Brunner & Suddarth's

Textbook of Medical-Surgical Nursing

Second South Asian Edition

Volume II

As per the competency-based syllabus prescribed by Indian Nursing Council

SAE Editors:

Suresh K. Sharma • S. Madhavi

International Editors:

Janice L. Hinkle • Kerry H. Cheever

Highlights:

- Content as per the revised competency-based B.Sc. Nursing curriculum outlined by Indian Nursing Council (INC)
- Sequential arrangement of chapters as per Adult Health Nursing I and II curriculum
- Inclusion of new disease conditions, concepts, and guidelines
- Online ancillaries for students and faculties

Wolters Kluwer

This edition is for sale and distribution in India, Pakistan, Sri Lanka, Bangladesh, Nepal, Bhutan and the Maldives only. It is prohibited and illegal to distribute this edition outside of these territories.

Preface

Brunner & Suddarth's Textbook of Medical-Surgical Nursing was published for the first time in 1964 under the leadership of Lillian Sholtis Brunner and Doris Smith Suddarth. Lillian and Doris pioneered a medical-surgical nursing textbook that has become a trusted learning resource all over the world. Medical-surgical nursing has significantly advanced since 1964 but continues to be strongly influenced by the expansion of a host of other disciplines and new developments in technology, as well as myriad social, cultural, economic, and environmental changes throughout the world. In today's environment, nurses must be particularly skilled in critical thinking and clinical decision making, as well as in consulting and collaborating with other members of the multidisciplinary healthcare team.

Since its inception, *Brunner & Suddarth's Textbook of Medical-Surgical Nursing* has significantly contributed into nursing education in Asia to prepare nurses to think critically and practice collaboratively within today's challenging and complex healthcare delivery system. The textbook focuses on physiologic, pathophysiologic, and psychosocial concepts as they relate to nursing care, and emphasis is placed on integrating a variety of concepts from other disciplines such as nutrition, pharmacology, and gerontology. Content relative to health care needs of nursing research findings, ethical considerations, evidence-based practice, prioritization, and people with disabilities has been expanded to provide opportunities for the nurse to refine clinical decision-making skills.

The several revised editions of *Brunner & Suddarth's Textbook of Medical-Surgical Nursing* were published over time to meet the advanced needs of the nurses and they are religiously used by the nursing fraternity around the globe; however, every region, continent, and country has its distinct contemporary health issues and healthcare infrastructure. Many clinical conditions and clinical perspectives are unique to India and other South Asian countries and their management guidelines are getting updated rapidly. The second South Asian edition of *Brunner & Suddarth's Textbook of Medical-Surgical Nursing* is designed to include these updates as well as conform to the competency-based curriculum outlined by the Indian Nursing Council.

Organization of the Second South Asian Edition

Brunner & Suddarth's Textbook of Medical-Surgical Nursing, the second South Asian Edition, is organized into two volumes spread across 22 units. These units mirror the undergraduate nursing curriculum prescribed by the Indian Nursing Council (INC). Units I through III cover core concepts related to medical-surgical nursing practice and Units IV through XXII discuss adult health conditions that are treated medically or surgically. Each of these units is structured in the following way to facilitate better comprehension:

- The first chapter in the unit covers assessment and includes a review of normal anatomy and physiology of the body system being discussed.
- Subsequent chapters in the unit cover management of specific disorders, pathophysiology, clinical manifestations, assessment and diagnostic findings, medical management, and nursing management. Nursing Process sections, provided for selected conditions, clarify and expand on the nurse's role in caring for patients with these conditions.

Special Features

When caring for patients, nurses assume many different roles, including practitioner, educator, advocate, and researcher. Many of the features in this textbook have been developed to help nurses fulfill these varied roles. Key updates to practice-oriented features in the second South Asian edition include new topics such as ethical and legal issues in surgical nursing, operation theater (OT) (types, design, and infrastructure), instruments and preparation of sets for common surgical procedures, types of suture materials and suture techniques used, monitoring of patients during surgical procedure, maintenance of therapeutic environment in OT, assisting in major and minor surgeries, handling of different specimens, legal aspects in OT, position and draping for common surgical procedures, wound dressing (types and techniques), management of patients with LVH, cor pulmonale, cyst of the liver, gall bladder cancer, tumors of parathyroid gland, Covid-19, swine flu, Pott's spine, chikungunya, and neurocysticercosis.

The mandatory module content on palliative care is readily available as one exclusive chapter.

Indian and Asian epidemiology of diseases and disorders is incorporated along with flowcharts of pathophysiology of diseases and disorders to facilitate the understanding of pathological basis of illnesses. In addition, Indian images and figures have been included, wherever needed, to facilitate better understanding and contemporary closeness to the content. Content specific to Indian context such as AIDS Control Program, agencies involved in AIDS prevention, counseling of AIDS patients, palliative care in the Indian scenario, National Program for the Health Care of Elderly, breaking bad news to patients and/or their families, various skin rejuvenation techniques, gender reassignment surgery, legal and ethical issues in plastic surgery, AERB regulation, radiation safety, National Policy on Disaster Management, legal issues, and Indian resources is provided with additional and latest information.

This edition also includes the most valuable features of the textbook such as Procedural Guidelines for important procedures, Critical Thinking Exercises, Nursing Alerts, Plan of Nursing Care charts, Genetics in Nursing Practice charts, Ethical Dilemma charts, and Home Care Checklist charts which provide relevant formats and updated information.

We are confident that *Brunner & Suddarth's Textbook of Medical-Surgical Nursing*, second South Asian Edition, will continue to be the most preferred textbook for the subject of Adult Health Nursing to cater the needs of Indian/Asian student nurses.

Prof. Dr. Suresh K. Sharma and Prof. Dr. S. Madhavi

Acknowledgments

This edition of *Brunner & Suddarth's Textbook of Medical-Surgical Nursing* is the result of collaboration with authors/editors of the international edition and the overwhelming response received for the first South Asian Edition. The adaptation of this exceptional textbook would not have been possible without the support of the following people:

- For the content contribution, suggestions, and support in adaptation of this textbook, I wish to acknowledge the following of my colleagues:
  - Priya Sharma, Tutor, College of Nursing, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, for her overall contribution in revision of the content of this edition.
  - Maneesh Sharma, Assistant Professor (Nursing), AIIMS-Rishikesh, for his contribution of epidemiological data and pathophysiological flowcharts for the respiratory system, cardiovascular system, and hematological system.
  - Dr. Rakesh Sharma, Assistant Professor (Nursing), AIIMS-Rishikesh, for his contribution of epidemiological data and pathophysiological flowcharts for the musculoskeletal system and neurological system.
  - Prasuna Jelly, Assistant Professor (Nursing), AIIMS-Rishikesh, for her contribution of epidemiological data and pathophysiological flowcharts for the male and female reproductive systems.
  - Ruchika Rani, Assistant Professor (Nursing), AIIMS-Rishikesh, for her contribution of epidemiological data and pathophysiological flowcharts for the oncological system.
  - Ravin Bishnoi, Nursing Officer & Diabetes Nurse Educator, AIIMS-Rishikesh, for his help in photography.
- The editorial and production professionals for their support, creativeness, dedication, and hard work. While there are many professionals involved in preparing this adapted textbook, I wish to acknowledge the following:
  - Sangeetha P, for her vision, organization, professionalism, energy, and support during this arduous work. Her motivation and support brought creativity and innovation in the content of this textbook.
  - Satheesh and Pooja, amazingly organized and talented individuals, who have done considerable behind-the-scenes work that has improved the accuracy and consistency in how we present content within the textbook. They too have limitless energy and are always willing to go the extra mile.
- My acknowledgement would be incomplete if I do not mention the names of the following people for their significant contribution toward adaptation of this textbook:
  - Patients and their relatives for giving the permission and cooperation for clinical photography.
  - My colleague Nipin Kalal, Assistant Professor, College of Nursing, AIIMS-Jodhpur, for his academic support toward the development of quality content for this textbook.
  - My wife Reena Sharma, daughter Simone Sharma, and Son Rishit Sharma who have provided me constant encouragement to keep going, even as they reminded me that there is life beyond the pages of a book. Above all, attendance of gratitude to my father Sh. Badri Narayan Sharma, whose unconditional love and belief in my capabilities provided me the energy to take work of this magnitude.
  - Last but not the least, my family, friends, and nursing fraternity of the South Asia for their support, care, and belief in me.

My collaboration toward the adaptation of this internationally renowned textbook gives me immense pleasure that I will be able to contribute to the nursing knowledge and practices and I strive for the nursing excellence in my country.

Suresh K. Sharma

The synergistic efforts and encouragement from many has resulted into the second South Asian edition of *Brunner & Suddarth's Textbook of Medical-Surgical Nursing*. I enjoyed every bit of this work. I owe a big thanks to the management of KMCH College of Nursing; Dr. Nalla G. Palaniswami, Chairman; Dr. Thavamani D. Palaniswami; and Dr. Arun N. Palaniswami for demanding excellence in the pursuit of nursing education and for their constant support to complete this work successfully. I appreciate the support extended by the KMCH family members.

I wish to express my gratitude to my Nursing Gurus for being the source of inspiration. I would also like to thank all my nursing students, past and present, for giving me the opportunity to experience the joy of teaching nursing.

I would like to extend my sincere thanks to Ms. Sangeetha, Sr. Publishing Manager, Wolters Kluwer (India), who has been meticulously looking into the minute details in the organization of the book so that this book becomes a true treasure of medical-surgical knowledge. I owe a big thanks to Dr. Satheesh Kumar who painstakingly mapped and edited the proposed contents with the revised curriculum so that every topic is covered with in-depth content, references, and illustrations. Thanks to Ms. Pooja Chauhan who did scrupulous editing and spent enormous time to bring this book to perfect shape.

Big thanks to the thumping support given by the avid readers and front-line warriors—my nursing fraternity members—who translate the knowledge gained from this textbook into clinical nursing practice every day.

I want to acknowledge the support and encouragement of my family members—my mother Ms. Pappa, my father Mr. Sambandam, my beloved husband Mr. Ramamoorthy, and my loving kids Niveditha and Narendira Shiva. They encouraged and supported me to accomplish this work.

VOLUME I

UNIT I **Basic Concept of Medical-Surgical Nursing** **1**

1. Introduction to Medical-Surgical Nursing 3
2. Critical Thinking, Ethical Decision Making, and the Nursing Process 22
3. Adult Health and Nutritional Assessment 43

UNIT II **Perioperative Concepts and Nursing Management** **63**

4. Preoperative Nursing Management 65
5. Intraoperative Nursing Management 83
6. Postoperative Nursing Management 128

UNIT III **Concepts and Challenges in Patient Management** **153**

7. Fluid and Electrolytes: Balance and Disturbance 155
8. Shock and Multiple Organ Dysfunction Syndrome 199
9. Pain Management 226

UNIT IV **Gas Exchange and Respiratory Function** **251**

10. Assessment of Respiratory Function 253
11. Respiratory Care Modalities 283
12. Management of Patients with Chest and Lower Respiratory Tract Disorders 329
13. Management of Patients with Chronic Pulmonary Disease 381

UNIT V **Digestive and Gastrointestinal Function** **419**

14. Assessment of Digestive and Gastrointestinal Function 421
15. Digestive and Gastrointestinal Treatment Modalities 439
16. Management of Patients with Oral and Esophageal Disorders 463
17. Management of Patients with Gastric and Duodenal Disorders 490
18. Management of Patients with Intestinal and Rectal Disorders 509

UNIT VI **Cardiovascular and Circulatory Function** **559**

19. Assessment of Cardiovascular Function 561
20. Management of Patients with Dysrhythmias and Conduction Problems 599
21. Management of Patients with Coronary Vascular Disorders 635
22. Management of Patients with Structural, Infectious, and Inflammatory Cardiac Disorders 676
23. Management of Patients with Complications from Heart Disease 705
24. Assessment and Management of Patients with Vascular Disorders and Problems of Peripheral Circulation 730
25. Assessment and Management of Patients with Hypertension 773

UNIT VII **Hematologic Function** 789

26. Assessment of Hematologic Function and Treatment Modalities 791
27. Management of Patients with Nonmalignant Hematologic Disorders 814
28. Management of Patients with Hematologic Neoplasms 858

UNIT VIII **Metabolic and Endocrine Function** 891

29. Assessment and Management of Patients with Hepatic Disorders 893
30. Assessment and Management of Patients with Biliary Disorders 940
31. Assessment and Management of Patients with Diabetes 969
32. Assessment and Management of Patients with Endocrine Disorders 1015

UNIT IX **Integumentary Function** 1057

33. Assessment of Integumentary Function 1059
34. Management of Patients with Dermatologic Disorders 1074

UNIT X **Musculoskeletal Function** 1109

35. Assessment of Musculoskeletal Function 1111
36. Musculoskeletal Care Modalities 1127
37. Management of Patients with Musculoskeletal Disorders 1156
38. Management of Patients with Musculoskeletal Trauma 1183

UNIT XI **Communicable and Infectious Diseases** 1229

39. Management of Patients with Communicable and Infectious Diseases 1231

VOLUME II

UNIT XII **Sensory Function** 1271

40. Assessment and Management of Patients with Nose and Throat Disorders 1273
41. Assessment and Management of Patients with Hearing and Balance Disorders 1302
42. Assessment and Management of Patients with Eye and Vision Disorders 1329

UNIT XIII **Kidney and Urinary Function** 1367

43. Assessment of Kidney and Urinary Function 1369
44. Management of Patients with Kidney Disorders 1387
45. Management of Patients with Urinary Disorders 1434

UNIT XIV **Male Reproductive Function** 1467

46. Assessment and Management of Patients with Male Reproductive Disorders 1469

UNIT XV **Burns, Reconstruction, and Cosmetic Surgery** 1507

47. Assessment and Management of Burn Injury, Reconstruction, and Cosmetic Surgery 1509

UNIT XVI **Neurologic Function** 1541

48. Assessment of Neurologic Function 1543
49. Management of Patients with Neurologic Dysfunction 1569
50. Management of Patients with Cerebrovascular Disorders 1606
51. Management of Patients with Neurologic Trauma 1630
52. Management of Patients with Neurologic Infections, Autoimmune Disorders, and Neuropathies 1673
53. Management of Patients with Oncologic or Degenerative Neurologic Disorders 1702

UNIT XVII **Immunologic Function** 1737

54. Assessment of Immune Function 1739
55. Management of Patients with Immune Deficiency Disorders 1756
56. Assessment and Management of Patients with Allergic Disorders 1793
57. Assessment and Management of Patients with Rheumatic Disorders 1817

Syllabus Mapping to the Contents of this Book

Volume I				
Unit	**Hours**	**Learning Outcomes**	**Content**	**Page No.**
I	6 (T)	Narrate the evolution of medical surgical nursing. Apply nursing process in caring for patients with medical surgical problems	**Introduction** • Evolution and trends of medical and surgical nursing • International classification of diseases	 4 6
		Execute the role of a nurse in various medical surgical setting	• Roles and responsibility of a nurse in medical and surgical settings – Outpatient department – Inpatient unit – Intensive care unit	9
		Develop skills in assessment and care of wound	• Introduction to medical and surgical asepsis – Inflammation, infection – Wound healing – stages, influencing factors – Wound care and dressing technique	 8, 10 139 139
		Develop competency in providing pre- and postoperative care	• Care of surgical patient – Preoperative – Postoperative • Alternative therapies used in caring for patients with medical surgical disorders	 65 128 8
II	11 (T)	Explain organizational set up of the operating theater	**Intraoperative care** • Organization and physical set up of the operation theater – Classification – OT design – Staffing – Members of the OT team	83
		Differentiate the role of scrub nurse and circulating nurse	• Duties and responsibilities of the nurse in OT	
		Describe the different positioning for various surgeries	• Position and draping for common surgical procedures • Instruments, sutures and suture materials, equipment for common surgical procedures	
		Apply principles of asepsis in handling the sterile equipment	• Disinfection and sterilization of equipment • Preparation of sets for common surgical procedures	
		Demonstrate skill in scrubbing procedures	• Scrubbing procedures – gowning, masking, and gloving	
		Demonstrate skill in assessing the patient and document accurately the surgical safety checklist	• Monitoring the patient during the procedures • Maintenance of the therapeutic environment in OT	
		Develop skill in assisting with selected surgeries	• Assisting in major and minor operation, handling specimen • Prevention of accidents and hazards in OT	
		Explain the types, functions, and nursing considerations for different types of anesthesia	• Anesthesia – types, methods of administration, effects and stages, equipment & drugs • Legal aspects	

Unit	Hours	Learning Outcomes	Content	Page No.
III	6 (T)	Identify the signs and symptoms of shock and electrolyte imbalances Develop skills in managing fluid and electrolyte imbalances Perform pain assessment and plans for the nursing management	**Nursing care of patients with common signs and symptoms and management** • Fluid and electrolyte imbalance • Shock • Pain	 159 199 226
IV	16 (T)	Demonstrate skill in respiratory assessment Differentiate different breath sounds and list the indications	**Nursing management of patients with respiratory problems** • Review of anatomy and physiology of respiratory system • Nursing assessment – history taking, physical assessment and diagnostic tests	 253 261
		Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of common respiratory problems	• Common respiratory problems: – Upper respiratory tract infections – Chronic obstructive pulmonary diseases – Pleural effusion – Empyema – Bronchiectasis – Pneumonia – Lung abscess – Cyst and tumors – Chest injuries – Acute respiratory distress syndrome – Pulmonary embolism	 329 381 353 354 395 333 351 367 372 356 361
		Describe the health behavior to be adopted in preventing respiratory illnesses	• Health behaviors to prevent respiratory illness	Discussed in respective chapters
V	15 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of gastrointestinal disorders	**Nursing management of patients with disorders of digestive system** • Review of anatomy and physiology of GI system	 421
		Demonstrate skill in gastrointestinal assessment	• Nursing assessment – history and physical assessment	425
		Prepare patient for upper and lower gastrointestinal investigations	• GI investigations	429
			• Common GI disorders: – Oral cavity – lips, gums and teeth – GI – bleeding, infections, inflammation, perforation – Tumors – Obstruction and peritonitis – Peptic and duodenal ulcer – Malabsorption, appendicitis, hernias – Hemorrhoids, fissures, fistulas	 463 463 Discussed in respective chapters 524 & 520 494 509 509

Unit	Hours	Learning Outcomes	Content	Page No.
			– Pancreas – inflammation, cysts, and tumors	953
			– Liver – inflammation, cysts, abscess, cirrhosis, portal hypertension, hepatic failure, tumors	898
			– Gall bladder – inflammation, cholelithiasis, tumors	942
		Demonstrate skill in gastric decompression, gavage, and stoma care	• Gastric decompression, gavage, and different feeding techniques	439
			• Stoma care	534
		Demonstrate skill in different feeding techniques	• Alternative therapies, drugs used in treatment of disorders of digestive system	Discussed in respective chapters
VI	15 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of cardiovascular disorders	**Nursing management of patients with cardiovascular problems**	
			• Review of anatomy and physiology of cardiovascular system	562
		Demonstrate skill in cardiovascular assessment	• Nursing assessment – history and physical assessment	568
		Prepare patient for invasive and noninvasive cardiac procedures	• Disorders of vascular system – hypertension arteriosclerosis, Raynaud's disease, aneurysm and peripheral vascular disorders	773 730
		Demonstrate skill in monitoring and interpreting clinical signs related to cardiac disorders	• Coronary artery diseases – coronary atherosclerosis, angina pectoris, myocardial infarction	635
			• Valvular disorders – congenital and acquired	676
			• Rheumatic heart disease – pericarditis, myocarditis, endocarditis, cardiomyopathies	676
			• Cardiac dysrrhythmias, heart block	599
			• Congestive heart failure, cor pulmonale, pulmonary edema, cardiogenic shock, cardiac tamponade	705
			• Cardiopulmonary arrest	705
VII	7 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of hematological disorders	• Review of anatomy and physiology of blood, nursing assessment – history, physical assessment and diagnostic tests	792
			• Anemia, polycythemia	814
		Interpret blood reports	• Bleeding disorders – clotting factor defects and platelets defects, thalassemia, leukemias, leukopenias, agranulocytosis	814
		Prepare and provide health education on blood donation	• Lymphomas, myelomas	876, 880
VIII	8 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of endocrine disorders	**Nursing management of patients with disorders of endocrine system**	
			• Review of anatomy and physiology of endocrine system	1016
		Demonstrate skill in assessment of endocrine organ dysfunction	• Nursing assessment – history and physical assessment	1018
			• Disorders of thyroid and parathyroid, adrenal and pituitary (hyper, hypo, tumors)	1019
		Prepare and provide health education on diabetic diet Demonstrate skill in insulin administration	• Diabetes mellitus	970

Unit	Hours	Learning Outcomes	Content	Page No.
IX	8 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of disorders of integumentary system	**Nursing management of patients with disorders of integumentary system**	
			• Review of anatomy and physiology of skin	1059
		Demonstrate skill in integumentary assessment	• Nursing assessment – history and physical assessment	1063
		Demonstrate skill in medicated bath	• Infection and infestations: Dermatitis	1074
			• Dermatoses; infectious and non-infectious	
		Prepare and provide health education on skin care	• Acne, allergies, eczema and pemphigus	
			• Psoriasis, malignant melanoma, alopecia	
			• Special therapies, alternative therapies	
			• Drugs used in treatment of disorders of integumentary system	
X	11 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of musculoskeletal disorders	**Nursing management of patients with musculoskeletal problems**	
		Demonstrate skill in musculoskeletal assessment	• Review of anatomy and physiology of the musculoskeletal system	1112
		Prepare patient for radiological and nonradiological investigations of musculoskeletal system	• Nursing assessment – history and physical assessment, diagnostic tests	1117
			• Musculoskeletal trauma: Fracture	1195
			• Dislocation, sprain, strain, contusion, amputation	1183
			• Musculoskeletal infections and tumors: Osteomyelitis, benign and malignant tumor	1165
		Demonstrate skill in crutch walking and splinting	• Orthopedic modalities: Cast, splint, traction, crutch walking	1127
			• Musculoskeletal inflammation: Bursitis, synovitis, arthritis	1156
			• Special therapies, alternative therapies	
			• Metabolic bone disorder: Osteoporosis, osteomalacia and Paget's disease	1165
			• Spinal column defects and deformities – tumor, prolapsed intervertebral disc, Pott's spine	1176
			• Rehabilitation, prosthesis	1209
		Demonstrate skill in care of patient with replacement surgeries	• Replacement surgeries	1140
		Prepare and provide health education on bone healing		
XI	17 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of patients with communicable diseases	**Nursing management of patients with communicable diseases**	1231
			• Overview of infectious diseases, the infectious process	
			• Nursing assessment – history and physical assessment, diagnostic tests	

Unit	Hours	Learning Outcomes	Content	Page No.
		Demonstrate skill in barrier and reverse barrier techniques	• Tuberculosis • Diarrheal diseases, hepatitis A-E, typhoid • herpes, chickenpox, smallpox, measles, mumps, influenza • Meningitis • Gas gangrene • Leprosy • Dengue, plague, malaria, chikungunya, swine flu, filariasis • Diphtheria, pertussis, tetanus, poliomyelitis	
		Demonstrate skill in execution of different isolation protocols	• Special infection control measures: notification, isolation, quarantine, immunization	

Volume II

Unit	Hours	Learning Outcomes	Content	Page No.
I	10 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic measures and medical, surgical, nutritional and nursing management of patients with ENT disorders	**Nursing management of patient with disorders of ear, nose and throat** (Includes etiology, pathophysiology, clinical manifestations, diagnostic measures and medical, surgical, nutritional and nursing management) • Review of anatomy and physiology of the ear, nose and throat • History, physical assessment, and diagnostic tests • **Ear** – External ear: deformities otalgia, foreign bodies and tumors – Middle ear: impacted wax, tympanic, membrane perforation, otitis media, and tumors – Inner ear: Meniere's disease, labyrinthitis, ototoxicity tumors • Upper respiratory airway infections–Rhinitis, sinusitis, tonsillitis, laryngitis • Epistaxis, nasal obstruction, laryngeal obstruction • Deafness and its management	1273, 1302
II	10 (T)	Explain the etiology, patho-physiology, clinical manifestations, diagnostic measures and management of patients with disorders of eye	**Nursing management of patient with disorder of eye** • Review of anatomy and physiology of the eye • History, physical assessment, diagnostic assessment **Eye disorders** • Refractive errors • Eyelids – infection, deformities • Conjunctiva – inflammation and infection bleeding • Cornea – inflammation and infection • Lens – cataract • Glaucoma • Retinal detachment • Blindness	1330
		Describe eye donation, banking and transplantation	• Eye banking, eye donation	

Unit	Hours	Learning Outcomes	Content	Page No.
III	9 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of kidney and urinary system disorders	**Nursing management of patient with kidney and urinary problems** • Review of anatomy and physiology of the genitourinary system	1369
		Demonstrate skill in genitourinary assessment	• History, physical assessment, diagnostic tests	1375
		Prepare patient for genitourinary investigations	• Urinary tract infections – acute, chronic, lower, upper	1434
			• Nephritis, nephrotic syndrome	Nephritis covered in chapters 44 and 45 & 1393
		Prepare and provide health education on prevention of renal calculi	• Renal calculi	1450
			• Acute and chronic renal failure	1387
			• Disorders of ureter, urinary bladder and urethra	1434
			• Disorders of prostate – inflammation, infection, stricture, obstruction, and benign prostate hypertrophy	1469
IV	5 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of male reproductive disorders	**Nursing management of disorders of male reproductive system** • Review of anatomy and physiology of the male reproductive system • History, physical assessment, diagnostic tests • Infections of testis, penis and adjacent structures – phimosis, epididymitis, and orchitis • Sexual dysfunction, infertility, contraception • Male breast disorders - gynecomastia, tumor, climacteric changes	1469
V	8 (T)	Explain the etiology, patho-physiology, clinical manifestations, types, diagnostic measures and management of patients with disorders of burns/cosmetic surgeries and its significance	**Nursing management of patient with burns, reconstructive and cosmetic surgery** • Review of anatomy and physiology of the skin and connective tissues • History, physical assessment, assessment of burns and fluid and electrolyte loss • Burns • Reconstructive and cosmetic surgery for burns, congenital deformities, injuries and cosmetic purposes, gender reassignment • Legal and ethical aspects • Special therapies: LAD, vacuumed dressing, laser, liposuction, skin health rejuvenation, use of derma fillers	1509
VI	16 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic measures and management of patients with neurological disorders	• Review of anatomy and physiology of the neurological system	1543
			• History, physical, neurological assessment, diagnostic tests	1553
			• Headache, head injuries	1600, 1631
			• Spinal injuries – paraplegia, hemiplegia, quadriplegia	1644
			• Spinal cord compression – herniation of intervertebral disc	1728
			• Intra cranial and cerebral aneurysms	1623

Unit	Hours	Learning Outcomes	Content	Page No.
			• Meningitis, encephalitis, brain abscess, neurocysticercosis	1673
			• Movement disorders – seizures, epilepsies, and chorea	1592, 1594 & 1702
			• Cerebrovascular disorders-CVA	
			• Cranial, spinal neuropathies – Bell's palsy, trigeminal neuralgia	1696, 1699
			• Peripheral neuropathies	1699
			• Degenerative diseases - Alzheimer's disease, Parkinson's disease	1712, 1716
			• Guillain-Barré syndrome, myasthenia gravis, and multiple sclerosis	1691, 1689 & 1682
			• Rehabilitation of patient with neurological deficit	1658
VII	12 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic tests, and medical, surgical, nutritional, and nursing management of immunological disorders	**Nursing management of patients with immunological problems**	
		Prepare and provide health education on prevention of HIV infection	• Review of immune system	1740
			• Nursing assessment – history and physical assessment	1748
			• HIV & AIDS: Epidemiology, transmission, prevention of transmission	1767
			• Role of nurse: Counseling, health education and home care consideration	1777
		Describe the national infection control programmes	• National AIDS Control Program – NACO, various national and international agencies, infection control programs	1786
		Describe the drug therapy for AIDS	• Rehabilitation	1789
VIII	10 (T)	Explain the etiology, pathophysiology, types, clinical manifestations, staging, diagnostic measures and management of patients with different cancer, treatment modalities including newer treatments	**Nursing management of patient with oncological conditions** • Structure and characteristics of normal and cancer cells • History, physically assessment, diagnostic tests. • Prevention screening early detections warning sign of cancer • Epidemiology, etiology classification, pathophysiology, staging clinical manifestations, diagnosis, treatment modalities and medical and surgical nursing management of oncological condition • Common malignancies of various body system eye, ear, nose, larynx, breast, cervix, ovary, uterus, sarcoma, renal, bladder, kidney, prostate, brain, spinal cord. • Oncological emergencies • Modalities of treatment – Chemotherapy; radiotherapy – Radiation safety, AERB regulations, surgical intervention, stem cell and bone marrow transplant, immunotherapy, gene therapy	1850 and covered in respective chapters

Unit	Hours	Learning Outcomes	Content	Page No.
			• Psychological aspects of cancer – anxiety, depression, insomnia, anger	
			• Palliative care	1952
			• Supportive care	Discussed in corresponding chapters
			• Hospice care	1954
IX	15 (T)	Explain the types, policies, guidelines, prevention and management of disaster, the etiology, pathophysiology, clinical manifestations, diagnostic measures and management of patients with acute emergencies	**Nursing management of patient in emergency and disaster situations** • Disaster nursing • Concept and principles of disaster nursing, related policies • Types of disaster: Natural and manmade • Disaster preparedness: Team, guidelines, protocols, equipment, resources • Etiology, classification, pathophysiology, staging, clinical manifestation, diagnosis, treatment modalities and medical and surgical nursing management of patient with medical and surgical emergencies – Polytrauma, bites, poisoning and thermal emergencies • Principles of emergency management • Medicolegal aspects	2013 1977
X	8 (T)	Explain the concept, physiological changes, and psychosocial problems of ageing Describe the nursing management of the elderly	**Nursing care of the elderly** • History and physical assessment • Aging process and age-related body changes and psychosocial aspects • Stress and coping in elder patient • Psychosocial and sexual abuse of elderly • Role of family and formal and non-formal caregivers • Use of aids and prosthesis (hearing aids, dentures) • Legal and ethical issues • National programs for elderly, privileges, community programs and health services • Home and institutional care	2035
XI	12 (T)	Explain the etiology, pathophysiology, clinical manifestations, diagnostic measures and management of patients in critical care units	**Nursing management of patients in critical care units** • Principles of critical care nursing • Organization: physical set-up, policies, staffing norms • Protocols, equipment, and supplies, • Special equipment: ventilators, cardiac monitors, defibrillators, infusion pump, resuscitation equipment • Advanced cardiac life support • Nursing management of critically ill patient • Transitional care • Ethical and legal aspects • Breaking bad news to patients and/or their families—Communication with patient and family • End of life care	2061
XII	5 (T)	Describe the etiology, pathophysiology, clinical manifestations, diagnostic measures and management of patients with occupational/ industrial health disorders	**Nursing management of patients occupational and industrial disorders** • History, physical examination, diagnostic tests • Occupational diseases and management	2087

UNIT

XII Sensory Function

Chapter 40 Assessment and Management of Patients with Nose and Throat Disorders 1273

Chapter 41 Assessment and Management of Patients with Hearing and Balance Disorders 1302

Chapter 42 Assessment and Management of Patients with Eye and Vision Disorders 1329

CHAPTER 40

Assessment and Management of Patients with Nose and Throat Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe nursing management of patients with upper airway disorders.
2. Compare and contrast the upper respiratory tract infections according to cause, incidence, clinical manifestations, management, and the significance of preventive health care.
3. Apply the nursing process as a framework for care of patients with upper airway infection.
4. Describe nursing management of the patient with epistaxis.
5. Apply the nursing process as a framework for care of patients undergoing laryngectomy.

