the patient is receiving radiation therapy. The radiation safety department will identify specific safety precautions to those people who will be in contact with the patient, including health care providers and family. Nursing concerns include providing the patient with emotional support and physical comfort. Further details about nursing management are provided in the earlier part of this chapter.

Atomic Energy Regulatory Board (AERB) Norms and Radiation Safety

The cancer care centers intending to start a radiation therapy unit need to obtain the license to run the unit by adhering to the guidelines before installation as prescribed by the AERB. In the radiation therapy unit, the hazardous radiation source materials are used. Any unintentional exposure during therapy or while handling by health care professionals leads to cancer. The installation of the linear accelerator or brachytherapy unit

and usage of radiation source-sealed or unsealed method of handling are clearly given by the AERB. The radiation source cannot be exposed to the environment even for seconds. Sealing is a method of containment of radiation activity within the lead coverings or radiation-impermeable devices.

The licensed health care facility has to adhere to the norms of construction of buildings. Before commissioning the teletherapy or brachytherapy units, etc., license of the AERB is mandatory. The facility has to house all the diagnostic and treatment facilities in one area where the public movement is minimum. The facility has to be built following all radiation safety norms in terms of thickness of the walls, ceiling, floor, etc. The straight entry into the radiation facility can possibly lead to unintentional radiation exposure to all passersby. The radiotherapy unit entrance needs to be accessible after crossing more than one or two turns in the corridors.

The ventilation, lighting, and air conditioning should be adequate. The doors of both the teletherapy and brachytherapy treatment rooms with remote afterloading need to have a proper door lock with warning light at the entrance to avert unintended entry of people into the treatment room. The light should glow in green while the device is off, yellow while the beam is on, and red while the radiation device is in transition.

A radiation zone monitor needs to be fixed at the entrance of the radiation facility. A warning message about entry restriction in different languages with radiation symbol needs to be fixed near the entrance of radiation unit.

The radiation source and the device should be handled by those licensed to do so. Maintenance of the devices also needs to be carried out only by those licensed to do it.

In the eventuality of any natural disaster such as flood or fire, appropriate safety measures need to be taken. The radiation therapy unit must always be prepared for emergency. At all times, the control room near the teletherapy unit must be ready with necessary devices and radiation monitoring instruments. All health care workers employed shall use the personal protective devices such as lead jacket and gloves while handling the source. Precautions must be taken to ensure that the radiation dose exposure is within acceptable limits.

All those employed in the radiotherapy unit shall wear the dosimeter badge and periodic evaluation is done for ensuring that safe limits are not exceeded. Pregnant women and children younger than 18 years shall not be allowed to enter the facility. The occupational exposure of radiation is expected not to exceed 20 mSv/year on an average dose for 5 years. In any single year, the maximum limit for exposure radiation is 30 mSv. All employees' records of annual exposure need to be maintained regularly. If anyone is found to have an exposure in excess of that recommended, he or she may be temporarily relieved from the area of exposure or may be given leave with pay.

Preparation, storage, and disposal of the radioactive source shall be done by competent personnel following the protocols with minimal exposure to self and the others. Post-brachytherapy, the linen, equipment, and other wastes generated from the facility have to be monitored for any contamination or loss of radiation source.

In case of teletherapy, the software utilized for control panel need to be periodically checked, updated, and monitored.

Safety Alerts for Nurses Working in Radiation Therapy Unit

Nurses working with patients receiving radiation need to wear the dosimeter. Wear personnel protective equipment. When handling patients with brachytherapy, ensure that the radiation source is retracted and the green light is on.

Radiation exposure can be minimized by minimizing the time spent near the source/patient and maximizing the distance between the source and self and shielding.

Organize all care activities and complete them at one stretch instead of interrupting the radiation treatment. This will help in reducing the radiation exposure.

Educate and follow the protocol in collecting the used materials, instruments, linen, and other things from the brachytherapy unit. It is considered as hazardous. Patients treated with systemic radiation have to be isolated and treated in a radiation-proof chamber or room. The feces and urine may contain the radioactive substance and should be handled with personal protective devices. Do not eat, drink, or apply cosmetics while working in the radiation therapy unit to prevent contamination. Avoid spillage of unprotected radiation sources.

Place laundry in a linen bag and save until surveyed and released by the radiation oncology or health physics department. Housekeeping staff may not enter the room unless escorted by a nurse. Only essential cleaning may be carried out.

Cancer Survivorship

Advances in cancer screening, treatment, and management of complications have contributed to a lengthened survival period for many, with long-term survival becoming possible for many patients. *Cancer survivorship* has been defined as the period from cancer diagnosis through the remaining years of life and focuses on the health and life of a person beyond diagnostic and treatment phases. Although individuals vary and many types of cancers and treatments exist, the acute, long-term, and late effects of cancer and its treatment may have multiple long-term physical, cognitive, psychological, social, and financial consequences that can impact activities of daily living, ultimately affecting quality of life (Given, 2015).

Survivorship care is often based on expert opinion and experience rather than on evidence-based practices. Knowledge regarding survivorship concerns continues to evolve. The Institute of Medicine has identified four components of survivorship care, the period that follows primary treatment for cancer and lasts until end of life. In addition to a summary of prior diagnosis and treatment, survivorship care includes monitoring and treatment for late effects related to disease and prior treatments, physical and vocational rehabilitation, psychosocial support and counseling as necessary, and surveillance and screening for new and recurrent cancer (Hewitt, Greenfield, & Stovall, 2006) (see Table 58-20). Advocacy organizations across the country have recommended that a survivorship care plan be provided to all patients with cancer and their primary provider at the completion of treatment. The survivorship care plan includes a summary of cancer diagnosis and treatment and recommendations for follow-up and care, including approaches to treat symptoms, rehabilitative needs, monitoring for late effects, and surveillance and screening for new and recurrent cancer. Referrals for specific services such as lymphedema therapy, chronic pain management, and genetic counseling are also provided. Nurses assist in the development of the survivorship care plan and provide education and care for cancer survivors. Nurses, other health care providers, public health professionals, and patient advocates design and conduct research to identify needs of cancer survivors and evidence-based approaches to care.

TABLE 58-20 Components of Survivorship Care

Component	Examples of Care
Prevention and detection of new and recurrent cancer	• Mammography (per ACS guidelines) • Papanicolaou (Pap) smears (per ACS guidelines) • Smoking cessation programs • Nutrition counseling
Surveillance for cancer spread, recurrence, or second cancers	• Colonoscopy post colon cancer • Mammography post breast cancer • Liver function tests post colon cancer • Prostate-specific antigen post prostate cancer
Intervention for consequences of cancer and its treatments	• Lymphedema therapy • Pain management • Enterostomal therapy • Fertility care • Psychosocial support or counseling • Reconstructive surgery
Coordination between specialists and primary providers to meet health needs	• Care for comorbidities (e.g., diabetes) • Influenza vaccination • Bone densitometry • Monitoring for chemotherapy induced cardiotoxicity

Providing Care to the Patient with Advanced Cancer

Providing Care in Oncologic Emergencies

Table 58-21 discusses selected nursing and medical care of oncologic emergencies.

As a result of advances in all aspects of cancer care, it is more common that individuals are living with cancer that has advanced beyond the original site of development to regional or distant sites. Patients with advanced cancer are likely to experience many of the problems described previously, although more often and to a greater degree. Symptoms of pain, anorexia, weight loss, CACS, fatigue, and impaired functional status and mobility make patients more susceptible to depressive symptoms, skin breakdown, fluid and electrolyte imbalances, and infection.

Treatment for the patient with advanced cancer is likely to be palliative rather than curative, with an emphasis on prevention and appropriate management of pain. The use of long-acting analgesic agents at set intervals, rather than on an "as needed" basis, is recommended in addressing pain management. Working with the patient and family, as well as with other health care providers, to manage pain is essential to increase the patient's comfort and offer some sense of control. Other medications (e.g., sedatives, tranquilizers, muscle relaxants, antiemetics) are added to assist in palliating additional symptoms and promoting quality of life.

If the patient is a candidate for radiation therapy or surgical interventions to relieve pain or other symptoms, the potential benefits and risks of these procedures (e.g., percutaneous nerve block, cordotomy) are explained to the patient and family.

TABLE 58-21 Oncologic Emergencies: Manifestations and Management

Emergency	Clinical Manifestations and Diagnostic Findings	Management
Superior Vena Cava Syndrome (SVCS) Compression or invasion of the superior vena cava by tumor; enlarged lymph nodes; intraluminal thrombus that obstructs venous circulation; or drainage of the head, neck, arms, and thorax. Most often associated with lung cancer, SVCS is also associated with lymphoma, thymoma, and testicular cancers and mediastinal metastases from breast cancer. If untreated, SVCS may lead to cerebral anoxia (because not enough oxygen reaches the brain), laryngeal edema, bronchial obstruction, and death.	**Clinical** Gradually or suddenly impaired venous drainage giving rise to: • Progressive shortness of breath (dyspnea), cough, hoarseness, chest pain, and facial swelling • Edema of the neck, arms, hands, and thorax and reported sensation of skin tightness, difficulty swallowing, and stridor • Possibly engorged and distended jugular, temporal, and arm veins • Dilated thoracic vessels causing prominent venous patterns on the chest wall • Increased intracranial pressure, associated visual disturbances, headache, and altered mental status **Diagnostic** Diagnosis is confirmed by: • Clinical findings • Chest x-ray • Thoracic computed tomography (CT) scan • Thoracic magnetic resonance imaging (MRI) • Venogram if intraluminal thrombosis is suspected	**Medical** • Radiation therapy to shrink tumor or enlarged lymph nodes and relieve symptoms • Chemotherapy for sensitive cancers (e.g., lymphoma, small cell lung cancer) or when the mediastinum has been irradiated to maximum tolerance • Anticoagulant or thrombolytic therapy for central venous catheter related intraluminal thrombosis • Percutaneously placed intravascular stents may be priority consideration rather than surgery unless symptoms are rapidly progressing. • Supportive measures such as oxygen therapy, corticosteroids, and diuretics (in cases of fluid overload) **Nursing** • Identify patients at risk for SVCS. • Provide patient education regarding signs and symptoms to report • Monitor and report clinical manifestations of SVCS. • Monitor cardiopulmonary and neurologic status. • Avoid upper extremity venipuncture and blood pressure measurement; instruct patient to avoid tight or restrictive clothing and jewelry on fingers, wrist, and neck.

(Continued)

(Continued)

		• Facilitate breathing and drainage from upper portion of body by instructing patient to maintain some elevation of head and upper body with semi-Fowler position; avoid completely supine or prone position (this helps to promote comfort and reduce anxiety associated with dependent and progressive edema). • Promote energy conservation to minimize shortness of breath. • Monitor the patient's fluid volume status; administer fluids cautiously to minimize edema. • Assess for thoracic radiation-related problems such as mucositis with resultant dysphagia (difficulty swallowing) and esophagitis. • Monitor for chemotherapy-related problems, such as myelosuppression. • Provide postoperative care as appropriate.
Spinal Cord Compression Most commonly caused by compression of the cord and its nerve roots by a metastatic paravertebral tumor that extends into the epidural space; vertebral bone metastasis leading to bone collapse and displacement impinging on the spinal cord or nerve roots; and less commonly, primary malignancy of the cord. May potentially lead to significant and permanent neurologic impairment associated with multiple physical, psychosocial consequences. Most often associated with cancers that metastasize to the bone such as breast, lung, and prostate cancers and lymphoma. Also seen in nasopharyngeal cancer and multiple myeloma. About 70% of compressions occur at the thoracic level, 20% in the lumbosacral level, and 10% in the cervical and sacral regions. The prognosis depends on the severity and rapidity of onset.	**Clinical** • Local inflammation, edema, venous stasis, and impaired blood supply to nerve tissues • Local or radicular back or neck pain along the dermatomal areas innervated by the affected nerve root (e.g., thoracic radicular pain extends in a band around the chest or abdomen) • Pain exacerbated by movement, supine recumbent position, coughing, sneezing, or the Valsalva maneuver • Neurologic dysfunction and related motor and sensory deficits (numbness, tingling, feelings of coldness in the affected area, inability to detect vibration, loss of positional sense) • Motor loss ranging from subtle weakness to flaccid paralysis • Bladder and/or bowel dysfunction depending on level of compression (above S2, overflow incontinence; from S3 to S5, flaccid sphincter tone and bowel incontinence). **Diagnostic** • Percussion tenderness at the level of compression • Abnormal reflexes • Sensory and motor abnormalities • MRI is a preferred diagnostic tool; may also utilize x-rays, bone scans, and CT scan.	**Medical** • Radiation therapy to reduce tumor size and halt progression; corticosteroid therapy to decrease inflammation and swelling at the compression site • Surgery to debulk tumor and stabilize the spine if symptoms progress despite radiation therapy or if vertebral fracture or bone fragments lead to additional nerve damage; surgery is also an option when the tumor is not radiosensitive or is located in an area that was previously irradiated. • Minimally invasive surgical procedures, referred to as vertebral augmentation, may be used for patients with vertebral fractures to attain stability of the bone, prevent nerve compression, and decrease pain. Procedures include: • Vertebroplasty: involves percutaneous injection of polymethyl methacrylate (PMMA), a bone cement filler, into the vertebral body • Kyphoplasty: a balloon is inserted into the damaged vertebral body and then inflated to create a cavity within the bone that can be filled with bone cement. The balloon helps to compress the fracture fragments together as the cavity is created. • Radiofrequency vertebral augmentation: similar to kyphoplasty; instead of the balloon, a small navigational canula is inserted into the vertebra to create small pathways for cement. The cement is heated with radiofrequency to create an ultra high viscosity that is thought to promote bone stability • Chemotherapy as adjuvant to other local therapies for patients with chemosensitive cancers such as lymphoma or small cell lung cancer • *Note:* Despite treatment, patients with poor neurologic function before treatment are less likely to regain complete motor and sensory function; patients who develop complete paralysis usually do not regain all neurologic function. **Nursing** • Perform ongoing assessment of neurologic function to identify existing and progressing dysfunction. • Control pain with pharmacologic and nonpharmacologic measures. • Prevent complications of immobility resulting from pain and decreased function (e.g., skin breakdown, urinary stasis, thrombophlebitis, decreased clearance of pulmonary secretions).

(Continued)

(Continued)

		• Maintain muscle tone by assisting with range-of-motion exercises in collaboration with physical and occupational therapists; patients with unstable vertebral fractures do not initiate physical therapy until spine stabilization procedures have been completed. • Institute intermittent urinary catheterization and bowel training programs for patients with bladder or bowel dysfunction. • Provide encouragement and support to patient and family coping with pain and altered functioning, lifestyle, roles, and independence. • Institute appropriate referrals for home care and physical and occupational therapy.
Hypercalcemia Hypercalcemia is a potentially life-threatening metabolic abnormality resulting when the calcium released from the bones is more than the kidneys can excrete or the bones can reabsorb. • It may result from production of cytokines, hormonal substances, and growth factors by cancer cells, or by the body in response to substances produced by cancer cells, which lead to bone breakdown and calcium release. • Most commonly seen in breast, lung, and renal cancers; myeloma; and some types of leukemia	**Clinical** Fatigue, weakness, confusion, decreased level of responsiveness, hyporeflexia, nausea, vomiting, constipation, ileus, polyuria (excessive urination), polydipsia (excessive thirst), dehydration, and dysrhythmias **Diagnostic** Total serum calcium level >10.5 mg/dL (2.74 mmol/L) Ionized serum calcium >1.29 mmol/L	**Medical** • Identify patients at risk for hypercalcemia and assess for signs and symptoms of hypercalcemia. • Educate patient and family; prevention and early detection can prevent fatality. • Educate at-risk patients to recognize and report signs and symptoms of hypercalcemia. • Provide patient and family education regarding: • Need to consume 2–4 L of fluid daily unless contraindicated by existing renal or cardiac disease • Use of dietary and pharmacologic interventions such as stool softeners and laxatives for constipation • Maintenance of nutritional intake without restricting normal calcium intake • Antiemetic therapy for nausea and vomiting • Promotion of mobility and emphasis on importance in preventing demineralization and breakdown of bones • Safety precautions for patients with impaired mental and mobility status
Tumor Lysis Syndrome (TLS) Potentially fatal complication that occurs spontaneously or more commonly following radiation, biotherapy, or chemotherapy-induced cell destruction of large or rapidly growing cancers such as leukemia, lymphoma, and small cell lung cancer. The release of tumor intracellular contents (nuclei acids, electrolytes, and debris) leads to rapidly induced electrolyte imbalances—hyperkalemia, hyperphosphatemia (leading to hypocalemia), and hyperuricemia—that can have life-threatening end-organ effects on the myocardium, kidneys, and central nervous system	**Clinical** Clinical manifestations depend on the extent of metabolic abnormalities. Clinical TLS is diagnosed when ≥1 of 3 conditions arise either 3 days prior to or 7 days after cytotoxic cancer therapy: acute kidney injury (defined as a rise in creatinine to ≥1.5 times the upper limit of normal that is not attributable to medications), dysrhythmias (including sudden cardiac death), and seizures. • *Neurologic:* Fatigue, weakness, memory loss, altered mental status, muscle cramps, tetany, paresthesias (numbness and tingling), seizures • *Cardiac:* Elevated blood pressure, shortened QT complexes, widened QRS waves, altered T waves, dysrhythmias, cardiac arrest • GI: Anorexia, nausea, vomiting, abdominal cramps, diarrhea, increased bowel sounds • Renal: Flank pain, oliguria, anuria, kidney injury, acidic urine pH • Other: Gout, malaise, pruritis **Diagnostic** • Electrolyte imbalances identified by serum electrolyte measurement and urinalysis (see Chapter 7); electrocardiogram to detect cardiac dysrhythmias	**Medical** • To prevent kidney injury and restore electrolyte balance, aggressive fluid hydration is initiated 24–48 hours before and after the initiation of cytotoxic therapy to increase urine volume and eliminate uric acid and electrolytes; urine is alkalinized by adding sodium bicarbonate to IV fluid to maintain a urine pH of 7–7.5; this prevents kidney injury secondary to uric acid precipitation in the kidneys. • Diuresis with a loop diuretic or osmotic diuretic if urine output is not sufficient • Allopurinol (Zyloprim) therapy to inhibit the conversion of nucleic acids to uric acid; rasburicase (Elitek) may be used to convert already formed uric acid to allantoin, which is highly water soluble and eliminated in urine. • Administration of a cation-exchange resin, such as sodium polystyrene sulfonate (Kayexalate), to treat hyperkalemia by binding and eliminating potassium through the bowel • Administration of IV sodium bicarbonate, hypertonic dextrose, and regular insulin temporarily shifts potassium into cells and lowers serum potassium levels if a rapid decrease in potassium is necessary. • Administration of phosphate-binding gels, such as aluminum hydroxide, to treat hyperphosphatemia by promoting phosphate excretion in the feces

(Continued)

(Continued)

	• Hemodialysis when patients are unresponsive to the standard approaches for managing uric acid and electrolyte abnormalities. • Identify at-risk patients. • Institute essential preventive measures (e.g., fluid hydration, medications) as prescribed. • Assess patient for signs and symptoms of electrolyte imbalances. • Assess urine pH to confirm alkalization. • Monitor serum electrolyte and uric acid levels for evidence of fluid volume overload secondary to aggressive hydration. • Instruct patients to monitor for and report symptoms indicating electrolyte disturbances.

MRI, magnetic resonance imaging; CT, computed tomography.

Cancer: Principles & Practice of Oncology. Philadelphia, PA: Lippincott Williams & Wilkins.

Measures are taken to prevent complications that result from altered sensation, immobility, and changes in bowel and bladder function.

Weakness, altered mobility, fatigue, and inactivity typically increase with advanced cancer as a result of the disease, treatment, inadequate nutritional intake, or dyspnea. The nurse works with the patient and family to identify realistic goals and promote comfort. Measures include use of energy conservation methods to accomplish tasks and activities that the patient values most.

Efforts are made to provide the patient with as much control and independence as desired but with assurance that support and assistance are available when needed. In addition, health care teams work with the patient and family to ascertain and comply with the patient's wishes about treatment methods and care as the terminal phase of illness and death approach.

Hospice

The needs of patients with end-stage illness are best met by a comprehensive interdisciplinary specialty program that focuses on quality of life; palliation of symptoms; and provision of physical, psychosocial, and spiritual support for patients and families when cure and control of the disease are no longer possible. The concept of hospice best addresses these needs.

Hospice care is often delivered through coordination of specialty services provided by hospitals, home care programs, and the community. Patients need to be referred to hospice services in a timely fashion so that complex patient and family needs can be addressed. (See Chapter 59 for detailed discussion of end-of-life care.)

CRITICAL THINKING EXERCISES

1. A 63-year-old man previously treated for stage III prostate cancer with HDR brachytherapy and androgen deprivation therapy returns to the cancer center for a follow-up visit. While you are assessing his vital signs, he tells you that he has been having back pain for the last 3 weeks that he attributes to sleeping on an old mattress. What are the priorities to include in your nursing assessment of this patient? Identify the diagnostic procedures that you anticipate will be required to further evaluate this patient's back pain. What are your priorities for care of this patient?
2. An 80-year-old woman, who lives alone, was just recently diagnosed with stage IV colon cancer. She is being discharged from the hospital following a palliative colon resection. What will be the focus of educating this patient for self-care? Describe at least three age-related implications that will be important to consider. What type of referrals might be appropriate for this woman?
3. You are caring for a 32-year-old woman who is a breast cancer survivor. The patient takes tamoxifen 20 mg orally once daily and this will continue for the next 5 years. Are there any preventive measures that should be considered to address survivorship needs? What is the evidence for these interventions and education that you identified? How strong is that evidence, and what criteria did you use to assess the strength of that evidence?
4. A 43-year-old lady Mrs. J is diagnosed with cancer in the cervix and she is subjected to radical hysterectomy surgery followed by pelvic irradiation using teletherapy protocols. What are the priorities of care for Mrs. J? What are the evidence-based interventions you may plan for her?

CHAPTER 59

Palliative Care and End-of-Life Care

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1 Discuss the historical, legal, and sociocultural perspectives of palliative and end-of-life care.
2 Define palliative and end-of-life care.
3 Explain the current scenario of palliative care in India.
4 Compare and contrast the settings where palliative care and end-of-life care are provided.
5 Describe the principles and components of hospice care.
6 Identify barriers to improving care at the end of life.
7 Reflect on personal experience with and attitudes toward death and dying.
8 Apply skills for communicating with seriously ill patients and their families.
9 Provide culturally and spiritually sensitive care to seriously ill patients and their families.
10 Implement nursing measures to manage physiologic responses to terminal illness.
11 Support imminently dying patients and their families.
12 Identify components of uncomplicated grief and mourning and implement nursing measures to support patients and families.

GLOSSARY

assisted suicide: providing another person the means to end their own life
autonomy: self-determination; in the health care context, the right of the individual to make choices about the use and discontinuation of medical interventions
bereavement: period during which mourning for a loss takes place
euthanasia: Greek for "good death"; has evolved to mean the intentional killing by act or omission of a dependent human being for their alleged benefit
grief: personal feelings that accompany an anticipated or actual loss
hospice: a coordinated program of interdisciplinary care and services for terminally ill patients and their families that in the United States is provided primarily in the home
interdisciplinary collaboration: communication and cooperation among members of diverse health care disciplines jointly to plan, implement, and evaluate care
mourning: individual, family, group, and cultural expressions of grief and associated behaviors
palliative care: philosophy of and system for delivering care that expands on traditional medical care for serious, progressive illness to include a focus on quality of life, function, decision making, and opportunities for personal growth
palliative sedation: the use of pharmacologic agents, at the request of the terminally ill patient or the patient's legal proxy, to induce sedation, or near-sedation, when symptoms have not responded to other management measures; the purpose is not to hasten the patient's death but to relieve intractable symptoms
prognosis: the expected course of an illness and the chance for recovery
spirituality: personal belief systems that focus on a search for meaning and purpose in life, intangible elements that impart meaning and vitality to life, and a connectedness to a higher or transcendent dimension
terminal illness: progressive, irreversible illness that despite cure-focused medical treatment will result in the patient's death

Introduction

Nurses can have a significant and lasting effect on the way patients live until they die, the manner in which the death occurs, and the enduring memories of that death for the families. The contemporary definition of nursing includes "…the diagnosis and treatment of human responses, and advocacy in the care of individuals, families, groups, communities, and populations" (American Nurses Association [ANA], 2015), p. 1). There may be no group more important than seriously ill and dying patients.

Knowledge about palliative and end-of-life principles of care and patients' and families' unique responses to illness is essential to supporting their unique values and goals. Nurses have an opportunity to bring research, education, and practice together to impact the culture of dying, bringing much-needed improvement to care that is relevant across practice settings, age groups, cultural backgrounds, and illnesses. The National Institute of Nursing Research established the Office of End-of-Life and Palliative Care Research (OEPCR) to further advance the science and coordinate research-related to end-of-life care within the National Institutes of Health (NIH). Nurses in all settings are likely to encounter seriously ill patients and families who can benefit from palliative care during advanced illness and at end of life. This chapter presents concepts about death and dying, settings for end-of-life care of the dying, and ways that nurses can address the health issues of terminally ill patients.

Nursing and End-of-Life Care

Death and Dying

Focus on care of the dying is motivated by the aging of the population, the prevalence of and publicity surrounding life-threatening illnesses, and the increasing likelihood of a prolonged period of chronic illness prior to death (e.g., cancer and noncancer diagnoses such as heart failure, chronic

obstructive pulmonary disease (COPD), and Alzheimer's disease). Although there are more opportunities than ever before to support peaceful death, the technologies that are often applied in advanced illness and at end of life continue to make the process of dying anything but peaceful. Patients, families, and clinicians may view death as what happens when medicine fails. This attitude places death and improvement of the dying process outside the focus of modern medicine and health care. Numerous initiatives aimed at improving end-of-life care have been launched in recent years.

In USA, the National Consensus Project for Quality Palliative Care (NCP, 2013) identified the following eight key domains underlying a more comprehensive and humane approach to care of the dying. These include:

- **Structure and processes of care:** The timely plan of care is based on a comprehensive interdisciplinary assessment of the patient and the family.
- **Physical aspects of care:** Pain, other symptoms, and side effects are managed based on the best available evidence, with attention to disease-specific pain and symptoms, which is skillfully and systematically applied.
- **Psychological and psychiatric aspects of care:** Psychological status is assessed and managed based on the best available evidence, which is skillfully and systematically applied. When necessary, psychiatric issues are addressed and treated.
- **Social aspects of care:** Comprehensive interdisciplinary assessment identifies the social needs of patients and their families, and a plan of care is developed to respond to these needs as effectively as possible.
- **Spiritual, religious, and existential aspects of care:** Spiritual and existential dimensions are assessed and responded to based on the best available evidence, which is skillfully and systematically applied.
- **Cultural aspects of care:** The palliative care program assesses and attempts to meet the needs of the patient, family, and community in a culturally sensitive manner.
- **Care of the patient at the end of life:** Signs and symptoms of impending death are recognized and communicated in developmentally appropriate language for children and patients with cognitive disabilities with respect to family preferences. Care appropriate to this phase of illness is provided to the patient and the family.
- **Ethical and legal aspects of care:** The patient's goals, preferences, and choices are respected within the limits of applicable state and federal law, within current accepted standards of medical care, and form the basis for the plan of care.

The practice guidelines specified under each of these domains have been endorsed by more than 50 national organizations such as the AARP (formerly known as the American Association for Retired Persons), American Cancer Society (ACS), Hospice and Palliative Nurses Association (HPNA), and the National Hospice and Palliative Care Organization (NHPCO) to structure and evaluate quality palliative and end-of-life programs.

In 2014, the Institute of Medicine (IOM) released a consensus report titled *Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life.* The report presents a summary of findings from a review of the evidence and recommendations for improving palliative and end-of-life care. The authors noted that patients experienced many transitions in settings, frequent and potentially avoidable hospital readmission, and inconsistent referral to palliative care. Recommendations include widespread and timely access to, and comprehensive coverage for palliative care services, improved communication between providers, greater emphasis on advance care planning, professional education and development, and stronger public education and engagement (IOM, 2014a). It is expected that such initiatives will also be followed in developing countries including India.

Technology and End-of-Life Care

In the 20th century, chronic, degenerative diseases replaced communicable diseases as the major causes of death. In the earlier part of the 20th century, most deaths occurred at home and most families had direct experience with death, providing care to family members at the end of life and then mourning their losses. As the place of death shifted from home to hospitals, families became increasingly distanced from the death experience.

The application of technology to prolong life raises numerous ethical issues. One major question is: Because we *can* prolong life through increasingly sophisticated technology, does it necessarily follow that we *must* do so? In the latter half of the 20th century, a "technologic imperative" practice pattern among health care professionals emerged, along with an expectation among patients and families that every available means to extend life must be tried.

In the 21st century, technological intervention at the end of life continues to have profound implications, affecting how clinicians care for the dying, how family and friends participate in care, how patients and families understand and choose among end-of-life care options, how families prepare for terminal illness and death, and how they heal after the death of a loved one.

Sociocultural Context

Although terminal illness, a progressive, irreversible illness that despite cure-focused medical treatment will result in the patient's death, is experienced uniquely by each person, it is also shaped by the broader social and cultural contexts in which it occurs. The new approach to serious illness has been described as "death denying"—that is, the health care system has been built on management of acute illness and the use of technology to cure (when possible) and to extend life. As a result, life-threatening illness, life-sustaining treatment decisions, dying, and death occur in a social environment in which illness is largely considered an enemy. Many common expressions reflect this dominant sociocultural view. For example, people talk about the "war" against cancer or "fighting" illness, and when patients choose not to pursue the most aggressive course of medical treatment available, many health care providers and indeed patients and families perceive this as "giving up." A care/cure dichotomy has persisted in which health care providers may view cure as the ultimate good and care as second best, a good only when cure is no longer possible. In such a model, alleviating suffering is not as valued as curing disease. Patients who cannot be cured feel distanced from the health care team, and when curative treatments have failed, they may feel that they too have failed. Patients and families may fear that any shift from curative goals to comfort-focused care will result in no care or lower-quality care, and that the clinicians on whom they have come to rely will abandon them if they withdraw from a focus on cure.

The statement in late-stage illness that exemplifies this care versus cure dichotomy is "nothing more can be done." This all-too-frequently used statement communicates the belief of

many clinicians that there is nothing of value to offer patients beyond cure; however, in a care-focused perspective, there is always more that can be done. This expanded notion of healing implies that healing can take place throughout life. There are many opportunities for physical, spiritual, emotional, and social healing, even as body systems begin to fail at the end of life.

Clinicians' Attitudes Toward Death

Clinicians' attitudes toward the terminally ill and dying remain the greatest barrier to improving care at the end of life. Kübler-Ross illuminated the concerns of the seriously ill and dying in her seminal work, *On Death and Dying,* first published in 1969. At that time, it was common for patients to be kept uninformed about life-threatening diagnoses, particularly cancer, and for physicians and nurses to avoid open discussion of death and dying with their patients. Kübler-Ross's work revealed that, given open discussion, adequate time, and some help in working through the process, patients could reach a stage of acceptance in which they were neither angry nor depressed about their fate (see later discussion).

Clinicians' reluctance to discuss disease and death openly with patients stems from their own anxieties about death as well as misconceptions about what and how much patients want to know about their illnesses. In an early study of care of the dying in hospital settings, sociologists Glaser and Strauss (1965) discovered that health care professionals in hospital settings avoided direct communication about dying in the hope that the patient would discover it on their own. They identified four "awareness contexts":

1. **Closed awareness:** The patient is unaware of their terminal state, whereas others are aware. Closed awareness may be characterized as a conspiracy between the family and the health care professionals to guard the "secret," fearing that the patient may not be able to cope with full disclosure about their status and the patient's acceptance of others' accounts of their "future biography" as long as the others give him or her no reason to be suspicious.
2. **Suspected awareness:** The patient suspects what others know and attempts to find out details about their condition. Suspected awareness may be triggered by inconsistencies in the family's and the clinician's communication and behavior, discrepancies between clinicians' accounts of the seriousness of the patient's illness, or a decline in the patient's condition or other environmental cues.
3. **Mutual pretense awareness:** The patient, the family, and the health care professionals are aware that the patient is dying, but all pretend otherwise.
4. **Open awareness:** The patient, the family, and the health care professionals are aware that the patient is dying and openly acknowledge that reality.

Glaser and Strauss (1965) also identified a pattern of clinician behavior in which those clinicians who feared or were uncomfortable discussing death developed and substituted "personal mythologies" for appraisals of what level of disclosure their patients actually wanted. For example, clinicians avoided direct communication with patients about the seriousness of their illness based on their beliefs that (1) patients already knew the truth or would ask if they wanted to know, or (2) patients would subsequently lose all hope, give up, or be psychologically harmed by disclosure.

Although Glaser and Strauss's findings were published decades ago, their observations remain valid today. The growth of palliative and hospice care programs has led to greater numbers of health care providers becoming comfortable with and skilled in assessing patients' and families' information needs and disclosing honest information about the seriousness of illness (Bernacki & Block, 2014). However, in many settings, clinicians still avoid the topic of death in the hope that patients will ask or find out on their own. Despite progress on many health care fronts, many who work with seriously ill and dying patients recognize a persistent conspiracy of silence about dying.

How to communicate truthfully with patients and encourage patient autonomy (the right of the individual to make choices) in a way that acknowledges where they are on the continuum of acceptance is a challenge. Despite continued reluctance of health care providers to engage in open discussion about end-of-life issues, patients want information about their illness and end-of-life choices and are not harmed by open discussion about death (The Conversation Project, 2013); (Hoff & Hermeren, 2014). Timing of sensitive discussion takes experience, but speaking the truth can be a relief to patients and families, enhancing their autonomy by making way for truly informed consent as the basis for decision making. (See later section for detailed discussion of communication skills.)

Patient and Family Concerns

Patient and family denial about the seriousness of terminal illness has also been cited as a barrier to discussion about end-of-life treatment options. Yet, research demonstrates that denial can be a useful coping mechanism that enables the patient to gain temporary emotional distance from a situation that is too painful to contemplate fully (Benkel, Wijk, & Molander, 2010). Denial may become a *barrier* to care if patients or families refuse to acknowledge a diagnosis or refuse to hear about treatment options. Nurses must accept patients regardless of the degree to which they are in denial about their illness and work with other health care providers to present a consistent message.

Patient and family awareness of prognosis is a key factor in acceptance of and planning for death. Even patients and families who have received clear and honest information may not fully accept the situation. For patients who have been informed about terminal illness, their understanding of treatment goals and prognosis is dynamic and may sometimes require reinforcement.

Another concern is that patients' and their caregivers' understanding of treatment goals and prognosis can differ dramatically. In a study of patients receiving palliative radiation therapy for metastases, researchers found that 25% of patients believed that radiation therapy would cure the cancer and prolong their lives (Mitera, Zhang, Sahgal, et al., 2012). Such misunderstandings can complicate both delivery of effective care and informed consent for care.

Patients with noncancer diagnoses, such as heart failure, COPD, kidney injury, dementia, or neurodegenerative diseases such as amyotrophic lateral sclerosis, frequently do not receive adequate information and support to fully understand their prognosis, yet they often desire clear and honest information. For example, they may have troublesome symptoms and reduced quality of life paralleling or exceeding that of patients with cancer. Patients may want but are unlikely to receive clear information about disease progression, advance care planning, and prognosis. Research is needed to examine the complex interactions between patients' misconceptions about advanced

Chart 59-1 ETHICAL DILEMMA

What if a Patient Asks You to Help Her End Her Life?

Case Scenario

You are a hospice nurse making a first home visit to a 54-year-old woman, a registered nurse, with stage IV ovarian cancer with metastases to her lungs and liver. She now reports severe dyspnea and chest and abdominal pain that is increasing and unrelieved by any of the pharmacologic and nonpharmacologic interventions that have been tried. In addition, she appears grossly jaundiced and cachectic. Prior to her illness, she worked as a staff nurse in an oncology unit at a local hospital. She is married, with three children, one of whom is in college and studying nursing, and two of whom are in high school. The patient tells you "My oldest daughter is ready to enter her senior year of nursing school. She has told me she is going to drop out of school so she can take care of me and I don't want her to do that." She then tells you "I know what is in store for me and I don't want to go through that, and I do not want to ruin my daughter's career and her life. I want you to help me end things and if you do not, I will take care of ending things myself, on my own terms."

Discussion

Assisted suicide remains a highly controversial topic—is it a matter of personal choice (i.e., does it preserve the autonomy of those who are dying), or does it constitute homicide by health care professionals who should "first do no harm" (i.e., nonmaleficence)? At this time, five states in the United States (Oregon, Washington, Montana, Vermont, and California) legally permit physician-assisted suicide. However, the laws in these states include highly prescriptive criteria that must be present before a patient may be given a lethal prescription to end their own life. The American Nurses Association, in its *Euthanasia, Assisted Suicide, and Aid in Dying Position Statement* (ANA, 2013), acknowledges the importance of the patient's right to self-determination, advocates that nurses must deliver optimal, compassionate care but avows that the nurse must never deliberately end a patient's life by euthanasia or physician-assisted suicide.

Analysis

How might you proceed with providing further consultation or follow-up with this patient? Would this follow-up be based upon whether or not she resided in a state where physician-assisted suicide is legal? Would her state of residence have any effect on your personal decision-making process?

Further describe the ethical principles that are in conflict in this case and in other cases that surround requests for assisted suicide (see Chart 2-3). Which principle do you believe should have preeminence in deciding whether or not patients have the right to request assistance in suicide at the end of life? Identify other resources or referrals that could be made to assist this patient in her end-of-life care.

illness, their underlying psychological states, and barriers to clinicians' explanations of treatment expectations and prognosis.

Euthanasia

On 7 March 2018, the Supreme Court of India legalized passive euthanasia by means of the withdrawal of life support to patients in a permanent vegetative state (see Chart 59-1). The decision was made as part of the verdict in a case involving Aruna Shanbaug, who was in a persistent vegetative state (PVS) until her death in 2015.

In March 2015, the Supreme Court of India passed a historic judgement—law permitting passive euthanasia in the country. This judgment was passed in the wake of Pinki Virani's plea to lust the highest court in December 2009 under the Constitutional provision of "Next Friend." It's a landmark law which places the power of choice in the hands of the individual over government, medical, or religious control which see all suffering as "destiny."

Settings for End-of-Life Care

Palliative Care

Palliative care is an approach to care for the seriously ill that has long been a part of cancer care. More recently, it has been expanded to address the comprehensive symptom management, psychosocial care, and spiritual support needed to enhance the quality of life for any person with advanced illness. Although hospice care is considered by many to be the gold standard for palliative care, the term hospice is generally associated with palliative care that is delivered at home or in special facilities to patients who are approaching the end of life (see later discussion). Palliative care and hospice care have been recognized as important bridges between cure-oriented treatment and the needs of terminally ill patients and their families for comprehensive care in the final years, months, or weeks of life. Advocates for improved care for the dying have stated that acceptance, management, and understanding of death should become fully integrated concepts in mainstream health care.

Palliative care, which is conceptually broader than hospice care, is both an approach to care and a structured system for care delivery that aims to optimize "quality of life by anticipating, preventing and treating suffering" (NCP, 2013), p. 9). Palliative care is characterized by interdisciplinary communication and coordination across the trajectory of serious illness, emphasizing management of psychological, social, and spiritual problems in addition to control of pain and other physical symptoms. As the definition suggests, palliative care does not begin when cure-focused treatment ends but instead is offered "concurrently with or independent of curative or life-prolonging care" (NCP, 2013), p. 9). The goal of palliative care is to improve the patient's and family's quality of life, and indeed many aspects of this type of comprehensive, comfort-focused approach to care are applicable earlier in the process of life-threatening disease and in conjunction with cure-focused treatment.

In palliative care, interdisciplinary collaboration is necessary to bring about the desired outcomes for patients and their families. Interdisciplinary collaboration, which is different from

multidisciplinary practice, is based on communication and cooperation among the various disciplines, with each member of the team contributing to a single integrated care plan that addresses the needs of the patient and the family. In contrast, multidisciplinary care refers to participation of clinicians with varied backgrounds and skill sets but without coordination and integration.

Palliative Care at the End of Life

The broadening of the application of palliative care *followed* the development of hospice programs. All hospice care is palliative care; however, not all palliative care is hospice care. The difference is that hospice care is an application of palliative care delivered at the end of life. Hospice care focuses on quality of life, and by necessity, it usually includes realistic emotional, social, spiritual, and financial preparation for death.

Hospice providers endeavor to make the services available to all persons with advanced illness, regardless of diagnosis. Many chronic progressive diseases do not have a predictable "end stage" that fits hospice eligibility criteria, and as a result, many patients die after a long, slow, and often painful decline, without the benefit of the coordinated palliative care that is unique to hospice programs. The palliative approach to care could benefit many more patients if it were available across care settings and earlier in the disease process. Palliative care programs are now being developed in other settings for patients who are either not eligible for hospice or who do not choose to enroll in a formal hospice program. At this time, there is no dedicated reimbursement to providers for palliative care services when they are delivered outside the hospice setting, making the sustainability of such programs challenging.

Palliative Care in the Hospital Setting

Hospitals have a financial incentive to transfer patients with terminal illnesses who are no longer in need of acute care to receive care in other settings, such as long-term care facilities and home. Despite the economic and human costs associated with death in the hospital setting, approximately 30% of all deaths occur in acute care settings.

Many patients will continue to opt for hospital care or will by default find themselves in hospital settings at the end of life. Increasingly, hospitals are conducting system-wide assessments of end-of-life care practices and outcomes and are developing innovative models for delivering high-quality, person-centered care to patients approaching the end of life. A growing body of evidence supports the role of palliative care that is delivered *concurrently* with standard medical treatment. For example, in a landmark study of referral to palliative care for patients newly diagnosed with metastatic non–small cell lung cancer (a disease with very poor prognosis), researchers found that those patients randomized to the palliative care plus standard oncology care arm of the trial not only showed improved quality of life and mood but also had longer median survival than those who received standard oncology care alone (Temel, Greer, Muzikansky, et al., 2010). This study underscores the value of palliative care and undercuts one of the principal objections to palliative care, which equates it with "giving up."

In 2011, The Joint Commission launched an advanced certification program for palliative care to recognize hospitals that provide exceptional patient and family-centered care. Despite early financial barriers to providing high-quality palliative care in acute care settings (Connor, 2007–2008), palliative care services in hospitals have grown significantly; in 2015, almost all large hospitals (90%) had a palliative care program (Center to Advance Palliative Care [CAPC], 2015a). Public policy changes have been called for that would reimburse hospitals for care delivered via designated hospital-wide palliative care beds, clustered palliative care units, or palliative care consultation services in acute care settings. Resources are available for developing hospital–hospice partnerships to provide high-quality palliative care for hospitalized patients and for addressing the palliative care needs of other specialized populations, such as patients receiving such care in intensive care units (ICUs), pediatric patients, residents of long-term care facilities, and patients receiving care in community settings (CAPC, 2015b). In a statewide survey of hospitals, researchers found that although 89% of Maryland providers already had a palliative care program in place, 41% indicated that they did not have procedures in place for ensuring timely delivery of services (Gibbs, Mahon, Truss, et al., 2015). This action by the Maryland legislature is an example of state policy that can contribute to wider adoption of palliative care.

Outpatient Palliative Care

As palliative care has become more prevalent in hospitals, skilled nursing settings, and in home hospice programs, outpatient palliative care has emerged as an approach to providing services and support to patients and families who opt not to or are not eligible for home hospice but could benefit from comprehensive palliative care in the community. Outpatient palliative care benefits both patients and their families and other providers by providing expert consultation and management of symptoms and other needs. Studies demonstrate that outpatient palliative care increases patient satisfaction with care, improves symptom management and quality of life, reduces utilization of other health care services (such as avoidable acute care admissions), and may lengthen survival for some patients (Rabow, Kvale, Barbour, et al., 2013).

Palliative Care: The Indian Scenario

Magnitude of the Problem

According to WHO (2020), more than 56 million people, with an equal proportion of men and women, are in need of palliative care worldwide. The regional distribution of people needing palliative care varies widely across the globe. In the Western Pacific region, more than 25% of population are in need of palliative care, whereas in the South-East region, 17% of population need palliative care. In Africa, people requiring palliative care are primarily those suffering from HIV/AIDS. In all the regions of the world, a higher proportion of people diagnosed with cancer require palliative care.

In India, nearly 5 million people are in need of palliative care but only 1% of them have access to it. Every year, 2.5 million new cases of cancers are identified in India. Out of that, two-thirds reach the hospital in an incurable state suffering severe pain. Nearly 80% of patients with AIDS suffer moderate to severe pain. Patients suffering from other diseases such as heart failure and COPD add to the burden. The common distressing symptoms are pain, dyspnea, fatigue, nausea, vomiting, dry mouth, diarrhea, constipation, urinary incontinence, wound with smelly discharge, confusion, delirium, and dementia. To meet the palliative care needs of patients, the Government of India plans to integrate it into the primary care delivery system.

In India, only 908 palliative care centers are available, mostly in the state of Kerala (Khanna & Lal, 2016). In 2008, Kerala state brought into effect the palliative care policy followed by Maharashtra in 2012. In 2013, the Government of India launched

its National Programme for Palliative Care. Subsequently, in 2014, the Narcotic Drugs and Psychotropic Substances Act was amended and paved way for easier access to opioid medication which is necessary for pain relief. In 2016, in the International Palliative Care Conference held at Pune, a declaration was made urging the Government of India to integrate palliative care with noncommunicable diseases program and also with TB and AIDS control program so that patients with both communicable (HIV/AIDS) and noncommunicable diseases will receive the palliative care (Khanna & Lal, 2016).

With the introduction of the new National Health Policy (2017), the palliative care is given more importance. Recently, basic palliative care is integrated into the undergraduate medical and nursing curriculum by the National Medical Commission of India and Indian Nursing Council, respectively. Under the Ayushman Bharat scheme, medical officers, staff nurses, and ASHA workers are trained in palliative care delivery (Government of India, 2021).

Delivery of Palliative Care in India

As per the National Health Policy (2017), palliative care is provided at the primary health center level on an outpatient basis or inpatient basis. Whenever necessary, patients are referred to higher-level centers with palliative care specialists. The training modules provide step-by-step guidelines on symptom assessment and management. See Figure 59-1 for the algorithm for delivery of palliative care. In countries like India, home care palliative services are economically beneficial. Family members' involvement and natural environment give the patients more satisfaction; especially at the time of dying, people prefer to be with their loved ones in their home environment and follow the rituals or spiritual practices of their community. The secondary and tertiary level palliative care centers provide palliative services alongside other treatment modalities (e.g. spine care centers, palliative care centers along with oncology units).

Nurses' Role in Palliative Care

- Play a vital role in primary, secondary, and tertiary palliative care settings
- Play a major role in accurately assessing and managing distressing physical symptoms
- Coordinate with other health providers such as physicians, physiotherapists, and counselors
- Play a supervisory role and supervise the works of axillary nurse midwives (ANMs), accredited social health activist (ASHA) workers, and family caregivers
- Provide specialized palliative care services such as ostomy care, wound management, and lymphedema management
- Titrate pain medication and other drugs based on the protocols and manage the side effects if any
- Communicate effectively with family members and patients to facilitate good coping
- Educate and train the patients, family caregivers, and volunteers on effective home care with available resources
- Monitor and maintain the accurate records of palliative care services
- Provide referral services as appropriate
- Coordinate with the counselor in the terminal phase of illness
- Follow ethical and legal aspects of nursing while rendering palliative care services.