GLOSSARY

alaryngeal communication: alternative modes of speaking that do not involve the normal larynx; used by patients whose larynx has been surgically removed
aphonia: impaired ability to use one's voice due to disease or injury to the larynx
apnea: cessation of breathing
dysphagia: difficulties in swallowing
epistaxis: hemorrhage from the nose due to rupture of tiny, distended vessels in the mucous membrane of any area of the nose
herpes simplex (cold sore): a cutaneous viral infection with painful vesicles and erosions on the tongue, palate, gingiva, buccal membranes, or lips
laryngectomy: surgical removal of all or part of the larynx and surrounding structures
laryngitis: inflammation of the larynx; may be caused by voice abuse, exposure to irritants, or infectious organisms
nuchal rigidity: stiffness of the neck or inability to bend the neck
pharyngitis: inflammation of the throat; usually viral or bacterial in origin
rhinitis: inflammation of the mucous membranes of the nose; may be infectious, allergic, or inflammatory in origin
rhinitis medicamentosa: rebound nasal congestion commonly associated with overuse of over-the-counter nasal decongestants
rhinorrhea: drainage of a large amount of fluid from the nose
rhinosinusitis: inflammation of the nares and paranasal sinuses, including frontal, ethmoid, maxillary, and sphenoid sinuses; replaces the term *sinusitis*
tonsillitis: inflammation of the tonsils, usually due to an acute infection
xerostomia: dryness of the mouth from a variety of causes

Introduction

Upper respiratory tract disorders are those that involve the nose, paranasal sinuses, pharynx, larynx, trachea, or bronchi. Many of these conditions are relatively minor, and their effects are limited to mild and temporary discomfort and inconvenience for the patient. However, others are acute, severe, and life threatening and may require permanent alterations in breathing and speaking. Therefore, the nurse must have expert assessment skills, an understanding of the wide variety of disorders that may affect the upper airway, and an awareness of the impact of these alterations on patients. Patient education is an important aspect of nursing care because many of these disorders are treated outside the hospital or at home by patients themselves. When caring for patients with acute, life-threatening disorders, the nurse needs highly developed assessment and clinical management skills, along with a focus on rehabilitation needs.

UPPER AIRWAY INFECTIONS

Upper airway infections (otherwise known as upper respiratory infections or URIs) are the most common cause of illness and affect most people on occasion. Some infections are acute, with symptoms that last several days; others are chronic, with symptoms that may last for months or recur. URI is defined as an infection of the mucous membranes from the nose down to the respiratory tree or bronchi (Fashner, Erickson, & Werner, 2012).

The common cold is the most frequently occurring example of a URI. URIs occur when microorganisms such as viruses and bacteria are inhaled. There are many causative organisms, and people are susceptible throughout life. Viruses, the most common cause of URIs, affect the upper respiratory passages and lead to subsequent mucous membrane inflammation (Fashner et al., 2012). URIs are the most common reason for seeking health care and for absences from school and work.

URIs affect the nasal cavity; ethmoidal air cells; and frontal, maxillary, and sphenoid sinuses; as well as the pharynx, larynx, and trachea. On average, adults typically develop 2 to 4 URIs per year because of the wide variety of respiratory viruses that circulate in the community. Although patients are rarely hospitalized for the treatment of URIs. Nurses working in community settings or long-term care facilities may encounter patients who have these infections. It is important for nurses to recognize the signs and symptoms of URIs and provide appropriate care. Nurses in these settings also can influence patient outcomes through patient education. Special considerations with regard to URIs in older adults are summarized in Chart 40-1.

Rhinitis

Rhinitis is a group of disorders characterized by inflammation and irritation of the mucous membranes of the nose. These

Chart 40-1

Upper Respiratory Tract Disorders in Older Adults

- Upper respiratory infections in older adults may have more serious consequences if patients have concurrent medical problems that compromise their respiratory or immune status.
- Influenza causes exacerbations of chronic obstructive pulmonary disease and reduced pulmonary function.
- Antihistamines and decongestants used to treat upper respiratory disorders must be used cautiously in older adults because of their side effects and potential interactions with other medications.
- With anticipated future growth in the older adult population, the need for endoscopic sinus surgery will increase. Older patients with CRS present with symptoms similar to those of younger adults and experience a similar degree of improvement and quality of life after endoscopic sinus surgery.
- The structure of the nose changes with aging; it lengthens and the tip droops from loss of cartilage. This can cause restriction in airflow and predispose older adult patients to geriatric rhinitis, characterized by increased thin, watery sinus drainage. These structural changes may also adversely affect the sense of smell.
- Laryngitis in older adults is common and may be secondary to gastroesophageal reflux disease (GERD). Older adults are more likely to have impaired esophageal peristalsis and a weaker esophageal sphincter. Treatment measures include sleeping with the head of the bed elevated and the use of medications such as histamine-2 receptor blockers (e.g., famotidine [Pepcid], ranitidine [Zantac]) or proton pump inhibitors (omeprazole [Prilosec]).
- Age-related loss of muscle mass and thinning of the mucous membranes can cause structural changes in the larynx that may change characteristics of the voice. In general, the pitch of voice becomes higher in older adult men and lower in older adult women. The voice also "thins" (decreased projection) and may sound tremulous. These changes should be discriminated from signs that could indicate pathologic conditions.

Chart 40-2

Examples of Common Indoor and Outdoor Allergens

Common Indoor Allergens

- Dust mite feces
- Dog dander
- Cat dander
- Cockroach droppings
- Molds

Common Outdoor Allergens

- Trees (e.g., oak, elm, western red cedar, ash, birch, sycamore, maple, walnut, and cypress)
- Weeds (e.g., ragweed, tumbleweed, sagebrush, pigweed, cockle weed, and Russian thistle)
- Grasses (e.g., timothy, orchard, sweet vernal, bermuda, sour dock, redtop, and bluegrass)
- Molds (*Alternaria, Cladosporium, Aspergillus*)

Adapted from Aljubran, S. & Lockey, R. F. (2014) Aeroallergens. Retrieved on 3/9/2016 at www.emedicine.medscape.com/article/137911-overview

conditions can have a significant impact on quality of life and contribute to sinus, ear, and sleep problems and learning disorders. Rhinitis often coexists with other respiratory disorders, such as asthma. It affects between 10% and 30% of the population worldwide annually. Viral rhinitis, especially the common cold, affects approximately one billion individuals yearly (Krouse & Krouse, 2014).

Rhinitis may be acute or chronic, and allergic or nonallergic. Allergic rhinitis is further classified as seasonal or perennial rhinitis and is commonly associated with exposure to airborne particles such as dust, dander, or plant pollens in people who are allergic to these substances. Seasonal rhinitis occurs during pollen seasons, and perennial rhinitis occurs throughout the year. See Chapter 56 for detailed descriptions of allergic disorders, including allergic rhinitis.

Pathophysiology

Rhinitis may be caused by a variety of factors, including changes in temperature or humidity; odors; infection; age; systemic disease; use of over-the-counter (OTC) and prescribed nasal decongestants; and the presence of a foreign body. Allergic rhinitis may occur with exposure to allergens such as foods (e.g., peanuts, walnuts, Brazil nuts, wheat, shellfish, soy, cow's milk, and eggs), medications (e.g., penicillin, sulfa medications, and aspirin), and particles in the indoor and outdoor environment (see Chart 40-2). The most common cause of nonallergic rhinitis is the common cold (Seidman, Gurgel, Lin, et al., 2015).

Drug-induced rhinitis may occur with antihypertensive agents, such as angiotensin-converting enzyme (ACE) inhibitors and beta-blockers; "statins," such as atorvastatin (Lipitor) and simvastatin (Zocor); antidepressants and antipsychotics such as risperidone (Risperdal); aspirin; and some antianxiety medications. Figure 40-1 shows the pathologic processes involved in rhinitis and rhinosinusitis. Other causes of rhinovirus are identified in Table 40-1.

Clinical Manifestations

The signs and symptoms of rhinitis include rhinorrhea (excessive nasal drainage, runny nose); nasal congestion; nasal discharge (purulent with bacterial rhinitis); sneezing; and pruritus of the nose, roof of the mouth, throat, eyes, and ears. Headache may occur, particularly if rhinosinusitis is also present. Nonallergic rhinitis can occur throughout the year.

Medical Management

The management of rhinitis depends on the cause, which may be identified through the history and physical examination. The nurse asks the patient about recent symptoms as well as possible exposure to allergens in the home, environment, or workplace. If viral rhinitis is the cause, medications may be prescribed to relieve the symptoms. In allergic rhinitis, allergy tests may be performed to identify possible allergens. Depending on the severity of the allergy, desensitizing immunizations and corticosteroids may be required (see Chapter 56 for more details). If symptoms suggest a bacterial infection, an antimicrobial agent is used (see later discussion of rhinosinusitis). Patients with nasal septal deformities or nasal polyps may be referred to an ear, nose, and throat specialist.

Pharmacologic Therapy

Medication therapy for allergic and nonallergic rhinitis focuses on symptom relief. Antihistamines and corticosteroid nasal sprays may be useful. Antihistamines remain the most

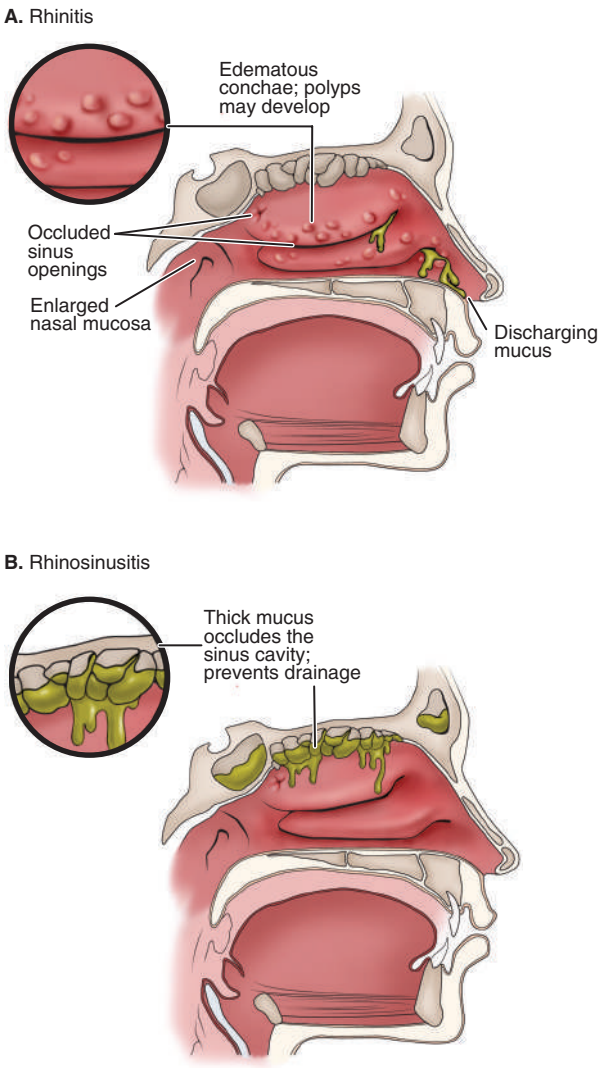

Figure 40-1 • Pathophysiologic processes in rhinitis and rhinosinusitis. Although pathophysiologic processes are similar in rhinitis and rhinosinusitis, they affect different structures. **A.** In rhinitis, the mucous membranes lining the nasal passages become inflamed, congested, and edematous. The swollen nasal conchae block the sinus openings, and mucus is discharged from the nostrils. **B.** Rhinosinusitis is also marked by inflammation and congestion, with thickened mucous secretions filling the sinus cavities and occluding the openings.

common treatment and are given for sneezing, pruritus, and rhinorrhea. (Examples of commonly prescribed antihistamines are discussed in more detail in Chapter 56.) Brompheniramine/pseudoephedrine (Dimetapp) is an example of combination antihistamine/decongestant medications. Cromolyn (NasalCrom), a mast cell stabilizer that inhibits the release of histamine and other chemicals, is also used in the treatment of rhinitis. Oral decongestant agents may be used for nasal obstruction. The use of saline nasal spray can act as a mild decongestant and can liquefy mucus to prevent crusting. Two inhalations of intranasal ipratropium (Atrovent) can be given in each nostril two to three times per day for symptomatic relief of rhinorrhea. In addition, intranasal corticosteroids may be used for severe congestion, and ophthalmic agents (cromolyn ophthalmic solution 4%) may be used to relieve irritation, itching, and redness of the eyes. Appropriate allergy treatments may include leukotriene modifiers (e.g., montelukast [Singulair], zafirlukast [Accolate], zileuton [Zyflo]), and immunoglobulin E modifiers (omalizumab [Xolair]), which are also components of asthma treatment guidelines (discussed further in Chapter 13). The choice of medications depends on the symptoms, adverse reactions, adherence factors, risk of drug interactions, and cost to the patient.

TABLE 40-1 Causes of Rhinosinusitis

Category	Causes
Vasomotor	Idiopathic Abuse of nasal decongestants (rhinitis medicamentosa) Psychological stimulation (anger, sexual arousal) Irritants (smoke, air pollution, exhaust fumes, cocaine)
Mechanical	Tumor Deviated septum Crusting Hypertrophied turbinates Foreign body Cerebrospinal fluid leak
Chronic inflammatory	Polyps (in cystic fibrosis) Sarcoidosis Wegener granulomatosis Midline granuloma
Infectious	Acute viral infection Acute or chronic rhinosinusitis Rare nasal infections (syphilis, tuberculosis)
Hormonal	Pregnancy Use of oral contraceptives Hypothyroidism

Nursing Management

Educating Patients about Self-Care

The nurse instructs the patient with allergic rhinitis to avoid or reduce exposure to allergens and irritants, such as dusts, molds, animals, fumes, odors, powders, sprays, and tobacco smoke. Patient education is essential when assisting the patient in the use of all medications. To prevent possible drug interactions, the patient is cautioned to read drug labels before taking any OTC medication.

The nurse instructs the patient about the importance of controlling the environment at home and at work. Saline nasal sprays or aerosols may be helpful in soothing mucous membranes, softening crusted secretions, and removing irritants. The nurse instructs the patient in correct administration of nasal medications. To achieve maximal relief, the patient is instructed to blow the nose before applying any medication into the nasal cavity. In addition, the patient is taught to keep the head upright; spray quickly and firmly into each nostril away from the nasal septum; and wait at least 1 minute before administering the second spray. The container should be cleaned after each use and should never be shared with other people to avoid cross-contamination.

In the case of infectious rhinitis, the nurse reviews hand hygiene technique with the patient as a measure to prevent transmission of organisms. This is especially important for those in contact with vulnerable populations such as the very young, older adults, or people who are immunosuppressed

(e.g., patients with human immune deficiency virus [HIV] infection, those taking immunosuppressive medications). In older adults and other high-risk populations, the nurse reviews the importance of receiving an influenza vaccination each year to achieve immunity before the beginning of the flu season.

Viral Rhinitis (Common Cold)

Viral rhinitis is the most frequent viral infection in the general population (Krouse & Krouse, 2014). The term *common cold* often is used when referring to a URI that is self-limited and caused by a virus. The term *cold* refers to an infectious, acute inflammation of the mucous membranes of the nasal cavity characterized by nasal congestion, rhinorrhea, sneezing, sore throat, and general malaise. More broadly, the term refers to an acute URI, whereas terms such as *rhinitis, pharyngitis,* and *laryngitis* distinguish the sites of the symptoms. The term is also used when the causative virus is influenza (the flu). Colds are highly contagious because virus is shed for about 2 days before the symptoms appear and during the first part of the symptomatic phase.

Colds caused by rhinoviruses tend to occur in the early fall and spring. Other viruses tend to cause winter colds (Centers for Disease Control and Prevention [CDC], 2015). Seasonal changes in relative humidity may affect the prevalence of colds. The most common cold-causing viruses survive better when humidity is low, in the colder months of the year.

Colds are caused by as many as 200 different viruses (National Institute of Allergy and Infectious Diseases, 2015). Rhinoviruses are the most likely causative organisms. Other viruses implicated in the common cold include coronavirus, adenovirus, respiratory syncytial virus, influenza virus, and parainfluenza virus. Each virus may have multiple strains; as a result, people are susceptible to colds throughout life. Development of a vaccine against the multiple strains of virus is almost impossible. Immunity after recovery is variable and depends on many factors, including a person's natural host resistance and the specific virus that caused the cold. Despite popular belief, cold temperatures and exposure to cold rainy weather do not increase the incidence or severity of the common cold.

Clinical Manifestations

Signs and symptoms of viral rhinitis may include low-grade fever, nasal congestion, rhinorrhea and nasal discharge, halitosis, sneezing, tearing watery eyes, "scratchy" or sore throat, general malaise, chills, and often headache and muscle aches. As the illness progresses, cough usually appears. In some people, the virus exacerbates herpes simplex, commonly called a *cold sore* (see Chart 40-3).

The symptoms of viral rhinitis may last from 1 to 2 weeks. If severe systemic respiratory symptoms occur, it is no longer considered viral rhinitis but one of the other acute URIs. Allergic conditions can affect the nose, mimicking the symptoms of a cold.

Medical Management

Management consists of symptomatic therapy that includes adequate fluid intake, rest, prevention of chilling, and the use of expectorants as needed. Warm salt-water gargles soothe the sore throat, and nonsteroidal anti-inflammatory drugs

Chart 40-3

Colds and Cold Sores (Herpes Simplex Virus)

Herpes labialis is an infection that is caused by herpes simplex virus type 1 (HSV-1). It is characterized by an eruption of small, painful blisters on the skin of the lips, mouth, gums, tongue, or the skin around the mouth. The blisters are commonly referred to as cold sores or fever blisters. Once the person is infected with this virus, it can lie latent in the cells for a period of time. The incubation period is about 2 to 12 days. Between 50% and 80% of Americans are infected by age 30 years, because HSV-1 is typically transmitted during childhood through nonsexual contact. Herpes labialis is extremely contagious and can be spread through contaminated razors, towels, and dishes. It is activated by overexposure to sunlight or wind, colds, influenza and similar infections, heavy alcohol use, and physical or emotional stress.

Although herpes simplex virus type 2 (HSV-2) typically causes painful vesicular and ulcerative lesions in the genital and anal areas, HSV-1 may also cause genital herpes. Oral–genital contact can spread oral herpes to the genitals (and vice versa). People with active herpetic lesions should avoid oral sex. It is extremely important for patients to understand that the virus can be transmitted by asymptomatic people. Estimates suggest that 80% of people infected are asymptomatic.

Early symptoms of herpes labialis include burning, itching, and increased sensitivity or tingling sensation. These symptoms may occur several days before the appearance of lesions. The lesions appear as macules or papules, progressing to small blisters (vesicles) filled with clear, yellowish fluid. They are raised, red, and painful and can break and ooze. The lesions typically extend through the epidermis and penetrate into the underlying dermis, consistent with a partial-thickness wound. Eventually, yellow crusts slough to reveal pink, healing skin. Typically, the virus is no longer detectable in the lesion or wound 5 days after the vesicle has developed.

Medications used in the management of herpes labialis include acyclovir (Zovirax) and valacyclovir (Valtrex), which help to minimize the symptoms and the duration or length of flare-up. Acetaminophen/paracetamol may be given for analgesia. Topical anesthetics such as lidocaine (Xylocaine) can help in the control of discomfort. Occlusive dressings have been shown to speed the healing process. Not only do such dressings prevent desiccation and scab formation but they also maintain an aqueous wound environment rich in growth factors and matrix materials. However, occlusive dressings are not practical for lip and mucosal lesions. In this case, alternatives include occlusive ointments such as Herpecin-L or docosanol (Abreva).

(NSAIDs), such as aspirin or ibuprofen, relieve aches and pains. Antihistamines are used to relieve sneezing, rhinorrhea, and nasal congestion. Petroleum jelly can soothe irritated, chapped, and raw skin around the nares (National Institute of Allergy and Infectious Diseases, 2015).

Guaifenesin (Mucinex), an expectorant, is available without a prescription and is used to promote removal of secretions. Antimicrobial agents (antibiotics) should not be used, because they do not affect the virus or reduce the incidence of bacterial complications. In addition, their inappropriate use has been implicated in the development of organisms resistant to therapy.

Topical nasal decongestants (e.g., phenylephrine nasal [Neo-Synephrine] and oxymetazoline nasal [Afrin]) should be used with caution. Topical therapy delivers medication directly to the nasal mucosa, and its overuse can produce **rhinitis medicamentosa,** or rebound rhinitis. Most patients treat the common cold with OTC medications that produce moderate clinical benefits, such as relief of symptoms.

In addition, alternative medicines (e.g., echinacea, zinc lozenges, and zinc nasal spray) are frequently used to treat the common cold; however, evidence regarding their effectiveness in shortening the symptomatic phase is limited (Karsch-Volk, Barrett, Keifer, et al., 2014). The inhalation of steam or heated, humidified air has been a mainstay of home remedies to treat the common cold; however, the value of this therapy has not been demonstrated.

Nursing Management

Educating Patients about Self-Care

Most viruses can be transmitted in several ways: direct contact with infected secretions, inhalation of large particles from others' coughing or sneezing, or inhalation of small particles (aerosol) that may be suspended in the air for up to an hour. Implementation of appropriate hand hygiene measures (see Chart 1-4 for further information on hand hygiene methods) remains the most effective measure to prevent transmission of organisms. The nurse educates the patient about how to break the chain of infection with appropriate hand hygiene and the use of tissues to avoid the spread of the virus with coughing and sneezing, and to cough or sneeze into the upper arm if tissues are not readily available. The nurse instructs the patient about methods to treat symptoms of the common cold and provides both verbal and written information to assist in the prevention and management of URIs.

Rhinosinusitis

Rhinosinusitis, formerly called *sinusitis,* is an inflammation of the paranasal sinuses and nasal cavity. The American Academy of Otolaryngology–Head and Neck Surgery Foundation (Rosenfeld, Andes, Bhattacharyya, et al., 2015) recommends the use of the term *rhinosinusitis* because sinusitis is almost always accompanied by inflammation of the nasal mucosa. Around 134 million Indians suffer from chronic sinusitis annually which is more than those who suffer from coronary artery disease, diabetes, or asthma (Khanna & Gharpure, 2012) Uncomplicated rhinosinusitis occurs without extension of inflammation outside of the paranasal sinuses and nasal cavity. Rhinosinusitis is classified by duration of symptoms as acute (less than 4 weeks), subacute (4 to 12 weeks), and chronic (more than 12 weeks). Rhinosinusitis can be caused by a bacterial or viral infection.

Acute Rhinosinusitis

Acute rhinosinusitis is classified as acute bacterial rhinosinusitis (ABRS) or acute viral rhinosinusitis (AVRS). Recurrent acute rhinosinusitis is characterized by four or more acute episodes of ABRS per year (Rosenfeld et al., 2015) and is discussed with chronic rhinosinusitis (CRS).

Pathophysiology

Acute rhinosinusitis usually follows a viral URI or cold, such as an unresolved viral or bacterial infection, or an exacerbation of allergic rhinitis. Normally, the sinus openings into the nasal passages are clear and infections resolve promptly. However, if their drainage is obstructed by a deviated septum or by hypertrophied turbinates, spurs, or nasal polyps or tumors, sinus infection may persist as a smoldering (persistent) secondary infection or progress to an acute suppurative process (causing purulent discharge).

Nasal congestion, caused by inflammation, edema, and transudation of fluid secondary to URI, leads to obstruction of the sinus cavities (see Fig. 40-1). This provides an excellent medium for bacterial growth. Other conditions and activities that can block the normal flow of sinus secretions include abnormal structures of the nose, enlarged adenoids, diving and swimming, tooth infection, trauma to the nose, tumors, and the pressure of foreign objects. Some people are more prone to rhinosinusitis because exposure to environmental hazards such as paint, sawdust, and chemicals may result in chronic inflammation of the nasal passages.

Bacterial organisms account for more than 60% of the cases of acute rhinosinusitis. Typical pathogens include *Streptococcus pneumoniae, Haemophilus influenzae,* and less commonly *Staphylococcus aureus,* and *Moraxella catarrhalis* (Brook, 2015). Biofilms, which consist of organized, heterogeneous communities of bacteria, have been found to be 10 to 1000 times more resistant to antibiotic treatment and more likely to contribute to host resistance when compared with other bacteria. They serve as bacterial reservoirs that can cause systemic illness when released into the circulation. Although antibiotics kill bacteria in the biofilm margin, cells deep in the biofilm are not affected, allowing for regrowth once antibiotic therapy has been discontinued. Pathogens in the upper respiratory tract that form biofilms include those species listed earlier as well as *Pseudomonas aeruginosa.*

Other organisms that are occasionally isolated include *Chlamydia pneumoniae, Streptococcus pyogenes,* viruses, and fungi (*Aspergillus fumigatus*). Fungal infections occur most often in immunosuppressed patients (Brook, 2015).

Clinical Manifestations

Symptoms of ABRS include purulent nasal drainage (anterior, posterior, or both) accompanied by nasal obstruction or a combination of facial pain, pressure, or a sense of fullness (referred to collectively as facial pain–pressure–fullness), or both (Rosenfeld et al., 2015). The facial pain–pressure–fullness may involve the anterior face or the periorbital region. The patient may also report cloudy or colored nasal discharge congestion, blockage, or stuffiness as well as a localized or diffuse headache. Patients with ABRS may present with a high fever (i.e., 39°C [102°F] or higher). In addition, the occurrence of symptoms for 10 days or more after the initial onset of upper respiratory symptoms indicates ABRS (Brook, 2015).

The symptoms of AVRS are similar to those of ABRS, except the patient does not present with a high fever, nor with the same

intensity of symptoms (e.g., there tends to be an absence of facial pain–pressure–fullness), nor with symptoms that persist for as long a period of time. Symptoms of AVRS occur for fewer than 10 days after the onset of upper respiratory symptoms and do not worsen (Tierney, McPhee, & Papadakis, 2015).

Assessment and Diagnostic Findings

A careful history and physical examination are performed. The head and neck, particularly the nose, ears, teeth, sinuses, pharynx, and chest, are examined. There may be tenderness to palpation over the infected sinus area. The sinuses are percussed using the index finger, tapping lightly to determine whether the patient experiences pain. Although less frequently performed, transillumination of the affected area may reveal a decrease in the transmission of light with rhinosinusitis (see Chapter 10). Diagnostic imaging (x-ray, computed tomography [CT], magnetic resonance imaging [MRI]) is not recommended and generally not needed for the diagnosis of acute rhinosinusitis if the patient meets clinical diagnostic criteria (Rosenfeld et al., 2015). When a complication or alternative diagnosis is suspected, CT scans may be indicated because these scans are sensitive to inflammatory changes and bone destruction and identify anatomic variations that can guide sinus surgery if indicated.

To confirm the diagnosis of maxillary and frontal rhinosinusitis and identify the pathogen, sinus aspirates may be obtained. Flexible endoscopic culture techniques and swabbing of the sinuses have been used for this purpose (Krouse & Krouse, 2015).

Complications

If untreated, acute rhinosinusitis may lead to severe complications. Local complications include osteomyelitis and mucocele (cyst of the paranasal sinuses). Osteomyelitis requires prolonged antibiotic therapy and at times removal of necrotic bone. Intracranial complications, although rare, include cavernous sinus thrombosis, meningitis, brain abscess, ischemic brain infarction, and severe orbital cellulitis (Tierney et al., 2015). Mucoceles may require surgical treatment to establish intranasal drainage or complete excision with ablation of the sinus cavity. Brain abscesses occur by direct spread and can be life threatening. Frontal epidural abscesses are usually quiescent but can be detected by CT scan.

Medical Management

Treatment of acute rhinosinusitis depends on the cause; a 5- to 7-day course of antibiotics is prescribed for bacterial cases (Tewfik, 2015). The goals of treatment for acute rhinosinusitis are to shrink the nasal mucosa, relieve pain, and treat infection. Because of the inappropriate use of antibiotics for nonbacterial illness, including AVRS, and the resulting resistance that has occurred, oral antibiotics are only prescribed when there is sufficient empiric evidence that the patient has ABRS (e.g., high fever or symptoms that persist for at least 10 days or worsening symptoms following a viral respiratory illness).

Antibiotics should be given as soon as the diagnosis of ABRS is established. Amoxicillin–clavulanic acid (Augmentin) is the antibiotic of choice. For patients who are allergic to penicillin, doxycycline (Vibramycin) or respiratory quinolones such as levofloxacin (Levaquin) or moxifloxacin (Avelox) can be used. Other antibiotics prescribed previously to treat ABRS, including cephalosporins such as cephalexin (Keflex), cefuroxime (Ceftin), cefaclor (Ceclor), and cefixime (Suprax), trimethoprim–sulfamethoxazole (Bactrim, Septra), and macrolides such as clarithromycin (Biaxin) and azithromycin (Zithromax), are no longer recommended because they are not effective in treating antibiotic-resistant organisms that are now more commonly implicated in ABRS (Tewfik, 2015). Intranasal saline lavage is an effective adjunct therapy to antibiotics in that it may relieve symptoms, reduce inflammation, and help clear the passages of stagnant mucus. Neither decongestants nor antihistamines are recommended adjunctive medications for treating ABRS (Tewfik, 2015).

Treatment of AVRS typically involves nasal saline lavage and decongestants (guaifenesin/pseudoephedrine [Entex PSE]). Decongestants or nasal saline sprays can increase patency of the ostiomeatal unit and improve drainage of the sinuses. Topical decongestants should not be used for longer than 3 or 4 days. Oral decongestants must be used cautiously in patients with hypertension. OTC antihistamines, such as diphenhydramine (Benadryl) and cetirizine (Zyrtec), and prescription antihistamines, such as fexofenadine (Allegra), are used if an allergic component is suspected.

Intranasal corticosteroids have been shown to produce complete or marked improvement in acute symptoms of either bacterial or viral rhinosinusitis; however, they are only recommended for use in patients with a previous history of allergic rhinitis (Krouse & Krouse, 2014); (Rosenfeld et al., 2015). Examples of intranasal corticosteroids, side effects, and contraindications are presented in Table 40-2.

Nursing Management

Educating Patients About Self-Care

Patient education is an important aspect of nursing care for the patient with acute rhinosinusitis. The nurse instructs the patient about symptoms of complications that require immediate follow-up. Referral to the primary provider is indicated if periorbital edema and severe pain on palpation occur. The nurse instructs the patient about methods to promote drainage of the sinuses, including humidification of the air in the home

TABLE 40-2 Selected Nasal Corticosteroids and Common Side Effects

Nasal Corticosteroids	Side Effects	Contraindications (for all Nasal Corticosteroids)
Beclomethasone (Beconase AQ)	Nasal irritation, headache, nausea, lightheadedness, epistaxis, rhinorrhea, watering eyes, sneezing, dry nose and throat	Avoid in patients with recurrent epistaxis, glaucoma, and cataracts. Patients who have been exposed to measles/varicella or who have adrenal insufficiency should avoid these medications.
Budesonide (Rhinocort)	Epistaxis, pharyngitis, cough, nasal irritation, bronchospasm	
Mometasone (Nasonex)	Headache, viral infection, pharyngitis, epistaxis, cough, dysmenorrhea, musculoskeletal pain, arthralgia	
Triamcinolone (Nasacort AQ)	Pharyngitis, epistaxis, cough, headache	

Adapted from Peters, A. (2015). Rhinosinusitis: Synopsis. Retrieved on 10/8/2015 at: www.worldallergy.org/professional/allergic_diseases_center/rhinosinusitis/sinusitissynopsis.php

and the use of warm compresses to relieve pressure. The patient is advised to avoid swimming, diving, and air travel during the acute infection. Patients using tobacco are instructed to immediately stop smoking or using any form of tobacco. Most patients use nasal sprays incorrectly, which can lead to several side effects that include nasal irritation, nasal burning, bad taste, and drainage in the throat or even epistaxis. Therefore, if an intranasal corticosteroid is prescribed, it is important to instruct the patient about the correct use of prescribed nasal sprays through demonstration, explanation, and return demonstration to evaluate the patient's understanding of the correct method of administration. The nurse also educates the patient about the side effects of prescribed and OTC nasal sprays and about rebound congestion (rhinitis medicamentosa). Once the decongestant is discontinued, the nasal passages close and congestion results. Appropriate medications to use for pain relief include acetaminophen/paracetamol (Tylenol) and NSAIDs such as ibuprofen (Advil), naproxen sodium (Aleve), and aspirin for adults older than 20 years.

The nurse tells patients with recurrent rhinosinusitis to begin decongestants, such as pseudoephedrine (Sudafed), at the first sign of rhinosinusitis. This promotes drainage and decreases the risk of bacterial infection. Patients should also check with their primary provider or pharmacist before using OTC medications because many cold medications can worsen symptoms or other health problems, specifically hypertension.

The nurse stresses the importance of following the recommended antibiotic regimen because a consistent blood level of the medication is critical to treat the infection. The nurse educates the patient about the early signs of a sinus infection and recommends preventive measures such as following healthy practices and avoiding contact with people with URIs.

The nurse explains to the patient that fever, severe headache, and nuchal rigidity (stiffness of the neck or inability to bend the neck) are signs of potential complications. Patients with chronic symptoms of rhinosinusitis who do not have marked improvement in 4 weeks with continuous medical treatment may be candidates for functional endoscopic sinus surgery (FESS, see later discussion) (Krings, Kallogjeri, Wineland, et al., 2014).

Nursing Alert: Patients with nasotracheal and nasogastric tubes in place are at the risk for development of sinus infections. Thus, accurate assessment of patients with these tubes is critical. Removal of the nasotracheal or nasogastric tube as soon as the patient's condition permits allows the sinuses to drain, possibly avoiding septic complications.

Chronic Rhinosinusitis and Recurrent Acute Rhinosinusitis

Chronic rhinosinusitis is one of the common causes of visit to the ENT outpatient department (OPD) in India. According to a large-scale study done in Uttar Pradesh, chronic rhinosinusitis was the most common form with a prevalence of 46.1% followed by acute rhinosinusitis (Khan & Siddiqui, 2020). It is defined as the inflammation of the nose and paranasal sinuses with 12 weeks or longer duration with any two or more of the following symptoms: mucopurulent drainage, nasal obstruction, facial pain–pressure–fullness, or hyposmia (decreased sense of smell). It is estimated that in about 40% of patients, CRS is accompanied by nasal polyps (Rosenfeld et al., 2015). Recurrent acute rhinosinusitis is diagnosed when four or more episodes of ABRS occur per year with no signs or symptoms of rhinosinusitis between the episodes. The use of antibiotics in patients with recurrent acute rhinosinusitis is higher than in patients with CRS. Both CRS and recurrent acute rhinosinusitis affect quality of life as well as physical and social function (Rosenfeld et al., 2015).

Pathophysiology

Mechanical obstruction in the ostia of the frontal, maxillary, and anterior ethmoid sinuses (known collectively as the ostiomeatal complex) is the usual cause of CRS and recurrent acute rhinosinusitis. Obstruction prevents adequate drainage of the nasal passages, resulting in accumulation of secretions and an ideal medium for bacterial growth. Persistent blockage in an adult may occur because of infection, allergy, or structural abnormalities. Other associated conditions and factors may include cystic fibrosis, ciliary dyskinesia, neoplastic disorders, gastroesophageal reflux disease, tobacco use, and environmental pollution (Rosenfeld et al., 2015).

Both aerobic and anaerobic bacteria have been implicated in CRS and recurrent rhinosinusitis. Common aerobic bacteria include alpha-hemolytic streptococci, microaerophilic streptococci, and *S. aureus.* Common anaerobic bacteria include gram-negative bacilli, *Peptostreptococcus,* and *Fusobacterium.*

In addition, immunodeficiency should be considered in patients with CRS or acute recurrent rhinosinusitis. Acute fulminant/invasive rhinosinusitis is a life-threatening illness and is commonly attributed to *Aspergillus* in immunocompromised patients. Chronic fungal sinusitis also poses a risk. Chronic invasive fungal sinusitis occurs in immunocompromised patients along with fungus ball/mycetoma and allergic fungal sinusitis—the more common forms of chronic fungal sinusitis—which are considered noninvasive conditions in immunocompromised patients. The fungus ball is characterized by the presence of a noninvasive accumulation of a dense conglomeration of fungal hyphae in one sinus cavity, usually the maxillary sinus. The fungus generally remains contained in the fungus ball, which consists of mucopurulent cheesy or claylike materials within the sinus, but can become invasive when immunosuppression occurs, leading to encephalopathy (Lal, 2015). Symptoms include nasal stuffiness, nasal discharge, and facial pain. Vision loss, headache, and cranial nerve palsies have been identified in patients with a sphenoid sinus fungal ball (Lal, 2015).

Clinical Manifestations

Clinical manifestations of CRS include impaired mucociliary clearance and ventilation, cough (because the thick discharge constantly drips backward into the nasopharynx), chronic hoarseness, chronic headaches in the periorbital area, periorbital edema, and facial pain. As a result of chronic nasal congestion, the patient is usually required to breathe through the mouth. Snoring, sore throat, and, in some situations, adenoidal hypertrophy may also occur. Symptoms are generally most pronounced on awakening in the morning. Fatigue and nasal congestion are also common. Many patients experience a decrease in smell and taste and a sense of fullness in the ears.

Assessment and Diagnostic Findings

The health assessment focuses on onset and duration of symptoms. It addresses the quantity and quality of nasal discharge and cough, the presence of pain, factors that relieve or aggravate the pain, and allergies. It is essential to obtain any history of comorbid conditions, including asthma and history of tobacco use. A history of fever, fatigue, previous episodes and treatments and previous response to therapies is also obtained.

In the physical assessment, the external nose is evaluated for any evidence of anatomic abnormality. A crooked-appearing external nose may imply septal deviation internally. The nasal mucous membranes are assessed for erythema, pallor, atrophy, edema, crusting, discharge, polyps, erosions, and septal perforations or deviations. Appropriate lighting improves visualization of the nasal cavity and should be used in every examination. Pain on examination of the teeth, with tapping with a tongue blade, suggests tooth infection (Bickley & Szilagyi, 2013).

Assessment of the posterior oropharynx may reveal purulent or mucoid discharge, which is indicative of an infection caused by CRS. The patient's eyes are examined for conjunctival erythema, tearing, photophobia, and edema of the lids. Additional assessment techniques include transillumination of the sinuses and palpation of the sinuses. The frontal and maxillary sinuses are palpated, and the patient is asked whether this produces tenderness. The pharynx is inspected for erythema and discharge and palpated for cervical node adenopathy (Rosenfeld et al., 2015).

Imaging studies such as x-ray, sinoscopy, ultrasound, CT scanning, and MRI may be used in the diagnosis of CRS. X-ray is an inexpensive and readily available tool to assess disorders of the paranasal sinuses. A CT scan of the paranasal sinuses can identify mucosal abnormalities, sinus ostial obstruction, anatomic variants, sinonasal polyposis, and neoplastic disease. In addition, nasal endoscopy allows for visualization of the posterior nasal cavity, nasopharynx, and sinus drainage pathways and can identify posterior septal deviation and polyps. Osseous destruction, extrasinus extension of the disease process, and local invasion suggest malignancy (Rosenfeld et al., 2015). (See Chapter 10 for further discussion of CT, MRI, and x-ray.)

Complications

Complications of CRS, although uncommon, include severe orbital cellulitis, subperiosteal abscess, cavernous sinus thrombosis, meningitis, encephalitis, and ischemic infarction. CRS can lead to intracranial infection either by direct spread through bone or via venous channels, resulting in epidural abscess, subdural empyema, meningitis, and brain abscess. Clinical sequelae can include personality changes with frontal lobe abscesses, headache, symptoms of elevated intracranial pressure to include alterations of consciousness, visual changes, focal neurologic deficits, seizures, and, ultimately, coma and death.

Frontal rhinosinusitis can lead to osteomyelitis of the frontal bones. Patients typically present with headache, fever, and a characteristic doughy edema over the involved bone. Ethmoid rhinosinusitis may result in orbital cellulitis, which usually begins with edema of the eyelids and rapidly progresses to ptosis (droopy eyelid), proptosis (bulging eye), chemosis (edema of the bulbar conjunctiva), and diminished extraocular movements. Patients are usually febrile and acutely ill and require immediate attention, because pressure on the optic nerve can lead to loss of vision and spread of infection can lead to intracranial infection. Cavernous sinus thrombophlebitis can result from extension of infection along venous channels from the orbit, ethmoid or frontal sinuses, or nose. Symptoms may include altered consciousness, lid edema, and proptosis, as well as third, fourth, and sixth cranial nerve palsies.

Medical Management

Medical management of CRS and recurrent acute rhinosinusitis is similar to that of acute rhinosinusitis. General measures include encouraging adequate hydration and recommending the use of OTC nasal saline sprays, analgesics such as acetaminophen/paracetamol or NSAIDs, and decongestants such as oxymetazoline and pseudoephedrine (Tewfik, 2015); (Brook, 2015). Patients are instructed to sleep with the head of the bed elevated and to avoid exposure to cigarette smoke and fumes. Patients are cautioned to avoid caffeine and alcohol, which can cause dehydration.

Prescribed antibiotics may include amoxicillin-clavulanic acid, erythromycin–sulfisoxazole (Eryzole), second- or third-generation cephalosporins such as cefuroxime or cefixime, or newer fluoroquinolones such as moxifloxacin (Avelox) (Brook, 2015). The course of antibiotic treatment for CRS and recurrent ABRS is typically as long as 2 to 4 weeks to effectively eradicate the offending organism, and may be indicated for up to 12 months in some cases (Brook, 2015). Corticosteroid nasal sprays such as fluticasone (Flonase) or beclomethasone (Beconase AQ) may be indicated in patients with concomitant allergic rhinitis or nasal polyps. Patients with allergic rhinitis may also benefit from the addition of a mast cell stabilizer such as cromolyn. For patients with concomitant asthma, leukotriene inhibitors such as montelukast and zafirlukast may be used (Brook, 2015).

Surgical Management

If standard medical therapy fails and symptoms persist, FESS may be indicated to correct structural deformities that obstruct the ostia (openings) of the sinuses. FESS is a minimally invasive surgical procedure that is associated with reduced postoperative discomfort and improvement in the patient's quality of life. In particular, FESS is associated with either complete or moderate relief of symptoms in more than 85% to 91% of patients (Patel, 2014). Some of the specific procedures performed include excising and cauterizing nasal polyps, correcting a deviated septum, incising and draining the sinuses, aerating the sinuses, and removing tumors. Antimicrobial agents may be given before and after surgery. Computer-assisted or computer-guided surgery is used to increase the precision of the surgical procedure and to minimize complications (Patel, 2014).

Surgical intervention may be required in acute invasive fungal rhinosinusitis to excise the fungus ball and necrotic tissue and drain the sinuses. Patients require aggressive surgical débridement and drainage as well as systemic antifungal medications.

Nursing Management

Patients usually perform care measures for rhinosinusitis at home; therefore, nursing management consists of good patient education.

Educating Patients about Self-Care

Many people with sinus infections tend to blow their nose frequently and with force to clear their nasal passages. Doing so often increases the symptoms; therefore, the patient is instructed to blow the nose gently and to use tissue to remove the nasal drainage. Increasing fluid intake, applying local heat (hot wet packs), and elevating the head of the bed promote drainage of the sinuses. The nurse also instructs the patient about the importance of following the prescribed medication regimen. Instructions on the early signs of a sinus infection are provided, and preventive measures are reviewed. The nurse instructs the patient about signs and symptoms that require follow-up and provides these instructions verbally and in writing. Instructions in alternate formats (e.g., large font, patient's language) may be needed to increase the patient's understanding and adherence to the treatment plan. The nurse encourages the patient to follow up with their primary provider if symptoms persist.

Nursing Alert: URIs, specifically CRS and recurrent acute rhinosinusitis, may be linked to primary or secondary immune deficiency or treatment with immunosuppressive therapy (e.g., for cancer or organ transplantation). Typical symptoms may be blunted or absent due to immunosuppression. Immunocompromised patients are at the increased risk for acute or chronic fungal infections; these infections can progress rapidly and become life threatening. Thus, assessment, early reporting of symptoms to the patient's primary provider and immediate initiation of treatment are essential.

Pharyngitis

Acute Pharyngitis

Acute pharyngitis is a sudden painful inflammation of the pharynx, the back portion of the throat that includes the posterior third of the tongue, soft palate, and tonsils. It is commonly referred to as a sore throat. Because of environmental exposure to viral agents and poorly ventilated rooms, the incidence of viral pharyngitis peaks during winter and early spring in regions that have warm summers and cold winters. Viral pharyngitis spreads easily in the droplets of coughs and sneezes, as well as from unclean hands that have been exposed to the contaminated fluids.

Pathophysiology

Viral infection causes most cases of acute pharyngitis. Responsible viruses include the adenovirus, influenza virus, Epstein–Barr virus, and herpes simplex virus. Bacterial infection accounts for the remainder of cases. Ten percent of adults with pharyngitis have group A beta-hemolytic streptococcus (GABHS), which is commonly referred to as group A streptococcus (GAS) or streptococcal pharyngitis. Streptococcal pharyngitis warrants the use of antibiotic treatment. When GAS causes acute pharyngitis, the condition is known as strep throat. The body responds by triggering an inflammatory response in the pharynx. This results in pain, fever, vasodilation, edema, and tissue damage, manifested by redness and swelling in the tonsillar pillars, uvula, and soft palate. A creamy exudate may be present in the tonsillar pillars (see Fig. 40-2). Other bacterial organisms implicated in acute pharyngitis include groups B and G streptococci, *Neisseria gonorrhoeae, Mycoplasma pneumoniae, C. pneumoniae, Arcanobacterium haemolyticum,* and HIV (Randel, 2013).

Uncomplicated viral infections usually subside promptly, within 3 to 10 days after onset. However, pharyngitis caused by more virulent bacteria, such as GAS, is a more severe illness. If left untreated, the complications can be severe and life threatening. Complications include rhinosinusitis, otitis media, peritonsillar abscess, mastoiditis, and cervical adenitis. In rare cases, the infection may lead to bacteremia, pneumonia, meningitis, rheumatic fever, and nephritis.

Clinical Manifestations

The signs and symptoms of acute pharyngitis include a fiery-red pharyngeal membrane and tonsils, lymphoid follicles that are swollen and flecked with white-purple exudate, enlarged and tender cervical lymph nodes, and no cough. Fever (higher than 38.3°C [101°F]), malaise, and sore throat also may be present. Occasionally, patients with GAS pharyngitis exhibit vomiting, anorexia, and a scarlatina-form rash with urticaria known as scarlet fever.

People who have streptococcal pharyngitis suddenly develop a painful sore throat 1 to 5 days after being exposed to the streptococcus bacteria. They usually report malaise, fever (with or without chills), headache, myalgia, painful cervical adenopathy, and nausea. The tonsils appear swollen and erythematous, and they may or may not have an exudate. The roof of the mouth is often erythematous and may demonstrate petechiae. Bad breath is common.

Assessment and Diagnostic Findings

Accurate diagnosis of pharyngitis is essential to determine the cause (viral or bacterial) and to initiate treatment early. Rapid antigen detection testing (RADT) uses swabs that collect specimens from the posterior pharynx and tonsil. RADT is reported to be 90% to 95% sensitive, thus facilitating earlier treatment and earlier symptom improvement and reductions in pathogen transmission. Negative results should be confirmed by a throat culture (Randel, 2013). In most communities, preliminary culture reports are available in 24 hours. Once a definitive diagnosis of GAS is made, administration of appropriate antibiotics hastens symptom resolution and reduces the transmission of the illness.

Medical Management

Viral pharyngitis is treated with supportive measures because antibiotics have no effect on the causal organism. Bacterial pharyngitis is treated with a variety of antimicrobial agents.

Pharmacologic Therapy

If the cause of pharyngitis is bacterial, penicillin is usually the treatment of choice. Penicillin V potassium given orally for 5 days is the regimen of choice. Penicillin injections are recommended only if there is a concern that the patient will not adhere to therapy (Tierney et al., 2015).

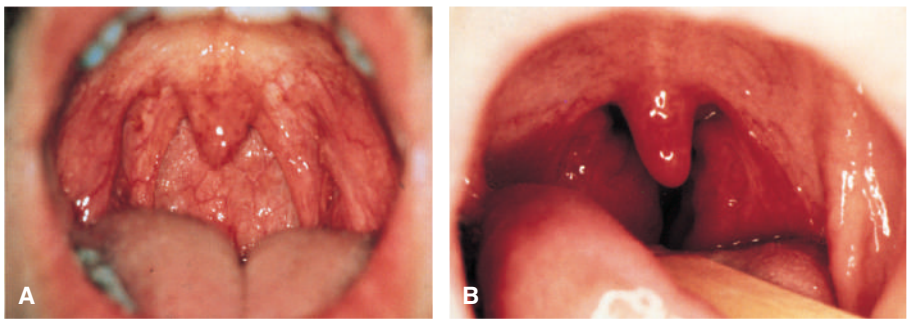

Figure 40-2 • Pharyngitis—inflammation without exudate. **A.** Redness and vascularity of the pillars and uvula are mild to moderate. **B.** Redness is diffuse and intense. Each patient would probably complain of a sore throat. From the Wellcome Trust, National Medical Slide Bank, London, UK.

For patients who are allergic to penicillin or have organisms that are resistant to erythromycin (one fifth of GAS and most *S. aureus* organisms are resistant to penicillin and erythromycin), cephalosporins and macrolides (clarithromycin and azithromycin) may be used. Once-daily azithromycin may be given for only 3 days due to its long half-life (Tierney et al., 2015). A 5- or 10-day course of cephalosporin may be prescribed. Five-day administration of cefpodoxime and cefuroxime has also been successful in producing bacteriologic cures.

Severe sore throats can also be relieved by analgesic medications, as prescribed. For example, aspirin or acetaminophen/paracetamol can be taken at 4- to 6-hour intervals; if required, acetaminophen/paracetamol with codeine can be taken three or four times daily. In severe cases, gargles with benzocaine may relieve symptoms.

Nutritional Therapy

A liquid or soft diet is provided during the acute stage of the disease, depending on the patient's appetite and the degree of discomfort that occurs with swallowing. Cool beverages, warm liquids, and flavored frozen desserts such as ice pops are often soothing. Occasionally, the throat is so sore that liquids cannot be taken in adequate amounts by mouth. In severe situations, intravenous (IV) fluids may be needed. Otherwise, the patient is encouraged to drink as much fluid as possible (at least 2 to 3 L/day).

Nursing Management

Nursing care for patients with viral pharyngitis focuses on symptomatic management. For patients who demonstrate signs of strep throat and have a history of rheumatic fever, who have scarlet fever, or who have symptoms suggesting peritonsillar abscess, nursing care focuses on prompt initiation and correct administration of prescribed antibiotic therapy. The nurse instructs the patient about signs and symptoms that warrant prompt contact with the primary provider. These include dyspnea, drooling, inability to swallow, and inability to fully open the mouth.

The nurse instructs the patient to stay in bed during the febrile stage of illness and to rest frequently once up and about. Used tissues should be disposed of properly to prevent the spread of infection. The nurse (or the patient or family member, if the patient is not hospitalized) should examine the skin once or twice daily for possible rash, because acute pharyngitis may precede some other communicable diseases (e.g., rubella).

Depending on the severity of the pharyngitis and the degree of pain, warm saline gargles or throat irrigations are used. The benefits of this treatment depend on the degree of heat that is applied. The nurse educates the patient about these procedures and about the recommended temperature of the solution, which should be high enough to be effective and as warm as the patient can tolerate, usually 40.6°C to 43.3°C (105°F to 110°F). Irrigating the throat may reduce spasm in the pharyngeal muscles and relieve soreness of the throat.

An ice collar also can relieve severe sore throats. Mouth care may promote the patient's comfort and prevent the development of fissures (cracking) of the lips and oral inflammation when bacterial infection is present. The nurse instructs the patient to resume activity gradually and to delay returning to work or school until after 24 hours of antibiotic therapy. A full course of antibiotic therapy is indicated in patients with strep infection because of the potential complications such as nephritis and rheumatic fever, which may have their onset 2 or 3 weeks after the pharyngitis has subsided. The nurse instructs the patient and family about the importance of taking the full course of therapy and informs them about the symptoms to watch for that may indicate complications.

In addition, the nurse instructs the patient about preventive measures that include not sharing eating utensils, glasses, napkins, food, or towels; cleaning telephones after use; using a tissue to cough or sneeze; disposing of used tissues appropriately; coughing or sneezing into the upper arm if tissues are not readily available; and avoiding exposure to tobacco and secondhand smoke. The nurse also instructs the patient with pharyngitis, especially streptococcal pharyngitis, to replace their toothbrush with a new one.

Chronic Pharyngitis

Chronic pharyngitis is a persistent inflammation of the pharynx. It is common in adults who work in dusty surroundings, use their voice to excess, suffer from chronic cough, or habitually use alcohol and tobacco.

There are three types of chronic pharyngitis:

- **Hypertrophic**—characterized by general thickening and congestion of the pharyngeal mucous membrane
- **Atrophic**—probably a late stage of the first type (the membrane is thin, whitish, glistening, and at times wrinkled)
- **Chronic granular**—characterized by numerous swollen lymph follicles on the pharyngeal wall

Clinical Manifestations

Patients with chronic pharyngitis complain of a constant sense of irritation or fullness in the throat, mucus that collects in the throat and can be expelled by coughing, and difficulty swallowing. This is often associated with intermittent postnasal drip that causes minor irritation and inflammation of the pharynx. A sore throat that is worse with swallowing in the absence of pharyngitis suggests the possibility of thyroiditis, and patients with this symptom are referred for the evaluation of possible thyroiditis.

Medical Management

Treatment of chronic pharyngitis is based on relieving symptoms; avoiding exposure to irritants; and correcting any upper respiratory, pulmonary, gastrointestinal, or cardiac condition that might be responsible for a chronic cough.

Nasal congestion may be relieved by short-term use of nasal sprays or medications containing ephedrine sulfate or phenylephrine. For a patient with a history of allergy, one of the antihistamine decongestant medications, such as pseudoephedrine or brompheniramine/pseudoephedrine, is prescribed orally every 4 to 6 hours. Aspirin (for patients older than 20 years) or acetaminophen/paracetamol is recommended for its analgesic properties.

For adults with chronic pharyngitis, tonsillectomy may be an effective option. For further information, see the Tonsillitis and Adenoiditis section.

Nursing Management

Educating Patients about Self-Care

The nurse recommends avoidance of alcohol, tobacco, secondhand smoke, and exposure to cold or to environmental or occupational pollutants. The patient may minimize exposure to pollutants by wearing a disposable facemask. The nurse encourages the patient to drink plenty of fluids. Gargling with warm saline solution may relieve throat discomfort. Lozenges keep the throat moistened.

Tonsillitis and Adenoiditis

The tonsils are composed of lymphatic tissue and are situated on each side of the oropharynx. The faucial or palatine tonsils and lingual tonsils are located behind the pillars of fauces and tongue, respectively. They frequently serve as the site of acute infection (tonsillitis). Acute tonsillitis can be confused with pharyngitis. Chronic tonsillitis is less common and may be mistaken for other disorders such as allergy, asthma, and rhinosinusitis.

The adenoids or pharyngeal tonsils consist of lymphatic tissue near the center of the posterior wall of the nasopharynx. Infection of the adenoids frequently accompanies acute tonsillitis. Frequently occurring bacterial pathogens include GABHS, the most common organism. The most common viral pathogen is Epstein–Barr virus, although cytomegalovirus may also cause tonsillitis and adenoiditis. Often thought of as a childhood disorder, tonsillitis can occur in adults.

Clinical Manifestations

The symptoms of tonsillitis include sore throat, fever, snoring, and difficulty swallowing. Enlarged adenoids may cause mouth breathing, earache, draining ears, frequent head colds, bronchitis, foul-smelling breath, voice impairment, and noisy respiration. Unusually enlarged adenoids fill the space behind the posterior nares, making it difficult for the air to travel from the nose to the throat and resulting in nasal obstruction. Infection can extend to the middle ears by way of the auditory (eustachian) tubes and may result in acute otitis media, which can lead to spontaneous rupture of the tympanic membranes (eardrums) and further extension of the infection into the mastoid cells, causing acute mastoiditis. The infection also may reside in the middle ear as a chronic, low-grade, smoldering process that eventually may cause permanent deafness.