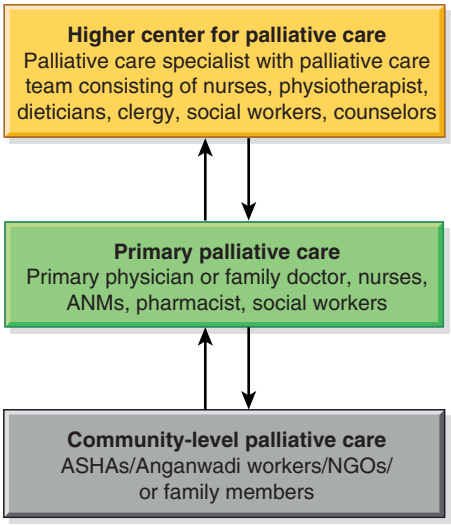

Figure 59-1 • Palliative care delivery algorithm. Training module on palliative care (for doctors and nurses).

Hospice Care

Hospice is a coordinated program of interdisciplinary services provided by professional caregivers and trained volunteers to patients with serious, progressive illnesses that are not responsive to cure. The root of the word *hospice* is *hospes,* meaning "host." According to Cicely Saunders, who founded the world-renowned St. Christopher's Hospice in London, the principles underlying hospice are as follows:

- Death must be accepted.
- The patient's total care is best managed by an interdisciplinary team whose members communicate regularly with one another.
- Pain and other symptoms of terminal illness must be managed.
- The patient and the family should be viewed as a single unit of care.
- Home care of the dying is necessary.
- Bereavement care must be provided to family members.
- Research and education should be ongoing.

Nursing Care of Terminally Ill Patients

Many patients suffer unnecessarily when they do not receive adequate attention for the symptoms accompanying serious illness. Careful evaluation of the patient should include not only the physical problems but also the psychosocial and spiritual dimensions of the patient's and family's experience of serious illness. This approach contributes to a more comprehensive understanding of how the patient's and family's life has been affected by illness and leads to nursing care that addresses their needs in every dimension.

Psychosocial and Regulatory Issues

Nurses are responsible for educating patients and their caregivers and for supporting them as they adapt to life with the illness. Nurses can assist patients and families with life review, values clarification, treatment decision making, and end-of-life goals. The only way to do this effectively is to try to appreciate and understand the illness from the patient's perspective.

Nurses should be both culturally aware and sensitive in their approaches to communication with patients and families about death. Attitudes toward open disclosure about terminal illness

vary widely among different cultures, and direct communication with patients about such matters may be viewed as harmful (Sarafis, Tsounis, Malliarou, et al., 2014). To provide effective patient- and family-centered care at the end of life, nurses must be willing to set aside their own assumptions and attitudes so that they can discover what type and amount of disclosure is most meaningful to each patient and family within their unique belief systems (see Table 59-1).

The social and legal evolution of advance directive documents represents some progress in people's willingness to both contemplate and communicate their wishes concerning the end of life (see Chart 59-2). Furthermore, the existence of a properly executed advance directive does not reduce the complexity of end-of-life decisions.

Communication

Remarkable strides have been made in the ability to prolong life; however, attention to care for the dying lags behind. On one level, this should come as no surprise. Each of us will eventually face death, and most would agree that one's own demise is a subject that he or she would prefer not to contemplate. Confronting death in our patients often uncovers our own deeply rooted fears.

To develop a level of comfort and expertise in communicating with seriously and terminally ill patients and their families, nurses must first consider their own experiences with and values concerning illness and death. Reflection, reading, and talking with family members, friends, and colleagues can help nurses examine beliefs about death and dying. Talking with people from different cultural and religious backgrounds can help nurses view personally held beliefs through a different lens and can increase their sensitivity to death-related beliefs and practices in other cultures. Discussion with nursing and nonnursing colleagues can also be useful; it may reveal the values shared by many health care professionals and may also identify diversity in the values of patients in their care. Values clarification and personal death awareness exercises can provide a starting point for self-discovery and discussion.

TABLE 59-1 Overview of Religious and Cultural Beliefs and Views on Death and Dying

Religion	General Religious/Cultural Beliefs	Views About Death/Preparing for Death
Hinduism	• Each caste has a different view of death. • This life is a transition between the previous life and the next. • Postdeath rituals are important. Bodies are cremated. During the first 10 days after death, relatives must create a new ethereal body. • Karma is the manner through which one reaps benefits and penalties of past actions. "Good karma" leads to good rebirth or release, and "bad karma" leads to bad rebirth. • Astrological timing of birth and death is important	• No firmly established medical ethics, principles, or codes to guide decision making/care. • Many older adults withdraw into their homes, where they prepare for death through prayer and meditation. • Family is very important; health care decisions may be made communally with senior family member as final authority. Deference to spouse and family may be especially prevalent among women (acquiescing autonomy to a family member). • A "good death" is timely, in the right place (on the ground at home), conscious and prepared, with the mind on God. All affairs should be in order. • A "bad death" is untimely, violent, and unprepared. The worst death is suicide. • Pain and suffering may be viewed as consequence of past actions, "bad karma".
Buddhism	• There is no central authority in the Buddhist religion. • Taboo and religious purity play little, if any, role, and religious law imposes no special requirements for medical treatment. • Treatment by someone of the same gender is preferable. • Cremation is the most common way of disposing of the dead. • Some Buddhists may be unwilling to take pain-relieving medications or strong sedatives. It is believed that an unclouded mind can lead to a better rebirth. • Buddhists believe that after death there is either rebirth or nirvana—the latter being enlightenment that frees the soul from the cycle of death and rebirth.	• Life is basically good and preserving it is important. Enlightenment can only be achieved through living. • Teachings emphasize the inevitability of death; therefore, Buddhists tend to be psychologically prepared to accept impending death with calmness and dignity. • Death occurs when a body is bereft of vitality, heat, and sentiency. Brain death is disputed as meeting the requirements for death. • It is often appropriate to decide that the patient is beyond medical help and to allow events to take their course. In these cases, it is justifiable to refuse or withdraw treatment in light of the overall prognosis. • Buddhism supports the use of hospice.
Islam	• Muslims believe in one God. • God revealed the message of God to Muhammad, the prophet, in the Qur'an (Koran), which states that Muslims should maintain a balanced diet and exercise. • Muslim patients may wish to engage in ritual prayer, practiced five times during the day. • Fasting during the month of Ramadan is a pillar of Islam. • Completion of the pilgrimage (*hajj*) to Mecca (money and health permitting), at least once, is also a pillar of Islam.	• Everyone will face death, and the way a person dies is of great individual importance. • Death cannot happen except by God's permission. However, it is recognized that diseases and trauma cause death. • There is a belief that God is the one who cures and primary providers are a means to enact God's will. • Decisions are made within families, and disclosure of diagnosis and prognosis must be considered in this context. • Pain is a cleansing instrument of God. Pain can also be viewed as having an educational purpose (pain can compensate for sin).

(Continued)

(Continued)

		• The killing of a terminally ill person is an act of disobedience against God. However, pain relief or withholding or withdrawing of life support when there is no doubt that the person's disease is causing untreatable suffering is permissible as long as there is formal agreement among all parties concerned. • Withholding and withdrawing artificial nutrition and hydration (ANH) at the end of life raises concerns. Nutritional support is considered basic care and not medical treatment and should be continued unless it would hasten death or cause more harm than benefit.
Traditional Christianity	• Christians believe in one God. • The belief in eternal salvation sets Christianity apart. • Beliefs vary. Some Christians hope to attain eternal salvation. • Even within family, religious views can differ. Some family members may not follow the religion at all.	• Each human life has inherent and equal dignity. • Intentionally bringing about death by either omission or commission is prohibited. • The appropriateness of analgesia and sedation to avoid terminal suffering and despair is acceptable, if it does not, by clouding consciousness, take away the final opportunity for repentance. • Christians are not obligated to postpone death; it is forbidden to try to save life at all costs. • However, there could be a duty to use high-technology medicine to gain a last opportunity for repentance. • ANH is obligatory for most patients except when the means to provide ANH cause complications, the patient has progressive illness, or clearly refuses ANH.
		• Impending death offers a final chance to become reconciled with those whom one has harmed and to ask God's forgiveness. • Liturgical (ceremonial) Christians generally regard last rites as integral to the relationship with God. Repentance can include confessing formally and receiving Communion and final anointing. This often involves particular ministers. • Christians who follow the religion at a cultural level are likely to have secular approaches to end-of-life decisions. • Advance directives allow patients to appoint decision makers and to provide instructions that ensure that their wishes are followed.

Chart 59-2

Methods of Stating End-of-Life Preferences

Advance directives: written documents that allow the individual of sound mind to document preferences regarding end-of-life care that should be followed when the signer is terminally ill and unable to verbally communicate their wishes. The documents are generally completed in advance of serious illness but may be completed after a diagnosis of serious illness if the signer is still of sound mind. The most common types are the durable power of attorney for health care and the living will.

Do Not Resuscitate: A medical order to withhold cardiopulmonary resuscitation (CPR) in the event of cardiac arrest. In some settings, the term "allow natural death" (AND) is used in place of do not resuscitate (DNR).

Durable power of attorney for health care: a legal document through which the signer appoints and authorizes another individual to make medical decisions on their behalf when he or she is no longer able to speak for himself or herself. This is also known as a health care power of attorney, medical power of attorney, or a proxy directive.

Living will: a type of advance directive in which the individual documents treatment preferences. It provides instructions for care in the event that the signer is terminally ill and not able to communicate their wishes directly and often is accompanied by a durable power of attorney for health care. This is also known as a medical directive or treatment directive.

Physician orders for life-sustaining treatment (POLST): a form that translates patient preferences expressed in advance directives to medical "orders" that are transferable across settings and readily available to all health care providers, including emergency medical personnel. The POLST form is a brightly colored form that specifies preferences related to CPR and use of IV medications or fluids, antibiotics, artificial nutrition, and other medical interventions. The form is signed by the patient or surrogate and the physician, advanced practice nurse, or physician assistant. The use of the POLST is subject to state laws and regulations. Numerous states have endorsed the POLST or a similar form.

Information about the advance care planning and state-specific advance directive documents and instructions is available at www.caringinfo.org. Information about the POLST is available at www.polst.org

Skills for Communicating with the Seriously Ill

Nurses need to develop skill and comfort in assessing patients' and families' responses to serious illness and planning interventions that support their values and choices throughout the continuum of care (Wittenberg-Lyles, Goldmith, Ferrell, et al., 2013). Throughout the course of a serious illness, patients and their families encounter complicated treatment options and bad news about disease progression. They may have to make difficult decisions at the time of diagnosis, when disease-focused treatment fails, when the effectiveness of a particular intervention is being discussed, and when decisions about hospice care are presented. These critical points on the treatment continuum demand patience, empathy, and honesty from nurses. Discussing sensitive issues such as serious illness, hopes for survival, and fears associated with death is never easy. However, the art of therapeutic communication can be learned and, like other skills, must be practiced to gain expertise. Like other skills, communication should be practiced in a "safe" setting, such as a classroom or clinical skills laboratory with other students and clinicians.

In practice, communication with each patient and family should be tailored to their particular level of understanding and values concerning disclosure. Before disclosing any health information about a patient to family members, nurses should follow their agency's policy for obtaining patient consent.

Nursing Interventions when Patients and Families Receive Bad News

Communicating about a life-threatening diagnosis or disease progression is best accomplished in any setting by the interdisciplinary team: A physician, nurse, and social worker, should be present whenever possible to provide information, facilitate discussion, and address concerns. Most important, the presence of the team conveys caring and respect for the patient and the family. If the patient wishes to have family present for the discussion, arrangements should be made to have the discussion at a time that is best for everyone. Creating the right setting is particularly important. A quiet area with a minimum of disturbances should be used. All clinicians present should turn off pagers, cell phones, and other communication devices for the duration of the meeting and should allow sufficient time for the patient and the family to absorb and respond to the news. Finally, the space in which the meeting takes place should be conducive to seating all participants at eye level. It is difficult enough for the patient and the family to be the recipients of bad news without having an array of clinicians standing uncomfortably over them at the foot of the patient's bed (see Chart 59-3).

After the initial discussion of a life-threatening illness or progression of a disease, the patient and the family will probably have many questions and may need to be reminded of factual information. Coping with news about a serious diagnosis or poor prognosis is an ongoing process. The nurse should be sensitive to these ongoing needs and may need to repeat previously provided information or simply be present while the patient and the family react emotionally. The most important intervention the nurse can provide is listening empathetically. Seriously ill patients and their families need time and support to cope with the changes brought about by serious illness and the prospect of impending death. The nurse who is able to listen without judging and without trying to solve the patient's and family's problems provides an invaluable intervention. Keys to effective listening include the following:

- Resist the impulse to fill the "empty space" in communication with talk.
- Allow the patient and the family sufficient time to reflect and respond after asking a question.
- Prompt gently: "Do you need more time to think about this?"
- Avoid distractions (noise, interruptions).

Chart 59-3

COMFORT: A Framework for Communication in Palliative Care

Communication (C)

- Narrative clinical practice: Elicit and be fully present for the patient's and family's story.
- Verbal clarity: Use compassionate, nonambiguous language.
- Nonverbal immediacy: Use eye contact, body position, and self-awareness to show attentiveness.

Orientation (O)

- Support health literacy.
- Acknowledge vulnerability.
- Express cultural sensitivity.

Mindfulness (M)

- Stay in the moment: Avoid scripted responses.
- Avoid prejudgment: Do not have expectations that this patient and family will or should respond as others have in the past.
- Adapt to rapid changes: Be ready to shift to new topics and concerns that are revealed.

Family (F)

- Think of the family as a "second-order" patient: The family and the patient comprise the unit of care.
- Know that the family is a bridge to the patient: You must gain the family's trust to work effectively.
- Use family meetings (patient included) to clarify goals for treatment.

Openings (O)

- Address essential transitions in care or status.
- Seek a higher level of understanding of the disease process.
- Engage spiritual concerns.

Relating (R)

- Prioritize the turning point in illness.
- Understand that communication should be nonlinear: The patient and the family may need to revisit topics multiple times and on multiple occasions.
- Know that the patient's and family's acceptance must drive communication.

Team (T)

- The interdisciplinary team includes members trained in various aspects of palliative care.
- Assure the patient and the family that they will not be abandoned.
- Ensure continuity of care across settings: Goals and plans should be clearly communicated to other providers.

Adapted with permission from Wittenberg-Lyles, E., Goldsmith, J., & Ragan, S. L. (2010). The COMFORT initiative: Palliative nursing and the centrality of communication. Journal of Hospice and Palliative Nursing, 12(5), 282–292.

Chart 59-4 NURSING RESEARCH PROFILE

Perceptions of Helpful Interventions During End-of-Life Care

Cronin, C., Arnstein, P., & Flanagan, J. (2015). Family members' perceptions of most helpful interventions during end-of-life care. Journal of Hospice & Palliative Nursing, 17(3), 223–228.

Purpose

Hospice care and support is directed not just to the patient but to those whom the patient considers family, as well. Numerous studies have provided insight to nurses' perceptions of priorities for as well as barriers to and facilitators of end-of-life care. Better understanding of families' needs could improve their experience of hospice care. This study aimed to explore the needs of family members and friends while their loved ones received end-of-life care in a hospital setting.

Design

This was a qualitative study in which the researchers used semi-structured interviews to collect data from a family member or close friend of a patient enrolled in hospice in a hospital setting. Nine potential study participants were identified through convenience sampling on an 18-bed gynecologic oncology unit in a large academic medical center; seven of the nine agreed to participate. Interview questions focused on perceived helpfulness of nurses' and other staff members' activities, perceptions of communication, and adequacy and helpfulness of referred services (e.g., chaplaincy). Data were compiled as transcripts from handwritten interview notes and analyzed using content analysis techniques.

Findings

Importantly, the principal investigator observed that although she had anticipated that participants might be uncomfortable being interviewed at such a difficult time, she found that participants were not only comfortable, they appreciated the chance to tell their stories and would have been willing to share even more than was requested. Researchers identified four principal themes from the data analysis: (1) family/friend awareness of nursing vigilance provided them with a sense of being cared for, (2) nursing presence enhanced mutual connectedness and appreciation, (3) when death was imminent, family/friends wanted to understand the process, be included in discussions, and be validated after decisions were made, and (4) attention to the environment of care provided peace and relaxation at a difficult time.

Nursing Implications

Nurses working in end-of-life care need to keep in mind that support for family members and validation of difficult decisions are vital components of their communication. Furthermore, this communication is essential to increase family members' levels of comfort and trust in the entire health care team.

- Avoid the impulse to give advice.
- Avoid canned responses: "I know just how you feel."
- Ask questions.
- Assess understanding—your own and the patient's—by restating, summarizing, and reviewing.

(See the Nursing Research Profile in Chart 59-4.)

Responding with Sensitivity to Difficult Questions

Patients often direct questions or concerns to nurses before they have been able to fully discuss the details of their diagnosis and prognosis with their physicians or the entire health care team. Using open-ended questions allows the nurse to elicit the patient's and family's concerns, explore misconceptions and needs for information, and form the basis for collaboration with physicians and other team members.

For example, a seriously ill patient might ask the nurse, "Am I dying?" The nurse should avoid making unhelpful responses that dismiss the patient's real concerns or defer the issue to another care provider. Nursing assessment and intervention are always possible, even when a need for further discussion with a physician is clearly indicated. Whenever possible, discussions in response to a patient's concerns should occur when the patient expresses a need, although that may be the least convenient time for the nurse. Creating an uninterrupted space of just 5 minutes can do much to identify the source of the concern, allay anxieties, and plan for follow-up.

In response to the question "Am I dying?" the nurse could establish eye contact and follow with a statement acknowledging the patient's fears ("This must be very difficult for you") and an open-ended statement or question ("Tell me more about what is on your mind"). The nurse then needs to listen intently, ask additional questions for clarification, and provide reassurance only when it is realistic. In this example, the nurse might quickly ascertain that the patient's question emanates from a need for specific information—about diagnosis and prognosis from the physician, about the physiology of the dying process from the nurse, or perhaps about financial implications for the family from the social worker.

As a member of the interprofessional team caring for the patient at the end of life, the nurse plays an important role in facilitating the team's understanding of the patient's values and preferences, family dynamics concerning decision making, and the patient's and the family's response to treatment and changing health status. Many dilemmas in patient care at the end of life are related to poor communication between team members and the patient and the family, as well as to failure of team members to communicate with one another effectively. Regardless of the care setting, the nurse can ensure a proactive approach to the psychosocial care of the patient and the family. Periodic, structured assessments provide an opportunity for all parties to consider their priorities and plan for an uncertain future. The nurse can help the patient and the family clarify their values and preferences concerning end-of-life care by using a structured approach. Sufficient time must be devoted to each step so that the patient and the family have time to process new information, formulate questions, and consider their options. The nurse may need to plan several meetings to facilitate communication to accomplish the steps described in Chart 59-3.

Providing Culturally Sensitive Care at the End of Life

Although death, grief, and mourning are universally accepted aspects of living, the values, expectations, and practices during serious illness as death approaches and after death are culturally bound and expressed. Health care providers may share similar values concerning end-of-life care and may find that they are inadequately prepared to assess for and implement care plans that support culturally diverse perspectives. Historical mistrust of the health care system and unequal access to even basic medical care may underlie the beliefs and attitudes among

ethnically diverse populations (see Table 59-1). In addition, lack of education or knowledge about end-of-life care treatment options and language barriers influence decisions among many socioeconomically disadvantaged groups.

The nurse's role is to assess the values, preferences, and practices of every patient, regardless of ethnicity, socioeconomic status, or background. The nurse can share knowledge about a patient's and family's cultural beliefs and practices with the health care team and facilitate the adaptation of the care plan to accommodate these practices. For example, a nurse may find that a male patient prefers to have his eldest son make all of his care decisions. Institutional practices and laws governing informed consent are also rooted in the Western notion of autonomous decision making and informed consent. If a patient wishes to defer decisions to his son, the nurse can work with the team to negotiate informed consent, respecting the patient's right not to participate in decision making and honoring his family's cultural practice.

The nurse should assess and document the patient's and family's specific beliefs, preferences, and practices regarding end-of-life care, preparation for death, and after-death rituals. Chart 59-5 identifies topics that the nurse should cover and questions the nurse may use to elicit the information.

The nurse must use judgment and discretion about the timing and setting for eliciting this information. Some patients may wish to have a family member speak for them or may be unable to provide information because of advanced illness. The nurse should give the patient and the family a context for the discussion, such as

> It is very important to us to provide care that addresses your needs and the needs of your family. We want to honor and support your wishes, and want you to feel free to tell us how we are doing, and what we could do to better meet your needs. I'd like to ask you some questions; what you tell me will help me to understand and support what is most important to you at this time. You don't need to answer anything that makes you uncomfortable. Is it all right to ask some questions?

The assessment of end-of-life beliefs, preferences, and practices should be carried out in short segments over a period of time (e.g., across multiple days of an inpatient hospital stay or in conjunction with multiple patient visits to an outpatient setting or over several home care visits). The discomfort of novice nurses with asking questions and discussing this type of sensitive content can be reduced by prior practice in a classroom or clinical skills laboratory, observation of interviews conducted by experienced nurses, and partnering with experienced nurses during the first few assessments.

Goal Setting in Palliative Care at the End of Life

As treatment goals begin to shift to emphasize comfort care with or in lieu of aggressive disease-focused treatment, symptom relief and patient/family-defined quality of life assume greater prominence in treatment decision making. Throughout the course of the illness, and especially as the patient's functional status and symptoms indicate approaching death, the clinician should help the patient and the family weigh the benefits of continued diagnostic testing and disease-focused medical treatment in the context of their goals for care. The patient and the family may be extremely reluctant to forego monitoring that has become routine throughout the illness (e.g., blood testing, x-rays) but that may contribute little to a primary focus on

Chart 59-5 ASSESSMENT

Assessing End-of-Life Care Beliefs, Preferences, and Practices

Disclosure/truth telling: "Tell me how you/your family talk about very sensitive or serious matters."
- Content: "Are there any topics that you or your family are uncomfortable discussing?"
- Person responsible for disclosure: "Is there one person in the family who assumes responsibility for obtaining and sharing information?"
- Disclosure practices regarding children: "What kind of information may be shared with children in your family, and who is responsible for communicating with the children?"
- Sharing of information within the family or community group: "What kind/how much information should be shared with your immediate family? Your extended family? Others in the community (e.g., members of a religious community)?"

Decision-making style: "How are decisions made in your family? Who would you like to be involved in decisions about your treatment or care?"
- Individual
- Family centered
- Family elder or patriarch/matriarch
- Deference to authority (such as the physician)

Symptom management: "How would you like us to help you to manage the physical effects of your illness?"
- Acceptability of medications used for symptom relief
- Beliefs regarding expression of pain and other symptoms
- Degree of symptom management desired

Life-sustaining treatment expectations: "Have you thought about what type of medical treatment you or your loved one would want as the end of life is nearing? Do you have an advance directive (living will and/or durable power of attorney)?"
- Nutrition/hydration at the end of life
- Cardiopulmonary resuscitation
- Ventilator
- Dialysis
- Antibiotics
- Medications to treat infection

Desired location of dying: "Do you have a preference about being at home or in some other location when you die?"
- Desired role for family members in providing care: "Who do you want to be involved in caring for you at the end of life?"
- Gender-specific prohibitions: "Are you uncomfortable having either males or females provide your care or your loved one's personal care?"

Spiritual/religious practices and rituals: "Is there anything that we should know about your spiritual or religious beliefs about death? Are there any practices that you would like us to observe as death is nearing?"

Care of the body after the death: "Is there anything that we should know about how a body/your body should be treated after death?"

Expression of grief: "What types of losses have you and your family experienced? How do you and your family express grief?"

Funeral and burial practices: "Are there any rituals or practices associated with funerals or burial that are especially important to you?"

Mourning practices: "How have you and your family carried on after a loss in the past? Are particular behaviors or practices expected or required?"

comfort. Likewise, health care providers may have difficulty discontinuing such diagnostic testing or medical treatment.