Assessment and Diagnostic Findings

The diagnosis of acute tonsillitis is primarily clinical, with attention given to whether the illness is viral or bacterial in nature. As in acute pharyngitis, RADT is quick and convenient; however, it is less sensitive than the throat swab culture.

A thorough physical examination is performed and a careful history is obtained to rule out related or systemic conditions. The tonsillar site is cultured to determine the presence of bacterial infection. When cytomegalovirus infection is present, the differential diagnosis should include HIV, hepatitis A, and rubella. In adenoiditis, if recurrent episodes of suppurative otitis media result in hearing loss, comprehensive audiometric assessment is warranted (see Chapter 41).

Medical Management

Tonsillitis is treated with supportive measures that include increased fluid intake, analgesics, salt-water gargles, and rest. Bacterial infections are treated with penicillin (first-line therapy) or cephalosporins. Viral tonsillitis is not effectively treated with antibiotic therapy.

Tonsillectomy (with or without adenoidectomy) continues to be a commonly performed surgical procedure and remains the treatment of choice for patients with chronic tonsillitis (Shah, 2015). Adults who have undergone a tonsillectomy to treat recurrent streptococcal infections experience a decrease in the number of episodes of streptococcal or other throat infections or days with throat pain.

Tonsillectomy is indicated if the patient has had repeated episodes of tonsillitis despite antibiotic therapy; hypertrophy of the tonsils and adenoids that could cause obstruction and obstructive sleep apnea (OSA); repeated attacks of purulent otitis media; and suspected hearing loss due to serous otitis media that has occurred in association with enlarged tonsils and adenoids. Indications for adenoidectomy include chronic nasal airway obstruction, chronic rhinorrhea, obstruction of the eustachian tube with related ear infections, and abnormal speech. Surgery is also indicated if the patient has developed a peritonsillar abscess that occludes the pharynx, making swallowing difficult and endangering the patency of the airway (particularly during sleep). The presence of persistent tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma (Tierney et al., 2015). Antibiotic therapy may be initiated for patients undergoing tonsillectomy or adenoidectomy. Therapy may include oral penicillin or a cephalosporin (e.g., cefdinir [Omnicef] or moxifloxacin).

Nursing Management

Providing Postoperative Care

Continuous nursing observation is required in the immediate postoperative and recovery periods because of the risk of hemorrhage, which may also compromise the patient's airway (Seshamani, Vogtmann, Gattwood, et al., 2014). In the immediate postoperative period, the most comfortable position is prone, with the patient's head turned to the side to allow drainage from the mouth and pharynx. The nurse must not remove the oral airway until the patient's gag and swallowing reflexes have returned. The nurse applies an ice collar to the neck, and a basin and tissues are provided for the expectoration of blood and mucus.

Symptoms of postoperative complications include fever, throat pain, ear pain, and bleeding. Pain can be effectively controlled with analgesic medications. Postoperative bleeding may be seen as bright red blood if the patient expectorates it before swallowing it. If the patient swallows the blood, it becomes brown because of the action of the acidic gastric juice. If the patient vomits large amounts of dark blood or bright-red blood at frequent intervals, or if the pulse rate and temperature rise and the patient is restless, the nurse notifies the surgeon immediately. The nurse should have the following items ready for the examination of the surgical site for bleeding: a light, a mirror, gauze, curved hemostats, and a waste basin.

Occasionally, suture or ligation of a bleeding vessel is required. In such cases, the patient is taken to the operating room and given general anesthesia. After ligation, continuous nursing observation and postoperative care are required, as in the initial postoperative period. If there is no bleeding, water and ice chips may be given to the patient as soon as desired. The patient is instructed to refrain from too much talking and coughing, because these activities can produce throat pain. (See Chapter 6 for further discussion of postoperative nursing care.)

Educating Patients About Self-Care

Tonsillectomy and adenoidectomy are usually performed as outpatient surgery, and the patient is sent home from the recovery room once awake, oriented, and able to drink liquids and void. The patient and family must understand the signs and symptoms of hemorrhage. Bleeding may occur up to 8 days after surgery. The nurse instructs the patient about the use of liquid acetaminophen/paracetamol with or without codeine for pain control and explains that the pain will subside during the

first 3 to 5 days. The nurse informs the patient about the need to take the full course of any prescribed antibiotic for the first postoperative week (Drake & Carr, 2015).

Alkaline mouthwashes and warm saline solutions are useful in coping with the thick mucus and halitosis that may be present after surgery. The nurse should explain to the patient that a sore throat, stiff neck, minor ear pain, and vomiting may occur in the first 24 hours. The patient should eat an adequate diet with soft foods, which are more easily swallowed than hard foods. The patient should avoid spicy, hot, acidic, or rough foods. Milk and milk products (ice cream and yogurt) may be restricted because they make removal of mucus more difficult for some patients. The nurse instructs the patient about the need to maintain good hydration. The patient is advised to avoid vigorous tooth brushing or gargling because these activities can cause bleeding. The nurse encourages the use of a cool-mist vaporizer or humidifier in the home postoperatively. The patient should avoid smoking and heavy lifting or exertion for 10 days.

Peritonsillar Abscess

Peritonsillar abscess (also called *quinsy*) is the most common major suppurative complication of sore throat accounting for roughly 30% of soft tissue head and neck abscesses. It most commonly afflicts adults between the ages of 20 to 40 years, with the incidence roughly the same between men and women (Flores, 2015). This collection of purulent exudate between the tonsillar capsule and the surrounding tissues, including the soft palate, may develop after an acute tonsillar infection that progresses to a local cellulitis and abscess. Several bacteria are typically implicated in the pathogenesis of these abscesses, including *S. pyogenes, S. aureus, Neisseria* species, and *Corynebacterium* species (Flores, 2015); (Shah, 2015). In more severe cases, the infection can spread over the palate and to the neck and chest. Edema can cause airway obstruction, which can be a life threatening medical emergency. Peritonsillar abscess can be life threatening with mediastinitis, intracranial abscess, and empyema resulting from spread of infection. Early detection and aggressive management are essential (Flores, 2015).

Clinical Manifestations

The patient with a peritonsillar abscess is acutely ill with a severe sore throat, fever, trismus (inability to open the mouth), and drooling. Inflammation of the medial pterygoid muscle that lies lateral to the tonsil results in spasm, severe pain, and difficulty in opening the mouth fully. The pain may be so intense that the patient has difficulty swallowing saliva. The patient's breath often smells rancid. Other symptoms include a raspy voice, odynophagia (a severe sensation of burning, squeezing pain while swallowing), dysphagia (difficulty swallowing), and otalgia (pain in the ear). Odynophagia is caused by the inflammation of the superior constrictor muscle of the pharynx that forms the lateral wall of the tonsil. This causes pain on lateral movement of the head. The patient may also have tender and enlarged cervical lymph nodes. Examination of the oropharynx reveals erythema of the anterior pillar and soft palate as well as a purulent tonsil on the side of the peritonsillar abscess. The tonsil is pushed inferomedially, and the uvula is shifted contralaterally (Flores, 2015).

Assessment and Diagnostic Findings

Emergency department (ED) physicians frequently are the providers who diagnose patients with peritonsillar abscesses. When this occurs in the ED setting, the ED physician decides whether aspiration—an invasive procedure—should be carried out based on the patient's clinical picture. Intraoral ultrasound and transcutaneous cervical ultrasound are used in the diagnosis of peritonsillar cellulitis and abscesses.

Medical Management

Antimicrobial agents and corticosteroid therapy are used for the treatment of peritonsillar abscess. Antibiotics (usually penicillin) are extremely effective in controlling the infection, and if they are prescribed early in the course of the disease, the abscess may resolve without needing to be incised. However, if the abscess does not resolve, treatment choices include needle aspiration, incision and drainage under local or general anesthesia, and drainage of the abscess with simultaneous tonsillectomy. Following needle aspiration (discussed later) intramuscular administration of clindamycin (Cleocin) can be used in the outpatient setting, thus reducing both antibiotic and hospital costs. The use of topical anesthetic agents and throat irrigations may be prescribed to promote comfort along with administration of prescribed analgesic agents.

Patients with complications require hospitalization for IV antibiotics, imaging studies, observation, and proper airway management. Rarely, the patient with a peritonsillar abscess presents with acute airway obstruction and requires immediate airway management. Procedures may include intubation, cricothyroidotomy, or tracheotomy (Flores, 2015).

Surgical Management

Needle aspiration may be preferred over a more extensive procedure due to its high efficacy, low cost, and patient tolerance. The mucous membrane over the swelling is first sprayed with a topical anesthetic and then injected with a local anesthetic. Single or repeated needle aspirations are performed to decompress the abscess. Alternatively, the abscess may be incised and drained. These procedures are performed best with the patient in the sitting position to make it easier to expectorate the pus and blood that accumulate in the pharynx. The patient experiences almost immediate relief. Incision and drainage is also an effective option but is more painful than needle aspiration.

Tonsillectomy is considered for patients who are poor candidates for needle aspiration or incision and drainage. The risk of hemorrhage following tonsillectomy to treat peritonsillar abscess is higher than that of elective tonsillectomy and may be due to the patient's previous use of aspirin for pain relief.

Nursing Management

If the patient requires intubation, cricothyroidotomy, or tracheotomy to treat airway obstruction, the nurse assists with the procedure and provides support to the patient before, during, and after the procedure. The nurse also assists with the needle aspiration when indicated.

The nurse encourages the patient to use prescribed topical anesthetic agents and assists with throat irrigations or the frequent use of mouthwashes or gargles, using saline or alkaline solutions at a temperature of 40.6°C to 43.3°C (105°F to 110°F). Gentle gargling after the procedure with a cool normal saline gargle may relieve discomfort. The patient must be upright and clearly expectorate forward. The nurse instructs the patient to gargle *gently* at intervals of 1 or 2 hours for 24 to 36 hours. Liquids that are cool or at room temperature are usually well tolerated. Adequate fluids must be provided to treat dehydration and prevent its recurrence.

The nurse also observes the patient for complications and instructs the patient about signs and symptoms of complications that require prompt attention by the patient's primary provider. At discharge, the nurse provides verbal and written instructions regarding foods to avoid, when to return to work, and the need to refrain from or cease smoking. The need for continuation of good oral hygiene is also reinforced.

Laryngitis

Laryngitis, an inflammation of the larynx, often occurs as a result of voice abuse or exposure to dust, chemicals, smoke, and other pollutants or as part of a URI. It also may be caused by isolated infection involving only the vocal cords. Laryngitis is also associated with gastroesophageal reflux (referred to as reflux laryngitis).

Laryngitis is very often caused by the pathogens that cause the common cold and pharyngitis; the most common cause is a virus, and laryngitis is often associated with allergic rhinitis or pharyngitis. Bacterial invasion may be secondary. The onset of infection may be associated with exposure to sudden temperature changes, dietary deficiencies, malnutrition, or an immunosuppressed state. Viral laryngitis is common in the winter and is easily transmitted to others.

Clinical Manifestations

Signs of acute laryngitis include hoarseness or aphonia (loss of voice) and severe cough. Chronic laryngitis is marked by persistent hoarseness. Other signs of acute laryngitis include sudden onset made worse by cold dry wind. The throat feels worse in the morning and improves when the patient is indoors in a warmer climate. At times, the patient presents with a dry cough and a dry, sore throat that worsens in the evening hours. If allergies are present, the uvula will be visibly edematous. Many patients also complain of a "tickle" in the throat that is made worse by cold air or cold liquids.

Medical Management

Management of acute laryngitis includes resting the voice, avoiding irritants (including smoking), resting, and inhaling cool steam or an aerosol. If the laryngitis is part of a more extensive respiratory infection caused by a bacterial organism or if it is severe, appropriate antibacterial therapy is instituted. The majority of patients recover with conservative treatment; however, laryngitis tends to be more severe in older adult patients and may be complicated by pneumonia.

For chronic laryngitis, the treatment includes resting the voice, eliminating any primary respiratory tract infection, eliminating smoking, and avoiding secondhand smoke. Corticosteroids, such as beclomethasone, may be given. These preparations have few systemic or long-lasting effects and may reduce local inflammatory reactions. Treatment of reflux laryngitis typically involves use of proton pump inhibitors such as omeprazole (Prilosec) given once daily.

Nursing Management

The nurse instructs the patient to rest the voice and to maintain a well-humidified environment. If laryngeal secretions are present during acute episodes, expectorant agents are suggested, along with a daily fluid intake of 2 to 3 L to thin secretions. The nurse instructs the patient about the importance of taking prescribed medications, including proton pump inhibitors, and using continuous positive airway therapy at bedtime, if prescribed for OSA. In cases involving infection, the nurse informs the patient that the symptoms of laryngitis often extend a week to 10 days after completion of antibiotic therapy. The nurse instructs the patient about signs and symptoms that require contacting the primary provider. These signs and symptoms include loss of voice with sore throat that makes swallowing saliva difficult, hemoptysis, and noisy respirations. Continued hoarseness after voice rest or laryngitis that persists for longer than 5 days must be reported because of the possibility of malignancy.

NURSING PROCESS

The Patient with Upper Airway Infection

Assessment

A health history may reveal signs and symptoms of headache, sore throat, pain around the eyes and on either side of the nose, difficulty in swallowing, cough, hoarseness, fever, stuffiness, and generalized discomfort and fatigue. Determining when the symptoms began, what precipitated them, what if anything relieves them, and what aggravates them is part of the assessment. The nurse should also determine any history of allergy or the existence of a concomitant illness. Inspection may reveal swelling, lesions, or asymmetry of the nose as well as bleeding or discharge. The nurse inspects the nasal mucosa for abnormal findings such as increased redness, swelling, exudate, and nasal polyps, which may develop in chronic rhinitis. The mucosa of the nasal turbinates may also be swollen (boggy) and pale bluish-gray. The nurse palpates the frontal and maxillary sinuses for tenderness, which suggests inflammation and then inspects the throat by having the patient open the mouth wide and take a deep breath. Redness, asymmetry, or evidence of drainage, ulceration, or enlargement of the tonsils and pharynx is abnormal. Palpation of the neck lymph nodes for enlargement and tenderness is necessary.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Ineffective airway clearance related to excessive mucus production secondary to retained secretions and inflammation
- Acute pain related to upper airway irritation secondary to an infection
- Impaired verbal communication related to physiologic changes and upper airway irritation secondary to infection or swelling
- Deficient fluid volume related to decreased fluid intake and increased fluid loss secondary to diaphoresis associated with a fever
- Deficient knowledge regarding prevention of URIs, treatment regimen, surgical procedure, or postoperative self-care

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include:

- Sepsis
- Meningitis or brain abscess
- Peritonsillar abscess, otitis media, or rhinosinusitis

Planning and Goals

The major goals for the patient may include maintenance of a patent airway, relief of pain, maintenance of effective means

of communication, normal hydration, knowledge of how to prevent upper airway infections, and absence of complications.

Nursing Interventions

Maintaining a Patent Airway

An accumulation of secretions can block the airway in patients with an upper airway infection. As a result, changes in the respiratory pattern occur and the work of breathing increases to compensate for the blockage. The nurse can implement several measures to loosen thick secretions or to keep the secretions moist so that they can be easily expectorated. Increasing fluid intake helps thin the mucus. The use of room vaporizers or steam inhalation also loosens secretions and reduces inflammation of the mucous membranes. To enhance drainage from the sinuses, the nurse instructs the patient about positioning; this depends on the location of the infection or inflammation. For example, drainage for rhinosinusitis or rhinitis is achieved in the upright position. In some conditions, topical or systemic medications, when prescribed, help relieve nasal or throat congestion.

Promoting Comfort

URIs usually produce localized discomfort. In rhinosinusitis, pain may occur in the area of the sinuses, or a general headache may be produced. In pharyngitis, laryngitis, or tonsillitis, a sore throat occurs. The nurse encourages the patient to take analgesics, such as acetaminophen with codeine, as prescribed, to relieve this discomfort. A pain intensity rating scale (see Chapter 9) may be used to assess effectiveness of pain relief measures. Other helpful measures include topical anesthetic agents for symptomatic relief of herpes simplex blisters (see Chart 40-3) and sore throats, hot packs to relieve the congestion of rhinosinusitis and promote drainage, and warm water gargles or irrigations to relieve the pain of a sore throat. The nurse encourages rest to relieve the generalized discomfort and fever that accompany many upper airway conditions (especially rhinitis, pharyngitis, and laryngitis). For postoperative care after tonsillectomy and adenoidectomy, an ice collar may reduce swelling and decrease bleeding.

Promoting Communication

Upper airway infections may result in hoarseness or loss of speech. The nurse instructs the patient to refrain from speaking as much as possible and, if possible, to communicate in writing instead. Additional strain on the vocal cords may delay full return of the voice. The nurse encourages the patient and family to use alternative forms of communication, such as a memo pad or a bell to signal for assistance.

Encouraging Fluid Intake

Upper airway infections lead to fluid loss. Sore throat, malaise, and fever may interfere with a patient's willingness to eat and drink. The nurse provides a list of easily ingested foods to increase caloric intake during the acute phase of illness. These include soups, gelatin, pudding, yogurt, cottage cheese, high-protein drinks, water, ice, and ice pops. The nurse encourages the patient to drink 2 to 3 L of fluid per day during the acute stage of airway infection, unless contraindicated, to thin the secretions and promote drainage. Liquids (hot or cold) may be soothing, depending on the disorder.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Prevention of most upper airway infections is challenging because of the many potential causes. But because most URIs are transmitted by hand-to-hand contact, the nurse educates the patient and family about techniques to minimize the spread of infection to others, including implementing hand hygiene measures. The nurse advises the patient to avoid exposure to people who are at the risk for serious illness if respiratory infection is transmitted (older adults, immunosuppressed people, and those with chronic health problems).

The nurse instructs patients and their families about strategies to relieve symptoms of URIs and reinforces the need to complete the treatment regimen, particularly when antibiotics are prescribed.

Continuing and Transitional Care. Referral for home, community-based, or transitional care is rare. However, it may be indicated for people whose health status was compromised before the onset of the respiratory infection and for those who cannot manage self-care without assistance. In such circumstances, the home care nurse assesses the patient's respiratory status and progress in recovery. The nurse may advise older adult patients and those at increased risk from a respiratory infection to consider annual influenza and pneumococcal vaccination. A follow-up appointment with the primary provider may be indicated for patients with compromised health status to ensure that the respiratory infection has resolved.

Monitoring and Managing Potential Complications

Although major complications of URIs are rare, the nurse must be aware of them and assess the patient for them. Because most patients with URIs are managed at home, patients and their families must be instructed to monitor for signs and symptoms and to seek immediate medical care if the patient's condition does not improve or if the patient's physical status appears to be worsening.

Sepsis or meningitis may occur in patients with compromised immune status or in those with an acute bacterial infection. The patient and caregiver are instructed to seek medical care if the patient's condition fails to improve within several days after the onset of symptoms, if unusual symptoms develop, or if the patient's condition deteriorates. They are instructed about signs and symptoms that require further attention: persistent or high fever, increasing shortness of breath, confusion, and increasing weakness and malaise. The patient with sepsis requires expert care to treat the infection, stabilize vital signs, and prevent or treat septic shock (see Chapter 8). Deterioration of the patient's condition necessitates intensive care measures (e.g., hemodynamic monitoring and administration of vasoactive medications, IV fluids, nutritional support, and corticosteroids) to monitor the patient's status and to support the patient's vital signs. High doses of antibiotics may be given to treat the causative organism. The nurse's role is to monitor the patient's vital signs, hemodynamic status, and laboratory values; administer needed treatment; alleviate the patient's physical discomfort; and provide explanations, education, and emotional support to the patient and family.

Peritonsillar abscess may develop after an acute infection of the tonsils. The patient requires treatment to drain the abscess and receives antibiotics for infection and topical anesthetic agents and throat irrigations to relieve pain and sore throat. Follow-up is necessary to ensure that the abscess resolves; tonsillectomy may be required. The nurse assists the patient in administering throat irrigations and instructs the patient and family about the importance of adhering to the prescribed treatment regimen and recommended follow-up appointments.

In some severe situations, peritonsillar abscess may progress to meningitis or brain abscess. The nurse assesses for changes in

mental status ranging from subtle personality changes through drowsiness to coma, nuchal rigidity, and focal neurologic signs that signal increasing cerebral edema around the abscess (see Chapter 52). Seizures, typically tonic–clonic, occur in this setting. Intensive care measures are necessary. High doses of antibiotics may be used to treat the causative organism. The nurse's role is similar to caring for the patient with sepsis in an intensive care setting. The nurse monitors the patient's neurologic status and reports changes immediately.

Otitis media and rhinosinusitis may develop with URI. The patient and family are instructed about the signs and symptoms of otitis media and rhinosinusitis and about the importance of follow-up with the primary provider to ensure adequate evaluation and treatment of these conditions.

Evaluation

Expected patient outcomes may include the following:

1. Maintains a patent airway by managing secretions
   a. Reports decreased congestion
   b. Assumes best position to facilitate drainage of secretions
   c. Uses self-care measures appropriately and consistently to manage secretions during the acute phase of illness
2. Reports relief of pain and discomfort using pain intensity scale
   a. Uses comfort measures: analgesics, hot packs, gargles, rest
   b. Demonstrates adequate oral hygiene
3. Demonstrates ability to communicate needs, wants, level of comfort
4. Maintains adequate fluid and nutrition intake
5. Utilizes strategies to prevent upper airway infections and allergic reactions
   a. Demonstrates hand hygiene technique
   b. Identifies the value of the influenza vaccine
6. Demonstrates an adequate level of knowledge and performs self-care adequately
7. Becomes free of signs and symptoms of infection
   a. Exhibits normal vital signs (temperature, pulse, respiratory rate)
   b. Absence of purulent drainage
   c. Free of pain in ears, sinuses, and throat
   d. Absence of signs of inflammation
8. Absence of complications
   a. No signs of sepsis: fever, hypotension, deterioration of cognitive status
   b. Vital signs and hemodynamic status normal
   c. No evidence of neurologic involvement
   d. No signs of development of peritonsillar abscess
   e. Resolution of URI without development of otitis media or rhinosinusitis
   f. No signs and symptoms of brain abscess

OBSTRUCTION AND TRAUMA OF THE UPPER RESPIRATORY AIRWAY

Obstructive Sleep Apnea

OSA is a disorder characterized by recurrent episodes of upper airway obstruction and a reduction in ventilation. It is defined as cessation of breathing (apnea) during sleep usually caused by repetitive upper airway obstruction. The estimated prevalence of OSA is approximately 26% of adults between the ages of 30 and 70 years (Peppard, Young, Barnet, et al., 2013). Based on cross-sectional studies, the prevalence of OSA in India is reported to be 13.7%. Higher prevalence of OSA is associated with diabetes and obesity (Viswanathan, Ramalingam, & Nagaraj, 2017). OSA interferes with people's ability to obtain adequate rest, thus affecting memory, learning, and decision making.

Risk factors for OSA include obesity, male gender, postmenopausal status, and advanced age. The major risk factor is obesity; a larger neck circumference and increased amounts of peripharyngeal fat narrow and compress the upper airway. Other associated factors include alterations in the upper airway, such as structural changes (e.g., tonsillar hypertrophy, abnormal posterior positioning of one or both jaws, and variations in craniofacial structures) that contribute to the collapsibility of the upper airway (Downey, 2015).

Pathophysiology

The pharynx is a collapsible tube that can be compressed by the soft tissues and structures surrounding it. The tone of the muscles of the upper airway is reduced during sleep. Mechanical factors such as reduced diameter of the upper airway or dynamic changes in the upper airway during sleep may result in obstruction. These sleep-related changes may predispose to upper airway collapse when small amounts of negative pressure are generated during inspiration.

Repetitive apneic events result in hypoxia (decreased oxygen saturation) and hypercapnia (increased concentration of carbon dioxide), which triggers a sympathetic response. As a consequence, patients with OSA have a high prevalence of hypertension. In addition, OSA is associated with an increased risk of myocardial infarction and stroke (cerebrovascular accident), which may be mitigated with appropriate treatment (Downey, 2015).

Clinical Manifestations

OSA is characterized by frequent and loud snoring with breathing cessation for 10 seconds or longer, for at least five episodes per hour, followed by awakening abruptly with a loud snort as the blood oxygen level drops. Patients with sleep apnea may have anywhere from five apneic episodes per hour to several hundred per night.

Classic signs and symptoms of OSA include the "3S's"—namely, *s*noring, sleepiness, and significant-other report of sleep apnea episodes. Common signs and symptoms of OSA are presented in Chart 40-4. Symptoms typically progress with increases in weight and aging (Downey, 2015). Patients are typically unaware of nocturnal upper airway obstruction during sleep. They frequently complain of insomnia, including difficulty in going to sleep, nighttime awakenings, and early morning awakenings with an inability to go back to sleep, as well as chronic fatigue and hypersomnolence (daytime sleepiness). When obtaining the health history, the nurse asks the patient about sleeping during normal activities such as eating or talking. Patients with this symptom are considered to have pathologic hypersomnolence (Downey, 2015).

Assessment and Diagnostic Findings

The diagnosis of sleep apnea is based on clinical features plus a polysomnographic finding (i.e., sleep study), which is the definitive test for OSA. The test is an overnight study, performed

Chart 40-4 ASSESSMENT

Assessing for Obstructive Sleep Apnea

Be alert for the following signs and symptoms of obstructive sleep apnea:

- Excessive daytime sleepiness
- Frequent nocturnal awakening
- Insomnia
- Loud snoring
- Morning headaches
- Intellectual deterioration
- Personality changes, irritability
- Impotence
- Systemic hypertension
- Dysrhythmias
- Pulmonary hypertension, cor pulmonale
- Polycythemia
- Enuresis

Adapted from Downey, R. (2015). Obstructive sleep apnea. Retrieved on 10/12/2015 at: www.emedicine.medscape.com/article/295807-overview

in a specialized sleep disorders center, which continuously measures multiple physiologic signals while the patient sleeps. These signals are analyzed as they are related to stages of sleep; measures include those taken by electroencephalogram (EEG), electro-oculogram, and chin electromyogram (EMG). In addition, cardiac rhythms and dysrhythmias are monitored with a single-lead electrocardiogram (ECG) and leg movements are recorded by an anterior tibialis EMG. Airflow at the nose and mouth is monitored using both a thermal sensor and a nasal pressure transducer, breathing effort is monitored using inductance plethysmography, and hemoglobin oxygen saturation is monitored by oximetry. The breathing pattern is analyzed for the presence of apneas and hypopneas. Characteristic findings consistent with OSA include apneic episodes occurring in the presence of respiratory muscle effort, clinically significant apneic episodes lasting 10 seconds or longer, and apneic episodes most prevalent during the rapid eye movement (REM) stage of sleep. Sleep disruption from automated patient arousal is usually seen at the termination of an episode of apnea (Downey, 2105).

Medical Management

Patients usually seek medical treatment because their sleeping partners express concern or because they experience excessive sleepiness at inappropriate times or settings (e.g., while driving a car). A variety of treatments are used. Weight loss, avoidance of alcohol, positional therapy (using devices that prevent patients from sleeping on their backs), and oral appliances such as mandibular advancement devices (MADs) are the first steps (American Sleep Apnea Association, 2015); (Downey, 2015). When applied correctly, an MAD advances the mandible so that it is slightly anterior to the upper front teeth, preventing airway obstruction by the tongue and soft tissue during sleep. A randomized controlled trial that compared the effectiveness of these devices among patients with OSA with the more conventional therapy, continuous positive airway pressure (CPAP), found no difference in short-term outcomes between MAD and CPAP, including daytime sleepiness and quality of life, suggesting that MAD is as effective a treatment as CPAP in patients with mild-to-moderate OSA (White & Shafazan, 2013). In more severe cases involving hypoxemia and severe hypercapnia, the treatment includes CPAP or bilevel positive airway pressure (BiPAP) therapy with supplemental oxygen via nasal cannula. CPAP is used to prevent airway collapse, whereas BiPAP makes breathing easier and results in a lower average airway pressure. (The use of CPAP and BiPAP is discussed in more detail in Chapter 11.)

Surgical Management

Surgical procedures also may be performed to correct OSA. Simple tonsillectomy may be effective for patients with larger tonsils when deemed clinically necessary, or when other options have failed or are refused by patients (Morgan, 2015). Uvulopalatopharyngoplasty is the resection of pharyngeal soft tissue and removal of approximately 15 mm of the free edge of the soft palate and uvula. Effective in about 50% of patients, it is more effective in eliminating snoring than apnea. Nasal septoplasty may be performed for gross anatomic nasal septal deformities. Maxillomandibular surgery may be performed to advance the maxilla and mandible forward in order to enlarge the posterior pharyngeal region (Morgan, 2015). Tracheostomy relieves upper airway obstruction but has numerous adverse effects, including speech difficulties and increased risk of infections. These procedures, as well as other maxillofacial surgeries, are reserved for patients with concomitant cardiovascular disease and life-threatening dysrhythmias or severe disability who have not responded to conventional therapy (Tierney et al., 2015).

Pharmacologic Therapy

Some medications are useful in managing symptoms associated with OSA. Modafinil (Provigil) has been used to reduce daytime sleepiness (Downey, 2015). Protriptyline (Triptil) given at bedtime may increase the respiratory drive and improve upper airway muscle tone. Medroxyprogesterone acetate (Provera) and acetazolamide (Diamox) have been used for sleep apnea associated with chronic alveolar hypoventilation; however, their benefits have not been well established. The patient must understand that these medications are not a substitute for CPAP, BiPAP, or MAD. Administration of low-flow nasal oxygen at night can help relieve hypoxemia in some patients but has little effect on the frequency or severity of apnea.

Nursing Management

The patient with OSA may not recognize the potential consequences of the disorder. Therefore, the nurse explains the disorder in terms that are understandable to the patient and relates symptoms (daytime sleepiness) to the underlying disorder. The nurse also instructs the patient and family about treatments, including the correct and safe use of CPAP, BiPAP, MAD, and oxygen therapy, if prescribed. The nurse educates the patient about the risk of untreated OSA and the benefits of treatment approaches.

Epistaxis (Nosebleed)

Epistaxis, a hemorrhage from the nose, is caused by the rupture of tiny, distended vessels in the mucous membrane of any area of the nose. Rarely does epistaxis originate in the densely vascular tissue over the turbinates. Most commonly, the site is the anterior septum, where three major blood vessels enter the nasal cavity: (1) the anterior ethmoidal artery on the forward part of the roof (Kiesselbach plexus), (2) the sphenopalatine artery in the posterosuperior region, and (3) the internal

Chart 40-5 RISK FACTORS

Epistaxis

- Local infections (vestibulitis, rhinitis, rhinosinusitis)
- Systemic infections (scarlet fever, malaria)
- Drying of nasal mucous membranes
- Nasal inhalation of corticosteroids (e.g., beclomethasone) or illicit drugs (e.g., cocaine)
- Trauma (digital trauma, blunt trauma, fracture, forceful nose blowing)
- Arteriosclerosis
- Hypertension
- Tumor (sinus or nasopharynx)
- Thrombocytopenia
- Use of aspirin
- Liver disease
- Osler–Weber–Rendu syndrome (hereditary hemorrhagic telangiectasia)

Adapted from Nguyen, Q. A. (2015). Epistaxis. Retrieved on 10/12/2015 at: www.emedicine.medscape.com/article/863220-overview

maxillary branches (the plexus of veins located at the back of the lateral wall under the inferior turbinate).

Several risk factors are associated with epistaxis (see Chart 40-5).

Medical Management

Management of epistaxis depends on its cause and the location of the bleeding site. A nasal speculum, penlight, or headlight may be used to identify the site of bleeding in the nasal cavity. Most nosebleeds originate from the anterior portion of the nose. Initial treatment may include applying direct pressure. The patient sits upright with the head tilted forward to prevent swallowing and aspiration of blood and is directed to pinch the soft outer portion of the nose against the midline septum for 5 or 10 minutes continuously. Application of nasal decongestants (phenylephrine, one or two sprays) to act as vasoconstrictors may be necessary. If these measures are unsuccessful in stopping the bleeding, the nose must be examined using good illumination and suction to determine the site of bleeding. Visible bleeding sites may be cauterized with silver nitrate or electrocautery (high-frequency electrical current). A supplemental patch of Surgicel or Gelfoam may be used (Tierney et al., 2015).

Alternatively, a cotton tampon may be used to try to stop the bleeding. Suction may be used to remove excess blood and clots from the field of inspection. The search for the bleeding site should shift from the anteroinferior quadrant to the anterosuperior, then to the posterosuperior, and finally to the posteroinferior area. The field is kept clear by using suction and by shifting the cotton tampon.

If the origin of the bleeding cannot be identified, the nose may be packed with gauze impregnated with petrolatum jelly or antibiotic ointment; a topical anesthetic spray and decongestant agent may be used before the gauze packing is inserted, or a balloon-inflated catheter may be used (see Fig. 40-3). Alternatively, a compressed nasal sponge may be used. Once the sponge becomes saturated with blood or is moistened with a small amount of saline, it will expand and produce tamponade to halt the bleeding. The packing may remain in place for 3 to 4 days if necessary to control bleeding (Nguyen, 2015). Antibiotics may be prescribed because of the risk of iatrogenic rhinosinusitis and sepsis.

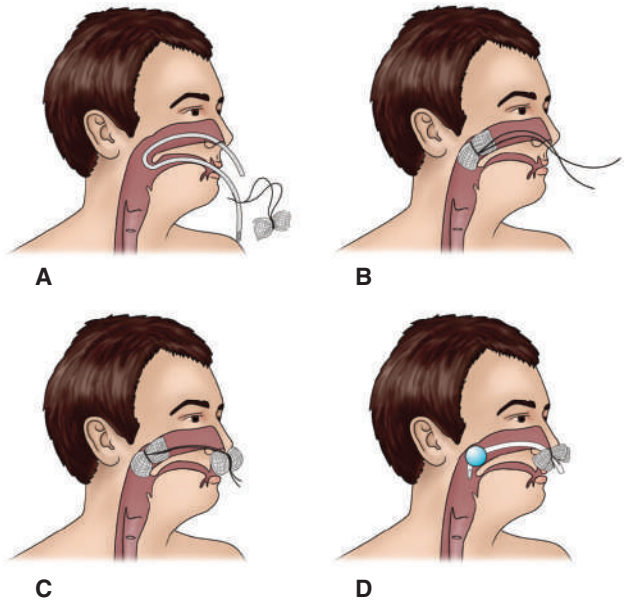

Figure 40-3 • Packing to control bleeding from the posterior nose. **A.** Catheter is inserted and packing is attached. **B.** Packing is drawn into position as the catheter is removed. **C.** Strip is tied over a bolster to hold the packing in place with an anterior pack installed "accordion pleat" style. **D.** Alternative method, using a balloon catheter instead of gauze packing.

Nursing Management

The nurse monitors the patient's vital signs, assists in the control of bleeding, and provides tissues and an emesis basin to allow the patient to expectorate any excess blood. It is common for patients to be anxious in response to a nosebleed. Blood loss on clothing and handkerchiefs can be frightening, and the nasal examination and treatment are uncomfortable. Assuring the patient in a calm, efficient manner that bleeding can be controlled can help reduce anxiety. The nurse continuously assesses the patient's airway and breathing as well as vital signs. On rare occasions, a patient with significant hemorrhage requires IV infusions of crystalloid solutions (normal saline) as well as cardiac and pulse oximetry monitoring.

Educating Patients About Self-Care

Once the bleeding is controlled, the nurse instructs the patient to avoid vigorous exercise for several days and to avoid hot or spicy foods and tobacco, because this may cause vasodilation and increase the risk of rebleeding. Discharge education includes reviewing ways to prevent epistaxis: avoiding forceful nose blowing, straining, high altitudes, and nasal trauma (including nose picking). Adequate humidification may prevent drying of the nasal passages. The nurse explains how to apply direct pressure to the nose with the thumb and the index finger for 15 minutes in the case of a recurrent nosebleed. If recurrent bleeding cannot be stopped, the patient is instructed to seek additional medical attention.

Nasal Obstruction

The passage of air through the nostrils is frequently obstructed by a deviation of the nasal septum, hypertrophy of the turbinate bones, or the pressure of nasal polyps. Chronic nasal congestion forces the patient to breathe through the mouth, thus producing

dryness of the oral mucosa and associated problems including persistent dry, cracked lips. Patients with chronic nasal congestion often suffer from sleep deprivation due to difficulty maintaining an adequate airway while lying flat and during sleep.

Persistent nasal obstruction also may lead to chronic infection of the nose and result in frequent episodes of nasopharyngitis. Frequently, the infection extends to the nasal sinuses. When rhinosinusitis develops and the drainage from these cavities is obstructed by deformity or swelling within the nose, pain is experienced in the region of the affected sinus.

Medical Management

The treatment of nasal obstruction requires the removal of the obstruction, followed by measures to treat whatever chronic infection exists. In many patients, an underlying allergy also requires treatment. Measures to reduce or alleviate nasal obstruction include nonsurgical as well as surgical techniques. Commonly used medications include nasal corticosteroids (see Table 40-2) as well as oral leukotriene inhibitors, such as montelukast. Treatment with nasal corticosteroids for 1 to 3 months is usually successful for the treatment of small polyps and may even reduce the need for surgical intervention. A short course of oral corticosteroids (6-day course of prednisone) may be beneficial in the treatment of nasal obstruction due to polyps (Tierney et al., 2015). Additional medications may include antibiotics for the treatment of underlying infection or antihistamines for the management of allergies. Hypertrophied turbinates may be treated by applying an astringent agent to shrink them.

A more aggressive approach in treating nasal obstruction caused by turbinate hypertrophy involves surgical reduction in the hypertrophy. Surgical procedures used to treat obstructive nasal conditions are collectively known as functional rhinoplasty. Technical advances with newer techniques provide a number of options for reconstruction and reshaping of the nose.

Nursing Management

When a surgical procedure is indicated, most often it is performed on an outpatient basis. The nurse explains the procedure to the patient. Postoperatively, the nurse elevates the head of the bed to promote drainage and to alleviate discomfort from edema. Frequent oral hygiene is encouraged to overcome dryness caused by breathing through the mouth. Before discharge from the outpatient or same-day surgical unit, the patient is instructed to avoid blowing the nose with force during the postoperative recovery period. The patient is also instructed about the signs and symptoms of bleeding and infection and when to contact the primary provider. The patient is provided with written postoperative instructions, including emergency phone numbers.

Fractures of the Nose

The location of the nose makes it susceptible to injury. Nasal fracture is the most common facial fracture and the most common fracture in the body (Becker, 2014). Fractures of the nose usually result from a direct assault. Nasal fractures may affect the ascending process of the maxilla and the septum. The torn mucous membrane results in a nosebleed. Complications include hematoma, infection, abscess, and avascular or septic necrosis. However, as a rule, serious consequences usually do not occur.

Clinical Manifestations

The signs and symptoms of a nasal fracture are pain, bleeding from the nose externally and internally into the pharynx, swelling of the soft tissues adjacent to the nose, periorbital ecchymosis, nasal obstruction, and deformity. The patient's nose may have an asymmetric appearance that may not be obvious until the edema subsides.

Assessment and Diagnostic Findings

The nose is examined internally to rule out the possibility that the injury may be complicated by a fracture of the nasal septum and a submucosal septal hematoma. Intranasal examination is performed in all cases to rule out septal hematoma (Tierney et al., 2015). Because of the swelling and bleeding that occur with a nasal fracture, an accurate diagnosis can be made only after the swelling subsides.

Clear fluid draining from either nostril suggests a fracture of the cribriform plate with leakage of cerebrospinal fluid. Usually, careful inspection or palpation discloses any deviations of the bone or disruptions of the nasal cartilages. An x-ray may reveal displacement of the fractured bones and may help rule out extension of the fracture into the skull.

Medical Management

A nasal fracture very often produces bleeding from the nasal passage. As a rule, bleeding is controlled with the use of packing. Cold compresses are used to prevent or reduce edema. For the patient who has sustained enough trauma to break the nose or any facial bone, the emergency medical team must consider the possibility of a cervical spine fracture. Therefore, it is essential to ensure a patent airway and to rule out a cervical spine fracture (see Chapter 51). Uncomplicated nasal fractures may be treated initially with antibiotics, analgesic agents, and a decongestant nasal spray.

Treatment of nasal fractures is aimed at restoring nasal function and returning the appearance of the nose to baseline. The patient is referred to a specialist to evaluate the need to realign the bones. Although improved outcomes are obtained when reduction in the fracture is performed during the first 3 hours after the injury, this is often not possible because of the edema. If immediate reduction in the fracture is not possible, it is performed within 3 to 7 days. Timing is important when treating nasal fractures because further delay in treatment may result in significant bone healing, which ultimately may require surgical intervention that includes rhinoplasty to reshape the external appearance of the nose. A septorhinoplasty is performed when the nasal septum needs to be repaired. In patients who develop a septal hematoma, the physician drains the hematoma through a small incision. A septal hematoma that is not drained can lead to permanent deformity of the nose.

Nursing Management

Immediately after the fracture, the nurse applies ice and encourages the patient to keep the head elevated. The nurse instructs the patient to apply ice packs to the nose to decrease swelling. The patient who experiences bleeding from the nose (epistaxis) is usually frightened and anxious and needs reassurance. The packing inserted to stop the bleeding may be uncomfortable and unpleasant, and obstruction of the nasal passages by the packing forces the patient to breathe through the mouth. This in turn causes the oral mucous membranes to become dry. Mouth rinses

help to moisten the mucous membranes and to reduce the odor and taste of dried blood in the oropharynx and nasopharynx. The use of analgesic agents such as acetaminophen/paracetamol or NSAIDs (i.e., ibuprofen or naproxen) is encouraged. When removing the cotton pledgets, the nurse carefully inspects the mucosa for lacerations or a septal hematoma. The nurse instructs the patient to avoid sports activities for 6 weeks.

Laryngeal Obstruction

Obstruction of the larynx because of edema is a serious condition that may be fatal without swift, decisive intervention. The larynx is a stiff box that will not stretch. It contains a narrow space between the vocal cords (glottis), through which air must pass. Swelling of the laryngeal mucous membranes may close off the opening tightly, leading to life-threatening hypoxia or suffocation. Edema of the glottis occurs rarely in patients with acute laryngitis, occasionally in patients with urticaria, and more frequently in patients with severe inflammation of the throat, as in scarlet fever. It is an occasional cause of death in severe anaphylaxis (angioedema).

Hereditary angioedema is also characterized by episodes of life-threatening laryngeal edema. Laryngeal edema in people with hereditary angioedema can occur at any age, although young adults are at greatest risk. Some causes of laryngeal obstruction appear in Table 40-3.

Foreign bodies frequently are aspirated into the pharynx, the larynx, or the trachea and cause a twofold problem. First, they obstruct the air passages and cause difficulty in breathing, which may lead to asphyxia; later, they may be drawn farther down, entering the bronchi or a bronchial branch and causing symptoms of irritation, such as a croupy cough, expectoration of blood or mucus, or labored breathing.

Clinical Manifestations

The patient's clinical presentation and x-ray findings confirm the diagnosis of laryngeal obstruction. The patient may demonstrate lowered oxygen saturation; however, normal oxygen saturation should not be interpreted as a sign that the obstruction is not significant. The use of accessory muscles to maximize airflow may occur and is often manifested by retractions in the neck or abdomen during inspirations. Patients who demonstrate these symptoms are at an immediate risk of collapse, and respiratory support (i.e., mechanical ventilation or positive-pressure ventilation) is considered.

TABLE 40-3 Causes of Laryngeal Obstruction

Precipitating Event	Mechanism of Obstruction
History of allergies; exposure to medications, latex, foods (peanuts, tree nuts [e.g., walnuts, pecans]), bee stings	Anaphylaxis
Foreign body	Inhalation/ingestion of meat or other food items, coin, chewing gum, balloon fragments, drug packets (ingested to avoid criminal arrest)
Heavy alcohol consumption; heavy tobacco use	Obstruction from tumor
Family history of airway problems	Suggests angioedema (type I hypersensitivity reaction)
Use of angiotensin-converting enzyme inhibitor	Increased risk of angioedema of the mucous membranes
Recent throat pain or recent fever	Infectious process
History of surgery or previous tracheostomy	Possible subglottic stenosis

Adapted from Reardon, R. F., Mason, P. E., & Clinton, J. E. (2014). Basic airway management and decision-making. In J. D. Roberts (Ed.). Roberts & Hedges' clinical procedures in emergency medicine (6th ed). Philadelphia, PA: Elsevier Saunders.

Assessment and Diagnostic Findings

A thorough history can be very useful in diagnosing and treating the patient with a laryngeal obstruction. However, emergency measures to secure the patient's airway should not be delayed to obtain a history or perform tests. If possible, the nurse obtains a history from the patient or family about heavy alcohol or tobacco consumption, current medications, history of airway problems, recent infections, pain or fever, dental pain or poor dentition, and any previous surgeries, radiation therapy, or trauma.

Medical Management

Medical management is based on the initial evaluation of the patient and the need to ensure a patent airway. If the airway is obstructed by a foreign body and signs of asphyxia are apparent, immediate treatment is necessary. Emergent maneuvers to clear an airway obstruction were presented in Chapter 60. If all efforts are unsuccessful, an immediate tracheotomy is necessary. If the obstruction is caused by edema resulting from an allergic reaction, treatment may include immediate administration of subcutaneous epinephrine and a corticosteroid (see Chapter 56). Ice may be applied to the neck in an effort to reduce edema. Continuous pulse oximetry is essential in the patient who has experienced acute upper airway obstruction.

Cancer of the Larynx

Cancer of the larynx accounts for approximately half of all head and neck cancers. Laryngeal cancer is the ninth common cancer in India and it is the seventh common cancer in Asia. Laryngeal cancer constitutes 3–6% of all cancers occurring among men. Males in the age group of 60–69 years are more affected than females and those in the younger age group. The age-adjusted rate of laryngeal cancer was 33,642 in 2015 and is expected to increase to 39,636 by 2020 (National Centre For Disease Informatics, 2017). There is huge regional variation in the age-adjusted rate of laryngeal cancer incidence with highest being reported from Kamrup urban registry—8.18 per 100,000 population—and lowest reported incidence is 1.26 from Nagaland (Bobdey, Jain, & Balasubramanium, 2015). Most common risk factor of laryngeal cancer is tobacco. Many other risk factors identified are presented in Chart 40-6.

Almost all malignant tumors of the larynx arise from the surface epithelium and are classified as squamous cell carcinoma. Approximately 55% of patients with laryngeal cancer present with involved lymph nodes at the time of diagnosis, with bilateral lesions present in 16% of patients (De Vita, Hellman, & Rosenberg, 2014). Recurrence occurs usually within the first 2 to 3 years after diagnosis. The presence of disease after 5 years is often secondary to a new primary malignancy. The incidence of distant metastasis with squamous cell carcinoma of the head and neck (including larynx cancer) is relatively low.

Chart 40-6 RISK FACTORS

Laryngeal Cancer

Carcinogens

- Tobacco (smoke, smokeless, e-cigarettes, hookahs)
- Combined effects of alcohol and tobacco
- Asbestos
- Secondhand smoke
- Paint fumes
- Wood dust
- Cement dust
- Chemicals
- Tar products
- Mustard gas
- Leather and metals

Other Factors

- Nutritional deficiencies (vitamins)
- History of alcohol abuse
- Genetic predisposition
- Age (higher incidence after 65 years of age)
- Gender (more common in men)
- Race (more prevalent in African Americans and Caucasians)
- Weakened immune system

Adapted from American Cancer Society. (2015). *What are the risk factors for laryngeal and hypopharyngeal cancers*? Retrieved on 3/9/2016 at: www.cancer.org/Cancer/LaryngealandHypopharyngealCancer/DetailedGuide/laryngeal-and-hypopharyngeal-cancer-risk-factors

Clinical Manifestations

Hoarseness of more than 2 weeks' duration occurs in the patient with cancer in the glottic area because the tumor impedes the action of the vocal cords during speech. The voice may sound harsh, raspy, and lower in pitch. Affected voice sounds are not always early signs of subglottic or supraglottic cancer, however. The patient may complain of a persistent cough or sore throat and pain and burning in the throat, especially when consuming hot liquids or citrus juices. A lump may be felt in the neck. Later symptoms include dysphagia, dyspnea (difficulty breathing), unilateral nasal obstruction or discharge, persistent hoarseness, persistent ulceration, and foul breath. Cervical lymph adenopathy, unintentional weight loss, a general debilitated state, and pain radiating to the ear may occur with metastasis.

Assessment and Diagnostic Findings

An initial assessment includes a complete history and physical examination of the head and neck. This includes identification of risk factors, family history, and any underlying medical conditions. An indirect laryngoscopy, using a flexible endoscope, is initially performed in the otolaryngologist's office to visually evaluate the pharynx, larynx, and possible tumor. Mobility of the vocal cords is assessed; if normal movement is limited, the growth may affect muscle, other tissue, and even the airway. The lymph nodes of the neck and the thyroid gland are palpated for enlargement.

Diagnostic procedures that may be used include fine-needle aspiration (FNA) biopsy, a barium swallow, endoscopy, CT or MRI scan, and a positron emission tomography (PET) scan (ACS, 2015). FNA biopsy may be done as an initial screening procedure to obtain samples of any enlarged lymph nodes in the neck. A barium swallow may be done if the patient initially presents with a chief complaint of difficulty in swallowing, to outline any structural anomalies of the neck that could pinpoint a tumor. However, if a tumor of the larynx is suspected on an initial examination, a direct laryngoscopic examination is indicated. Laryngoscopy is performed under local or general anesthesia to evaluate all areas of the larynx. In some cases, intraoperative examination obtained by direct microscopic visualization and palpation of the vocal folds may yield a more accurate diagnosis. Samples of the suspicious tissue are obtained for analysis. It is rare for human papillomavirus (HPV) to be implicated with laryngeal cancers, although it is frequently implicated in oral cancers. Whether or not the tumor is positive for HPV does not have an effect on the course of treatment (ACS, 2015).

The classification, including stage of the tumor (i.e., size and histology of the tumor, presence and extent of cervical lymph node involvement) and location of the tumor serve as a basis for treatment. CT scanning and MRI are used to assess regional adenopathy and soft tissues and to stage and determine the extent of a tumor. MRI is also helpful in posttreatment follow-up to detect a recurrence. PET scanning may also be used to detect recurrence of the laryngeal tumor after treatment.

Medical Management

The goals of treatment of laryngeal cancer include cure; preservation of safe, effective swallowing; preservation of useful voice; and avoidance of permanent tracheostoma (Tierney et al., 2015). Treatment options include surgery, radiation therapy, and adjuvant chemoradiation therapy. The prognosis depends on the tumor location (i.e., supraglottic, glottis, and subglottic), as well as the tumor grade and stage (i.e., using the TNM system; see Chapter 58). The treatment plan also depends on whether the cancer is an initial diagnosis or a recurrence. In addition, before treatment begins, a complete dental examination is performed to rule out any oral disease. A consultation with a dental oncologist may be warranted. Any dental problems are resolved, if possible, before surgery and radiotherapy (ACS, 2015).

For patients with early-stage tumors (i.e., stages I and II) and lesions without lymph node involvement, external-beam radiation therapy or conservation surgery (i.e., less invasive surgery, such as vocal cord stripping or cordectomy) may be effective. Other indicated surgical procedures may include transoral endoscopic laser excision or partial laryngectomy (NCI, 2015). Patients with stage III and IV tumors that are resectable may be advised to have either total laryngectomies with or without postoperative radiation therapy or radiation therapy with concurrent adjuvant chemotherapy (with single-agent cisplatin) and surgical resection aimed at preserving some of the larynx (i.e., organ preservation surgery). Patients with late-stage tumors that extend through cartilage and into soft tissues are generally advised to have total laryngectomies with postoperative radiation therapy (NCI, 2015).

Patients should be educated so that they carefully consider the various side effects and complications associated with the different treatment modalities. The presence of lymph node involvement in the neck can affect the outcome. Supraglottic tumors metastasize early and bilaterally even when there appears to be no lymph node involvement at the time of diagnosis. When the neck lymph nodes are involved, the treatment includes surgery, chemoradiation, or both (Tierney et al., 2015).

Surgical Management

The overall goals for the patient undergoing surgical treatment include minimizing the effects of surgery on speech, swallowing, and breathing while maximizing the cure of the cancer. Several

different curative procedures are available that can offer voice-sparing results while achieving a positive cure rate for the patient who has an early laryngeal carcinoma. Surgical options include vocal cord stripping, cordectomy, laser surgery, partial laryngectomy, or total laryngectomy (NCI, 2015).

Vocal Cord Stripping

Stripping of the vocal cord is used to treat dysplasia, hyperkeratosis, and leukoplakia and is often curative for these lesions. The procedure involves removal of the mucosa of the edge of the vocal cord, using an operating microscope. Early vocal cord lesions are initially treated with radiation therapy.

Cordectomy

Cordectomy, which is an excision of the vocal cord, is usually performed via transoral laser. This procedure is used for lesions limited to the middle third of the vocal cord. The resulting voice quality is related to the extent of tissue removed.

Laser Surgery

Laser microsurgery is well known to have several advantages for the treatment of early glottic cancers. Treatment and recovery are shorter, with fewer side effects, and treatment may be less costly than for other forms of therapy. Microelectrodes are useful for surgical resection of smaller laryngeal carcinomas. The carbon dioxide (CO_2) laser can be used for the treatment of many laryngeal tumors, with the exception of large vascular tumors. When compared with the results of other treatments for early laryngeal cancer, laser microsurgery is considered to be the method of choice based on patient outcomes (NCI, 2015).

Partial Laryngectomy

A partial laryngectomy (laryngofissure–thyrotomy) is often used for patients in the early stages of cancer in the glottic area when only one vocal cord is involved. The surgery is associated with a very high cure rate. It may also be performed for recurrence when high-dose radiation has failed. A portion of the larynx is removed, along with one vocal cord and the tumor; all other structures remain. The airway remains intact, and the patient is expected to have no difficulty swallowing. The voice quality may change, or the patient may sound hoarse.

Total Laryngectomy

Complete removal of the larynx (total laryngectomy) can provide a cure in most advanced laryngeal cancers, when the tumor extends beyond the vocal cords, or for cancer that recurs or persists after radiation therapy. In a total laryngectomy, the laryngeal structures are removed, including the hyoid bone, epiglottis, cricoid cartilage, and two or three rings of the trachea. The tongue, pharyngeal walls, and most of the trachea are preserved. A total laryngectomy results in permanent loss of the voice and a change in the airway, requiring a permanent tracheostomy (see Fig. 40-4). Occasionally, patients continue to have a laryngectomy tube in the stoma. Laryngectomy tubes are similar in appearance to tracheostomy tubes; however, a laryngectomy tube can be distinguished from a tracheostomy tube because the patient is unable to speak or breathe when the laryngectomy tube is occluded. Patients who have a total laryngectomy require alternatives to normal speech; these may include a prosthetic device, such as a Blom-Singer valve, to speak without aspirating (see later discussion).

Surgery is more difficult when the lesion involves the midline structures or both vocal cords. With or without neck dissection, a total laryngectomy requires a permanent tracheal stoma because the larynx that provides the protective sphincter is no longer present. The tracheal stoma prevents the aspiration of food and fluid into the lower respiratory tract. The patient has no voice but has normal swallowing. A total laryngectomy changes the manner in which airflow is used for breathing and speaking, as depicted in Figure 40-4. The patient has significant loss of the natural voice and the need to breathe through an opening (stoma) created in the lower neck. Complications that may occur include a salivary leak, wound infection from the development of a pharyngocutaneous fistula, stomal stenosis, and dysphagia secondary to esophageal stricture. In some cases, the patient may be a candidate for a near-total laryngectomy. In this situation, the patient would be a candidate for chemoradiation therapy regimens postoperatively. Voice preservation can be achieved in most cases and tends to be associated with overall improved quality of life (Aalia, 2014). Advances in surgical techniques for treating laryngeal cancer

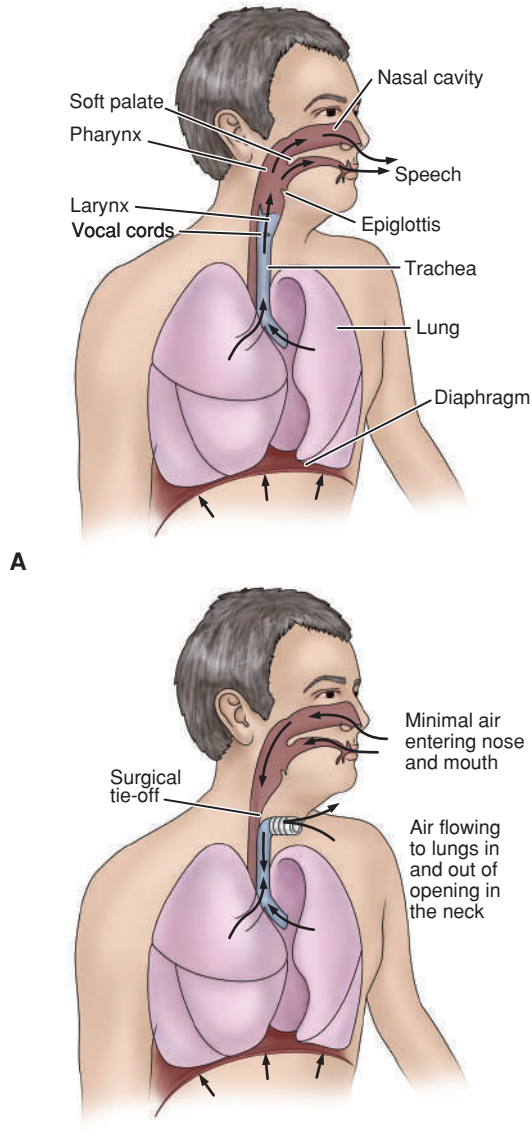

Figure 40-4 • Total laryngectomy produces a change in airflow for breathing and speaking. **A.** Normal airflow. **B.** Airflow after total laryngectomy.

may minimize the cosmetic and functional deficits previously seen with total laryngectomy. Some microlaryngeal surgery can be performed endoscopically.