Specifically, the nurse should collaborate with other members of the interdisciplinary team to share assessment findings, develop a coordinated plan of care, and make decisions about diagnostic testing at the end of life (see Fig. 59-2). In addition, the nurse should help the patient and the family clarify their goals, expected outcomes, and values as they consider treatment options (see Chart 59-6). The nurse should work with colleagues in other disciplines to ensure that the patient and the family are referred for continuing psychosocial support, symptom management, and assistance with other care-related challenges (e.g., arrangements for home care or hospice support, referrals for financial assistance).

Spiritual Care

Attention to the spiritual component of the illness experienced by the patient and the family is not new within the context of nursing care, yet many nurses lack the comfort or skills to assess and intervene in this dimension. Spirituality contains features of religiosity; however, the two concepts are not interchangeable. Spirituality includes domains such as how a person derives meaning and purpose from life, one's beliefs and faith, sources of hope, and attitudes toward death (Puchalski, Vitillo, Hull, et al., 2014). For most people, contemplating one's own death raises many issues, such as the meaning of existence, the purpose of suffering, and the existence of an afterlife. A survey on end-of-life

Chart 59-6 ASSESSMENT

Assessing the Patient and Family Perspective: Goal Setting in Palliative Care

- **Awareness of diagnosis, illness stage, and prognosis:** "Tell me your understanding of your illness right now."
- **Values:** "Tell me what is most important to you as you are thinking about the treatment options available to you/your loved one."
- **Preferences:** "You've said that being comfortable and pain free is most important to you right now. Where would you like to receive care (home, hospital, long-term care facility, doctor's office), and how can I help?"
- **Expected/desired outcomes:** "What are your hopes and expectations for this (diagnostic test [e.g., CT scan] or treatment)?"
- **Benefits and burdens:** "Is there a point at which you would say that the testing or treatment is outweighed by the burdens it is causing you (e.g., getting from home to the hospital, pain, nausea, fatigue, interference with other important activities)?"

CT, computed tomography.

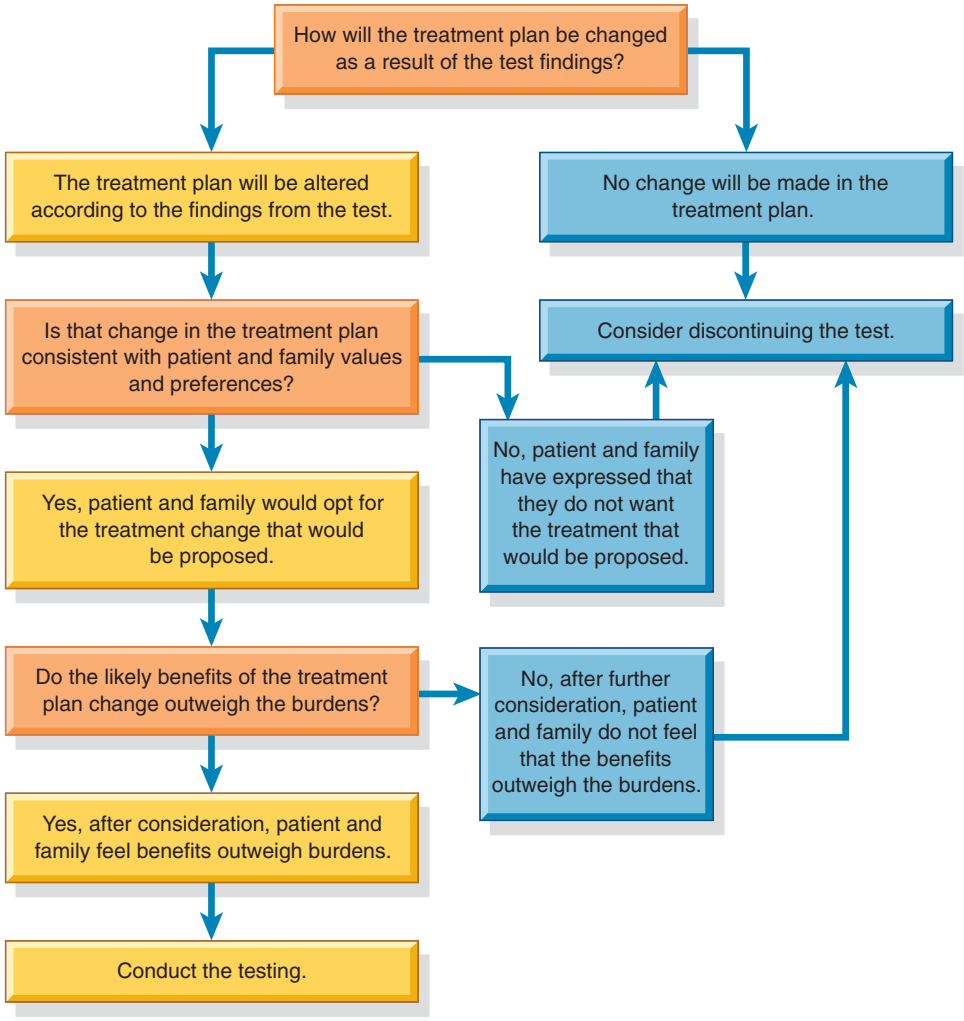

Figure 59-2 • An algorithm for decision making about diagnostic testing at the end of life.

issues conducted by the Pew Research Center (2013) revealed that personal attitudes and preferences concerning end-of-life treatment are related to religious affiliation, race, and ethnicity. The spiritual assessment is a key component of comprehensive nursing assessment for terminally ill patients and their families. Although the nursing assessment should include religious affiliation, spiritual assessment is conceptually much broader than religion and, therefore, is relevant regardless of a patient's expression of religious preference or affiliation. In addition to the assessment of the role of religious faith and practices, important religious rituals, and connection to a religious community (see Table 59-1), the nurse should further explore:

- The harmony or discord between the patient's and the family's beliefs
- Other sources of meaning, hope, and comfort
- The presence or absence of a sense of peace of mind and purpose in life
- Spiritual or religious beliefs about illness, medical treatment, and care of the sick

A four-step spiritual assessment process using the acronym FICA involves asking the following questions (Puchalski & Romer, 2000):

- *F*aith and belief: Do you consider yourself to be a spiritual or religious person? What is your *faith* or belief? What gives your life meaning?
- *I*mportance and *I*nfluence: What *importance* does faith have in your life? Have your beliefs influenced the way you take care of yourself and your illness? What role do your beliefs play in regaining your health?
- *C*ommunity: Are you a part of a spiritual or religious *community*? Is this of support to you and how? Is there a group of people you really love or who are important to you?
- *A*ddress in care: How would you like me to *address* these issues in your health care?

Hope

Clinicians and researchers have observed that although specific hopes may change over time, hope generally persists in some form across every stage of illness. In terminal illness, hope represents the patient's imagined future, forming the basis of a positive, accepting attitude and providing the patient's life with meaning, direction, and optimism. When hope is viewed in this way, it is not limited to cure of the disease; instead, it focuses on what is achievable in the time remaining. Many patients find hope in working on important relationships and creating legacies. Terminally ill patients can be extremely resilient, reconceptualizing hope repeatedly as they approach the end of life.

Numerous nurse researchers have studied the concept of hope, and they have related its presence to spirituality, quality of life, and transcendence (Knabe, 2013). Hope is a multidimensional construct that provides comfort as a person endures life threats and personal challenges. The following are hope-fostering and hope-hindering activities among terminally ill hospice patients with various diagnoses:

- *Hope-fostering categories:* Love of family and friends, spirituality/faith, setting goals and maintaining independence, positive relationships with clinicians, humor, personal characteristics, and uplifting memories
- *Hope-hindering categories:* Abandonment and isolation, uncontrollable pain/discomfort, and devaluation of personhood

Nurses can support hope for the patient and the family by using effective listening and communication skills, thus encouraging realistic hope that is specific to their needs for information, expectations for the future, and values and preferences concerning the end of life. Nurses must engage in self-reflection and identify their own biases and fears concerning illness, life, and death. As nurses become more skilled in working with seriously ill patients, they can become less determined to "fix" and more willing to listen; more comfortable with silence, grief, anger, and sadness; and more fully present with patients and their families.

Nursing interventions for enabling and supporting hope include the following:

- Listening attentively
- Encouraging sharing of feelings
- Providing accurate information
- Encouraging and supporting the patients' control over their circumstances, choices, and environment whenever possible
- Assisting patients to explore ways for finding meaning in their lives
- Encouraging realistic goals
- Facilitating effective communication within families
- Making referrals for psychosocial and spiritual counseling
- Assisting with the development of supports in the home or community when none exist

Managing Physiologic Responses to Terminal Illness

Patients approaching the end of life experience many of the same symptoms, regardless of their underlying disease processes. Symptoms in terminal illness may be caused by the disease, either directly (e.g., dyspnea owing to chronic obstructive lung disease) or indirectly (e.g., nausea and vomiting related to pressure in the gastric area), by the treatment for the disease, or by a coexisting disorder that is unrelated to the disease. Symptoms should be carefully and systematically assessed and managed. Questions that guide the assessment of symptoms are listed in Chart 59-7.

The patient's goals should guide symptom management. Medical interventions may be aimed at treating the underlying causes of the symptoms or reducing the impact of symptoms. For example, a medical intervention such as thoracentesis (an invasive procedure in which fluid is drained from the pleural space) may be performed to temporarily relieve dyspnea in a patient with pleural effusion secondary to lung cancer. Pharmacologic and nonpharmacologic methods of symptom management may be used in combination with medical interventions to modify the physiologic causes of

Chart 59-7 ASSESSMENT

Assessing Symptoms Associated with Terminal Illness

- How is this symptom affecting the patient's life?
- What is the meaning of the symptom to the patient? To the family?
- How does the symptom affect physical functioning, mobility, comfort, sleep, nutritional status, elimination, activity level, and relationships with others?
- What makes the symptom better?
- What makes it worse?
- Is it worse at any particular time of the day?
- What are the patient's expectations and goals for managing the symptom? The family's expectations?
- How is the patient coping with the symptom?
- What is the economic effect of the symptom and its management?

Adapted from Jacox, A., Carr, D. B., & Payne, R. (1994). Management of cancer pain. Rockville, MD: Agency for Health Care Policy and Research.

symptoms. For example, pharmacologic management with low-dose oral morphine effectively relieves dyspnea (Kamal, McGuire, Wheeler, et al., 2012), and mindful breathing can relive distress for patients and families receiving palliative care (Beng, Ahmad, Loong, et al., 2015). As is true with pain, the principles of pharmacologic symptom management are the use of the smallest dose of the medication to achieve the desired effect, avoidance of polypharmacy, anticipation and management of adverse effects, and creation of a therapeutic regimen that is acceptable to the patient based on their goals for maximizing quality of life.

The patient's goals take precedence over the clinicians' goals. Although clinicians may believe that symptoms must be completely relieved whenever possible, the patient might choose instead to decrease symptoms to a tolerable level rather than to relieve them completely if the side effects of medications are unacceptable to him or her. This often allows the patient to have greater independence, mobility, and alertness and to devote attention to issues that he or she considers of higher priority and greater importance.

Anticipating and planning interventions for symptoms is a cornerstone of both palliative and end-of-life care. Patients and family members cope more effectively with new symptoms and exacerbations of existing symptoms when they know what to expect and how to manage them. At the end of life, hospice programs typically provide "emergency kits" containing ready-to-administer doses of various medications that are useful to treat symptoms in advanced illness. For example, a kit might contain small doses of oral morphine liquid for pain or shortness of breath, a benzodiazepine for restlessness, and an acetaminophen/paracetamol suppository for fever. Family members can be instructed to administer a prescribed dose from the emergency kit, often avoiding prolonged suffering for the patient as well as rehospitalization for symptom management.

Pain

In the final stages of illnesses such as cancer, heart disease, COPD, and renal disease, pain and other symptoms are common. Pain results from the diseases as well as the modalities used to treat them. The Worldwide Palliative Care Alliance and World Health Organization (2014) called attention to the continuing, worldwide high prevalence of pain at the end of life and the inadequate supply of opioids, particularly in developing nations. Pain at the end of life is preventable or treatable in most cases: it is every nurse's role to ensure that pain is assessed, prevented where possible, and managed. Chapter 9 presents the importance of pain assessment, assessment principles for pain that include identifying the effect of the pain on the patient's life, and the importance of believing the patient's report of the pain and its effect. Although the means to relieve pain have existed for many years, the continued, pervasive undertreatment of pain has been well documented (Reynolds, Drew, & Dunwoody, 2013). Poorly managed pain affects the psychological, emotional, social, and financial well-being of patients. Despite studies demonstrating the negative effects of inadequate pain management, practice has been slow to change. Every clinician should be able to assess and oversee the basic management of pain (IOM, 2014b).

Patients who are receiving an established regimen of analgesics should continue to receive those medications as they approach the end of life. Inability to communicate pain should not be equated with the absence of pain (McGuire, Reifsnyder, Soeken, et al., 2011). Although most pain can be managed effectively using the oral route, as the end of life nears, patients may be less able to swallow oral medications due to somnolence or nausea. Patients who have been receiving opioids should continue to receive equianalgesic doses via rectal or sublingual routes. Concentrated morphine solution can be effectively delivered by the sublingual route, because the small liquid volume is well tolerated even if swallowing is not possible. As long as the patient continues to receive opioids, a regimen to combat constipation must be implemented. If the patient cannot swallow laxatives or stool softeners, rectal suppositories or enemas may be necessary.

The nurse should educate the family about continuation of comfort measures as the patient approaches the end of life, how to administer analgesics via alternative routes, and how to assess for pain when the patient cannot verbally report pain intensity. Because the analgesics given orally or rectally are short acting and typically scheduled as frequently as every 3 to 4 hours around the clock, there is always a strong possibility that a patient approaching the end of life will die in close proximity to the time of analgesic administration. If the patient is at home, family members administering analgesics should be prepared for this possibility. They need reassurance that they did not "cause" the death of the patient by administering a dose of analgesic medication.

Dyspnea

Dyspnea, an uncomfortable awareness of breathing, is one of the most prevalent symptoms at the end of life and can be challenging to manage (Kamal et al., 2012). A highly subjective symptom, dyspnea often is not associated with visible signs of distress, such as tachypnea, diaphoresis, or cyanosis. Although the underlying cause of the dyspnea can be identified and treated in some cases, the burdens of additional diagnostic evaluation and treatment aimed at the physiologic problem may outweigh the benefits. The treatment of dyspnea varies depending on the underlying cause, the patient's general physical condition, and imminence of death. For example, a blood transfusion may provide temporary symptom relief for a patient with anemia earlier in the disease process; however, as the patient approaches the end of life, the benefits are typically short-lived or absent.

Nursing Assessment

As with assessment of pain, reports of dyspnea by patients must be believed. As is true for physical pain, the meaning of dyspnea to an individual patient may increase their suffering. For example, the patient may interpret increasing dyspnea as a sign that death is approaching. For some patients, sensations of breathlessness may invoke frightening images of drowning or suffocation, and the resulting cycle of fear and anxiety may increase the sensation of breathlessness. Therefore, the nurse should conduct a careful assessment of the psychosocial and spiritual components of the dyspnea. Physical assessment parameters include symptom intensity, distress, and interference with activities; auscultation of lung sounds; assessment of fluid balance, including measurement of dependent edema (circumference of lower extremities) and abdominal girth; temperature; skin color; sputum quantity and character; and cough.

To determine the intensity of dyspnea and its interference with daily activities, the patient can be asked to report the severity of the dyspnea using a scale of 0 to 10, where 0 is no dyspnea and 10 is the worst imaginable dyspnea. The nurse should assess the patient's baseline rating before treatment and should elicit subsequent measurements taken during exacerbation of the symptom, periodically during treatment,

and whenever the treatment plan changes; these parameters provide ongoing objective evidence for the efficacy of the treatment plan. In addition, physical assessment findings may assist in locating the source of the dyspnea and selecting nursing interventions to relieve the symptom. The components of the assessment change as the patient's condition changes. For example, when the patient who has been on daily weights can no longer get out of bed, the goal of comfort may outweigh the benefit of continued weights. Like other symptoms at the end of life, dyspnea can be managed effectively in the absence of assessment and diagnostic data (e.g., arterial blood gases) that are standard when a patient's illness or symptom is acute and considered reversible. A numeric rating scale similar to one that is used for assessing pain can provide objective evidence of the severity of the patient's dyspnea.

Nursing Management

Nursing management of dyspnea at the end of life is directed toward administering medical treatment for the underlying pathology, monitoring the patient's response to treatment, helping the patient and the family manage anxiety (which exacerbates dyspnea), altering the perception of the symptom, and conserving energy (see Chart 59-8). Pharmacologic intervention is aimed at modifying lung physiology and improving performance as well as altering the perception of the symptom. Bronchodilators and corticosteroids are used to treat underlying obstructive pathology, thereby improving overall lung function. Low doses of opioids effectively relieve dyspnea, although the mechanism of relief is not entirely clear. Although dyspnea in terminal illness is typically not associated with diminished blood oxygen saturation, low-flow oxygen often provides psychological comfort to both patients and families, particularly in the home setting.

As mentioned previously, dyspnea may be exacerbated by anxiety, and anxiety may trigger episodes of dyspnea, setting off a respiratory crisis in which the patient and the family may panic. For patients receiving care at home, patient and family education should include anticipation and management of crisis situations and a clearly communicated emergency plan. The patient and the family should be instructed about medication administration, condition changes that should be reported to the physician and the nurse, and strategies for coping with diminished reserves and increasing symptomatology as the disease progresses. The patient and the family require reassurance that the symptom can be effectively managed at home without the need for activation of the emergency medical services or hospitalization and that a nurse will be available at all times via telephone and to make a visit.

Chart 59-8

Palliative Nursing Interventions for Dyspnea

Decrease Anxiety

- Administer prescribed anxiolytic medications as indicated for anxiety or panic associated with dyspnea.
- Assist with relaxation techniques, guided imagery.
- Provide patient with a means to call for assistance (call bell/light within reach in a hospital or long-term care facility; handheld bell or other device for home).

Treat Underlying Pathology

- Administer prescribed bronchodilators and corticosteroids (obstructive pathology).
- Administer blood products, erythropoietin as prescribed (typically not beneficial in advanced disease).
- Administer prescribed diuretics and monitor fluid balance.

Alter Perception of Breathlessness

- Administer prescribed oxygen therapy via nasal cannula, if tolerated; masks may not be well tolerated.
- Administer prescribed low-dose opioids via oral route (morphine sulfate is used most commonly).
- Provide air movement in the patient's environment with a portable fan.

Reduce Respiratory Demand

- Educate patient and family to implement energy conservation measures.
- Place needed equipment, supplies, and nourishment within reach.
- For home or hospice care, offer bedside commode, electrical bed (with head that elevates).

Nutrition and Hydration at the End of Life

Anorexia and cachexia are common in the seriously ill. The profound changes in the patient's appearance and a lack of interest in the socially important rituals of mealtime are particularly disturbing to families. The approach to the problem varies depending on the patient's stage of illness, level of disability associated with the illness, and desires. The anorexia–cachexia syndrome is characterized by disturbances in carbohydrate, protein, and fat metabolism; endocrine dysfunction; and anemia. The syndrome results in severe asthenia (loss of energy).

Anorexia and cachexia differ from starvation (simple food deprivation) in several important ways. Appetite is lost early in the process, the body becomes catabolic in a dysfunctional way, and supplementation by gastric feeding (tube feeding) or parenteral nutrition in advanced disease does not replenish lean body mass that has been lost.

Anorexia

Although causes of anorexia may be controlled for a period of time, progressive anorexia is an expected and natural part of the dying process. Anorexia may be related to or exacerbated by situational variables (e.g., the ability to have meals with the family vs. eating alone in the "sick room"), progression of the disease, treatment of the disease, or psychological distress. The patient and the family should be instructed in strategies to manage the variables associated with anorexia (see Table 59-2).

Use of Pharmacologic Agents to Stimulate Appetite

Several pharmacologic agents are commonly used to stimulate appetite in patients with anorexia, although only progestational agents (e.g., megestrol acetate [Megace]) and glucocorticoids (e.g., dexamethasone [Dexpak]) have been found to stimulate appetite when examined in well-controlled research studies (Bondly & Jatoi, 2015). However, these agents have not been found to improve survival or quality in life in patients approaching end of life (Arensmeyer, 2012). Dexamethasone initially increases appetite and may provide short-term weight gain in some patients. It should be considered for those patients whose life expectancy is limited because the beneficial effects may be limited to the first few weeks of therapy and side effects increase over time (Del Fabbro, 2015). Therapy may need to be discontinued in patients with a longer life expectancy; after 3 to 4 weeks, corticosteroids interfere with the synthesis of muscle protein.

TABLE 59-2 Measures for Managing Anorexia

Nursing Interventions	Patient and Family Education Tips
Initiate measures to ensure adequate dietary intake without adding stress to the patient at mealtimes.	Reduce the focus on "balanced" meals; offer the same food as often as the patient desires it.
Assess the impact of medications (e.g., chemotherapy, antiretrovirals) or other therapies (radiation therapy, dialysis) that are being used to treat the underlying illness.	Increase the nutritional value of meals. For example, add dry milk powder to milk, and use this fortified milk to prepare cream soups, milkshakes, and gravies.
Administer and monitor effects of prescribed treatment of nausea, vomiting, and delayed gastric emptying.	
Encourage patient to eat when effects of medications have subsided.	Allow and encourage the patient to eat when hungry, regardless of usual mealtimes.
Assess and modify environment to eliminate unpleasant odors and other factors that cause nausea, vomiting, and anorexia.	Eliminate or reduce noxious cooking odors, pet odors, or other odors that may precipitate nausea, vomiting, or anorexia.
Remove items that may reduce appetite (soiled tissues, bedpans, emesis basins, clutter).	Keep patient's environment clean, uncluttered, and comfortable.
Assess and manage anxiety and depression to the extent possible.	Make mealtime a shared experience away from the "sick" room whenever possible. Reduce stress at mealtimes. Avoid confrontations about the amount of food consumed. Reduce or eliminate routine weighing of the patient.
Position to enhance gastric emptying.	Encourage patient to eat in a sitting position; elevate the head of the patient's bed. Plan meals (food selection and portion size) that the patient desires. Provide small frequent meals if they are easier for patient to eat.
Assess for constipation and/or intestinal obstruction.	Ensure that patient and family understand that prevention of constipation is essential, even when the patient's intake is minimal.
Prevent and manage constipation on an ongoing basis, even when the patient's intake is minimal.	Encourage adequate fluid intake, dietary fiber, and the use of a bowel program to prevent constipation.
Provide frequent mouth care, particularly following nourishment.	Assist the patient to rinse after every meal. Avoid mouthwashes that contain alcohol or glycerine, which dry mucous membranes.
Ensure that dentures fit properly.	Weight loss may cause dentures to loosen and cause irritation. Remove them to inspect the gums and to provide oral care.
Administer and monitor effects of topical and systemic treatment for oropharyngeal pain.	The patient's comfort may be enhanced if medications for pain relief given on an as-needed basis for breakthrough pain are given before mealtimes.

Megestrol acetate produces temporary weight gain of primarily fatty tissue, with little effect on protein balance. This agent carries risk of serious side effects, including thromboembolism, and risk increases with prolonged use (Del Fabbro, 2015).

Dronabinol is a psychoactive compound found in cannabis that may be helpful in reducing nausea and vomiting, appetite loss, pain, and anxiety, thereby improving food and fluid intake in some patients. However, in most patients, it is not as effective as other agents for appetite stimulation. Although dronabinol may have beneficial effects on appetite in patients with advanced cancer, it has not been shown to be more effective than megestrol. In addition, it possesses undesirable central nervous system side effects (Del Fabbro, 2015).

Cachexia

Cachexia refers to severe lean muscle loss with or without fat loss that cannot be reversed by traditional nutritional interventions (Fearon, Strasser, Anker, et al., 2011). Although anorexia may exacerbate cachexia, it is not the primary cause. Cachexia is associated with anabolic and catabolic changes in metabolism that relate to activity of neurohormones and proinflammatory cytokines, resulting in profound protein loss. These processes appear to be similar at the end stages of both cancer and some noncancerous illnesses, such as AIDS (Del Fabbro, 2015). However, the pathophysiology of cachexia in terminal illness is not well understood. In terminal illness, the severity of tissue wasting is greater than would be expected from reduced food intake alone, and typically increasing appetite or food intake does not reverse cachexia.