Radiation Therapy

The goal of radiation therapy is to eradicate the cancer and preserve the function of the larynx. The decision to use radiation therapy is based on several factors, including the staging of the tumor and the patient's overall health status, lifestyle (including occupation), and personal preference. Excellent results have been achieved with radiation therapy in patients with early-stage glottic tumors when only one vocal cord is involved and there is normal mobility of the cord (i.e., with phonation), as well as in small supraglottic lesions. One of the benefits of radiation therapy is that patients retain a near-normal voice. A few may develop chondritis (inflammation of the cartilage) or stenosis; a small number may later require laryngectomy.

Radiation therapy may also be used preoperatively to reduce the tumor size. Radiation therapy is combined with surgery in advanced laryngeal cancer as adjunctive therapy to surgery or chemotherapy and as a palliative measure.

Complications from radiation therapy are a result of external radiation to the head and neck area, which may also include the parotid gland, which is responsible for mucus production. Symptoms may include acute mucositis, ulceration of the mucous membranes, pain, xerostomia (dry mouth), loss of taste, dysphasia, fatigue, and skin reactions. Later complications may include laryngeal necrosis, edema, and fibrosis (see Chapter 58).

Speech Therapy

The patient who undergoes a laryngectomy and the patient's family face potentially complex challenges, including significant changes in the ability to communicate. To minimize anxiety and frustration on the part of the patient and family, the loss or alteration of speech is discussed with them. To plan postoperative communication strategies and speech therapy, the speech therapist or pathologist conducts a preoperative evaluation (ACS, 2015). During this time, the nurse discusses with the patient and family the methods of communication that will be available in the immediate postoperative period. These include writing, lip speaking and reading, and communication or word boards. A system of communication is established with the patient, family, nurse, and primary provider and is implemented consistently after surgery.

In addition, a long-term postoperative communication plan for alaryngeal communication is developed. The three most common techniques of alaryngeal communication are esophageal speech, artificial larynx (electric larynx), and tracheoesophageal puncture. Training in these techniques begins once medical clearance is obtained from the primary provider.

Esophageal Speech

The patient needs the ability to compress air into the esophagus and expel it, setting off a vibration of the pharyngeal esophageal segment for esophageal speech. The technique can be taught once the patient begins oral feedings, approximately 1 week after surgery. First, the patient learns to belch and is reminded to do so an hour after eating. Then, the technique is practiced repeatedly. Later, this conscious belching action is transformed into simple explosions of air from the esophagus for speech purposes. The speech therapist continues to work with the patient to make speech intelligible and as close to normal as possible. Because it takes a long time to become proficient, the success rate is low (ACS, 2015).

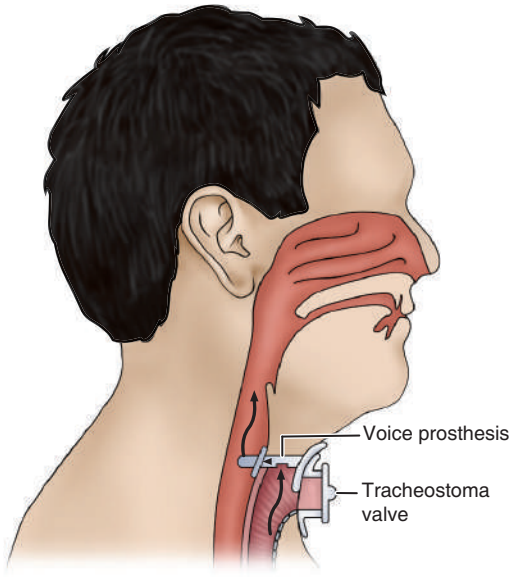

Figure 40-5 • Schematic representation of tracheoesophageal puncture speech. Air travels from the lung through a puncture in the posterior wall of the trachea into the esophagus and out the mouth. A voice prosthesis is fitted over the puncture site.

Artificial Larynx

If esophageal speech is not successful, or until the patient masters the technique, an electric larynx may be used for communication. This battery-powered apparatus projects sound into the oral cavity. When the mouth forms words (articulation), the sounds from the electric larynx become audible words. The voice that is produced sounds mechanical, and some words may be difficult to understand. The advantage is that the patient is able to communicate with relative ease while working to become proficient at either esophageal or tracheoesophageal puncture speech.

Tracheoesophageal Puncture

The third technique of alaryngeal speech is tracheoesophageal puncture (see Fig. 40-5). This technique for voice restoration is simple and has few complications. It is associated with high phonation success, good phonation quality, and steady long-term results. This technique is the most widely used because the speech associated with it most resembles normal speech (the sound produced is a combination of esophageal speech and voice), and it is easily achieved either during the initial surgery to treat the tumor or at a later date (ACS, 2015). A valve is placed in the tracheal stoma to divert air into the esophagus and out the mouth. Once the puncture is surgically created and has healed, a voice prosthesis (Blom-Singer) is fitted over the puncture site. A speech therapist teaches the patient how to produce sounds. Moving the tongue and lips to form the sound into words produces speech as before. To prevent airway obstruction, the prosthesis is removed and cleaned when mucus builds up.

NURSING PROCESS

The Patient Undergoing Laryngectomy

Assessment

The nurse obtains a health history and assesses the patient's physical, psychosocial, and spiritual domains. The health history

focuses on the following symptoms: hoarseness, sore throat, dyspnea, dysphagia, and pain or burning in the throat. The physical assessment includes a thorough head and neck examination with an emphasis on the patient's airway. In addition, the neck and thyroid are palpated for swelling, nodularity, or adenopathy.

The nurse also assesses the patient's general state of nutrition, including height and weight and body mass index and reviews laboratory values that assist in determining the patient's nutritional status (albumin, protein, glucose, and electrolyte levels). If treatment includes surgery, the nurse must know the nature of the surgery to plan appropriate care. If the patient is expected to have no voice as a result of the surgical procedure, a preoperative evaluation by the speech therapist is essential. The patient's ability to hear, see, read, and write is assessed. Visual impairment and functional illiteracy may create additional problems with communication and may require creative approaches to ensure that the patient is able to communicate any needs. Because alcohol abuse is a risk factor for cancer of the larynx, the patient's pattern of alcohol intake must be assessed. Patients who are accustomed to daily consumption of alcohol are at the risk for alcohol withdrawal syndrome (delirium tremens) when alcohol intake is stopped suddenly. It is also not uncommon that patients are active smokers at the time of diagnosis; assessment of readiness for smoking cessation should be done, and nicotine replacements prescribed to avoid nicotine withdrawal, as indicated (NCI, 2015) (see Chapter 21 Promoting Cessation of Tobacco Use).

In addition, the nurse assesses the psychological readiness of the patient and family. The fear of a diagnosis of cancer is compounded by the possibility of permanent voice loss and, in some cases, some degree of disfigurement. The nurse evaluates the patient's and family's knowledge of the planned surgical procedure and expected postoperative course and assesses their coping methods and support systems. The nurse assesses the patient's spirituality needs based on the patient's individual preferences, beliefs, and culture.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about the surgical procedure and postoperative course
- Anxiety related to the diagnosis of cancer and impending surgery
- Ineffective airway clearance related to excess mucus production secondary to surgical alterations in the airway
- Impaired verbal communication related to anatomic deficit secondary to removal of the larynx and to edema
- Imbalanced nutrition: less than body requirements, related to inability to ingest food secondary to swallowing difficulties
- Disturbed body image and low self-esteem secondary to major neck surgery, change in appearance, and altered structure and function
- Self-care deficit related to pain, weakness, fatigue, musculoskeletal impairment related to surgical procedure and postoperative course

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include the following:

- Respiratory distress (hypoxia, airway obstruction, tracheal edema)
- Hemorrhage, infection, and wound breakdown
- Aspiration
- Tracheostomal stenosis

Planning and Goals

The major goals for the patient may include attainment of an adequate level of knowledge, reduction in anxiety, maintenance of a patent airway (patient is able to handle own secretions), effective use of alternative means of communication, attainment of optimal levels of nutrition and hydration, improvement in body image and self-esteem, improved self-care management, and absence of complications.

Nursing Interventions

Providing Preoperative Patient Education

The diagnosis of laryngeal cancer often produces misconceptions and fears. Many people assume that loss of speech and disfigurement are inevitable with this condition. Once the primary provider explains the diagnosis and discusses treatment options with the patient and family, the nurse clarifies any misconceptions by identifying the location of the larynx, its function, the nature of the planned surgical procedure, and its effect on speech. Further, the patient's ability to sing, laugh, and whistle will be lost. Informational materials (written and audiovisual) about the surgery are given to the patient and family for review and reinforcement. If a complete laryngectomy is planned, the patient must understand that the natural voice will be lost, but that special training can provide a means for communicating. The patient needs to know that until training is started, communication will be possible by using the call light, by writing, or by using a communication device. The interdisciplinary team conducts an initial assessment of the patient and family. In addition to the nurse in charge of the patient's care and the primary provider, the team might include an advanced practice nurse (e.g., nurse practitioner), speech therapist, respiratory therapist, social worker, dietitian, and home care nurse.

The nurse also reviews equipment and treatments for postoperative care with the patient and family, teaches important coughing and deep-breathing exercises, and helps the patient perform return demonstrations. The nurse clarifies the patient's role in the postoperative and rehabilitation periods. The family's needs must also be addressed because family members are often responsible for complex care of the patient in the home.

Reducing Anxiety

Because surgery of the larynx is performed most often for a malignant tumor, the patient may have many questions: Will the surgeon be able to remove all of the tumor? Is it cancer? Will I die? Will I choke? Will I suffocate? Will I ever speak again? What will I look like? Because of these and other questions, the psychological preparation of the patient is as important as the physical preparation.

Any patient undergoing surgery may have many fears. In laryngeal surgery, these fears may relate to the diagnosis of cancer and the possibility of permanent loss of the voice and disfigurement. The nurse provides the patient and family with opportunities to ask questions, verbalize feelings, and discuss perceptions. The nurse should address any questions and misconceptions the patient and family have. During the preoperative or postoperative period, a visit from someone who has had a laryngectomy may reassure the patient that people are available to assist and that rehabilitation is possible.

In the immediate postoperative period, the nurse attempts to build trust and reduce the patient's anxiety. Active listening provides an environment that promotes open communication and allows the patient to verbalize feelings. Clear instructions and explanations are given to the patient and family in a calm, reassuring manner. The nurse listens attentively, encourages the patient, and identifies and reduces environmental stressors. The nurse seeks to learn from the patient what activities promote feelings of comfort and assists the patient in such activities (e.g., listening to music, reading). Relaxation techniques such as guided imagery and meditation are often helpful. The nurse remains with the patient during episodes of severe anxiety and includes the patient in decision making.

Maintaining a Patent Airway

The nurse helps maintain a patent airway by positioning the patient in the semi-Fowler or Fowler position after recovery from anesthesia. This position decreases surgical edema and promotes lung expansion. Observing the patient for restlessness, labored breathing, apprehension, and increased pulse rate helps identify possible respiratory or circulatory problems. The nurse assesses the patient's lung sounds and reports changes that may indicate impending complications. Medications that depress respiration, particularly opioids, should be used cautiously. However, adequate use of analgesic medications is essential for pain relief because postoperative pain can result in shallow breathing and an ineffective cough (see Chapter 9 for discussion of pain management). The nurse encourages the patient to turn, cough, and take deep breaths. If necessary, suctioning may be performed to remove secretions, but disruption of suture lines must be avoided. The nurse also encourages and assists the patient with early ambulation to prevent atelectasis, pneumonia, and venous thromboemboli formation (e.g., pulmonary embolism and deep vein thrombosis). Pulse oximetry is used to monitor the patient's oxygen saturation level.

If a total laryngectomy was performed, a laryngectomy tube will most likely be in place. In some instances a laryngectomy tube is not used; in others it is used temporarily; and in many it is used permanently. The laryngectomy tube, which is shorter than a tracheostomy tube but has a larger diameter, is the patient's only airway. The care of this tube is similar to that for a tracheostomy tube (see Chapter 11). The nurse changes the inner cannula (if present) every 8 hours if it is disposable. Although nondisposable tubes are used infrequently, if one is used, the nurse cleans the inner cannula every 8 hours or more often as needed. If a tracheostomy tube without an inner cannula is used, humidification and suctioning of this tube are essential to prevent formation of mucus plugs. If a T-shaped laryngectomy tube is used, both sides of the T-tube should be suctioned to prevent obstruction due to copious secretions. The nurse should also use secure tracheostomy ties to prevent tube dislodgement. The nurse cleans the stoma daily with soap and water or another prescribed solution and a soft cloth or gauze, taking care to prevent water and soap or solution from entering the stoma. If a non–oil-based antibiotic ointment is prescribed, it is applied around the stoma and suture line. If crusting appears around the stoma, the crusts are removed with sterile tweezers and additional ointment is applied.

Wound drains, inserted during surgery, may be in place to assist in removal of fluid and air from the surgical site. Suction also may be used, but cautiously, to avoid trauma to the surgical site and incision. The nurse observes, measures, and records drainage. When drainage is less than 30 mL/day for 2 consecutive days, the surgeon usually removes the drains.

Frequently, the patient coughs up large amounts of mucus through this opening. Because air passes directly into the trachea without being warmed and moistened by the upper respiratory mucosa, the tracheobronchial tree compensates by secreting excessive amounts of mucus. Therefore, the patient has frequent coughing episodes and may develop a brassy-sounding, mucus-producing cough. The nurse reassures the patient that these problems will diminish in time as the tracheobronchial mucosa adapts to the altered physiology.

After the patient coughs, the tracheostomy opening must be wiped clean and clear of mucus. A simple gauze dressing, washcloth, or even paper towel (because of its size and absorbency) worn below the tracheostomy may serve as a barrier to protect the clothing from the copious mucus that the patient may initially expel.

One of the most important factors in decreasing cough, mucus production, and crusting around the stoma is adequate humidification of the environment. Mechanical humidifiers and aerosol generators (nebulizers) increase the humidity and are important for the patient's comfort. The laryngectomy tube may be removed when the stoma is well healed, within 3 to 6 weeks after surgery. The nurse teaches the patient how to clean and change the tube (see Chapter 11) and remove secretions.

Promoting Alternative Communication Methods

Establishing an effective means of communication is usually the ultimate goal in the rehabilitation of the laryngectomy patient. To understand and anticipate the patient's postoperative needs, the nurse works with the patient, speech therapist, and family to encourage the use of alternative communication methods. These means of communication are established preoperatively and must be used consistently by all personnel who come in contact with the patient postoperatively. The patient is now unable to use an intercom system. A call bell or hand bell must be placed within easy reach of the patient. In the immediate postoperative period, a handheld communication device like a Magic Slate can be used for communication; as alternatives, electronic tablets, notebooks, and smart phones can be used if the patient has any of these devices. If the patient cannot write, a picture-word-phrase board or hand signals can be used. The nurse documents which hand is the patient's dominant hand (e.g., used for writing) so that the opposite arm can be used for IV infusions. (To ensure the patient's privacy, the nurse discards notes used for communication.)

Writing everything or communicating through gestures can be very time consuming and frustrating. The patient must be given adequate time to communicate their needs. The patient may become impatient and angry when not understood.

Promoting Adequate Nutrition and Hydration

Postoperatively, the patient may not be permitted to eat or drink for at least 7 days (Kishikova & Fleming, 2014). Alternative sources of nutrition and hydration include IV fluids, enteral feedings through a nasogastric or gastrostomy tube, and parenteral nutrition (see Chapter 15).

When the patient is ready to start oral feedings, a speech therapist or radiologist may conduct a swallow study (a video fluoroscopy radiology procedure) to evaluate the patient's risk of aspiration. Once the patient is cleared for oral feedings, the nurse explains that thick liquids will be used first because they are easy to swallow. Different swallowing maneuvers are attempted with various food consistencies. Once the patient is cleared for food intake, the nurse stays with the patient during initial oral feedings and keeps a suction setup at the bedside

for needed suctioning. The nurse instructs the patient to avoid sweet foods, which increase salivation and suppress the appetite. Solid foods are introduced as tolerated. The patient is instructed to rinse the mouth with warm water or mouthwash after oral feedings and to brush the teeth frequently.

Because taste and smell are so closely related, taste sensations are altered for a while after surgery because inhaled air passes directly into the trachea, bypassing the nose and the olfactory end organs. In time, however, the patient usually accommodates to this change and olfactory sensation adapts, often with return of interest in eating. The nurse observes the patient for any difficulty in swallowing, particularly when eating resumes, and reports its occurrence to the primary provider.

The patient's weight and laboratory data are monitored to ensure that nutritional and fluid intake are adequate. In addition, skin turgor and vital signs are assessed for signs of decreased fluid volume.

Promoting Positive Body Image and Self-Esteem

Disfiguring surgery and an altered communication pattern are threats to a patient's body image and self-esteem. The reaction of family members and friends is a major concern for the patient. The nurse encourages the patient to express feelings about the changes brought about by surgery, particularly feelings related to fear, anger, depression, and isolation.

Promoting Self-Care Management

A positive approach along with promotion of self-care activities is important when caring for the patient. The patient should begin participating in self-care activities as soon as possible. The nurse assesses the patient's readiness for decision making and encourages the patient to participate actively in performing care. The nurse provides positive reinforcement when the patient makes an effort in self-care. The nurse needs to be a good listener and a support to the family, especially when explaining the tubes, dressings, and drains that are in place postoperatively.

Monitoring and Managing Potential Complications

The potential complications after laryngectomy include respiratory distress and hypoxia, hemorrhage, infection, wound breakdown, aspiration, and tracheostomal stenosis.

Respiratory Distress and Hypoxia. The nurse monitors the patient for signs and symptoms of respiratory distress and hypoxia, particularly restlessness, irritation, agitation, confusion, tachypnea, the use of accessory muscles, and decreased oxygen saturation on pulse oximetry (SpO_2). Any change in respiratory status requires immediate intervention. Hypoxia may cause restlessness and an initial rise in blood pressure; this is followed by hypotension and somnolence. Cyanosis is a late sign of hypoxia. Obstruction needs to be ruled out immediately by suctioning and by having the patient cough and breathe deeply. Hypoxia and airway obstruction, if not treated immediately, are life threatening.

Other nursing measures include repositioning of the patient to ensure an open airway and administering oxygen as prescribed. Oxygen is used with caution in patients with chronic obstructive pulmonary disease. The nurse should always be prepared for possible intubation and mechanical ventilation. The nurse must be knowledgeable about the hospital's emergency code protocols and skilled in the use of emergency equipment. The nurse must remain with the patient at all times during respiratory distress and initiate a call to the rapid response team as necessary.

Hemorrhage. Bleeding from the drains at the surgical site or with tracheal suctioning may signal the occurrence of hemorrhage. The nurse promptly notifies the surgeon of any active bleeding, which can occur at a variety of sites, including the surgical site, drains, and trachea. Rupture of the carotid artery is especially dangerous. Should this occur, the nurse must apply direct pressure over the artery, summon assistance, and provide emotional support to the patient until the vessel is ligated. The nurse monitors vital signs for changes, particularly increased pulse rate, decreased blood pressure, and rapid deep respirations. Cold, clammy, pale skin may indicate active bleeding. IV fluids and blood components may be given and other measures implemented to prevent or treat hemorrhagic shock. (Management of the patient with shock is discussed in detail in Chapter 8.)

Infection. The nurse monitors the patient for signs of postoperative infection. These include an increase in temperature and pulse, a change in the type of wound drainage, and increased areas of redness or tenderness at the surgical site. Other signs include purulent drainage, odor, and increased wound drainage. The nurse monitors the patient's white blood cell (WBC) count; a rise in WBCs may indicate the body's effort to combat infection. In older adult patients, infection can be present without an increase in the patient's WBC count; therefore, the nurse must monitor the patient for more subtle signs, such as lethargy, weakness, and decreased appetite. WBCs are suppressed in the patient with decreased immune function (e.g., patients receiving chemotherapy or radiation therapy); this predisposes the patient to a severe infection and sepsis. Antimicrobial (antibiotic) medications must be given as scheduled. All suspicious drainage is cultured, and the patient may be placed on the appropriate infection prevention precautions. Strategies are implemented to minimize the exposure of the patient to microorganisms and their spread to others. The nurse reports any significant change in the patient's status to the surgeon.

Wound Breakdown. Wound breakdown caused by infection, poor wound healing, development of a fistula, radiation therapy, or tumor growth can create a life-threatening emergency. The carotid artery, which is close to the stoma, may rupture from erosion if the wound does not heal properly. The nurse observes the stoma area for wound breakdown, hematoma, and bleeding and reports their occurrence to the surgeon. If wound breakdown occurs, the patient must be monitored carefully and identified as at high risk for carotid hemorrhage.

Aspiration. The patient who has undergone a laryngectomy is at the risk for aspiration and aspiration pneumonia due to depressed cough, the sedating effects of anesthetic and analgesic medications, alteration in the airway, impaired swallowing, and the administration of tube feedings. The nurse assesses for the presence of nausea and administers antiemetic medications, as prescribed. The nurse keeps a suction setup available in the hospital and instructs the family to do so at home for use if needed. Patients receiving tube feedings are positioned with the head of the bed at 30° or higher during feedings and for 30 to 45 minutes after tube feedings. Patients receiving oral feedings are positioned with the head of the bed in an upright position for 30 to 45 minutes after feedings. For patients with a nasogastric or gastrostomy tube, the placement of the tube and residual gastric volume must be checked before each feeding. High amounts of residual volume (greater than 50% of previous intake) indicate delayed gastric emptying; this can lead to reflux and aspiration (Tierney, et al., 2015). Signs or symptoms of aspiration are reported to the primary provider immediately.

Tracheostomal Stenosis. Tracheostomal stenosis is an abnormal narrowing of the trachea or the tracheostomy stoma. Infection at the stoma site, excessive traction on the tracheostomy tube by the connecting tubing, and persistent high tracheostomy cuff pressure are risk factors for tracheostomal stenosis. The incidence of this condition varies widely, and it is often preventable. The nurse assesses the patient's stoma for signs and symptoms of infection and reports any evidence of this to the primary provider immediately. Tracheostomy care is performed routinely. The nurse assesses the connecting tubing (e.g., ventilation tubing) and secures the tubing to avoid excessive traction on the patient's tracheostomy. The nurse ensures that the tracheostomy cuff is deflated (for a patient with a cuffed tube) except for short periods, such as when the patient is eating or taking medications.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The nurse has an important role in the recovery and rehabilitation of the patient who has had a laryngectomy. To facilitate the patient's ability to manage self-care, discharge instruction begins as soon as the patient is able to participate. Nursing care and patient education in the hospital, outpatient setting, and rehabilitation or long-term care facility must take into consideration the many emotions, physical changes, and lifestyle changes experienced by the patient. In preparing the patient to go home, the nurse assesses the patient's readiness to learn and the level of knowledge about self-care management. The nurse also reassures the patient and family that most self-care management strategies can be mastered. The patient needs to learn a variety of self-care behaviors, including tracheostomy and stoma care, wound care, and oral hygiene. The nurse also instructs the patient about the need for adequate dietary intake, safe hygiene, and recreational activities.

Tracheostomy and Stoma Care. The nurse provides specific instructions to the patient and family about what to expect with a tracheostomy and its management. The nurse instructs the patient and caregiver how to perform suctioning and emergency measures and tracheostomy and stoma care. The nurse stresses the importance of humidification at home and instructs the family to obtain and set up a humidification system before the patient returns home. (See Chapter 11 for details about tracheostomy care.)

Hygiene and Safety Measures. The nurse instructs the patient and family about safety precautions that are needed because of the changes in structure and function resulting from the surgery. Special precautions are needed in the shower to prevent water from entering the stoma. Wearing a loose-fitting plastic bib over the tracheostomy or simply holding a hand over the opening is effective. Swimming is not recommended because a person with a laryngectomy can drown without submerging their face. Barbers and beauticians need to be alerted so that hair sprays, loose hair, and powder do not get near the stoma, because they can block or irritate the trachea and possibly cause infection. These self-care points are summarized in Chart 40-7.

The nurse educates the patient and caregiver about the signs and symptoms of infection and identifies indications that require contacting the primary provider after discharge. A discussion regarding cleanliness and infection control behaviors is essential. The nurse educates the patient and family to use hand hygiene before and after caring for the tracheostomy, to use tissues to remove mucus, and to dispose of soiled dressings and equipment properly. If the patient's surgery included cervical lymph node dissection, the nurse instructs the patient

Chart 40-7 HOME CARE CHECKLIST

The Patient with a Laryngectomy

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, communication, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify interventions and strategies (e.g., durable medical equipment, oxygen, nebulizer, humidifier) used in adapting to any permanent changes in structure or function.
- Describe ongoing postoperative therapeutic regimen, including stoma care, diet, and activities to perform (e.g., shoulder and neck exercises if a node dissection was performed) and to limit or avoid (e.g., swimming and contact sports).
  - Demonstrate tracheostomy care and tracheal suctioning to clear the airway and handle secretions.
  - Explain the rationale for maintaining adequate humidification with a humidifier or nebulizer.
  - Demonstrate how to clean the skin around the stoma and how to use ointments and tweezers to remove encrustations.
  - State the rationale for wearing a loose-fitting protective cloth at the stoma and covering the stoma when showering or bathing.
  - Discuss the need to avoid sprays, powders, particulates, and cold air from air-conditioning and the environment to prevent irritation of the airway.
  - Demonstrate safe technique in changing the laryngectomy/tracheostomy tube.
  - Identify fluid and caloric needs.
  - Describe mouth care and discuss its importance.
  - Identify the signs and symptoms of wound infection and state what to do about them.
  - Describe safety or emergency measures to implement in case of breathing difficulty or bleeding.
  - State the rationale for wearing or carrying special medical identification and ways to obtain help in an emergency.
  - Demonstrate alternative communication methods.
- Relate how to reach primary provider with questions or to report complications.
- State time and date of follow-up appointments.
- Obtain an annual influenza vaccine, and discuss vaccination against pneumonia with the primary provider.
- State understanding of community resources, support groups and referrals (if any).
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, and stress management), disease prevention and screening activities.

Resources

See Procedural Guidelines 11-1: Care of the Patient With a Tracheostomy Tube and Procedural Guidelines 11-2: Performing Tracheal Suction.

ADL, activities of daily living; IADL, independent activities of daily living.

about how to perform exercises to strengthen the shoulder and neck muscles.

Recreation and exercise are important for the patient's well-being and quality of life, and all but very strenuous exercise can be enjoyed safely. Avoidance of strenuous exercise and fatigue is important because the patient will have more difficulty speaking when tired, which can be discouraging. Additional safety points to address include the need for the patient to wear or carry medical identification, such as a bracelet or card, to alert medical personnel to the special requirements for resuscitation should this need arise. If resuscitation is needed, direct mouth-to-stoma ventilation should be performed. For home emergency situations, prerecorded emergency messages for police, the fire department, or other rescue services can be kept near the phone to be used quickly.

The nurse instructs and encourages the patient to perform oral care frequently to prevent halitosis and infection. If the patient is receiving radiation therapy, synthetic saliva may be required because of decreased saliva production. Patients receiving radiation therapy frequently report dry mouth, change in taste, lack of appetite, and mouth sores (Haisfield–Wolfe, Brown, Richardson, et al., 2015) (see Chart 40-8). The nurse instructs the patient to drink water or sugar-free liquids throughout the day and to use a humidifier at home. Brushing the teeth or dentures and rinsing the mouth several times a day will assist in maintaining proper oral hygiene.

Continuing and Transitional Care. Referral for home, community-based, or transitional care is an important aspect of postoperative care for the patient who has had a laryngectomy and will assist the patient and family in the discharge home. The nurse assesses the patient's general health status and the ability of the patient and family to care for the stoma and tracheostomy. The surgical incisions, nutritional and respiratory status, and adequacy of pain management are also assessed. The nurse assesses for signs and symptoms of complications and the patient's and family's knowledge of signs and symptoms to be reported to the physician. During the home visit, the nurse identifies and addresses other learning needs and concerns of the patient and family, such as adaptation to physical, lifestyle, and functional changes, as well as the patient's progress with learning and using new communication strategies. The nurse assesses the patient's psychological status, reinforces previous instructions, and provides reassurance and support to the patient and family caregivers as needed.

The person who has had a laryngectomy should have regular physical examinations and seek advice concerning any problems related to recovery and rehabilitation. The nurse reminds the patient to participate in health promotion activities and health screening and about the importance of keeping scheduled appointments with the physician, speech therapist, and other health care providers.

Evaluation

Expected patient outcomes may include the following:

1. Demonstrates an adequate level of knowledge, verbalizing an understanding of the surgical procedure and performing self-care adequately

Chart 40-8 NURSING RESEARCH PROFILE

Patterns of Symptom Severity of Patients with Cancer of the Head and Neck

Haisfield-Wolfe, M. E., Brown, C., Richardson, M. et al. (2015). Variations in symptom severity patterns among oropharyngeal and laryngeal cancer outpatients during radiation treatment: A pilot study. Cancer Nursing, 38(4), 279–287.

Purpose

Patients diagnosed with laryngeal and oropharyngeal cancer (head and neck cancer [HNC]) commonly receive radiotherapy (RT) treatment on an outpatient basis. Patients with HNC who receive RT treatment commonly experience disturbing symptoms that include pain, difficulty swallowing, dry mouth, change in taste, lack of appetite, and mouth sores. While it is known that these patients tend to experience these symptoms, the patterns and severity of these symptoms are unknown. This pilot study aimed to identify the individual symptom patterns that patients with HNC experience over the course of 6 weeks of RT treatment.