At one time, it was believed that patients with cancer with rapidly growing tumors developed cachexia because the tumor created an excessive nutritional demand and diverted nutrients from the rest of the body. Research links cytokines produced by the body in response to a tumor to a complex inflammatory-immune response present in patients whose tumors have metastasized, leading to anorexia, weight loss, and altered metabolism. An increase in cytokines occurs not only in cancer but also in AIDS and many other chronic diseases (Del Fabbro, 2015).

Artificial Nutrition and Hydration

Along with breathing, eating and drinking are essential to survival throughout life. Near the end of life, the body's nutritional needs change, and the desire for food and fluid may diminish. People may no longer be able to use, eliminate, or store nutrients and fluids adequately. Eating and sharing meals are important social activities in families and communities, and

food preparation and enjoyment are linked to happy memories, strong emotions, and hope for survival. For patients with serious illness, food preparation and mealtimes often become battlegrounds in which well-meaning family members argue, plead, and cajole to encourage ill people to eat. Seriously ill patients often lose their appetites entirely, develop strong aversions to foods that they have enjoyed in the past, or crave a particular food to the exclusion of all other foods.

Although nutritional supplementation may be an important part of the treatment plan in early or chronic illness, unintended weight loss and dehydration are expected characteristics of progressive illness. As illness progresses, patients, families, and clinicians may believe that without artificial nutrition and hydration, terminally ill patients will "starve," causing profound suffering and hastened death. However, starvation should not be viewed as the failure to insert tubes for nutritional supplementation or hydration of terminally ill patients with irreversible progression of disease. Research has demonstrated that terminally ill patients with cancer who were hydrated did not have improved biochemical parameters and exhibited lower serum albumin levels, leading to fluid retention. The use of artificial nutrition and hydration (tube and intravenous [IV] fluids and feeding) carries considerable risks and generally does not contribute to comfort at the end of life (Casarett, Kapo, & Kaplan, 2005). Similarly, survival is not increased when terminally ill patients with advanced dementia receive enteral feeding, and no data support an association between tube feeding and improved quality of life in these patients (Mitchell, Black, Ersek, et al., 2012). Furthermore, in patients who are close to death, symptoms associated with dehydration such as dry mouth, confusion, and diminished alertness are common and typically do not respond to artificial nutrition (Danis, Arnold, & Savarese, 2015). Dry mouth can generally be managed through nursing measures such as mouth care and environmental changes with medications to diminish confusion.

As the patient approaches the end of life, the family and the health care providers should offer the patient what he or she prefers and can most easily tolerate. The nurse should instruct the family how to separate feeding from caring and how to demonstrate love, sharing, and caring by being with the loved one in other ways. Preoccupation with appetite, feeding, and weight loss diverts energy and time that the patient and the family could use in other meaningful activities. In addition to those given in Table 59-2, the following are the tips to promote nutrition for terminally ill patients:

- Offer small portions of favorite foods.
- Be aware that cool foods may be better tolerated than hot foods.
- Offer cheese, eggs, peanut butter, mild fish, chicken, or turkey. Meat (especially beef) may taste bitter and unpleasant.
- Add milk shakes, meal replacement drinks, or other liquid supplements.
- Place nutritious foods at the bedside (fruit juices, milk shakes in insulated drink containers with straws).
- Schedule meals when family members can be present to provide company and stimulation.
- Offer ice chips made from frozen fruit juices.
- Allow the patient to refuse foods and fluids.

Delirium

Many patients remain alert, arousable, and able to communicate until very close to death. Others sleep for long intervals and awaken only intermittently, with eventual somnolence until death. Delirium refers to concurrent disturbances in the level of consciousness, attention, awareness, and cognitive capability that develop over a relatively short period of time (Wright, Brajtman, & Macdonald, 2014). In some patients, a period of agitated delirium precedes death, sometimes causing families to be hopeful that suddenly active patients may be getting better. Confusion may be related to underlying, treatable conditions such as medication side effects or interactions, pain or discomfort, hypoxia or dyspnea, or a full bladder or impacted stool. In patients with cancer, confusion may be secondary to brain metastases. Delirium may also be related to metabolic changes, infection, and organ failure.

Patients with delirium may become hypoactive or hyperactive, restless, irritable, and fearful. Sleep deprivation and hallucinations may occur. If treatment of the underlying factors contributing to these symptoms brings no relief, a combination of pharmacologic intervention with neuroleptics or benzodiazepines may be effective in decreasing distressing symptoms for some patients. There have been few randomized clinical trials to establish evidence for practice, nor are there current clinical guidelines for delirium management (Lawlor & Bush, 2014). The neuroleptic drug haloperidol (Haldol) is the most frequently used drug to treat delirium in palliative care settings and may reduce hallucinations and agitation at the end of life. Newer (atypical) neuroleptics, such as olanzapine (Zyprexa), quetiapine (Seroquel), and risperidone (Risperdal) have been less well studied (Lawlor & Bush, 2014). Benzodiazepines (e.g., lorazepam [Ativan]) can reduce anxiety but may contribute to worsening cognitive impairment if used alone.

Nursing interventions are aimed at identifying the underlying causes of delirium; acknowledging the family's distress over its occurrence; reassuring family members about what is normal; educating family members how to interact with and ensure safety for the patient with delirium; and monitoring the effects of medications used to treat severe agitation, paranoia, and fear. Confusion may mask the patient's unmet spiritual needs and fears about dying. Spiritual intervention, music therapy, gentle massage, and therapeutic touch may provide some relief. Reduction of environmental stimuli, avoidance of harsh lighting or very dim lighting (which may produce disturbing shadows), presence of familiar faces, and gentle reorientation and reassurance are also helpful.

Depression

Clinical depression should neither be accepted as an inevitable consequence of dying nor confused with sadness and anticipatory grieving, which are normal reactions to the losses associated with impending death. Emotional and spiritual support and control of disturbing physical symptoms are appropriate interventions for situational depression associated with terminal illness. Researchers have linked the psychological effects of cancer pain to suicidal thought and, less frequently, to carrying out a planned suicide (Robson, Scrutton, Wilkinson, et al., 2010). Patients and their families must be given space and time to experience sadness and to grieve; however, patients should not have to endure untreated depression at the end of their lives. An effective combined approach to clinical depression includes relief of physical symptoms, attention to emotional and spiritual distress, psychotherapy, and pharmacologic intervention with psychostimulants and antidepressants (Marks & Heinrich, 2013).

Palliative Sedation at the End of Life

Effective control of symptoms can be achieved under most conditions; however, some patients may experience distressing,

intractable symptoms. Although palliative sedation remains controversial, it is offered in some settings to patients who are close to death or who have symptoms that do not respond to conventional pharmacologic and nonpharmacologic approaches, resulting in unrelieved suffering. Palliative sedation is distinguished from euthanasia and physician-assisted suicide, which is not legal in India, in that the intent of palliative sedation is to relieve symptoms, not to hasten death. Palliative sedation is most commonly used when the patient exhibits intractable pain, dyspnea, seizures, or delirium, and it is generally considered appropriate in only the most difficult situations. Before implementing palliative sedation, the health care team should assess for the presence of underlying and treatable causes of suffering, such as depression or spiritual distress. Finally, the patient and the family should be fully informed about the use of this treatment and alternatives. Whereas proportionate palliative sedation uses the minimum drug necessary to relieve the symptom while preserving consciousness, palliative sedation induces unconsciousness, which is more controversial.

Palliative sedation is accomplished through an infusion of one or more pharmacologic agents in doses adequate to eliminate signs of discomfort and, in some cases, induce sleep. In a review of published guidelines for pharmacologic management of palliative sedation, researchers reported that although most published guidelines varied considerably, most mentioned the use of midazolam (Versed), a short-acting hypnotic sedative (Schildmann, Schildmann, & Kiesewetter, 2015). Nurses act as collaborating members of the interdisciplinary health care team, providing emotional support to patients and families, facilitating clarification of values and preferences, and providing comfort-focused physical care. Once sedation has been induced, the nurse should continue to comfort the patient, monitor the physiologic effects of the sedation, support the family during the final hours or days of their loved one's life, and ensure communication within the health care team and between the team and the family.

Nursing Care of Patients who are Close to Death

Providing care to patients who are close to death and being present at the time of death can be one of the most rewarding experiences a nurse can have. Patients and their families are understandably fearful of the unknown, and the approach of death may prompt new concerns or cause previous fears or issues to resurface. Family members who have always had difficulty communicating or who are part of families in which there are old resentments and hurts may experience heightened difficulty as their loved one nears death. However, the time at the end of life can also afford opportunities to resolve old hurts and learn new ways of being a family. Regardless of the setting, skilled practitioners can make dying patients comfortable, make space for their loved ones to remain present if they wish, and can give family members the opportunity to experience growth and healing. Likewise, patients and family members may be less apprehensive near the time of death if they know what to expect and how to respond.

Expected Physiologic Changes

As death approaches and organ systems begin to fail, observable, expected changes in the body take place. Nursing care measures aimed at patient comfort, such as pain medications (given rectally or sublingually), turning, mouth care, eye care, positioning to facilitate draining of secretions, and measures to protect the skin from urine or feces (if the patient is incontinent), should be continued. The nurse should consult with the interprofessional team about discontinuing measures that no longer contribute to patient comfort, such as drawing blood, administering tube feedings, suctioning (in most cases), and invasive monitoring. The nurse should prepare the family for the normal, expected changes that accompany the period immediately preceding death. Although the exact time of death cannot be predicted, it is often possible to identify when the patient is very close to death. Hospice programs frequently provide written information for families so that they know what to expect and what to do as death nears (see Chart 59-9).

If family members have been prepared for the time of death, they are less likely to panic and are better able to be with their loved one in a meaningful way. Noisy, gurgling breathing or moaning is generally most distressing to family members. In most cases, the sounds of breathing at the end of life are related to oropharyngeal relaxation and diminished awareness. Family members may have difficulty believing that the patient is not in pain or that the patient's breathing could not be improved by suctioning secretions. Patient positioning and family reassurance are the most helpful responses to these symptoms.

When death is imminent, patients may become increasingly somnolent and unable to clear sputum or oral secretions, which may lead to further impairment of breathing from pooled or dried and crusted secretions. The sound (terminal bubbling) and appearance of the secretions are often more distressing to family members than is the presence of the secretions to the patient. Family distress over the changes in the patient's condition may be eased by supportive nursing care. Continuation of comfort-focused interventions and reassurance that the patient is not in any distress can do much to ease family concerns. Gentle mouth care with a moistened swab or very soft toothbrush helps maintain the integrity of the patient's mucous membranes. In addition, gentle oral suctioning, positioning to enhance drainage of secretions, and sublingual or transdermal administration of anticholinergic drugs (see Table 59-3) reduce the production of secretions and provide comfort to the patient

TABLE 59-3 Secretions and Terminal Respiratory Congestion

Medication	Suggested Initial Dosing
Atropine 1% ophthalmic (Isopto-Atropine®)	1 to 2 drops PO/SL every 4 hours, scheduled or PRN
Atropine injection[a]	0.4 mg IV/SC/IM every 4 hours, scheduled or PRN
Glycopyrrolate[a] (Robinul®)	1 mg PO TID, scheduled or PRN, up to 6 mg/d, or 0.1 mg SC/IM/IV TID PRN or
Hyoscyamine[a] (Levsin®)	0.125 mg PO/SL every 4 hours PRN, up to 1.5 mg/d
Hyoscyamine extended-release[a] (Levbid®)	0.375 mg PO every 12 hours, up to 1.5 mg/d
Scopolamine (Transderm Scop®)	Apply 1 patch topically behind the ear every 72 hours, up to 3 patches/72 hours

IM, intramuscularly; IV, intravenously; PO, by mouth; PRN, as needed; SC, subcutaneously; SL, sublingually; TID, twice a day.

Chart 59-9 EDUCATING THE FAMILY

Signs of Approaching Death

The person shows less interest in eating and drinking. For many patients, refusal of food is an indication that they are ready to die. Fluid intake may be limited to that which will keep their mouths from feeling too dry.

- *What you can do:* Offer, but do not force, fluids and medication. Sometimes pain or other symptoms that have required medication in the past may no longer be present. For most patients, pain medications are still needed, and they can be provided by concentrated oral solutions placed under the tongue or by rectal suppository.

Urinary output may decrease in amount and frequency.

- *What you can do:* No response is needed unless the patient expresses a desire to urinate and cannot. Call the hospice nurse for advice if you are not sure.

As the body weakens, the patient will sleep more and begin to detach from the environment. He or she may refuse your attempts to provide comfort.

- *What you can do:* Allow your loved one to sleep. You may wish to sit with him or her, play soft music, or hold hands. Your loved one's withdrawal is normal and is not a rejection of your love.

Mental confusion may become apparent. This occurs because less oxygen is available to supply the brain. The patient may report strange dreams or visions.

- *What you can do:* As he or she awakens from sleep, remind him or her of the day and time, where he or she is, and who is present. This is best done in a casual, conversational way.

Vision and hearing may become somewhat impaired, and speech may be difficult to understand.

- *What you can do:* Speak clearly but no more loudly than necessary. Keep the room as light as the patient wishes, even at night. Carry on all conversations as if they can be heard, because hearing may be the last of the senses to cease functioning.
- Many patients are able to talk until minutes before death and are reassured by the exchange of a few words with a loved one.

Secretions may collect in the back of the throat and rattle or gurgle as the patient breathes through the mouth. He or she may try to cough, and their mouth may become dry and encrusted with secretions.

- *What you can do:* If the patient is trying to cough up secretions and is experiencing choking or vomiting, call the hospice nurse for assistance.
- Secretions may drain from the mouth if you place the patient on their side and provide support with pillows.
- Cleansing the mouth with moistened mouth swabs will help relieve the dryness that occurs with mouth breathing.
- Offer water in small amounts to keep the mouth moist. A straw with one finger placed over the end can be used to transfer sips of water to the patient's mouth.

Breathing may become irregular with periods of no breathing (apnea). The patient may be working very hard to breathe and may make a moaning sound with each breath. As the time of death nears, the breathing remains irregular and may become more shallow and mechanical.

- *What you can do:* Raising the head of the bed may help the patient to breathe more easily. The moaning sound does not mean that the patient is in pain or other distress; it is the sound of air passing over very relaxed vocal cords.

As the oxygen supply to the brain decreases, the patient may become restless. It is not unusual to pull at the bed linens, to have visual hallucinations, or even to try to get out of bed at this point.

- *What you can do:* Reassure the patient in a calm voice that you are there. Prevent him or her from falling by trying to get out of bed. Soft music or a back rub may be soothing.

The patient may feel hot one moment and cold the next as the body loses its ability to control temperature. As circulation slows, the arms and legs may become cool and bluish. The underside of the body may darken. It may be difficult to feel a pulse at the wrist.

- *What you can do:* Provide and remove blankets as needed. Avoid using electrical blankets, which may cause burns because the patient cannot tell you if he or she is too warm.
- Sponge the patient's head with a cool cloth if this provides comfort.

Loss of bladder and bowel control may occur around the time of death.

- *What you can do:* Protect the mattress with waterproof padding, and change the padding as needed to keep the patient comfortable.

As people approach death, many times they report seeing gardens, libraries, or family or friends who have died. They may ask you to pack their bags and find tickets or a passport. Sometimes they may become insistent and attempt to do these chores themselves. They may try getting out of bed (even if they have been confined to bed for a long time) so that they can "leave."

- *What you can do:* Reassure the patient that it is all right; he or she can "go" without getting out of bed. Stay close, share stories, and be present.

and support to the family. Deeper suctioning may cause significant discomfort to the dying patient and is rarely of any benefit because secretions reaccumulate rapidly.

The Death Vigil

Although each death is unique, it is often possible for experienced clinicians to assess that the patient is "actively" or imminently dying and to prepare the family in the final days or hours leading to death. As death nears, the patient may withdraw, sleep for longer intervals, or become somnolent. Death is generally preceded by a period of gradual diminishment of bodily functions, increased intervals between respirations, a weakened and irregular pulse, diminished blood pressure, and skin color changes or mottling. Family members should be encouraged to be with the patient, to speak and reassure the patient of their presence, to stroke or touch the patient, or to lie alongside the patient (even in the hospital or long-term care facility) if the family members are comfortable with this degree of closeness and can do so without causing discomfort to the patient.

The family may go to great lengths to ensure that their loved one will not die alone. However, despite the best intentions and efforts of the family and clinicians, the patient may die at a time when no one is present. In any setting, it is unrealistic for family members to be at the patient's bedside 24 hours a day. Experienced hospice clinicians have observed and reported that some patients appear to "wait" until family members are away from the bedside to die, perhaps to spare their loved ones the pain of being present at the time of death. Nurses can reassure family members throughout the death vigil by being present intermittently or continuously, modeling behaviors (such as touching and speaking to the patient), providing encouragement in relation to family caregiving, providing reassurance about normal physiologic changes, and encouraging

family rest breaks. If a patient dies while family members are away from the bedside, they may express feelings of guilt and profound grief and may need emotional support.

After-Death Care

For patients who have received adequate management of symptoms and for families who have received adequate preparation and support, the actual time of death is commonly peaceful and occurs without struggle. Nurses may or may not be present at the time of a patient's death. In many states, nurses are authorized to make the pronouncement of death and sign the death certificate when death is expected. Death is defined as the permanent cessation of respiratory and circulatory functions (Bernat, 2009). The determination of death is made through a physical examination that includes auscultation for the absence of breathing and heart sounds. Home care or hospice programs in which nurses make the time-of-death visit and pronounce death have policies and procedures to guide the nurse's actions during this visit. Immediately on cessation of vital functions, the body begins to change. It becomes dusky or bluish, waxen appearing, and cool; blood darkens and pools in dependent areas of the body (e.g., the back and the sacrum if the body is in a supine position); and urine and stool may be evacuated.

Immediately after death, family members should be allowed and encouraged to spend time with the deceased. Normal responses of family members at the time of death vary widely and range from quiet expressions of grief to overt expressions that include wailing and prostration. The family members' desire for privacy during their time with the deceased should be honored. Family members may wish to independently manage or assist with care of the body after death. In the home, after-death care of the body frequently includes culturally specific rituals such as bathing the body. Home care agencies and hospices vary in the policies surrounding removal of tubes. In the absence of specific guidance from the organization, the nurse should shut off infusions of any kind (IV or tube feeding) and leave IV access devices, feeding tubes, catheters, and wound dressings in place. When an expected death occurs in the home setting, the family generally will have received assistance with funeral arrangements in advance of the death. The funeral home has often been prearranged and the family and friends will transport the body directly to the funeral home. In the hospital or long-term care facility, nurses follow the facility's procedure for preparation of the body and transportation to the facility's morgue. However, the needs of families to remain with the deceased, to wait until other family members arrive before the body is moved, and to perform after-death rituals should be honored.

Some patients may have elected to donate tissue such as corneas, bone, veins, or heart valves for transplant. Typically, this information would be known to the care team before the patient dies. In some cases, such as late referral or an unexpectedly rapid progression, the patient's wishes with respect to donation might be unknown. If the patient died at home or in a nursing home and the deceased's wishes are known, a team member should contact the organ procurement organization through which the deceased had arranged to donate tissue. That organization will ordinarily transport the body for tissue procurement and to the funeral home.

Grief, Mourning, and Bereavement

A wide range of feelings and behaviors are normal, adaptive, and healthy reactions to the loss of a loved one. Grief refers to the personal feelings that accompany an anticipated or actual loss. Mourning refers to individual, family, group, and cultural expressions of grief and associated behaviors. Bereavement refers to the period of time during which mourning for a loss takes place. Both grief reactions and mourning behaviors change over time as people learn to live with the loss. Although the pain of the loss may be tempered by the passage of time, loss is an ongoing developmental process, and time does not heal the bereaved individual completely. That is, the bereaved do not get over a loss entirely, nor do they return to who they were before the loss. Rather, they develop a new sense of who they are and where they fit in a world that has changed dramatically and permanently.

Anticipatory Grief and Mourning

Denial, sadness, anger, fear, and anxiety are normal grief reactions in people with life-threatening illness and those close to them. Kübler-Ross (1969) described five common emotional reactions to dying that are applicable to the experience of any loss (see Table 59-4). Not every patient or family member experiences every stage; many patients never reach a stage of acceptance, and patients and families sometimes fluctuate on a daily basis in their emotional responses. Furthermore, although impending loss stresses the patient, the people who are close to him or her, and the functioning of the family unit, awareness of dying also provides a unique opportunity for family members to reminisce, resolve relationships, plan for the future, and say goodbye.

Individual and family coping with the anticipation of death is complicated by the varied and conflicting trajectories that grief and mourning may assume in families. For example, the patient may be experiencing sadness while contemplating role changes that have been brought about by the illness, and the patient's spouse or partner may be expressing or suppressing feelings of anger about the current changes in role and impending loss of the relationship. Others in the family may be engaged in denial (e.g., "Dad will get better. He just needs to eat more"), fear ("Who will take care of us?" or "Will I get sick, too?"), or profound sadness and withdrawal. Although each of these behaviors is normal, tension may arise when one or more family members perceive that others are less caring, too emotional, or too detached.

The nurse should assess the characteristics of the family system and intervene in a manner that supports and enhances the cohesion of the family unit. Parameters for assessing the family facing life-threatening illness are identified in Chart 59-10. The nurse can suggest that family members talk about their feelings and understand them in the broader context of anticipatory grief and mourning. Acknowledging and expressing feelings, continuing to interact with the patient in meaningful ways, and planning for the time of death and bereavement are adaptive family behaviors. Professional support provided by grief counselors, whether in the community, at a local hospital, in the long-term care facility, or associated with a hospice program, can help both the patient and the family sort out and acknowledge feelings and make the end of life as meaningful as possible.

Grief and Mourning After Death

When a loved one dies, family members enter a new phase of grief and mourning as they begin to accept the loss, feel the pain of permanent separation, and prepare to live a life without the deceased. Even if the loved one died after a long illness, preparatory grief experienced during the terminal illness does not preclude the grief and mourning that follow the death. With a death after a long or difficult illness, family members may experience conflicting feelings of relief that the

TABLE 59-4 Kübler-Ross's Five Stages of Grief

Stage	Nursing Implications
Denial: "This cannot be true." Feelings of isolation. May search for another health care professional who will give a more favorable opinion. May seek unproven therapies.	Denial can be an adaptive response, providing a buffer after bad news. It allows time to mobilize defenses but can be maladaptive when it prevents the patient or the family from seeking help or when denial behaviors cause more pain or distress than the illness or interfere with everyday functions. Nurses should assess the patient's and family's coping style, information needs, and understanding of the illness and treatment to establish a basis for empathetic listening, education, and emotional support. Rather than confronting the patient with information that he or she is not ready to hear, the nurse can encourage him or her to share fears and concerns. Open-ended questions or statements such as "Tell me more about how you are coping with this new information about your illness" can provide a springboard for expression of concerns.
Anger: "Why me?" Feelings of rage, resentment, or envy directed at God, health care professionals, family, others.	Anger can be very isolating, and loved ones or clinicians may withdraw. Nurses should allow the patient and family to express anger, treating them with understanding, respect, and knowledge that the root of the anger is grief over impending loss.
Bargaining: "I just want to see my grandchild's birth, then I'll be ready…." Patient and/or family plead for more time to reach an important goal. Promises are sometimes made with God.	Terminally ill patients are sometimes able to outlive prognoses and achieve some future goal. Nurses should be patient, allow expression of feelings, and support realistic and positive hope.
Depression: "I just don't know how my kids are going to get along after I'm gone." Sadness, grief, mourning for impending losses.	Normal and adaptive response. Clinical depression should be assessed and treated when present. Nurses should encourage the patient and the family to fully express their sadness. Insincere reassurance or encouragement of unrealistic hopes should be avoided.
Acceptance: "I've lived a good life, and I have no regrets." Patient and/or family are neither angry nor depressed.	The patient may withdraw as their circle of interest diminishes. The family may feel rejected by the patient. Nurses need to support the family's expression of emotions and encourage them to continue to be present for the patient.

Adapted from Kübler-Ross, E. (1969). On death and dying. New York, NY: Macmillan.

loved one's suffering has ended, compounded by guilt and grief related to unresolved issues or the circumstances of death. Grief work may be especially difficult if a patient's death was painful, prolonged, accompanied by unwanted interventions, or unattended. Families that had no preparation or support during the period of imminent death may have a more difficult time finding a place for the painful memories.

Although some family members may experience prolonged or complicated mourning, most grief reactions fall within a "normal" range. The feelings are often profound; however, bereaved people eventually reconcile the loss and find a way to reengage with their lives. Grief and mourning are affected by several factors, including individual characteristics, coping skills, and experiences with illness and death; the nature of the relationship to the deceased; factors surrounding the illness and the death; family dynamics; social support; and cultural expectations and norms. Uncomplicated grief and mourning are characterized by a range of emotions and behaviors from sadness and yearning to thoughts about or preoccupation with the deceased and for many, a temporary withdrawal from the activities of living in which they engaged before the death (Shear, 2012).

After-death rituals, including preparation of the body, funeral practices, and burial rituals, are socially and culturally significant ways in which family members begin to accept the reality and finality of death. Preplanning of funerals is becoming increasingly common, and hospice professionals in particular help the family make plans for death, often involving the patient, who may wish to play an active role. Preplanning of the funeral relieves the family of the burden of making decisions in the intensely emotional period after a death.

In general, the period of mourning is an adaptive response to loss during which mourners come to accept the loss as real and permanent, acknowledge and experience the painful emotions that accompany the loss, experience life without the deceased, overcome impediments to adjustment, and find a new way of living in a world without the loved one. Particularly immediately after the death, mourners begin to recognize the reality and permanence of the loss by talking about the deceased and telling and retelling the story of the illness and death.

In reality, the work of grief and mourning takes time, and avoiding grief work after the death often leads to long-term adjustment difficulties. According to Rando (2000), mourning for a loss involves the "undoing" of psychosocial ties that bind mourners to the deceased, personal adaptation to the loss, and learning to live in the world without the deceased. Six key processes of mourning allow people to accommodate to the loss in a healthy way (Rando, 2000):

1. Recognition of the loss
2. Reaction to the separation and experiencing and expressing the pain of the loss
3. Recollection and reexperiencing the deceased, the relationship, and the associated feelings
4. Relinquishing old attachments to the deceased
5. Readjustment to adapt to the new world without forgetting the old
6. Reinvestment

Although many people complete the work of mourning with the informal support of families and friends, many find that talking with others who have had a similar experience, such as in formal support groups, normalizes the feelings and experiences and provides a framework for learning new skills to cope with the loss and create a new life. Hospitals, hospices, religious organizations, and other community organizations often sponsor bereavement support groups. Groups for parents who have lost a child, children who have lost a parent, widows, widowers, and gay men and lesbians who have lost a life partner are some examples of specialized support groups

Chart 59-10 ASSESSMENT

Assessing for Anticipatory Mourning in the Family Facing Life-Threatening Illness

Family Constellation

- Identify the members who constitute the patient's family. Who is important to the patient?
- Identify roles and relationships among the family members:
- Who is the primary caregiver?
- By what authority is this person the primary caregiver?

Cohesion and Boundaries

- How autonomous/interdependent are family members?
  - Degree of involvement with each other as individuals and as a family
  - Degree of bonding between family members
  - Degree of "teamwork" in the family
  - Degree of reliance on individual family members for specific tasks/roles
- How do family members differ in:
  - Personality?
  - Worldview?
  - Priorities?
- What are the implicit and explicit expectations or "rules" for behavior within the family?

Flexibility and Adaptability

- What is the family's ability to integrate new information?
- How does the family manage change?
- How able are the family members to assume new roles and responsibilities?

Communication

- What is the style of communication in the family, in terms of:
  - Openness?
  - Directness?
  - Clarity?
- What are the constraints on communication?
- What topics are avoided?

available in many communities. Nursing interventions for those experiencing grief and mourning are identified in Chart 59-11.

Complicated Grief and Mourning

Complicated grief and mourning are characterized by prolonged feelings of sadness and feelings of general worthlessness or hopelessness that persist long after the death, prolonged symptoms that interfere with activities of daily living (anorexia, insomnia, fatigue, panic), or self-destructive behaviors such as alcohol or substance abuse and suicidal ideation or attempts (Howarth, 2011). Complicated grief and mourning require professional assessment and can be treated with psychological interventions and, in some cases, with medications.

Coping with Death and Dying: Professional Caregiver Issues

Whether practicing in a trauma center, ICU, or other acute care setting, home care, hospice, long-term care, or the many locations where patients and their families receive ambulatory services, nurses are closely involved with complex and emotionally laden issues surrounding loss of life. To be most effective and satisfied with the care they provide, nurses should

Chart 59-11

Nursing Interventions for Grief and Mourning

Support the Expression of Feelings

- Encourage the telling of the story using open-ended statements or questions (e.g., "Tell me about your husband").
- Assist the mourner to find an outlet for their feelings: talking, attending a support group, keeping a journal, finding a safe outlet for angry feelings (writing letters that will not be mailed, physical activity).
- Assess emotional affect and reinforce the normalcy of feelings.
- Assess for guilt and regrets:
  - "Are you especially troubled by a certain memory or thought?"
  - "How do you manage those memories?"

Assess for the Presence of Social Support

- "Do you have someone to whom you can talk about your husband?"
- "May I help you find someone you can talk to?"

Assess Coping Skills

- "How are you managing day to day?"
- "Have you experienced other losses? How did you manage those?"
- "Are there things that you are having trouble doing?"
- "Do you have/need help with specific tasks?"

Assess for Signs of Complicated Grief and Mourning and Offer Professional Referral

- Are you preoccupied with thoughts of the deceased that interfere with your ability to care for yourself?
- Do you have frequent and prolonged intense emotional pain?

attend to their own emotional responses to the losses witnessed every day. Well before exhibiting symptoms of stress or burnout, nurses should acknowledge the difficulty of coping with others' pain on a daily basis and establish healthy practices that guard against emotional exhaustion. In hospice settings, where death, grief, and loss are expected outcomes of patient care, interdisciplinary colleagues rely on one another for support, using meeting time to express frustration, sadness, anger, and other emotions; to learn coping skills from one another; and to speak about how they were affected by the lives of those patients who have died since the last meeting. In many settings, staff members organize or attend memorial services to support families and other caregivers, who find comfort in joining one another to remember and celebrate the lives of patients. Finally, healthy personal habits, including diet, exercise, stress reduction activities (e.g., dance, yoga, T'ai chi, meditation), and sleep, help guard against the detrimental effects of stress.

CRITICAL THINKING EXERCISES

1. Your patient is a 46-year-old man who is hospitalized for complications associated with advanced colon cancer. He has metastases to the liver and the bone, exhibits anorexia and cachexia, and reports that his pain is controlled but he feels that he cannot catch his breath. He has three young children with his same sex partner of 15 years. He will be discharged home on hospice care. You note that his breathing does not appear labored, nor is he tachypneic. Does he have dyspnea? What would your comprehensive dyspnea assessment include?

2. Your patient is a 65-year-old woman with Class IV heart failure. She lives with her husband and two adult daughters in a mobile home park near the outpatient practice where you are seeing her today. She tells you that she feels so tired that she does not even want to get out of bed or eat most days, and that she thinks she is losing weight. What is the evidence base about anorexia and cachexia care? How will you evaluate the evidence?
3. You are a new hospice nurse in your third week of night shift in a freestanding hospice inpatient unit. Your patient, a 55-year-old woman with advanced ovarian cancer was admitted 3 days prior. When you enter her room at the beginning of your shift, you note that she is not arousable and is having periods of apnea. It is 11 pm and the nurse who reported off told you that the patient's family left at approximately 9 pm. You are not sure but you think that your patient might be imminently dying. You have four other patients you have not seen yet. What should you do first? Why? What additional actions should be taken?

Emergency and Disaster Nursing

Chapter 60 Emergency Nursing 1977

Chapter 61 Terrorism, Mass Casualty, and Disaster Nursing 2012

CHAPTER 60

Emergency Nursing

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe emergency care as a collaborative, holistic approach that includes the patient, the family, and significant others.
2. Discuss priority emergency measures instituted for the patient with an emergency condition.
3. Identify the priorities of care for the patient with multiple system injuries.
4. Compare and contrast the emergency management of patients with heat stroke, frostbite, and hypothermia.
5. Specify the similarities and differences of the emergency management of patients with swallowed or inhaled poisons, skin contamination, animals and snake bites, and food poisoning.
6. Explain the emergency management of patients with drug overdose, those with acute alcohol intoxication, and those who have been sexually assaulted.
7. Differentiate between the emergency care of patients who are overactive, those who are violent, those who are depressed, and those who are suicidal.
8. Identify the legal and ethical issues involved in emergency nursing.

GLOSSARY

antivenin: antitoxin manufactured from venom of poisonous snakes to assist the patient's immune system response to an envenomation
carboxyhemoglobin: hemoglobin that is bound to carbon monoxide and therefore is unable to bind with oxygen, resulting in hypoxemia
corrosive poison: alkaline or acidic agent; causes tissue destruction after contact
cricothyroidotomy: surgical opening of the cricothyroid membrane to obtain an airway that is maintained with a tracheostomy or endotracheal tube
envenomation: injection of a poisonous material by sting, spine, bite, or other means
fasciotomy: surgical incision of the extremity to the level of the fascia to relieve pressure and restore neurovascular function to the extremity
multiple trauma: trauma caused by a single catastrophic event that causes life-threatening injuries to at least two distinct organs or organ systems
primary survey: an assessment of the patient triaged to the emergent or resuscitation category that focuses on stabilizing life-threatening conditions; uses the mnemonic ABCDE, which stands for *a*irway, *b*reathing, *c*irculation, *d*isability, and *e*xposure
rhabdomyolysis: a toxic syndrome caused by widespread injury to skeletal muscle, resulting in myoglobinuria and acute kidney injury
secondary survey: an assessment of the patient triaged to the emergent or resuscitation category that commences after the primary survey is completed and life-threatening insults addressed; includes obtaining vital signs, completing a head-to-toe examination, and obtaining the patient's pertinent medical-surgical history, including the history of the current event
sentinel event: an unanticipated event that results in patient harm
triage: process of assessing patients to determine management priorities

Introduction

The term *emergency management* traditionally refers to care given to patients with urgent and critical needs. However, because many people lack access to health care, the emergency department (ED) is increasingly used for nonurgent problems. Therefore, the philosophy of emergency management has broadened to include the concept that an emergency is whatever the patient or the family considers it to be.

The emergency nurse has had specialized education, training, experience, and expertise in assessing and identifying patients' health care problems in crisis situations. In addition, the emergency nurse establishes priorities, monitors, and continuously assesses patients who are acutely ill and injured, supports and attends to families, supervises allied health personnel, and educates patients and families within a time-limited, high-pressured care environment. Nursing interventions are accomplished interdependently, in consultation with or under the direction of a physician. The roles of nursing and medicine are complementary in an emergency situation. Appropriate nursing and medical interventions are anticipated based on assessment data. Members of the emergency health care staff work as a team in performing the highly technical, hands-on skills required to care for patients in emergency situations (Emergency Nurses Association [ENA], 2013).

Large numbers of people seek emergency care for serious life-threatening conditions, such as cardiac dysrhythmias, acute coronary syndrome, acute heart failure, pulmonary edema, and stroke. Priorities for managing these cardiac and other conditions are discussed in Chapters 20, 21, 23, and 50. Emergency management of trauma and conditions not found elsewhere in this book are discussed in this chapter.

ISSUES IN EMERGENCY NURSING CARE

Emergency nursing is demanding because of the diversity of conditions and situations that present unique challenges. These challenges include legal issues, occupational health and safety risks for ED staff, and the challenge of providing holistic care in the context of a fast-paced, technology-driven environment

in which serious illness and death are encountered on a daily basis. Another dimension of emergency nursing is nursing in disasters. With the increasing use of weapons of terror and mass destruction, both internationally and at home, the emergency nurse must recognize and treat patients exposed to biologic and other weapons, anticipating nursing care in the event of a mass casualty incident from natural causes or a terrorist event (see Chapter 61).

Documentation of Consent and Privacy

Consent to examine and treat the patient is part of the ED record. The patient needs to give consent for invasive procedures (e.g., angiography, lumbar puncture) unless he or she is unconscious or in a critical condition and unable to make decisions. If the patient is unconscious and brought to the ED without family or friends, this fact must be documented. Monitoring of the patient's condition, as well as all instituted treatments and the times at which they were performed, must be documented. After treatment, a notation is made on the record about the patient's condition, response to the treatment, and condition at discharge or transfer and about instructions given to the patient and family for follow-up care.

According to the Indian law, the patients who arrive with fatal accidents or injury due to violence also deserve the best possible timely care and it is the obligatory act expected from the emergency health care team (Pinto, 2017), In every ED, the physician must perform a medical screening examination on all patients arriving with an emergency medical complaint if their acute signs and symptoms could result in serious injury or death if left untreated. EDs are also required to provide treatment aimed at stabilizing each patient's condition. If the patient must be transferred to another facility, the patient's consent for transfer should be obtained, if possible. In addition, acceptance by the receiving facility and physician must be obtained, and an appropriate method of transfer for the patient should be secured. Documentation of assessment and treatment must be sent with the patient upon transfer (ENA, 2013).

Limiting Exposure to Health Risks

Because of the increasing numbers of people infected with hepatitis, human immune deficiency virus (HIV), tuberculosis, and other infectious diseases, health care providers are at an increased risk for exposure to communicable diseases through blood, respiratory droplets, or other body fluids. This risk is further compounded in the ED because of the common use of invasive treatments in patients who may have a wide range of conditions and are unable to provide a comprehensive medical history. All emergency health care providers must adhere strictly to standard precautions for minimizing exposure.

The re-emergence of tuberculosis and certain airborne infections like SARS warrant the nurses in the ED to be wearing a high-efficiency particulate air (HEPA) filter masks while treating patients with airborne diseases.

Nursing Alert: To limit the risk of exposure to airborne diseases, early identification and strict adherence to transmission-based precautions for patients who are potentially infectious is crucial.

The potential for exposure to highly contagious organisms, hazardous chemicals or gases, and radiation related to acts of terrorism or natural or man-made disasters presents additional risks to ED staff. See Chapter 61 for information about decontamination procedures.

Violence in the Emergency Department

Not only do ED staff members encounter patients who may be violent because of the effects of substance abuse, injury, or other emergencies, they may also encounter other violent situations. Patients and families waiting for assistance may be emotionally volatile. Often, waiting rooms are the sites where feelings of dissatisfaction, fear, and anger are channeled violently. Some EDs assign security officers or off duty police to the area and have installed silent alarm systems or metal detectors to identify weapons in order to protect patients, families, and staff. Safety is the first priority.

Patients and family members under the influence of illicit drugs or alcohol, or who may have psychiatric disorders, including delirium or dementia, or who may be influenced by social situations such as gang membership, are at risk for committing a violent act, whether intentional or not (Avander, Heikki, Bjersa, et al., 2016). The environment of the ED, including being subjected to long wait times and crowded conditions, may also increase their risk of committing violent events. Physical threats are most often accompanied by verbal abuse, which is the most common type of violence (American College of Emergency Physicians [ACEP], 2011). Although not a typical occurrence, a patient or family member may come to the ED armed. To avoid angry confrontations, members of gangs and families who are feuding need to be separated in the ED, in the waiting room, and later in the inpatient nursing unit. Nurses and other personnel must be prepared to deal with these circumstances. The ED should be locked against entry if security is questionable.

Patients who are violent or potentially violent must be vigilantly monitored by the ED staff. Care must be taken to avoid injury. Patients from prison and those who are under guard need to be handcuffed to the bed and appropriately assessed to ensure the safety of hospital staff and other patients. The emergency nurse must understand how to employ safe use of restraints. The Joint Commission has strict standards regarding documentation of the reason, monitoring for safety, and ensuring the dignity of the patient who is restrained (Solheim, 2016). Precautions to be taken to avoid injury include the following situations (ENA 2013); (Speroni, Fitch, Dawson, et al., 2014):

- For prisoners, the hand or ankle restraint (handcuff) is never released, and a guard is always present in the room.
- A mask can be placed on the patient to prevent spitting or biting.
- Nonrestraint techniques should be tried when possible—e.g., talking with the patient, minimizing environmental stimulation.
- Physical restraints are used on any patient who is violent only as needed and, if used, should be humanely and professionally given (ACEP, 2014); nonetheless, the staff should be cognizant that the patient could head-butt, even if restrained.
- Distance should be maintained from the patient to avoid grabbing; staff should not wear items that can be grabbed by the patient, such as dangling jewelry and stethoscopes. Furthermore, distance should be maintained between the

patient and the door so that an escape route for the staff member is preserved.
- Objects should not be left within patient reach; even an intravenous (IV) line spike can become a tool of violence if the patient is determined.
- Courses on safety (de-escalation and physical restraint techniques) assist the staff with preparing for various violent situations.

In the case of gunfire in the ED, self-protection is a priority. There is no advantage to protecting others if health care providers are injured. Security officers and police must gain control of the situation first, and then care is provided to the injured.

Providing Holistic Care

Patients and families experiencing sudden injury or illness are often overwhelmed by anxiety because they have not had time to adapt to the crisis. They experience real and terrifying fear of death, mutilation, immobilization, and other assaults on their personal identity and body integrity. When confronted with trauma, severe disfigurement, severe illness, or sudden death, the family experiences several stages of crisis. The stages begin with anxiety and progress through denial, remorse and guilt, anger, grief, and reconciliation. The initial goal for the patient and family is anxiety reduction, a prerequisite to effective and appropriate coping. During this stressful time, safety is of prime importance. Close observation and preplanning are essential and security personnel are stationed nearby in the event that a patient or family member responds to stress with physical violence.

Assessment of the patient and family's psychological function includes evaluating emotional expression, degree of anxiety, and cognitive functioning. Possible nursing diagnoses include:
- Anxiety or death anxiety related to uncertain potential outcomes of the illness or trauma
- Ineffective coping related to acute situational crisis

Possible nursing diagnoses for the family include:
- Grieving
- Interrupted family processes
- Compromised or disabled family coping related to acute situational crises

Patient-Focused Interventions

Clinicians caring for the patient should act confidently and competently to relieve anxiety and promote a sense of security. Explanations should be given that the patient can understand. Human contact and reassuring words reduce the panic of the person who is severely injured or ill and aid in dispelling fear of the unknown.

The patient who is unconscious should be treated as if conscious—that is, the patient should be touched, called by name, and given an explanation of every procedure that is performed. As the patient regains consciousness, the nurse should orient the patient by stating their name, the date, and the location. This basic information should be provided repeatedly, as needed, in a reassuring way.

Ensuring patient safety is a major focus in clinical practice settings. Some of the most common sentinel events (unanticipated events that result in patient harm) in the ED include delays to care and medication errors. Common root causes for these sentinel events revolve around nurse staffing patterns, patient volume, and specialty availability. Solutions to patient safety issues in the ED include ensuring optimal nurse staffing, pharmacy presence, and rapid diagnostics turnaround times to minimize wait time to diagnosis and fostering teamwork and support by leadership. All errors should be reported and investigated even if a patient was not harmed. In this way, future injury or death may be avoided (ENA, 2013).

Family-Focused Interventions

The family is kept informed about where the patient is, how he or she is doing, and the care that is being given. Encouraging family members to stay with the patient, when possible, also helps allay their anxieties. In many facilities, family presence during resuscitation is permitted to assist the family to cope through this difficult time. Many family members respond very well to this approach. One study found that families view emergency professionals favorably when a family member was resuscitated. They view their role as supportive and protective of the patient. Allowing family presence in the critical care areas of the hospital enhances the family role and builds trust in the caregivers (Leske, McAndrew, & Brasel, 2013). Posttraumatic stress disorder (PTSD) is less likely to occur if the family member is present during resuscitation (Jabre, Belpomme, Azoulay, et al., 2013). The presence of a family facilitator, who is trained to provide support to family members, is vital to the success of a family presence program. Additional interventions are based on the assessment of the stage of crisis that the family is experiencing. Measures to help family members cope with sudden death are presented in Chart 60-1.

Chart 60-1

Helping Family Members Cope with Sudden Death

The nurse takes the following actions:
- Take the family to a private place.
- Talk to the family together so that they can grieve together and hear the information given together.
- Reassure the family that everything possible was done; inform them of the treatment rendered.
- Avoid using euphemisms such as "passed on." Show the family that you care by touching, offering coffee and water.
- Encourage family members to support each other and to express emotions freely (grief, loss, anger, helplessness, tears, disbelief).
- Avoid giving sedation to family members; this may mask or delay the grieving process, which is necessary to achieve emotional equilibrium and to prevent prolonged depression.
- Encourage the family to view the body if they wish; this action helps to integrate the loss. Cover disfigured and injured areas before the family sees the body. Go with the family and do not leave them alone. Show acceptance by touching the body to give the family "permission" to touch.
- Spend time with the family, listening to them and identifying any needs that they may have for which the nursing staff can be helpful.
- Allow family members to talk about the deceased and what he or she meant to them; this permits ventilation of feelings of loss. Encourage the family to talk about events preceding admission to the emergency department. Do not challenge initial feelings of anger or denial.
- Avoid volunteering unnecessary information (e.g., the patient was drinking).

Anxiety and Denial

During these crises, family members are encouraged to recognize and talk about their feelings of anxiety. Asking questions is encouraged. Honest answers given at the level of the family's understanding must be provided. Although denial is an ego-defense mechanism that protects one from recognizing painful and disturbing aspects of reality, prolonged denial is not encouraged or supported. The family must be prepared for the reality of what has happened and what may come.

Remorse and Guilt

Expressions of remorse and guilt are common, with family members accusing themselves (or each other) of negligence or minor omissions. Family members are urged to verbalize their feelings to help them cope appropriately.

Anger

Expressions of anger, common in crisis situations, are a way of handling anxiety and fear. Anger is frequently directed by the family at the patient, but it is also often expressed toward the physician, the nurse, or admitting personnel. The therapeutic approach is to allow the anger to be expressed and to assist the family members to identify their feelings of frustration.

Grief

Grief is a complex emotional response to anticipated or actual loss. The key nursing intervention is to help family members work through their grief and to support their coping mechanisms, letting them know that it is normal and acceptable for them to cry, feel pain, and express loss.

Caring for Emergency Personnel

Concerted efforts have been made to focus on the needs of the ED staff, especially after serious and stressful events (ENA, 2013). Events can range from a local trauma case involving children; to treating someone known to the emergency worker, such as a colleague or family member; to a more complex natural disaster or multicasualty situation. It is important to remember that all staff members may not necessarily respond in the same way; an event that is stressful to one person may not be as stressful to another. Compassion fatigue may result from the continuous exposure to suffering and injury, and energy is expended on a daily basis. Fatigue occurs when the affected staff members cannot replenish the energy stores (Solheim, 2016). In addition, because stress is a daily occurrence in the ED, the staff may not recognize the personal effect of any one event or the cumulative effect of day-to-day crisis interventions. ED leadership should be aware of staff coping patterns and support systems, patterns of interactions between staff members, staff members' health problems, including addiction, and appropriately assist with identifying behaviors caused by workplace stress. The availability of nonjudgmental counseling is essential to promoting a healthy staff.