Design

This was a secondary study derived from a parent study that examined symptoms patients with HNC experience when RT therapy is initiated. The study sites included two university-affiliated outpatient cancer centers located in the eastern United States. There were 21 patients with HNC who consented to participate in this study. Eligible participants were at least 18 years of age, with a new diagnosis of HNC, receiving RT treatment, and able to speak and write English. Sampling yielded 21 participants, 5 with laryngeal cancer, and 16 with oropharyngeal cancer. The Memorial Symptom Assessment Scale, a validated and reliable Likert scale survey that measures 32 symptoms associated with cancer treatment, was used to measure participants' symptoms during RT treatment at the time of midtreatment (week 5), end of treatment (week 9), and 6 weeks post-treatment (week 12). Visual graphical analysis was performed to find patterns of symptoms.

Findings

Participants reported variability in symptoms they experienced over time. The most common symptom experienced was pain; peak pain severity was commonly reported by participants, with no detectable pattern based upon study time points. Difficulty swallowing frequently accompanied pain. The other four symptoms of dry mouth, mouth sores, change in taste, and lack of appetite, along with difficulty swallowing, were commonly experienced during midtreatment and at treatment completion. Three patterns were identified. The first pattern noted increase in symptom severity after RT treatment initiation and declined in severity by midtreatment. The second pattern revealed increase in severity of symptoms post-treatment. The last pattern revealed symptom severity that persisted from RT treatment initiation to the post-treatment period. The small sample size precluded conducting inferential statistical analysis.

Nursing Implications

Findings from this study confirm that patients diagnosed with HNC and who receive RT treatment commonly experience the symptoms of pain, difficulty swallowing, dry mouth, change in taste, lack of appetite, and mouth sores. However, patients' symptoms varied in this pilot both in terms of intensity and patterns over the course of RT treatment. Therefore, nurses should assess patients' symptoms and provide individualized plans of care. In particular, participants in this study reported peak pain intensity at different time points during RT treatment, suggesting that patients with HNC require frequent pain assessment, reassessment, and implementation of proactive preventive pain management strategies.

2. Demonstrates less anxiety
   a. Expresses a sense of hope
   b. Is aware of available community organizations and agencies that provide patient education and support groups
   c. Participates in support group for people with a laryngectomy
3. Maintains a clear airway and handles own secretions; also demonstrates practical, safe, and correct technique for cleaning and changing the tracheostomy or laryngectomy tube
4. Acquires effective communication techniques
   a. Uses assistive devices and strategies for communication (Magic Slate, call bell, picture board, sign language, speech reading, handheld electronic devices)
   b. Follows the recommendations of the speech therapist
   c. Demonstrates ability to communicate with new communication strategy
   d. Reports availability of prerecorded messages to summon emergency assistance by telephone
5. Maintains adequate nutrition and adequate fluid intake
6. Exhibits improved body image, self-esteem, and self-concept
   a. Expresses feelings and concerns
   b. Participates in self-care and decision making
   c. Accepts information about support group
7. Adheres to rehabilitation and home care program
   a. Practices recommended speech therapy
   b. Demonstrates proper methods for caring for stoma and laryngectomy or tracheostomy tube (if present)
   c. Verbalizes understanding of symptoms that require medical attention
   d. States safety measures to take in emergencies
   e. Performs oral hygiene as prescribed
8. Absence of complications
   a. Demonstrates a patent airway
   b. No bleeding from surgical site and minimal bleeding from drains; vital signs (blood pressure, temperature, pulse, respiratory rate) are normal
   c. No redness, tenderness, or purulent drainage at surgical site
   d. No wound breakdown
   e. Clear breath sounds; oxygen saturation level within acceptable range; chest x-ray clear
   f. No indications of infection, stenosis, or obstruction of tracheal stoma

CRITICAL THINKING EXERCISES

1. A 20-year-old female college student comes to the student health clinic with complaints of a terrible sore throat with difficulty swallowing and opening her mouth; in addition, she appears to be drooling. She states that she has had a fever lasting several days. What further questions do you have regarding her symptoms? What is your priority focus for your physical examination? What diagnostic tests and treatments may you anticipate?
2. A 65-year-old man presents to the family health clinic for a follow-up visit to check his blood pressure (BP), which has been generally high and difficult to control with antihypertensive medications. The patient is obese, with a body mass index of 38. In addition to his elevated BP, he also reports falling asleep during the day and not feeling like he has slept when he wakes up. You suspect that this patient may have OSA. What risk factors for OSA will your health history focus on? What are the common signs and symptoms of OSA? Describe how a patient with OSA is diagnosed and the treatment(s) that might be prescribed. What is the strength of the evidence that commonly prescribed therapies (such as CPAP) may be effective in alleviating symptoms and improving quality of life for patients with OSA?
3. You are attending a family reunion where a lively game of soccer is taking place. Two players collide and one falls to the ground holding his nose. You suspect that the injured player on the ground has a fractured nose. Briefly describe what you would do in this situation. What are your priority assessments? What are the signs and symptoms of a fractured nose? What are your priority interventions?
4. At the family practice clinic where you work, you are assessing a patient who reports having had a cold about ten days ago. Most of her symptoms have abated, but she is now complaining of a severe headache over the front of her face and a fever of 38.9° C (102° F). She states that the pain increases when she bends over to pick up something off the floor. What further questions do you have regarding her symptoms? What will you focus on during your physical assessment? Briefly, describe the treatment you anticipate could be prescribed for this patient.

CHAPTER 41

Assessment and Management of Patients with Hearing and Balance Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the anatomy and physiology of the ear.
2. Explain methods used to assess hearing and balance disorders.
3. List the manifestations that may be exhibited by a person with hearing and balance disorders.
4. Identify ways to communicate effectively with a person with a hearing disorder.
5. Differentiate problems of the external ear from those of the middle ear and inner ear.
6. Compare the various types of surgical procedures used for managing middle ear disorders and appropriate nursing care.
7. Use the nursing process as a framework of care for patients undergoing mastoid surgery.
8. Apply the nursing process as a framework of care for patients with vertigo.
9. Recognize the different types of inner ear disorders, including the clinical manifestations, diagnosis, and management.

GLOSSARY

acute otitis media: inflammation in the middle ear lasting less than 6 weeks
cholesteatoma: tumor of the middle ear or mastoid, or both, that can destroy structures of the temporal bone
chronic otitis media: repeated episodes of acute otitis media causing irreversible tissue damage
conductive hearing loss: loss of hearing in which efficient sound transmission to the inner ear is interrupted by some obstruction or disease process
deafness: partial or complete loss of the ability to hear
dizziness: altered sensation of orientation in space
endolymphatic hydrops: dilation of the endolymphatic space of the inner ear; the pathologic correlate of Ménière disease
exostoses: small, hard, bony protrusions in the lower posterior bony portion of the ear canal
external otitis (i.e., otitis externa): inflammation of the external auditory canal
labyrinthitis: inflammation of the labyrinth of the inner ear
Ménière disease: condition of the inner ear characterized by a triad of symptoms: episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss
middle ear effusion: collection of fluid in the middle ear without evidence of infection
myringotomy (i.e., tympanotomy): incision in the tympanic membrane
nystagmus: involuntary rhythmic eye movement
ossiculoplasty: surgical reconstruction of the middle ear bones to restore hearing
otalgia: sensation of fullness or pain in the ear
otorrhea: drainage from the ear
otosclerosis: a condition characterized by abnormal spongy bone formation around the stapes
presbycusis: progressive hearing loss associated with aging
rhinorrhea: drainage from the nose
sensorineural hearing loss: loss of hearing related to damage to the end organ for hearing or cranial nerve VIII, or both
tinnitus: subjective perception of sound with internal origin; unwanted noises in the head or ear
tympanoplasty: surgical repair of the tympanic membrane
vertigo: illusion of movement in which the individual or the surroundings are sensed as moving

Introduction

The ear is a delicate sensory organ with the dual functions of hearing and balance. The sense of hearing is essential for normal development and maintenance of speech as well as the ability to communicate with others. Balance, or equilibrium, is essential for maintaining body movement, position, and coordination.

The early detection and accurate diagnosis of disorders is necessary for preservation of normal hearing and balance. The diagnosis and treatment of these disorders requires skilled health care professionals such as otolaryngologists, internists, audiologists, and nurses. This chapter provides an overview of the anatomy and physiology of the ear and addresses the general assessment and management of hearing and balance disorders common to adults seen in many health care settings.

ASSESSMENT OF THE EAR

Anatomic and Physiologic Overview

The cranium encloses and protects the brain and surrounding structures, providing attachment for various muscles that control head and jaw movements. The ears are located on either side of the cranium at approximately eye level.

Anatomy of the External Ear

The external ear includes the auricle (pinna) and the external auditory canal (see Fig. 41-1). The external ear is separated from the middle ear by a disc-shaped structure called the *tympanic membrane* (eardrum).

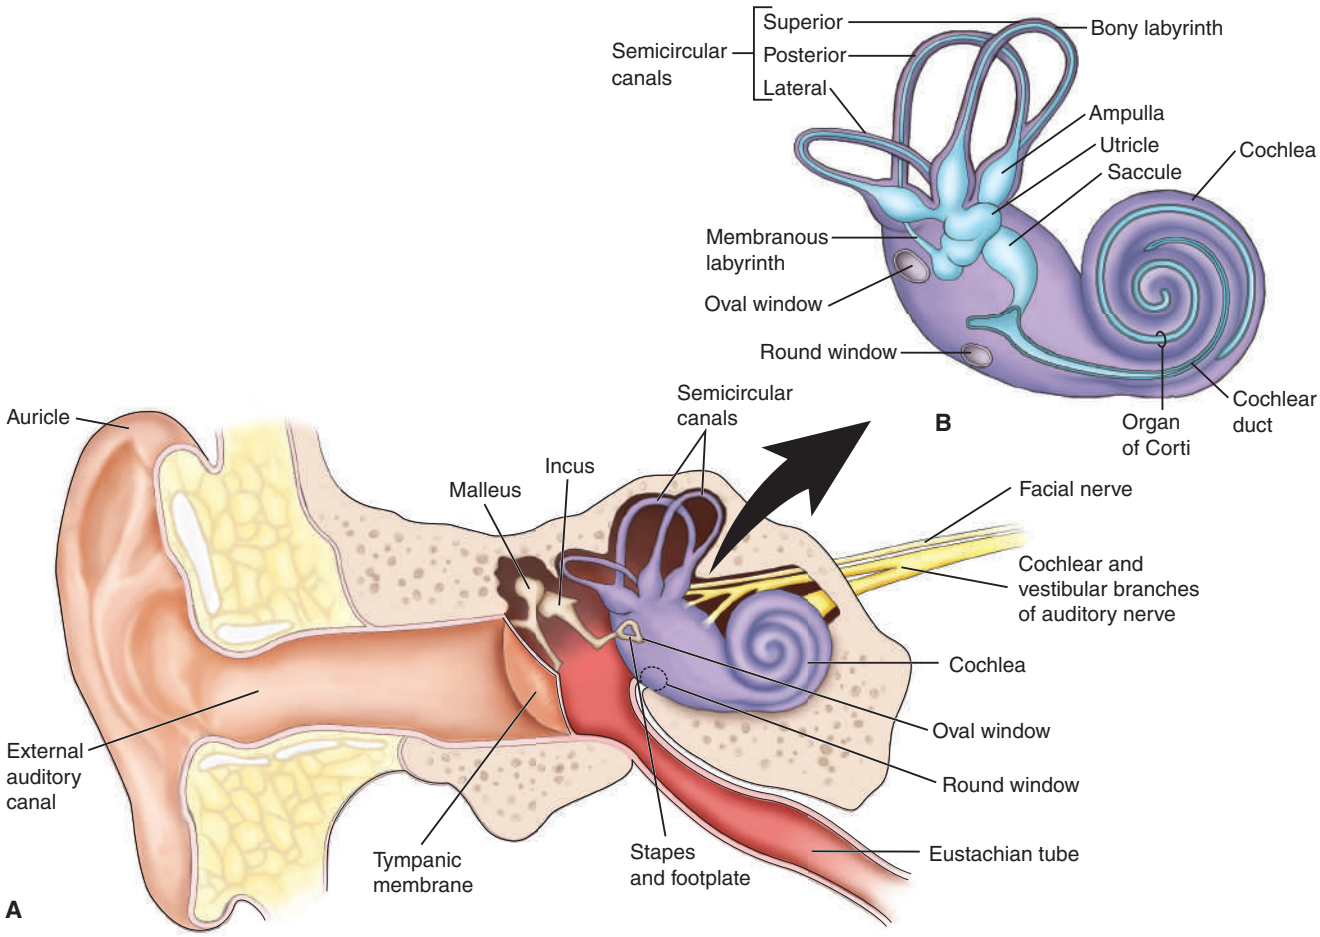

Figure 41-1 • A. Anatomy of the ear. **B.** The inner ear.

Auricle

The auricle, attached to the side of the head by skin, is composed mainly of cartilage, except for the fat and subcutaneous tissue in the earlobe. The auricle collects the sound waves and directs vibrations into the external auditory canal.

External Auditory Canal

The external auditory canal is approximately 2 to 3 cm long (Grossman & Porth, 2014). The lateral third is an elastic cartilaginous and dense fibrous framework to which thin skin is attached. The medial two thirds is bone lined with thin skin. The external auditory canal ends at the tympanic membrane.

The skin of the canal contains hair, sebaceous glands, and ceruminous glands, which secrete a brown, waxlike substance called *cerumen* (ear wax). The ear's self-cleaning mechanism moves old skin cells and cerumen to the outer part of the ear.

Just anterior to the external auditory canal is the temporomandibular joint. The head of the mandible can be felt by placing a fingertip in the external auditory canal while the patient opens and closes the mouth.

Anatomy of the Middle Ear

The middle ear, an air-filled cavity, includes the tympanic membrane laterally and the otic capsule medially. The middle ear cleft lies between the two. The middle ear is connected to the nasopharynx by the eustachian tube and is continuous with air-filled cells in the adjacent mastoid portion of the temporal bone.

The eustachian tube, which is approximately 1 mm wide and 35 mm long, connects the middle ear to the nasopharynx. Normally, the eustachian tube is closed, but it opens by action of the tensor veli palatini muscle when the person performs a Valsalva maneuver, yawns, or swallows. It drains normal and abnormal secretions of the middle ear and equalizes pressure in the middle ear with that of the atmosphere.

Tympanic Membrane

The tympanic membrane (eardrum), about 1 cm in diameter and very thin, is normally pearly gray and translucent (Weber & Kelley, 2014). It consists of three layers of tissue: an outer layer, continuous with the skin of the ear canal; a fibrous middle layer; and an inner mucosal layer, continuous with the lining of the middle ear cavity. Approximately 80% of the tympanic membrane is composed of all three layers and is called the *pars tensa.* The remaining 20% lacks the middle layer and is called the *pars flaccida.* The absence of this fibrous middle layer makes the pars flaccida more vulnerable to pathologic disorders than the pars tensa. Distinguishing landmarks include the annulus, the fibrous border that attaches the eardrum to the temporal bone; the short process of the malleus; the long process of the malleus; the umbo of the malleus, which attaches to the tympanic membrane in the center; the pars flaccida; and the pars tensa (see Fig. 41-2).

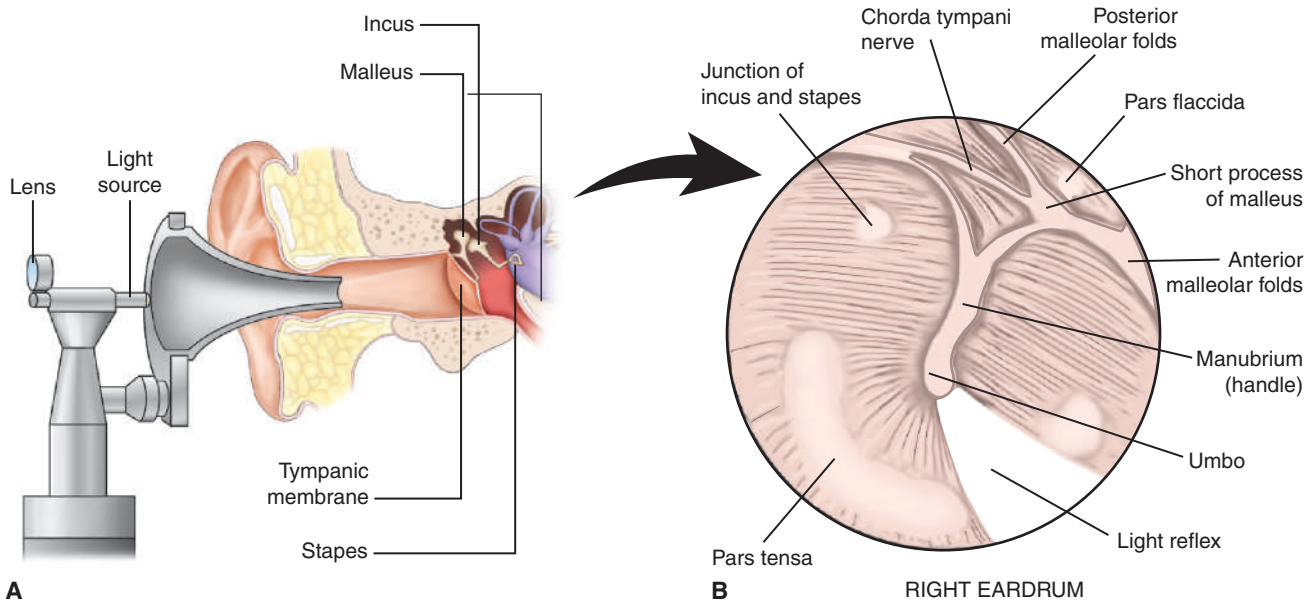

Figure 41-2 • Technique for using the otoscope (**A**) to see the tympanic membrane (**B**).

The tympanic membrane protects the middle ear and conducts sound vibrations from the external canal to the ossicles. The sound pressure is magnified 22 times as a result of transmission from a larger area to a smaller one.

Ossicles

The middle ear contains the three smallest bones (the ossicles) of the body: the malleus, the incus, and the stapes .The ossicles, which are held in place by joints, muscles, and ligaments, assist in the transmission of sound. Two small fenestrae (oval and round windows), located in the medial wall of the middle ear, separate the middle ear from the inner ear. The footplate of the stapes sits in the oval window, secured by a fibrous annulus (ring-shaped structure). The footplate transmits sound to the inner ear. The round window, covered by a thin membrane, provides an exit for sound vibrations (see Fig. 41-1).

Anatomy of the Inner Ear

The inner ear is housed deep within the temporal bone. The organs for hearing (cochlea) and balance (semicircular canals), as well as cranial nerves VII (facial nerve) and VIII (vestibulocochlear nerve), are all part of this complex anatomy (see Fig. 41-1). The cochlea and semicircular canals are housed in the bony labyrinth. The bony labyrinth surrounds and protects the membranous labyrinth, which is bathed in a fluid called *perilymph.*

Membranous Labyrinth

The membranous labyrinth is composed of the utricle, the saccule, the cochlear duct, the semicircular canals, and the organ of Corti, all of which are surrounded by a fluid called *endolymph.* The three semicircular canals—posterior, superior, and lateral, which lie at 90-degree angles to one another—contain sensory receptor organs that are arranged to detect rotational movement. These receptor end organs are stimulated by changes in the rate or direction of a person's movement. The utricle and saccule are involved with linear movements.

Organ of Corti

The organ of Corti is housed in the cochlea, a snail-shaped, bony tube about 3.5 cm long with two and a half spiral turns. Membranes separate the cochlear duct (scala media) from the scala vestibuli and the scala tympani from the basilar membrane. The organ of Corti is located on the basilar membrane that stretches from the base to the apex of the cochlea. As sound vibrations enter the perilymph at the oval window and travel along the scala vestibuli, they pass through the scala tympani, enter the cochlear duct, and cause movement of the basilar membrane. The organ of Corti, also referred to as the end organ for hearing, transforms mechanical energy into neural activity and separates sounds into different frequencies. This electrochemical impulse travels through the acoustic nerve to the temporal cortex of the brain to be interpreted as meaningful sound. In the internal auditory canal, the cochlear (acoustic) nerve, arising from the cochlea, joins the vestibular nerve, arising from the semicircular canals, utricle, and saccule, to become the vestibulocochlear nerve (cranial nerve VIII). This canal also houses the facial nerve and the blood supply from the ear to the brain.

Function of the Ears

Hearing

Hearing is conducted over two pathways: air and bone. Sounds transmitted by air conduction travel over the air-filled external and middle ear through vibration of the tympanic membrane and ossicles. Sounds transmitted by bone conduction travel directly through bone to the inner ear, bypassing the tympanic membrane and ossicles. Normally, air conduction is the more efficient pathway.

Sound Conduction and Transmission

Sound enters the ear through the external auditory canal and causes the tympanic membrane to vibrate. These vibrations transmit sound through the lever action of the ossicles to the oval window as mechanical energy. This mechanical energy is then transmitted through the inner ear fluids to the cochlea, stimulating the hair cells, and is subsequently converted to electrical energy. The electrical energy travels through the vestibulocochlear nerve to the central nervous system, where it is interpreted in its final form as sound.

Vibrations transmitted by the tympanic membrane to the ossicles of the middle ear are transmitted to the cochlea, located in the labyrinth of the inner ear. The stapes rocks, causing vibrations (waves) in fluids contained in the inner ear. These fluid waves cause movement of the basilar membrane, stimulating the hair cells of the organ of Corti in the cochlea to move in a wavelike manner. The movements of the tympanic membrane set up electrical currents that stimulate the various areas of the cochlea. The hair cells set up neural impulses that are encoded and then transferred to the auditory cortex in the brain, where they are decoded into a sound message.

The footplate of the stapes receives impulses transmitted by the incus and the malleus from the tympanic membrane. The round window, which opens on the opposite side of the cochlear duct, is protected from sound waves by the intact tympanic membrane, permitting motion of the inner ear fluids by sound wave stimulation. For example, in the normally intact tympanic membrane, sound waves stimulate the oval window first, and a lag occurs before the terminal effect of the stimulus reaches the round window. However, this lag phase is changed when a perforation of the tympanic membrane allows sound waves to impinge on the oval and round windows simultaneously. This effect cancels the lag and prevents the maximal effect of inner ear fluid motility and its subsequent effect in stimulating the hair cells in the organ of Corti. The result is a reduction in hearing ability (see Fig. 41-3).

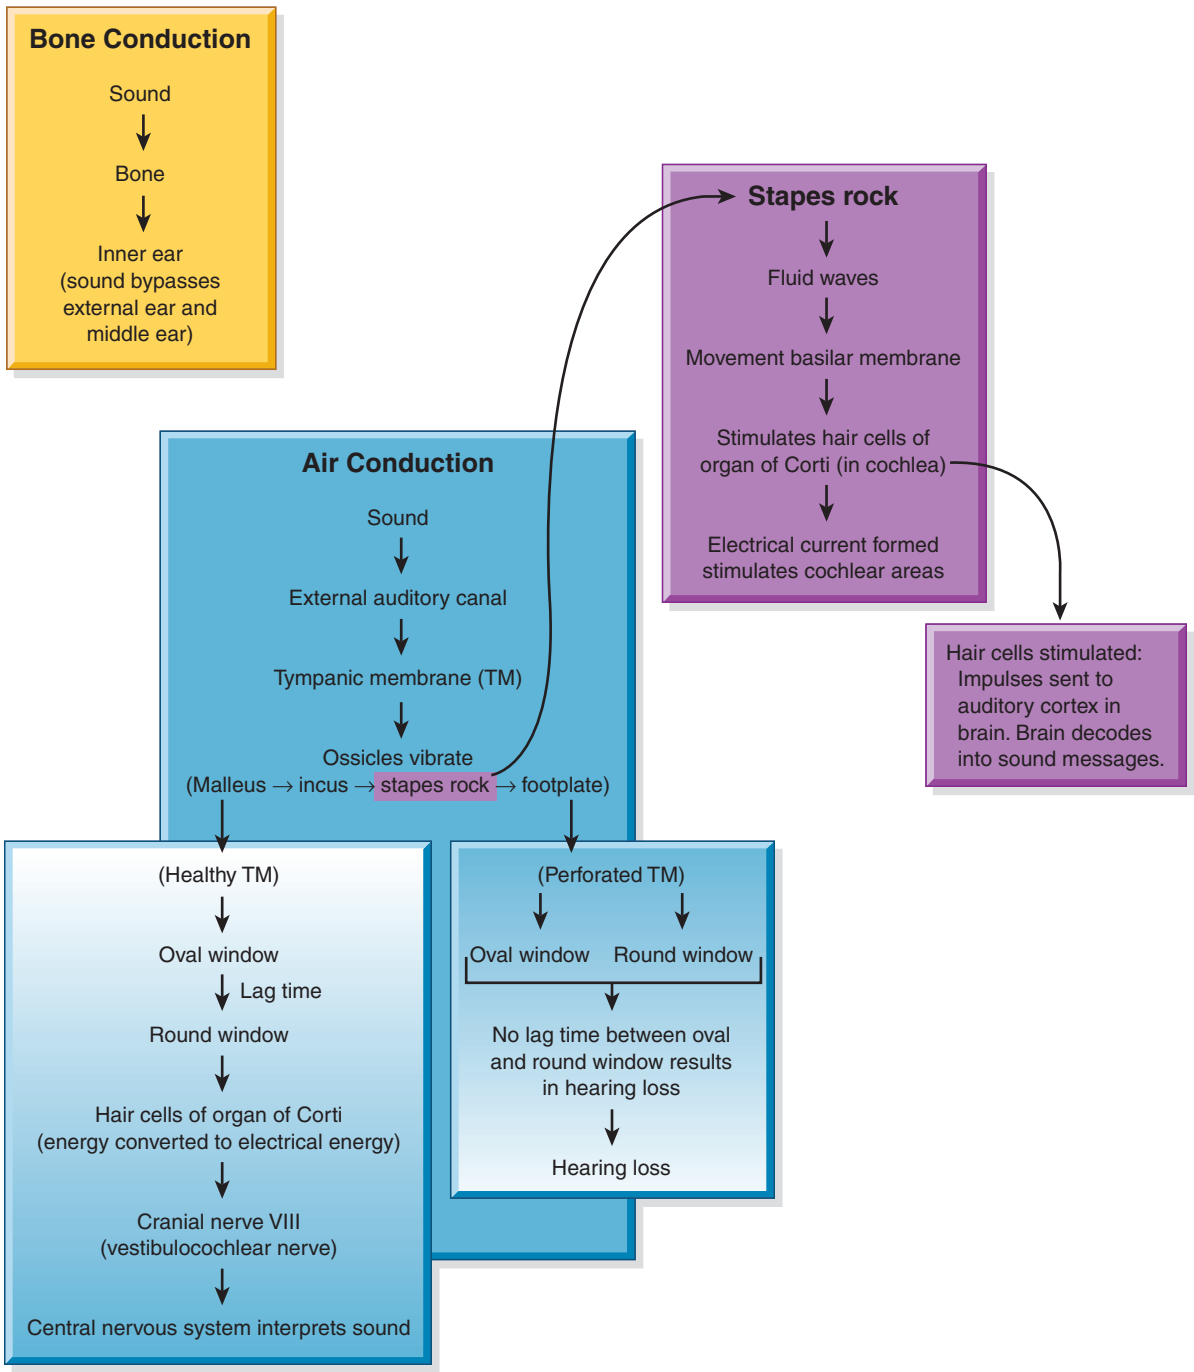

Figure 41-3 • Bone conduction compared to air conduction.

Bone conduction occurs by directly stimulating the bones of the skull that sends sound to the inner ear. An example of how this occurs can be done by striking a tuning fork and placing the tuning fork directly on the skull above the ear. Sound is transmitted to the inner ear.

Balance and Equilibrium

Body balance is maintained by the cooperation of the muscles and joints of the body (proprioceptive system), the eyes (visual system), and the labyrinth (vestibular system). These areas send their information about equilibrium, or balance, to the brain (cerebellar system) for coordination and perception in the cerebral cortex. The brain obtains its blood supply from the heart and arterial system. A problem in any of these areas, such as arteriosclerosis or impaired vision, can cause a disturbance of balance. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

Assessment

Assessment of hearing and balance involves inspection of the external, middle, and inner ear. Evaluation of gross hearing acuity also is included in every physical examination.

Inspection of the External Ear

Inspection of the external ear is a simple procedure, but it is often overlooked. The external ear is examined by inspection and direct palpation; the auricle and surrounding tissues should be inspected for deformities, lesions, and discharge, as well as size, symmetry, and angle of attachment to the head. Manipulation of the auricle does not normally elicit pain. If this maneuver is painful, acute external otitis is suspected (Cash & Glass, 2014). Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Occasionally, sebaceous cysts and tophi (subcutaneous mineral deposits) are present on the pinna. A flaky scaliness on or behind the auricle usually indicates seborrheic dermatitis and can be present on the scalp and facial structures as well.

Otoscopic Examination

The tympanic membrane is inspected with an otoscope and indirect palpation with a pneumatic otoscope. To examine the external auditory canal and tympanic membrane, the otoscope should be held in the examiner's right hand, in a pencil-hold position, with the examiner's hand braced against the patient's face (see Fig. 41-4). This position prevents the examiner from inserting the otoscope too far into the external canal. Using the opposite hand, the auricle is grasped and gently pulled back to straighten the canal in the adult.