After serious events, critical incident stress management (CISM) is necessary to critique individual and group performance and to facilitate healthy coping. Optimally, this may consist of three steps: defusing, debriefing, and follow-up. Defusing occurs immediately after the critical incident. During this session, affected staff are encouraged to discuss their feelings about the incident and are given contact information so that they may talk to someone if they have disturbing symptoms (e.g., sleeplessness, excessive worry). Debriefing typically occurs 1 to 10 days after the critical incident. Debriefing sessions follow a format similar to the initial defusing session; however, during these sessions, participating staff are encouraged to discuss their feelings about the incident and are reassured that their negative reactions and feelings are normal and that their negative feelings will diminish over time. At the end of these sessions, participants should have a feeling of closure and be able to resume their professional roles at an emotional level commensurate to that prior to the critical incident. Some staff may require further professional follow-up, however. Follow-up may occur after the debriefing session is completed for those participants who have persistent negative symptoms and may consist of continued individual or group counseling and therapy (Solheim, 2016).

EMERGENCY NURSING AND THE CONTINUUM OF CARE

A key principle underlying emergency care is that the patient is rapidly assessed, treated, and referred to the appropriate setting for ongoing care. This makes the ED a temporary point on the continuum of care. Only 11.9% of patients who receive emergency care are admitted to the hospital, which means emergency nurses must plan and facilitate the patient's safe discharge and follow-up care in the home, community, and the transitional care environment (Cadogan, Phillips, & Ziminski, 2016).

Discharge Planning

Before discharge, verbal and written instructions for continuing care are given to the patient and the family or significant others. Many EDs have preprinted standard instruction sheets for the more common conditions (i.e., concussion), which can then be individualized. Discharge instructions should be available in a variety of languages. A language interpreter should be used as necessary to provide both written and verbal instructions.

Instructions should include information about prescribed medications, treatments, diet, activity, and when to contact a health care provider or schedule follow-up appointments. Discharge planning is the "teachable moment" for the patient, providing the opportunity to present injury prevention or smoking cessation strategies, alcohol counseling opportunities, and more. It is imperative that instructions are written legibly, use simple language, and are clear in their important points. When providing discharge instructions, the nurse also considers any special needs the patient may have related to hearing or visual impairments. Alternate formats of instruction (e.g., large print, Braille, audiotape) should be available to meet the needs of patients with hearing or visual impairments.

Community and Transitional Services

Before discharge, some patients require the services of a social worker to help them meet continuing health care needs. Home care resources may be contacted before discharge to arrange services. This is particularly important for patients who are older adults or who have disabilities and who need assistance. Identifying continuing health care needs and making arrangements for meeting these needs can prevent return visits to the ED or readmission to the hospital.

For patients who are returning to long-term care facilities and for those who already rely on community agencies for continuing health care, communication about the patient's condition and any changes in health care needs that have occurred must be provided to the appropriate facilities or agencies. This communication is essential to promote continuity of care and to ensure ongoing care that meets the patient's changing health care needs.

Many patients who utilize EDs have health problems that are nonurgent. Moreover, some patients return repeatedly to the ED with nonurgent problems (ENA, 2015a). It is posited that patients who present to the ED with nonurgent problems do so because there is a dearth of outpatient health care resources to fill their needs.

Gerontologic Considerations

The ED is a common point of entry into the health care system for patients 65 years and older. The Centers for Disease Control and Prevention (CDC, 2013) reports that 36.5% of ED visits by patients older than 65 years resulted in hospital admission. As age increases, the percentage of admissions increases. Of these admissions, 29% were related to trauma, primarily falls (CDC, 2013). Older adult patients typically arrive with one or more presenting conditions. Nonspecific symptoms, such as weakness and fatigue, episodes of falling, incontinence, and change in mental status, may be manifestations of acute, potentially life-threatening illness in the older person. Emergencies in this age group may be more difficult to manage because older adult patients may have an atypical presentation, an altered response to treatment, a greater risk of developing complications, or a combination of these factors.

The older adult patient may perceive the emergency as a crisis signaling the end of an independent lifestyle or even resulting in death. The nurse should give attention to the patient's feelings of anxiety and fear.

The older patient may have limited sources of social and financial support during these times of crises. The nurse should assess the psychosocial resources of the patient (and of the caregiver, if necessary) and anticipate discharge needs

Obesity Considerations

The considerations in ED management of patients with obesity include an understanding that it is generally more challenging to insert IV lines and airways. Ventilation also can be a challenge from the increased weight of the chest wall and the increased incidence of hypoventilation and sleep apnea among patients with obesity. Special consideration must be taken with lipophilic medications, as they take longer to clear from the larger volume of adipose tissue. Weight-based medications must be calculated carefully using ideal body mass. X-rays may be difficult to visualize because of poor penetration.

Complications that patients with obesity are more prone to experience during hospitalization include respiratory failure, acute kidney injury, pneumonia, deep vein thrombosis, and pressure ulcers. Patients with severe obesity who have femur fractures have a significantly higher risk of death, as well as a higher risk of acute respiratory distress syndrome (ARDS) and sepsis than patients of normal weight (Weinlein, Deadrick, & Murphy, 2015). Although many of these complications do not occur until later in the hospital stay, some preventive measures (e.g., encouraging turning, coughing, and deep-breathing exercises to prevent atelectasis) may be initiated in the ED. Functional recovery time is extended in patients with obesity, resulting in longer lengths of stay and increased hospital costs. Initiating prevention measures in the ED, such as early backboard removal and providing early preventive respiratory care, are targeted to improve recovery time (Childs, Nahm, Dolenc, et al., 2015); (Dhungel, Liao, Raut, et al., 2015). Arranging transfers of patients with obesity must also take into consideration the availability of appropriately sized equipment.

PRINCIPLES OF EMERGENCY CARE

By definition, emergency care is care that must be rendered without delay. In an ED, several patients with diverse health problems—some life threatening, some not—may present to the ED simultaneously. One of the first principles of emergency care is triage.

Triage

The word triage comes from the French word *trier,* meaning "to sort." In the daily routine of the ED, triage is used to sort patients into groups based on the severity of their health problems and the immediacy with which these problems must be treated.

A basic and widely used triage system that had been in use for many years utilized three categories: emergent, urgent, and nonurgent. In this system, emergent patients had the highest priority, urgent patients had serious health problems but not immediately life-threatening ones, and nonurgent patients had episodic illnesses. Most of the Indian hospitals follow the three-category triaging system which is advocated by the National Disaster Management Authority of India.

Category I/Emergent category (Life-threatening illness): The patient needs medical care with zero delay. Acute severe chest pain, continuous seizures, massive bleeding, major trauma with hypotension, head injury with unconsciousness are some exemplars that fall in this category. These patients need continuous monitoring by the nurse and may be shifted to resuscitation bay and then to the ICU or operation theater (OR).

Category II/Urgent category (Potential for life-threatening illness): The possibility of impending or emerging life-threatening illness is expected but not with any life-threatening illness. Patients in this category may require careful medical evaluation and treatment initiated within 10 minutes. Dyspnea, high-grade fever, acute confusion, acute abdomen, serious injury to extremity can be placed in Category II.

Category III/(Non–life-threatening conditions): There is no obvious or impending life-threatening illness. These patients can be examined and treated in the order of their arrival to the ED in a non-hurried manner. Chronic pain, fever, simple fracture to limbs or dislocation of joints, minor injuries that need wound cleansing and dressing are few examples for this category (National Disaster Management Guidelines Hospital Safety, 2016).

A comprehensive, valid, and reliable five-level triage severity rating system that recognizes that EDs are used for both emergency and routine health care is also used. The increased number of triage levels assists the triage nurse to more precisely determine the needs of the patient and the urgency for treatment. Systems that meet these criteria for validity and

reliability that are commonly used in the United States are the Emergency Severity Index (ESI) and the Canadian Triage and Acuity Scale (CTAS). The ESI assigns patients into five levels, from level 1 (most urgent) to level 5 (least urgent). With the ESI, patients are assigned to triage levels based on both their acuity and their anticipated resource needs (Gilboy, Tanabe, Travers, et al., 2012). The CTAS system's five levels include time parameters that guide how frequently patients must be reassessed by either a nurse or provider. Patients assigned to the *resuscitation* category must receive continuous nursing surveillance, those in the *emergent* category must be reassessed at least every 15 minutes, patients in the *urgent* category must be reassessed at least every 30 minutes, patients in the *less urgent* category must be reassessed at least every 60 minutes, and those in the *nonurgent* category must be reassessed at least every 120 minutes. The goal of all triage is rapid assessment and decision-making, preferably under 5 minutes (ENA 2013).

Triage is an advanced skill. Emergency nurses spend many hours learning to classify different illnesses and injuries to ensure that patients most in need of care do not needlessly wait. Protocols may be followed to initiate laboratory or x-ray studies while the patient is in the triage area. Collaborative protocols are developed and used by the triage nurse based on their level of experience. Nurses in the triage area collect additional crucial baseline data: full vital signs including pain assessment, history of the current event and past medical history, neurologic assessment findings, weight, allergies (especially to latex and medications), domestic violence screening, and necessary diagnostic data. Some facilities collect these data in a computerized system, which help guide the nurse through assessment and documentation. Asking questions is key to appropriate triage decisions. The following questions reflect the minimum information that should be obtained from the patient or from the person who accompanied the patient to the ED (so long as that person is not suspected of abuse or neglect; see later discussion) and then are documented:

- What were the circumstances, precipitating events, location, and time of the injury or illness?
- When did the symptoms appear?
- Was the patient unconscious after the injury or onset of illness?
- How did the patient get to the ED?
- What was the health status of the patient before the injury or illness?
- Is there a history of medical illness or previous surgeries? A history of admissions to the hospital?
- Is the patient currently taking any medications, especially hormones, insulin, digitalis, or anticoagulants? Is the patient using any complementary or alternative therapies such as herbology, naturopathy, Reiki, massage, or acupuncture?
- Does the patient have any allergies, especially to latex, medications, eggs, or nuts?
- Does the patient use tobacco products or recreational drugs? How frequently? What type? When was the last time they were used?
- Does the patient have any fears? Does the patient feel that he or she is in danger or in an unsafe situation?
- When was the last meal eaten? (This is important if general anesthesia is to be given or if the patient is unconscious.)
- When was the last menstrual period?
- Is the patient under a physician's care? What are the name and contact information for the physician?
- What was the date of the patient's most recent tetanus immunization?

In addition to the collection of initial vital signs and medical history, triage consists of providing basic first aid, which may include application of ice, bleeding control, and basic wound care, as well as initiating protocol-based prescriptions (e.g., x-rays, administering antipyretic or mild analgesic agents, obtaining an electrocardiogram [ECG] or urinalysis, removing sutures). The triage nurse also is responsible for and monitors the waiting area, maintains a safe environment, reassesses patients who are waiting, and is the initial liaison to the families of patients.

Routine ED triage protocols differ significantly from the triage protocols used in disasters and mass casualty incidents (field triage). Routine triage directs all available resources to the patients who are most critically ill, regardless of potential outcome. In field triage (or hospital triage during a disaster), scarce resources must be used to benefit the most people possible. This distinction affects triage decisions (see Chapter 61).

Assess and Intervene

For the patient assigned to an urgent or higher triage category, stabilization, provision of critical treatments, and prompt transfer to the appropriate setting (intensive care unit, operating room, general care unit) are the priorities of emergency care. Although treatment is initiated in the ED, ongoing definitive treatment of the underlying problem is provided in other settings, and the sooner the patient is stabilized and moved to that area, the better the outcome.

A systematic approach to effectively establishing and treating health priorities is the primary survey/secondary survey approach. The primary survey focuses on stabilizing life-threatening conditions. The ED staff work collaboratively and follow the ABCDE (*a*irway, *b*reathing, *c*irculation, *d*isability, *e*xposure) method:

- Establish a patent airway.
- Provide adequate ventilation, employing resuscitation measures when necessary. Patients who have experienced trauma must have the cervical spine protected and chest injuries assessed first, immediately after the airway is established.
- Evaluate and restore cardiac output by controlling hemorrhage, preventing and treating shock, and maintaining or restoring effective circulation. This includes the prevention and management of hypothermia. In addition, peripheral pulses are examined, and any immediate closed reductions of fractures or dislocations are performed if an extremity is pulseless.
- Determine neurologic disability by assessing neurologic function using the Glasgow Coma Scale (GCS) (See Chapter 51, Chart 51-2) and a motor and sensory evaluation of the spine (see Chapter 48, Fig. 48-9). A quick neurologic assessment may be performed using the AVPU mnemonic:
  - *A*—alert. Is the patient alert and responsive?
  - *V*—verbal. Does the patient respond to verbal stimuli?
  - *P*—pain. Does the patient respond only to painful stimuli?
  - *U*—unresponsive. Is the patient unresponsive to all stimuli, including pain?
- Undress the patient quickly but gently so that any wounds or areas of injury are identified; this may entail cutting away articles of clothing (American College of Surgeons [ACS], 2013).

After these priorities have been addressed, the ED team proceeds with the secondary survey. This includes the following:

- Complete health history, including the history of the current event
- Head-to-toe assessment (includes a reassessment of airway and breathing parameters and vital signs)
- Diagnostic and laboratory testing
- Insertion or application of monitoring devices such as ECG electrodes, arterial lines, or urinary catheters
- Splinting of suspected fractures
- Cleansing, closure, and dressing of wounds
- Performance of other necessary interventions based on the patient's condition

Once the patient has been assessed, stabilized, and tested, appropriate medical and nursing diagnoses are formulated, initial important treatment is started, and plans for the proper disposition of the patient are made. Many emergent and urgent conditions and priority emergency interventions are discussed in detail in the remaining sections of this chapter.

In addition to the management of the illness or injury, the ED nurse must also focus on providing comfort and emotional support to the patient and family. Included in this is pain management. Effective pain management must be instituted early and should include rapid-acting agents that result in minimal sedation so that the patient can continue to interact with the staff for ongoing assessment. Moderate sedation can help facilitate short procedures in the ED; the patient will not remember the procedure later. The patient is closely monitored during the procedure and then rapidly awakens when it is complete

It is essential that family crisis intervention services are available for families of patients in the ED. Even if a patient's condition is not emergent, the situation may be perceived as such by the family. Every family needs attention and support.

AIRWAY OBSTRUCTION

Acute upper airway obstruction is a life-threatening medical emergency.

Pathophysiology

The airway may be partially or completely occluded. Partial obstruction of the airway can lead to progressive hypoxia, hypercarbia, and respiratory and cardiac arrest. If the airway is completely obstructed, permanent brain injury or death will occur within 3 to 5 minutes secondary to hypoxia. Air movement is absent in the presence of complete airway obstruction. Oxygen saturation of the blood decreases rapidly because obstruction of the airway prevents entry of air into the lungs. Oxygen deficit occurs in the brain, resulting in unconsciousness, with death following rapidly.

Upper airway obstruction has a number of causes, including aspiration of foreign bodies, anaphylaxis, viral or bacterial infection, trauma, and inhalation or chemical burns. For older adult patients, especially those in extended care facilities, sedative and hypnotic medications, diseases affecting motor coordination (e.g., Parkinson disease), and mental dysfunction (e.g., dementia, intellectual disability) are risk factors for asphyxiation by food. As patients grow older, atrophy of the posterior pharynx occurs, resulting in aspiration or difficulty swallowing. In adults, aspiration of a bolus of meat is the most common cause of airway obstruction. Peritonsillar abscesses, epiglottitis, and other acute infectious processes of the posterior pharynx can also result in airway obstruction. The most common causes of airway obstruction are from an allergic reaction (i.e., causing laryngospasm), infection, or angioedema (ENA, 2013).

Clinical Manifestations

Typically, a person with a foreign-body airway obstruction cannot speak, breathe, or cough. The patient may clutch the neck between the thumb and fingers (i.e., universal distress signal). Other common signs and symptoms include choking, apprehensive appearance, refusing to lie flat, inspiratory and expiratory stridor, labored breathing, the use of accessory muscles (suprasternal and intercostal retraction), flaring nostrils, increasing anxiety, restlessness, and confusion. Cyanosis and loss of consciousness, which develop as hypoxia worsens, are late signs. Action must be taken before these manifestations develop, if possible, or immediately if the patient has already exhibited these signs.

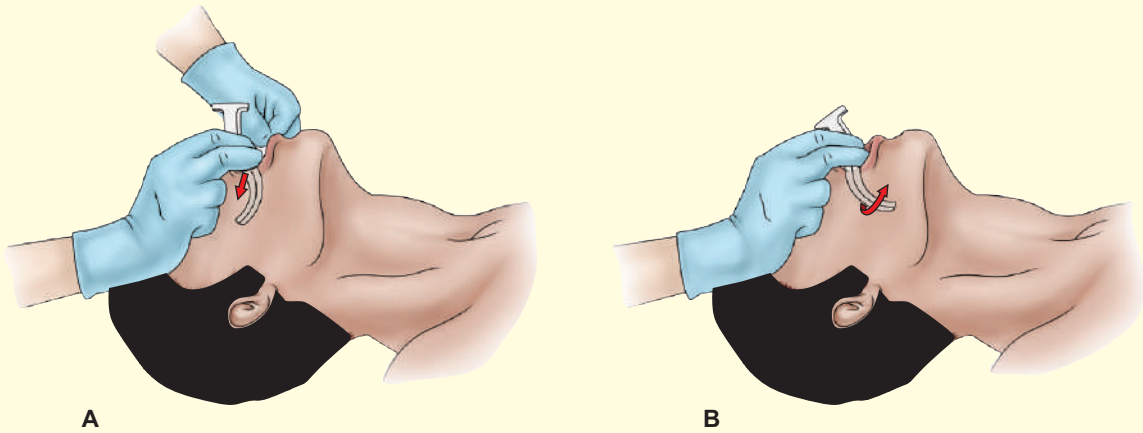
Assessment and Diagnostic Findings

Assessment of the patient who has a foreign object occluding the airway may involve simply asking the person whether he or she is choking and requires help. If the person is unconscious, inspection of the oropharynx may reveal the offending object. X-rays, laryngoscopy, or bronchoscopy also may be performed. Oxygen supplementation should be considered immediately.

Management

If the patient can breathe and cough spontaneously, a partial obstruction should be suspected. The victim is encouraged to cough forcefully and to persist with spontaneous coughing and breathing efforts as long as good air exchange exists. There may be some wheezing between coughs. If the patient demonstrates a weak, ineffective cough, high-pitched noise while inhaling, increased respiratory difficulty, or cyanosis, the patient should be managed as if there were complete airway obstruction.

After the obstruction is removed, rescue breathing is initiated. If the patient has no pulse, cardiac compressions are instituted. These measures provide oxygen to the brain, heart, and other vital organs until definitive medical treatment can restore and support normal heart and ventilatory activity (ENA, 2013). See Chapter 23 for review of current CPR guidelines.



Establishing an Airway

Establishing an airway may be as simple as repositioning the patient's head to prevent the tongue from obstructing the pharynx. Alternatively, other maneuvers, such as the head-tilt/chin-lift maneuver, the jaw-thrust maneuver, or insertion of specialized equipment, may be needed to open the airway, remove a foreign body, or maintain the airway. In all maneuvers, the cervical spine must be protected from injury. After these maneuvers are performed, the patient is assessed for breathing by watching for chest movement and listening and feeling for air movement. In such a case, nursing diagnoses would include ineffective airway clearance related to obstruction of the airway by the tongue, an object, or fluids (blood, saliva) and ineffective breathing pattern related to airway obstruction or injury. See Chapter 11, Chart 11-6 for information regarding how to clear an upper airway obstruction.

Chart 60-2

Inserting an Oropharyngeal Airway

1. Measure the oral airway alongside the head. The airway should reach from lip to ear.
2. Extend the patient's head by placing one hand under the bony chin (*only if the cervical spine is uninjured*). With the other hand, tilt the head backward by applying pressure to the forehead while simultaneously lifting the chin forward.
3. Open the patient's mouth.
4. **A**. Insert the oropharyngeal airway with the tip facing up toward the roof of the mouth until it passes the uvula. **B**. Rotate the tip 180 degrees so that the tip is pointed down toward the pharynx. This displaces the tongue anteriorly, and the patient then breathes through and around the airway. An alternate method is to use a tongue blade to hold the tongue and insert the oropharyngeal airway directly without rotation.
5. The distal end of the oropharyngeal airway is in the hypopharynx, and the flange is approximately at the patient's lips. Make sure that the tongue has not been pushed into the airway.

Adapted from Walsh, K & Woten, M. (2016). Oropharyngeal airway: Inserting in adults. In D. Pravikoff (Ed.). Nursing practice and skill. Glendale, CA: CINAHL Information Systems.

Oropharyngeal/Nasopharyngeal Airway Insertion

An oropharyngeal airway is a semicircular tube or tubelike plastic device that is inserted over the back of the tongue into the lower posterior pharynx in a patient who is breathing spontaneously but who is unconscious (see Chart 60-2). This type of airway prevents the tongue from falling back against the posterior pharynx and obstructing the airway. It also allows health care providers to suction secretions. The nasopharyngeal airway provides the same airway access but is inserted through the nares. With an airway in place the patient may breathe spontaneously. If breathing is ineffective or absent, bag-valve-mask ventilation is necessary.

Nursing Alert: In the case of potential facial trauma or basal skull fracture, the nasopharyngeal airway should not be used because it could enter the brain cavity instead of the pharynx.

Endotracheal Intubation

The purpose of endotracheal intubation is to establish and maintain the airway in patients with respiratory insufficiency or hypoxia. Endotracheal intubation is indicated to establish an airway for a patient who cannot be adequately ventilated with an oropharyngeal or nasopharyngeal airway, bypass an upper airway obstruction, prevent aspiration, permit connection of the patient to a resuscitation bag or mechanical ventilator, or facilitate the removal of tracheobronchial secretions (see Fig. 60-1). Because of the level of skill required, endotracheal intubation is performed only by those who have had extensive training. These may include physicians, nurse practitioners in critical care, and respiratory therapists. However, the emergency nurse commonly assists with intubation.

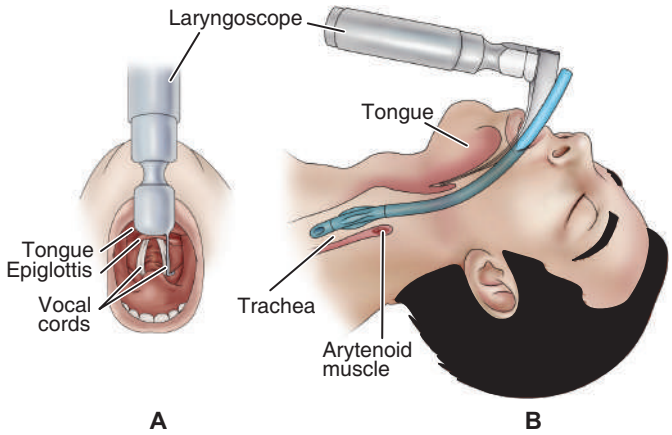


Figure 60-1 • Endotracheal intubation in a patient without a cervical spine injury. **A**. The primary glottic landmarks for tracheal intubation as visualized with proper placement of the laryngoscope. **B**. Positioning the endotracheal tube.

Rapid sequence intubation may be indicated, which provides management of the patient in a situation similar to that in the operating room. Medications used to facilitate rapid sequence intubation include a sedative, an analgesic, and a neuromuscular blockade agent; these are usually given by the practitioner performing the intubation.

Intubation with a King Tube or Laryngeal Mask Airway

If the patient is not hospitalized and cannot be intubated in the field, emergency medical personnel may insert a King Tube, which rapidly provides pharyngeal ventilation. When the tube

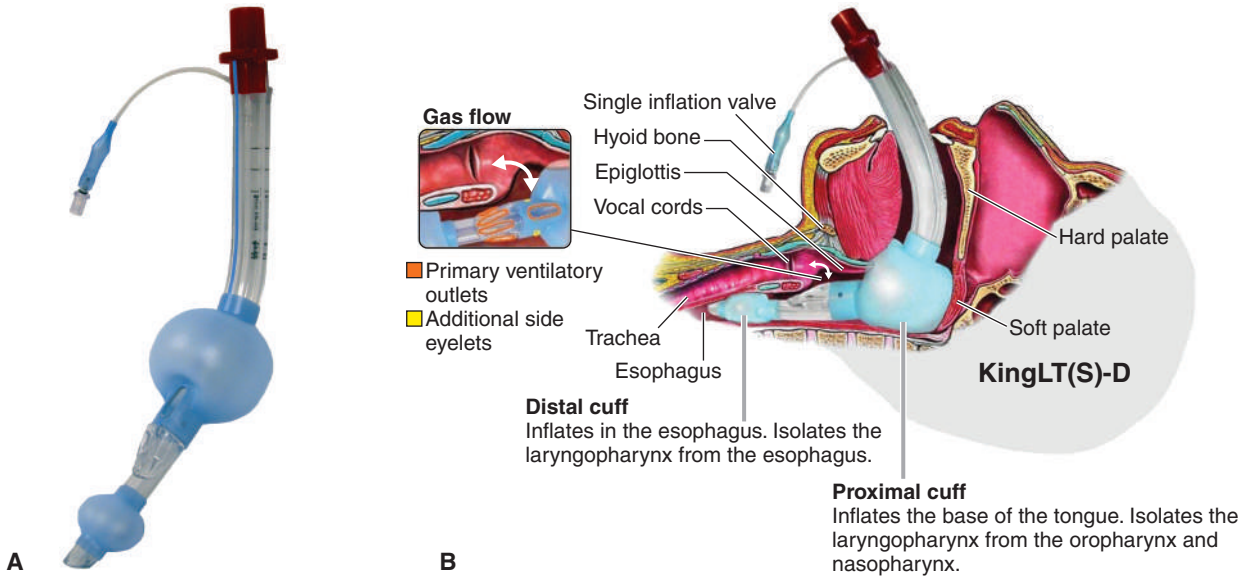

Figure 60-2 • King Tube (**A**) correctly placed in esophageal position (**B**). Reprinted with permission from King Systems Corporation, Noblesville, Indiana.

is inserted into the trachea, it functions like an endotracheal tube (see Fig. 60-2).

The two balloons that surround the tube are inflated after the tube is inserted. One balloon is large and occludes the oropharynx. This permits ventilation by forcing air through the larynx. The smaller balloon is inflated with air and occludes the esophagus at a site distal to the glottis. Breath sounds are auscultated after balloon inflation to make sure that the oropharyngeal balloon (or cuff) does not obstruct the glottis. One variant type of King Tube is designed so that a gastric tube may also be passed for suction. If it is difficult to establish an airway, a laryngeal mask airway (LMA) may be inserted as an interim airway device. The design of the LMA provides a "mask" in the subglottic airway with a cuff inflated within the esophagus. It allows easy insertion for rapid airway control until a more definitive airway can be placed. Some LMAs also permit removal of secretions from the esophagus (see Chapter 5, Fig. 5-13A).

Cricothyroidotomy (Cricothyroid Membrane Puncture)

Cricothyroidotomy is the opening of the cricothyroid membrane to establish an airway. This procedure is used in emergency situations in which endotracheal intubation is either not possible or contraindicated, as in airway obstruction from extensive maxillofacial trauma, cervical spine injuries, laryngospasm, laryngeal edema (after an allergic reaction or extubation), hemorrhage into neck tissue, or obstruction of the larynx. A cricothyroidotomy is replaced with a formal tracheostomy when the patient is able to tolerate this procedure.

Maintaining Ventilation

After the airway is determined to be unobstructed, the nurse must ensure that ventilation is adequate by checking for equal bilateral breath sounds. Satisfactory management of ventilations may prevent hypoxia and hypercapnia. The nurse must quickly assess for absent or diminished breath sounds, open chest wounds, and difficulty delivering artificial breaths for the patient. The nurse should monitor pulse oximetry, capnography, and arterial blood gases if the patient requires airway or ventilatory assistance. A tension pneumothorax can mimic hypovolemia, so ventilatory assessment precedes assessment for hemorrhage. A pneumothorax (both simple and tension) or sucking (open) chest wound is managed with a chest tube and occlusion of the sucking wound; immediate relief of increasing positive intrathoracic pressure and maintenance of adequate ventilation should occur.

HEMORRHAGE

Stopping bleeding is essential to the care and survival of patients in an emergency or disaster situation. Hemorrhage that results in the reduction of circulating blood volume is a main cause of shock. Minor bleeding, which is usually venous, generally stops spontaneously unless the patient has a bleeding disorder or has been taking anticoagulant agents. Internal hemorrhage can hide in many anatomic spaces and compartments, resulting in shock without external evidence of hemorrhage. The internal spaces and compartments that are capable of housing large amounts of blood include the retroperitoneum, pelvis, chest, and thighs (ACS, 2013).

The patient is assessed for signs and symptoms of shock: cool, moist skin (resulting from poor peripheral perfusion), decreasing blood pressure, increasing heart rate, delayed capillary refill, and decreasing urine volume (see Chapter 8). The goals of emergency management are to control the bleeding, maintain adequate circulating blood volume for tissue oxygenation, and prevent shock. Patients who hemorrhage are at risk for cardiac arrest caused by hypovolemia with secondary anoxia. Nursing interventions are carried out collaboratively with other members of the emergency health care team.

Management

Fluid Replacement

Whenever a patient is hemorrhaging—whether externally or internally—a loss of circulating blood results in a fluid volume deficit and decreased cardiac output. Therefore, fluid replacement is imperative to maintain circulation. Typically, two large-gauge IV catheters are inserted, preferably

in an uninjured extremity, to provide a means for fluid and blood replacement. Blood samples are obtained for analysis, typing, and cross-matching. Replacement fluids are given as prescribed, depending on clinical estimates of the type and volume of fluid lost. Replacement fluids may include isotonic electrolyte solutions (e.g., lactated Ringer's, normal saline), colloids, and blood component therapy.

Packed red blood cells are infused when there is massive blood loss, which may also necessitate transfusion of other blood components, including platelets and clotting factors. See Chapter 26 for full discussion of blood component therapy indications and treatment.

Nursing Alert: The infusion rate is determined by the severity of the blood loss and the clinical evidence of hypovolemia. Any blood replacement therapy should be given via warmer when possible, because administration of large amounts of blood that has been refrigerated has a core cooling effect that may lead to cardiac arrest and coagulopathy.

Control of External Hemorrhage

If a patient is hemorrhaging externally (e.g., from a wound), a rapid physical assessment is performed as the patient's clothing is cut away in an attempt to identify the area of hemorrhage. Direct, firm pressure is applied over the bleeding area or the involved artery at a site that is proximal to the wound (see Fig. 60-3). Most bleeding can be stopped or at least controlled by application of direct pressure. Otherwise, unchecked arterial bleeding results in death. A firm pressure dressing is applied, and the injured part is elevated to stop venous and capillary bleeding, if possible. If the injured area is an extremity, the extremity is immobilized to control blood loss.

A tourniquet is applied to an extremity when the external hemorrhage cannot be controlled in any other way and until surgery can be performed. The tourniquet is applied just proximal to the wound and tied tightly enough to control arterial blood flow. The patient is tagged with a skin-marking pencil or on adhesive tape on the forehead with a "T," stating the location of the tourniquet and the time applied. If the patient has suffered a traumatic amputation with uncontrollable hemorrhage, the tourniquet remains in place until the patient is in the operating room. Time of tourniquet application and removal should be documented. Tourniquet placement among military personnel with battle-associated trauma has demonstrated clear mortality reduction, although it occasionally has led to amputation or fasciotomy (Inaba, Siboni, Resnick, et al., 2015).

Control of Internal Bleeding

If the patient shows no external signs of bleeding but exhibits tachycardia, falling blood pressure, thirst, apprehension, cool and moist skin, or delayed capillary refill, internal hemorrhage is suspected. Typically, packed red blood cells, plasma, and platelets are given at a rapid rate, and the patient is prepared for more

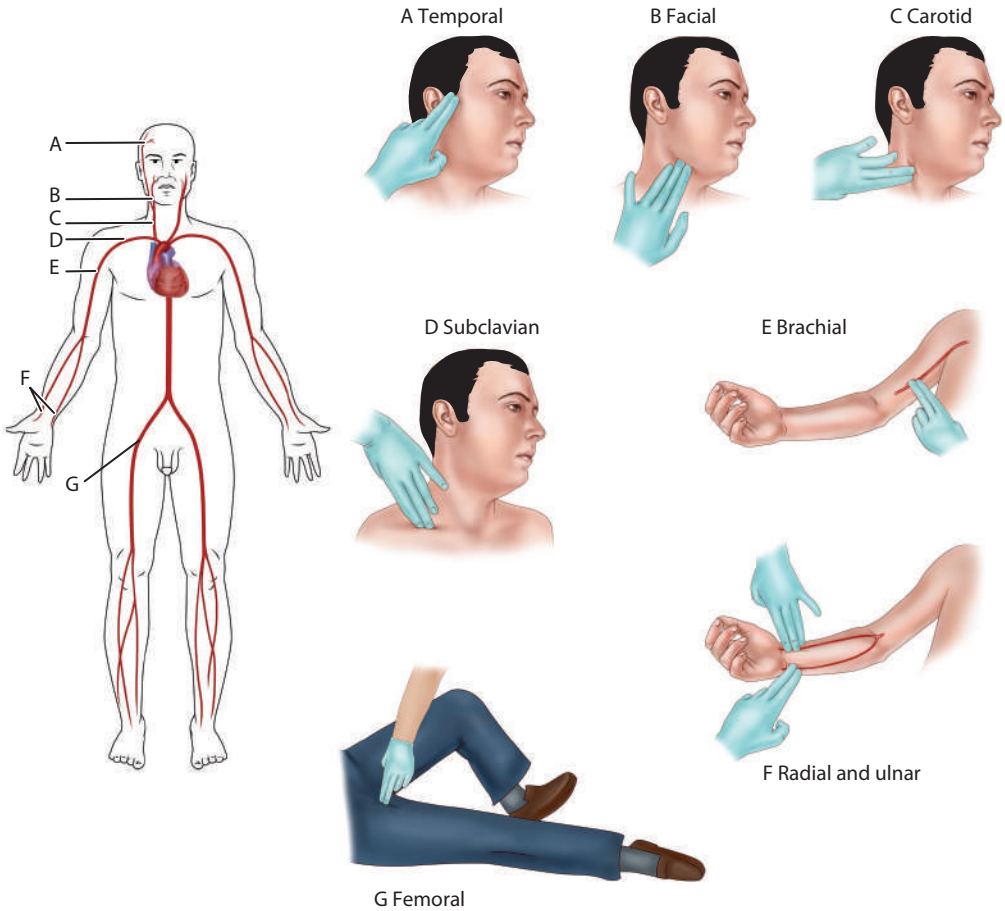

Figure 60-3 • Pressure points for control of hemorrhage.

definitive treatment (e.g., surgery, pharmacologic therapy). In addition, arterial blood gas specimens are obtained to evaluate pulmonary function and tissue perfusion and to establish baseline hemodynamic parameters, which are then used as an index for determining the amount of fluid replacement the patient can tolerate and the response to therapy. The patient is maintained in the supine position and monitored closely until hemodynamic or circulatory parameters improve, or until he or she is transported to the operating room or intensive care unit.

HYPOVOLEMIC SHOCK

Shock is a condition in which there is loss of effective circulating blood volume. Inadequate organ and tissue perfusion follows, ultimately resulting in cellular metabolic derangements. In any emergency situation, the onset of shock should be anticipated by immediately assessing all people who are injured. The underlying cause of shock (hypovolemic, cardiogenic, neurogenic, anaphylactic, or septic) must be determined. Of these, hypovolemia is the most common cause. See Chapter 8 for further discussion of management of hypovolemic shock.

WOUNDS

Wounds involving injury to soft tissues can vary from minor tears to severe crushing injuries. The types of wounds that may occur are defined in Chart 60-3. The main goal of treatment is to restore the physical integrity and function of the injured tissue while minimizing scarring and preventing infection. Proper documentation of the characteristics of the wound, using precise descriptions and correct terminology, is essential. Such information may be needed in the future for forensic evidence. Photographs are helpful because they provide an accurate, visible depiction of the wound. Photographs also become important for exigent wounds (i.e., wounds that will eventually heal). Patients involved in domestic violence or trauma may need the photographs later to visually describe the extent of injury.

Determining *when* and *how* the wound occurred is important because a treatment delay increases infection risk. Using aseptic technique, the clinician inspects the wound to determine the extent of damage to underlying structures or the presence of a foreign body. Sensory, motor, and vascular function is evaluated for changes that might indicate complications.

Chart 60-3

Definition of Terms: Wounds

Laceration: skin tear with irregular edges and vein bridging
Avulsion: tearing away of tissue from supporting structures
Abrasion: denuded skin
Ecchymosis/contusion: blood trapped under the surface of the skin
Hematoma: tumorlike mass of blood trapped under the skin
Stab: incision of the skin with well-defined edges, usually caused by a sharp instrument; a stab wound is typically deeper than long
Cut: incision of the skin with well-defined edges, usually longer than deep
Patterned: wound representing the outline of the object (e.g., steering wheel) causing the wound

Management

Wound Cleansing

Hair around the wound may be clipped (only as directed) if it is anticipated that the hair will interfere with wound closure. Typically, the area around the wound is cleansed with normal saline solution or a polymer agent (e.g., Shur-Clens). The antibacterial agent povidone-iodine (Betadine) should not be allowed to get deep into the wound without thorough rinsing. Povidone-iodine is used only for the initial cleansing because it injures exposed and healthy tissue, resulting in further tissue damage (ENA, 2013).

If indicated, the area is infiltrated with a local intradermal anesthetic through the wound margins or by regional block. Patients with soft tissue injuries usually have localized pain at the site of injury. The nurse then assists with cleaning and débriding the wound. The wound is irrigated gently and copiously with sterile isotonic saline solution to remove surface dirt. Devitalized tissue and foreign matter are removed because they impede healing and may promote infection. Any small bleeding vessels are clamped, tied, or cauterized. After wound treatment, a nonadherent dressing is applied to protect the wound and to serve as a splint and as a reminder to the patient that the area is injured.

Primary Closure

The decision to suture a wound depends on the nature of the wound, the time since the injury was sustained, the degree of contamination, and the vascularity of tissues. If primary closure is indicated, the wound is sutured or stapled, usually by the physician, with the patient receiving either local anesthesia or moderate sedation (see Chapter 5). Wound closure begins when subcutaneous fat is brought together loosely with a few sutures to close off the dead space. The subcuticular layer is then closed, and finally the epidermis is closed. Sutures are placed near the wound edge, with the skin edges leveled carefully to promote optimal healing. Instead of sutures, sterile strips of reinforced microporous tape or a bonding agent (skin glue) may be used to close clean, superficial wounds.

Delayed Primary Closure

Delayed primary closure may be indicated if tissue has been lost or there is a high potential for infection. A thin layer of gauze (to ensure drainage and prevent pooling of exudate), covered by an occlusive dressing, may be used. The wound is splinted in a functional position to prevent motion and decrease the possibility of contracture.

If there are no signs of suppuration (formation of purulent drainage), the wound may be sutured (with the patient receiving a local anesthetic). The use of antibiotic agents to prevent infection depends on factors such as how the injury occurred, the age of the wound, and the risk of contamination. The site is immobilized and elevated to limit accumulation of fluid in the interstitial spaces of the wound.

Tetanus prophylaxis is given as prescribed, based on the condition of the wound and the patient's immunization status. If the patient's last tetanus booster was given more than 5 years ago, or if the patient's immunization status is unknown, a tetanus booster must be given (ACS, 2013). The patient is instructed about signs and symptoms of infection and is instructed to contact the primary provider or clinic if there is sudden or

persistent pain, fever or chills, bleeding, rapid swelling, foul odor, drainage, or redness surrounding the wound.

TRAUMA

Trauma (an unintentional or intentional wound or injury inflicted on the body from a mechanism against which the body cannot protect itself) is the first leading cause of death in urban areas of India in the 15–29 years age group and second leading cause of death next to suicides in rural India in the same age group. It is also the sixth leading cause of death in the 30–69 years age group people in India (Causes of Death Statistics 2010–2013, Registrar General of India). Motor vehicle accidents and unintentional nonmotor vehicle injury in workplace are also major contributors.

Collection of Forensic Evidence

In assessing and managing any patient with an emergency condition, but especially the patient experiencing trauma, meticulous documentation is essential. Included in documentation are descriptions of all wounds, mechanism of injury, time of events, and collection of evidence. In trauma care, the nurse must be exceedingly careful with all potential evidence, handling and documenting it properly.

The basics of care management for patients with traumatic injury include an understanding that trauma in any patient (living or dead) has potential legal or forensic science implications if criminal activity is suspected. Hence, proper management from both a medical and forensic evidence perspective is essential.

When clothing is removed from the patient who has experienced trauma, the nurse must be careful not to cut through or disrupt any tears, holes, blood stains, or dirt present on the clothing if criminal activity is suspected. Each piece of clothing should be placed in an individual paper bag. Plastic bags are not used because they retain moisture; moisture may promote mold and mildew formation, which can destroy evidence. If the clothing is wet, it should be hung to dry. Clothing should not be given to families. Valuables should be inventoried and either placed in the hospital safe or clearly documented to which family member they were given. If a police officer is present to collect clothing or any other items from the patient, each item is labeled and the transfer of custody to the officer, the officer's name, the date, and the time are documented. Evidence cannot be left unattended in the room; a formal chain of custody must be maintained for the evidence to be valid and useful for legal purposes (Foresman-Capuzzi 2014); (Nayduch, 2009).

All deaths of patients who experienced trauma are reported to the medical examiner. If suicide or homicide is suspected in a patient who experienced trauma, the medical examiner examines the body on site or has the body moved to the mortuary for autopsy. All tubes and lines must remain in place. The patient's hands must be covered with paper bags to protect evidence on the hands or under the fingernails. In the patient who has survived trauma, tissue specimens may be swabbed from the hands and nails as potential evidence. Photographs of wounds or clothing are essential and should include a reference ruler in one photo and another without the ruler.

Documentation should also include any statements made by the patient in the patient's own words and surrounded by quotation marks. A chain of evidence is essential. If the patient's case is reviewed in a court of law in the future, clear documentation assists the judicial process and helps to identify the activities that occurred in the ED.

Injury Prevention

Any discussion of trauma management must address injury prevention. A component of the emergency nurse's daily role is to provide injury prevention information to every patient with whom there is contact, including patients admitted for reasons other than injury (Edwards, Stephens-Stidham, Contreras, et al., 2016). The only way to reduce the incidence of trauma is through prevention.

There are three components of injury prevention. The first is education. Providing information and materials to help prevent violence and to maintain safety at home and in vehicles is important. Involvement in local injury prevention organizations, nursing organizations, and health fairs promotes wellness and safety. In practice, nursing and other health care professionals should avoid using the word *accident,* because trauma events are *preventable* and should be viewed as such rather than as "fate" or "happenstance." Responsibility and accountability must be assigned to traumatic incidents, particularly because of the high rate of trauma recidivism (repeated trauma). People who are at risk for trauma and trauma recidivism should be identified and provided with education and counseling directed toward altering risky behaviors and preventing further trauma (ENA, 2013).

Second component of injury prevention is through legal action. Laws may be enacted to prevent unsafe, high speed driving; driving under the influence of alcohol; driving without helmet; etc.

The third component is automatic protection. Airbags and automotive design are included in this category. These mechanisms provide for safety without requiring personal intervention.

Multiple Trauma

Multiple trauma is caused by a single catastrophic event that causes life-threatening injuries to at least two distinct organs or organ systems. Patients with single-system trauma still receive full assessment, because even single-system injuries can be life threatening or more severe than they initially appear. Mortality in patients with multiple trauma is related to the severity of the injuries, the number of systems and organs involved, and the severity of each injury alone and in combination. Immediately after injury, the body is hypermetabolic, hypercoagulable, and severely stressed.

Care of the patient with multiple injuries requires a team approach, with one person responsible for coordinating the treatment. The nursing staff assumes responsibility for assessing and monitoring the patient, ensuring/maintaining airway and IV access, administering prescribed medications, collecting laboratory specimens, and documenting activities and the patient's subsequent responses.

Assessment and Diagnostic Findings

External evidence of trauma may be sparse or absent. Patients with multiple trauma should be assumed to have a spinal cord injury until it is proven otherwise. The injury regarded as the least significant in appearance may be the most lethal.

For example, the pelvic fracture not identified until an x-ray is obtained may cause rapid and massive hemorrhage into the pelvic cavity, but an obvious amputation of the arm may have already stopped bleeding from the body's normal response of vasoconstriction.

Management

The goals of treatment are to determine the extent of injuries and to establish priorities of treatment. Any injury interfering with a vital physiologic function (e.g., airway, breathing, circulation) is an immediate threat to life and has the highest priority for immediate treatment. Essential lifesaving procedures are performed simultaneously by the emergency team. As soon as the patient is resuscitated, clothes are removed or cut off and a rapid physical assessment is performed. Transfer from field management to the ED must be orderly and controlled, with attention and silence given to listen to the verbal report from EMS personnel. Treatment in a trauma center is appropriate for patients experiencing major trauma. Treatment priorities are presented in Chart 60-4.

Intra-Abdominal Injuries

Intra-abdominal injuries are categorized as penetrating or blunt trauma. *Penetrating* abdominal injuries (i.e., gunshot wounds, stab wounds) are serious and usually require surgery. Penetrating abdominal trauma results in a high incidence of injury to hollow organs, particularly the small bowel. The liver is the most frequently injured solid organ due to its size and anterior placement in the right upper quadrant of the abdomen. In gunshot wounds, the most important prognostic factor is the velocity at which the missile enters the body. High-velocity missiles (bullets) produce extensive tissue damage. All abdominal gunshot wounds that cross the peritoneum or are associated with peritoneal signs require surgical exploration. On the other hand, some stab wounds may be managed nonoperatively due to low velocity and less penetration of the implement (i.e., weapon) (ACS, 2013).

Blunt trauma to the abdomen may result from motor vehicle crashes, falls, blows, or explosions. Blunt trauma is commonly associated with extra-abdominal injuries to the chest, head, or extremities. Patients with blunt trauma are a challenge because injuries may be difficult to detect. The incidence of delayed and trauma-related complications is greater than for penetrating injuries. This is especially true of blunt injuries involving the liver, kidneys, spleen, or blood vessels, which can lead to massive blood loss into the peritoneal cavity (ACS, 2013).

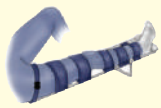
Chart 60-4

Priority Management in Patients with Multiple Injuries

1. **Establish airway and ventilation.**

2. **Control hemorrhage.**

3. **Prevent and treat hypovolemic shock.**



4. **Assess for head and neck injuries.**

5. **Evaluate for other injuries -** expose and reassess head and neck, chest; assess abdomen, back and extremities.

6. **Splint fractures and then reassess pulses and neurovascular status.**

7. **Perform a more thorough and ongoing examination and assessment; diagnostic studies.**

Adapted from American College of Surgeons. (2013). Advanced trauma life support (9th ed.). Chicago, IL: Author.

Assessment and Diagnostic Findings

As the history of the traumatic event is obtained, the abdomen is inspected as a part of the secondary survey for obvious signs of injury, including penetrating injuries, bruises, and abrasions. Abdominal assessment continues with auscultation of bowel sounds to provide baseline data from which changes can be noted. Absence of bowel sounds may be an early sign of intraperitoneal involvement, although stress can also decrease or halt peristalsis and thus bowel sounds. Further abdominal assessment may reveal progressive abdominal distention, involuntary guarding, tenderness, pain, muscular rigidity, or rebound tenderness along with changes in bowel sounds, all of which are signs of peritoneal irritation. Hypotension and signs and symptoms of shock may also be noted. In addition, the chest and other body systems are assessed for injuries that frequently accompany intra-abdominal injuries (ACS, 2013).

Laboratory studies that aid in assessment include the following:

- Serial hemoglobin and hematocrit levels to evaluate trends reflecting the presence or absence of bleeding
- Lactate to determine acidosis and need for continued resuscitation
- Arterial blood gas (ABG) for pH (acidosis), base deficit for resuscitation evaluation, and ventilation parameters ($PaCO_2$, PaO_2)
- International normalized ratio (INR) to identify coagulopathy or presence of chemically induced anticoagulation
- White blood cell (WBC) count to detect elevation (generally associated with trauma)