The speculum is slowly inserted into the ear canal, with the examiner's eye held close to the magnifying lens of the otoscope to visualize the canal and tympanic membrane. The largest speculum that the canal can accommodate (usually 5 mm in an adult) is guided gently down into the canal and slightly forward. Because the distal portion of the canal is bony and covered by a sensitive layer of epithelium, only light pressure can be used without causing pain. The external auditory canal is examined for discharge, inflammation, or a foreign body.

The healthy tympanic membrane is pearly gray and is positioned obliquely at the base of the canal. The following landmarks are identified, if visible (see Fig. 41-2): the pars tensa, the umbo, the manubrium of the malleus, and its short process. A slow, circular movement of the speculum allows further visualization of the malleolar folds and periphery. The position and color of the membrane and any unusual markings or deviations from normal are documented. The presence of fluid, air bubbles, blood, or masses in the middle ear also should be noted.

Proper otoscopic examination of the external auditory canal and tympanic membrane requires that the canal be free of large amounts of cerumen. Cerumen is normally present in the external canal, and small amounts should not interfere with otoscopic examination. If the tympanic membrane cannot be visualized because of cerumen, the cerumen may be removed by gently irrigating the external canal with warm water (unless contraindicated). If adherent cerumen is present, a small amount of mineral oil or over-the-counter cerumen softener may be instilled into the ear canal and the patient instructed to

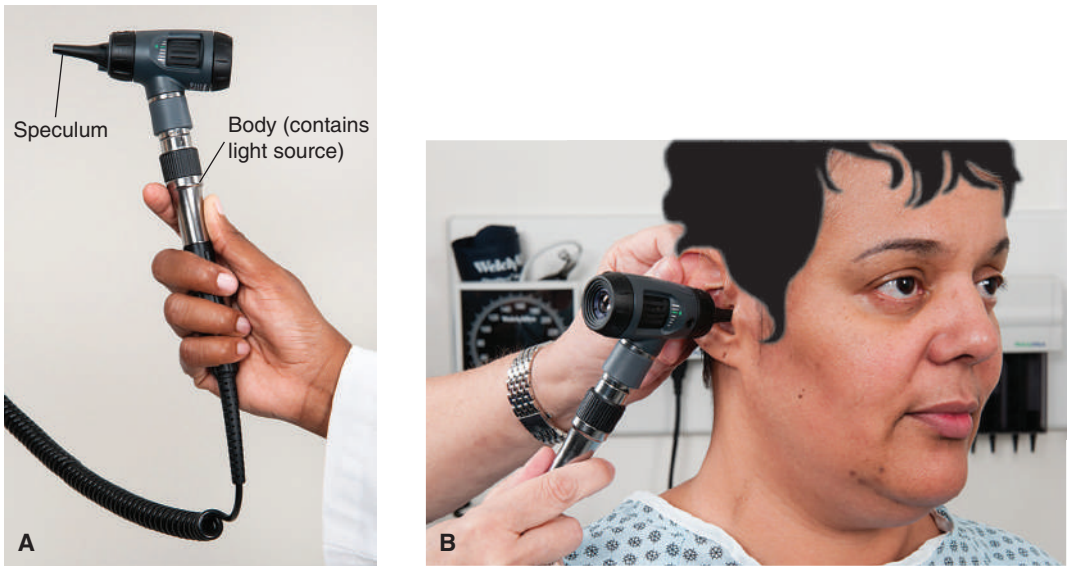

Figure 41-4 • A. The otoscope. **B.** Proper technique for examining the ear. Hold the otoscope in the right or left hand, in a "pencil-hold" position. From Weber, J., & Kelley, J. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Figure 41-5 • A. The Weber test assesses bone conduction of sound. **B.** The Rinne test assesses both air and bone conduction of sound.

TABLE 41-1 Comparison of Weber and Rinne Tests

Hearing Status	Weber	Rinne
Normal hearing	Sound is heard equally in both ears.	Air conduction is audible longer than bone conduction in both ears.
Conductive hearing loss	Sound is heard best in affected ear (hearing loss).	Sound is heard as long or longer in affected ear (hearing loss).
Sensorineural hearing loss	Sound is heard best in normal hearing ear.	Air conduction is audible longer than bone conduction in affected ear.

Adapted from Weber, J., & Kelley, J. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

return for subsequent removal of the cerumen and inspection of the ear. The use of instruments such as a cerumen curette for cerumen removal is reserved for otolaryngologists and nurses with specialized training because of the danger of perforating the tympanic membrane or excoriating the external auditory canal. Cerumen buildup is a common cause of hearing loss and local irritation (Grossman & Porth, 2014).

Evaluation of Gross Auditory Acuity

A general estimate of hearing can be made by assessing the patient's ability to hear a whispered phrase, testing one ear at a time. The Weber and Rinne tests may be used to distinguish conductive loss from sensorineural loss when hearing is impaired (Weber & Kelley, 2014). These tests are part of the usual screening physical examination and are useful if a more specific assessment is needed, if hearing loss is detected, or if confirmation of audiometric results is desired.

Whisper Test

To exclude one ear from the testing, the examiner covers the untested ear with the palm of the hand. The examiner then whispers softly from a distance of 1 or 2 feet from the unoccluded ear and out of the patient's sight. The patient with normal acuity can correctly repeat what was whispered.

Weber Test

The Weber test uses bone conduction to test lateralization of sound. A tuning fork (ideally, 512 Hertz [Hz]), set in motion by grasping it firmly by its stem and tapping it on the examiner's knee or hand, is placed on the patient's head or forehead (see Fig. 41-5A). A person with normal hearing hears the sound equally in both ears or describes the sound as centered in the middle of the head. A person with conductive hearing loss, such as from otosclerosis or otitis media, hears the sound better in the affected ear. A person with sensorineural hearing loss, resulting from damage to the cochlear or vestibulocochlear nerve, hears the sound in the better-hearing ear. The Weber test is useful for detecting unilateral hearing loss (see Table 41-1).

Results of the Weber test are used to determine whether the patient has conductive hearing loss (sounds are heard better in the affected ear) or sensorineural hearing loss (sounds are heard better in the normal ear).

Rinne Test

In the Rinne test (pronounced *rin-ay*), the examiner shifts the stem of a vibrating tuning fork between two positions: 2 inches from the opening of the ear canal (for air conduction) and against the mastoid bone (for bone conduction) (see Fig. 41-5B). As the position changes, the patient is asked to indicate which tone is louder or when the tone is no longer audible.

The Rinne test is useful for distinguishing between conductive and sensorineural hearing loss. A person with normal hearing reports that air-conducted sound is louder than bone-conducted sound. A person with a conductive hearing loss hears bone-conducted sound as long as or longer than air-conducted sound. A person with a sensorineural hearing loss hears air-conducted sound longer than bone-conducted sound.

Diagnostic Evaluation

Many diagnostic procedures are available to measure the auditory and vestibular systems indirectly. These tests are usually performed by a certified audiologist. The nurse educates

the patient about the purpose, what to expect, and any possible side effects related to testing. The nurse notes trends in results because they provide information about disease progression as well as the patient's response to therapy.

Audiometry

In detecting hearing loss, audiometry is the single most important diagnostic instrument. Audiometric testing is of two kinds: pure-tone audiometry, in which the sound stimulus consists of a pure or musical tone (the louder the tone before the patient perceives it, the greater the hearing loss), and speech audiometry, in which the spoken word is used to determine the ability to hear and discriminate sounds and words.

When evaluating hearing, three characteristics are important: frequency, pitch, and intensity. *Frequency* refers to the number of sound waves emanating from a source per second, measured as cycles per second, or Hertz. The normal human ear perceives sounds ranging in frequency from 20 to 20,000 Hz. The frequencies from 500 to 2000 Hz are important in understanding everyday speech and are referred to as the speech range or speech frequencies. *Pitch* is the term used to describe frequency; a tone with 100 Hz is considered of low pitch, and a tone of 10,000 Hz is considered of high pitch.

The unit for measuring loudness (*intensity* of sound) is the decibel (dB), the pressure exerted by sound. Hearing loss is measured in decibels—a logarithmic function of intensity that is not easily converted into a percentage. The critical level of loudness is approximately 30 dB. The shuffling of papers in quiet surroundings is about 15 dB; a low conversation, 40 dB; and a jet plane 100 feet away, about 150 dB. Sound louder than 80 dB is perceived by the human ear to be harsh and can be damaging to the inner ear. Table 41-2 classifies hearing loss based on decibel level. In surgical treatment of patients with hearing loss, the aim is to improve the hearing level to 30 dB or better within the speech frequencies.

With audiometry, the patient wears earphones and signals to the audiologist when a tone is heard. When the tone is applied directly over the external auditory canal, air conduction is measured. When the stimulus is applied to the mastoid bone, bypassing the conductive mechanism (i.e., the ossicles), nerve conduction is tested. For accuracy, testing is performed in a soundproof room. Responses are plotted on a graph known as an audiogram, which differentiates conductive from sensorineural hearing loss.

Tympanogram

A tympanogram, or impedance audiometry, measures middle ear muscle reflex to sound stimulation and compliance of the tympanic membrane by changing the air pressure in a sealed ear canal. Compliance is impaired with middle ear disease.

TABLE 41-2 Severity of Hearing Loss

Loss in Decibels	Interpretation
0–15	Normal hearing
>15–25	Slight hearing loss
>25–40	Mild hearing loss
>40–55	Moderate hearing loss
>55–70	Moderate to severe hearing loss
>70–90	Severe hearing loss
>90	Profound hearing loss

Auditory Brain Stem Response

The auditory brain stem response is a detectable electrical potential from cranial nerve VIII and the ascending auditory pathways of the brain stem in response to sound stimulation. Electrodes are placed on the patient's scalp and on each earlobe (Fischbach & Dunning, 2015). Acoustic stimuli (e.g., clicks) are made in the ear. The resulting electrophysiologic measurements can determine at which decibel level a patient hears and whether there are any impairments along the nerve pathways (e.g., tumor on cranial nerve VIII). Patients are instructed to wash and rinse their hair prior to this study but to avoid applying any other hair product. Auditory brain stem response assessment should be used in conjunction with audiometry for the most accurate results (Bhattacharyya & Meyers, 2015).

Electronystagmography

Electronystagmography is the measurement and graphic recording of the changes in electrical potentials created by eye movements during spontaneous, positional, or calorically evoked nystagmus. It is also used to assess the oculomotor and vestibular systems and their corresponding interaction. It helps to diagnose causes of unilateral hearing loss of unknown origin, vertigo, or tinnitus. Any vestibular suppressants, such as caffeine and alcohol, are withheld for 48 hours before testing. Medications such as tranquilizers, stimulants, or antivertigo agents are withheld for 5 days before the test (Fischbach & Dunning, 2015).

Platform Posturography

Platform posturography is recommended for patients with dizziness and balance disorders (American Academy of Otolaryngology – Head and Neck Surgery, 2014). It can be used to determine if a patient's vertigo is worsening or to evaluate a patient's response to treatment. The integration of visual, vestibular, and proprioceptive cues (i.e., sensory integration) with motor response output and coordination of the lower limbs is tested. The patient stands on a platform, surrounded by a screen, and different conditions such as a moving platform with a moving screen or a stationary platform with a moving screen are presented. The responses from the patient on six different conditions are measured and indicate which of the anatomic systems may be impaired. Preparation for the testing is the same as for electronystagmography.

Sinusoidal Harmonic Acceleration

Sinusoidal harmonic acceleration, or a rotary chair, is used to assess the vestibulo-ocular system by analyzing compensatory eye movements in response to the clockwise and counterclockwise rotation of the chair. Although such testing cannot identify the side of the lesion in unilateral disease, it helps to identify disease (e.g., Ménière disease and tumors of the auditory canal) and evaluate the course of recovery. The same patient preparation is required as that for electronystagmography.

Middle Ear Endoscopy

Using endoscopes with very small diameters and acute angles, the ear can be examined by an endoscopist specializing in otolaryngology. Middle ear endoscopy is performed safely and effectively as an office procedure to evaluate suspected

perilymphatic fistula and new-onset conductive hearing loss, the anatomy of the round window before transtympanic treatment of Ménière disease, and the tympanic cavity before ear surgery to treat chronic middle ear and mastoid infections.

The tympanic membrane is anesthetized topically for about 10 minutes before the procedure. Then, the external auditory canal is irrigated with sterile normal saline solution. With the aid of a microscope, a tympanotomy is created with a laser beam or a myringotomy knife so that the endoscope can be inserted into the middle ear cavity. Video and photo documentation can be accomplished through the scope.

HEARING LOSS

In the United States, hearing impairment has been reported to occur in 2 to 3 of every 1000 births, and approximately one half of the time it is related to genetic factors (U.S. Department of Health and Human Services [HHS], 2016). Genetic syndromes associated with hearing impairment include Waardenburg syndrome, Usher syndrome, Pendred syndrome, and Jervell and Lange-Nielsen syndrome (Antonio, 2016). Chart 41-1 contains more information about hearing disorders that have a genetic cause. There are also acquired causes of hearing loss which may be caused by TORCH infections (TOxoplasmosis, Rubella, Cytomegalovirus, Herpes) during pregnancy as well as trauma or chronic exposure to loud noise (Antonio, 2016). Most hospitals or birthing centers offer universal hearing screenings for newborns after birth and prior to discharge.

All over the world, 432 million adults are suffering from hearing loss. Around 80% people with hearing loss are from low- and middle-income countries (WHO, 2021). Hearing loss occurs in men more often than women. Approximately 2% of adults between the ages of 45 and 54 years have disabling hearing loss. This percentage increases to 8.5% in the 55 to 64 age group, to 25% of adults in the 65 to 74 age group and up to 50% for those over 75 years of age (HHS, 2016). The prevalence of deafness in SouthEast Asian countries ranges from 4.6% to 8.8%. The adult and child-onset deafness prevalence in India was found to be 7.6% and 2% respectively. The preventable deafness attributed by impacted cerumen accounts for 15.9% of the deaf population in India (Varshney, 2016).

Hearing loss is an important health issue, and as people age, hearing screening and treatment are indicated.

Many people are exposed on a daily basis to noise levels that produce high-frequency hearing loss. Occupations such as carpentry, plumbing, and coal mining have the highest risk of noise-induced hearing loss. Wise Ears was developed by the National Institute on Deafness and Other Communication Disorders (NIDCD) and the National Institute for Occupational Safety and Health (NIOSH). It aims to educate the public about noise-induced hearing loss and ways to prevent this hearing loss (NIDCD, 2010).

Conductive hearing loss usually results from an external ear disorder, such as impacted cerumen, or a middle ear disorder, such as otitis media or otosclerosis. In such instances, the efficient transmission of sound by air to the inner ear is interrupted. A sensorineural hearing loss involves damage to the cochlea or vestibulocochlear nerve.

Mixed hearing loss and functional hearing loss also may occur. Patients with mixed hearing loss have conductive loss and sensorineural loss, resulting from dysfunction of air and bone conduction. A functional (or psychogenic) hearing loss is nonorganic and unrelated to detectable structural changes in the hearing mechanisms; it is usually a manifestation of an emotional reaction.

Chart 41-1 GENETICS IN NURSING PRACTICE

Hearing Disorders

Several hearing disorders are associated with genetic abnormalities and have various patterns of inheritance:

Autosomal dominant:
- Branachiootorenal syndrome
- Neurofibromatosis type 2
- Otosclerosis
- Stickler syndrome
- Waardenburg syndrome

Autosomal recessive:
- Connexin 26 gene hearing loss (the majority of cases are recessive; however, there is an autosomal dominant form that occurs less commonly)
- Jervell and Lange-Nielsen syndrome
- Pendred syndrome
- Refsum disease
- Usher syndrome

X-Linked syndromic hearing loss:
- Alport syndrome

Nursing Assessments

Family History Assessment Specific to Hearing Disorders
- Assess for other family members in several generations with hearing loss (autosomal dominant hearing loss).
- Inquire about genetic relatedness (e.g., individuals who are related, such as first cousins, have a higher chance to share the same recessive genes—autosomal recessive hearing loss).
- Inquire about age at onset of hearing loss.

Patient Assessment Specific to Genetic Hearing Disorders
- Assess for:
  - Dizziness
  - Facial numbness or weakness
  - Headaches
  - Tinnitus
- Assess for related genetic conditions, such as vision impairment (e.g., retinitis pigmentosa in Usher syndrome; thyroid disorder in Pendred syndrome).
- Assess for iris, pigment, and hair alterations (white forelock) seen in Waardenburg syndrome.
- Assess for exposure to loud noises (e.g., industrial).
- Assess for presence of rubella, toxoplasmosis, herpes, or cytomegalovirus during pregnancy.
- Determine if patient had taken medications associated with ototoxicity.

Genetics Resources

Hear-It, www.Hear-it.org/Genetic-hearing-loss
Neurofibromatosis Network, www.nfnetwork.org/

Clinical Manifestations

Deafness is the partial or complete loss of the ability to hear. Early manifestations may include tinnitus, increasing inability to hear when in a group, and a need to turn up the volume of the television. Hearing impairment can also trigger changes in attitude, the ability to communicate, the awareness of surroundings, and even the ability to protect oneself, thus affecting a person's quality of life. In a classroom, a student with impaired hearing may be uninterested and inattentive and have failing grades. A person at home may feel isolated because of an inability to hear the clock chime or to hear the telephone. A pedestrian who is hearing impaired may attempt to cross the street and fail to hear an approaching car. People with impaired hearing may miss parts of a conversation. Many people are unaware of their gradual hearing impairment. Often, it is not the person with the hearing loss but the people with whom he or she is communicating who recognizes the impairment first (see Chart 41-2).

For various reasons, some people with hearing loss refuse to seek medical attention or wear a hearing aid. They may feel self-conscious about wearing a hearing aid. Other people, however, may feel comfortable asking those with whom they are trying to communicate to let them know whether difficulties in communication exist. The attitudes and behaviors of patients who need hearing assistance should be taken into account when counseling them. The decision to wear a hearing aid is a personal one that is affected by these attitudes and behaviors.

Chart 41-2 ASSESSING

Hearing Loss

The nurse should be alert to the following:

Speech deterioration: The person who slurs words, drops word endings, or produces flat-sounding speech may not be hearing correctly. The ears guide the voice, both in loudness and in pronunciation.

Fatigue: If a person tires easily when listening to conversation or to a speech, fatigue may be the result of straining to hear. Under these circumstances, the person may become irritable very easily.

Indifference: It is easy for the person who cannot hear what others say to become depressed and disinterested in life in general.

Social withdrawal: Not being able to hear what is going on causes the person who is hearing impaired to withdraw from situations that might prove embarrassing.

Insecurity: Lack of self-confidence and fear of mistakes create a feeling of insecurity in many people who are hearing impaired. No one likes to say the wrong thing or do anything that might appear foolish.

Indecision and procrastination: Loss of self-confidence makes it increasingly difficult for a person who is hearing impaired to make decisions.

Suspiciousness: The person who is hearing impaired—who often hears only part of what is being said—may suspect that others are talking about him or her, or that portions of the conversation are deliberately spoken softly so that he or she will not hear them.

False pride: The person who is hearing impaired wants to conceal the hearing loss and thus often pretends to be hearing when he or she actually is not.

Loneliness and unhappiness: Although everyone wishes for quiet now and then, *enforced* silence can be boring and even somewhat frightening. People with a hearing loss often feel isolated.

Tendency to dominate the conversation: Many people who are hearing impaired tend to dominate the conversation, knowing that as long as it is centered on them and they can control it, they are not so likely to be embarrassed by some mistake.

Prevention

Many environmental factors have an adverse effect on the auditory system and with time result in permanent sensorineural hearing loss. The most common is noise. Noise (unwanted and unavoidable sound) has been identified as one of today's environmental hazards. The volume of noise that surrounds us daily has increased into a potentially dangerous source of physical and psychological damage.

Loud, persistent noise has been found to cause constriction of peripheral blood vessels, increased blood pressure and heart rate (because of increased secretion of adrenalin), and increased gastrointestinal activity. Although research is needed to address the overall effects of noise on the human body, a quiet environment is more conducive to peace of mind. A person who is ill feels more at ease when noise is kept to a minimum.

Numerous factors contribute to hearing loss (see Chart 41-3). *Noise-induced hearing loss* refers to hearing loss that follows a long period of exposure to loud noise (e.g., heavy machinery, engines, artillery, rock-band music). *Acoustic trauma* refers to hearing loss caused by a single exposure to an extremely intense noise, such as an explosion. Usually, noise-induced hearing loss occurs at a high frequency (about 4000 Hz). However, with continued noise exposure, the hearing loss can become more severe and include adjacent frequencies. The minimum noise level known to cause noise-induced hearing loss, regardless of duration, is about 85 to 90 dB.

Noise exposure is inherent in many jobs (e.g., mechanics, printers, pilots, flight attendants, musicians) and in hobbies such as woodworking and hunting. Noise level regulations are based on the amount of noise a person is exposed to, with the maximum legal amount being exposure to noise over an average working day or week of 80 dB, with a peak sound pressure of 135 dB (HHS, 2016). The Occupational Safety and Health Administration (OSHA) requires that workers wear ear protection to prevent noise-induced hearing loss when exposed to noise above the legal limits. Ear protection against noise is the most effective preventive measure available. Hearing loss due to noise is permanent because the hair cells in the organ of Corti are destroyed.

Gerontologic Considerations

With aging, changes occur in the ear that may eventually lead to hearing deficits. Although few changes occur in the external ear, cerumen tends to become harder and drier, posing a greater chance of impaction. In the middle ear, the tympanic membrane may atrophy or become sclerotic. In the inner ear, cells at the base of the cochlea degenerate. A familial predisposition to sensorineural hearing loss is also seen, manifested by inability to hear high-frequency sounds, followed in time by the loss of

Chart 41-3 RISK FACTORS

Hearing Loss

- Family history of sensorineural impairment
- Congenital malformations of the cranial structure (ear)
- Low birth weight (<1500 g)
- Use of ototoxic medications (e.g., gentamycin, loop diuretics)
- Recurrent ear infections
- Bacterial meningitis
- Chronic exposure to loud noises
- Perforation of the tympanic membrane

Chart 41-4 ETHICAL DILEMMA

When Might Someone's Commitment to an Independent Lifestyle Put Himself or Others at Risk?

Case Scenario

You work as a nurse manager in a family practice clinic in the neighborhood where you also live. A 67-year patient tells you that he continues to work full time in a large automotive factory, where he has been employed for the past 40 years. He expresses that he feels incompetent at times and stressed by the noise level. He states, "My boss wants to reassign me from the floor because I can't always hear the alarms when they go off which could cause an accident." He further states, "I think they are just trying to get rid of me because of my age." After reviewing the patient's electronic health record, you find that the patient has a documented history of significant hearing loss. Although he was screened by an audiologist 3 years ago and fitted with hearing aids, he does not wear them.

Discussion

Most adults who have adult onset hearing loss are 65 years of age or older and have been exposed to excessive noise. Hearing loss may put them at risk for injury because they may miss hearing signals that herald changes in the work environment, which could result in injury. Failure to adhere to safety codes and restrictions could also place other employees in the workplace at jeopardy.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have preeminence as you proceed to work with this patient?
- Is it possible to preserve this patient's autonomy? If so, what steps you might take to ensure that the patient's rights to "self-rule" are maintained?
- The employer recommends a change of workplace environment, which is perceived by the patient as ageism. Are there any indicators of paternalism or ageism in this scenario?

Resources

See Chapter 2, Chart 2-6 for ethics resources.

Adapted from Brock, D. W., Park, J. K., & Wendler, D. (2014). Making treatment decisions for oneself: Weighing the value. The Hastings Center Report, 46(3), 22–30.

middle and lower frequencies. The term presbycusis is used to describe this progressive hearing loss (Eliopoulos, 2018).

In addition to age-related changes, other factors can affect hearing in the older adult population, such as lifelong exposure to loud noises. Certain medications, such as aminoglycosides, aspirin, loop diuretics, and platinum-based antineoplastic medications have ototoxic effects when kidney changes result in delayed medication excretion and increased levels of the medications in the blood.

Psychogenic factors, other disease processes (e.g., diabetes), and medications may be partially responsible for sensorineural hearing loss. The Rights of Person with Disability Bill was passed by Government of India in 2016 which ensures no discrimination for people with 21 different disabilities including deafness (Press information Bureau, Govt of India, 2016). Chart 41-4 describes ethical issues surrounding older adults with hearing loss (Brock, Park, & Wendler, 2014).

Even with the best health care, people with hearing loss must learn to adjust to it. Care of older patients includes recognizing emotional reactions related to hearing loss, such as suspicion of others because of an inability to hear adequately; frustration and anger, with repeated statements such as "I didn't hear what you said!"; and feelings of insecurity because of the inability to hear the telephone or alarms.

Depression, isolation, and a decrease in cognitive function can have a negative impact on quality of life in the older adult with hearing loss. Feelings of social isolation, confusion, alterations in daily living activities, and increasing risk of falls have all been associated with hearing loss in older adults (Mener, Betz, Genther, et al., 2013). Hearing loss can also interfere with relationships due to a loss of communication. A hearing screening is usually recommended as part of the preventive health checkup in most of the hospitals that offer preventive services.

Medical Management

If a hearing loss is permanent or untreatable or if the patient elects not to be treated, aural rehabilitation (discussed at the end of the chapter) may be beneficial.

Nursing Management

Early detection of hearing loss is one of the objectives of (*Healthy People 2020,*) and nurses are in a position to assist in meeting this goal (HHS, 2010). Another objective is for people diagnosed with hearing loss or deafness to use rehabilitation services and supplemental devices to improve communication with other people. Resources are available in workplaces and in schools. Questions used to assess for hearing loss may include:

- Have you experienced any hearing loss in the past?
- Are you experiencing any hearing loss now?
- Do your family members think that you are having difficulty hearing and/or experiencing any hearing loss?

These questions should be included in any routine nursing assessment and referrals made for further evaluation as needed.

Nurses who understand the different types of hearing loss are more successful in adopting a communication style to fit the needs and preferences of each patient. Trying to speak in a loud voice to a person who cannot hear high-frequency sounds only makes understanding more difficult. However, strategies such as talking into the less impaired ear and using gestures and facial expressions can help (see Chart 41-5).

A major issue for many people who are deaf or hearing impaired is that they have other health problems that often do not receive attention, in large part because of communication barriers with their health care providers. To meet the health care needs of these patients, providers are legally obligated to make accommodations for a patient's inability to hear. Providing interpreters for those who can communicate through sign language is essential in many situations so that effective communication occurs.

During health care and screening procedures, the provider (e.g., dentist, physician, nurse) must be aware that patients who are deaf or hearing impaired are unable to read lips, see a signer, or read written materials in the dark rooms required during some diagnostic tests. The same situation exists if the provider is wearing a mask or is not in sight (e.g., x-ray studies, magnetic resonance imaging [MRI], colonoscopy).

Chart 41-5

Communicating with People who are Hearing Impaired

For the Person who is Hearing Impaired whose Speech is Difficult to Understand

- Determine how the person prefers to communicate with others. Do not assume that writing, gestures, or other means are the best or preferred technique.
- Consider if the person uses sign language
- Devote full attention to what the person is saying. Look and listen—do not try to attend to another task while listening.
- Engage the speaker in conversation when it is possible for you to anticipate the replies. This enables you to become accustomed to any peculiarities in speech patterns.
- Try to determine the essential context of what is being said; you can often fill in the details from context.
- Do not try to appear as if you understand if you do not.
- If you cannot understand at all or have serious doubt about your ability to understand what is being said, have the person write the message rather than risk misunderstanding. Having the person repeat the message in speech, after you know its content, also aids you in becoming accustomed to the person's pattern of speech.
- Written communication is an excellent resource. Material should be written at a third-grade level so that the majority of people can understand it.

For the Person who is Hearing Impaired who Speech Reads

- When speaking, always face the person as directly as possible.
- Make sure that your face is as clearly visible as possible. Locate yourself so that your face is well lighted; avoid being silhouetted against strong light. Do not obscure the person's view of your mouth in any way; avoid talking with any object held in your mouth.
- Be sure that the patient knows the topic or subject before going ahead with what you plan to say. This enables the person to use contextual clues in speech reading.
- Speak slowly and distinctly, pausing more frequently than you would normally.
- If you question whether some important direction or instruction has been understood, check to be certain that the patient has the full meaning of your message.
- If for any reason your mouth must be covered (as with a mask) and you must direct or instruct the patient, write the message.

Nurses and other health care providers must work with patients who are deaf or hearing impaired and their families to identify practical and effective means of communication. Nurses can serve as catalysts throughout the health care system to ensure that accommodations are made to meet the communication needs of these patients.

CONDITIONS OF THE EXTERNAL EAR

Cerumen Impaction

Cerumen normally accumulates in the external canal in various amounts and colors. Although wax does not usually need to be removed, impaction occasionally occurs, causing otalgia (a sensation of fullness or pain in the ear) with or without a hearing loss. Accumulation of cerumen as a cause of hearing loss is especially significant in older adult patients (Eliopoulos, 2018). Attempts to clear the external auditory canal with matches, hairpins, and other implements are dangerous because trauma to the skin, infection, and damage to the tympanic membrane can occur.

Management

Cerumen can be removed by irrigation, suction, or instrumentation. Unless the patient has a perforated eardrum or an inflamed external ear (i.e., otitis externa), gentle irrigation with warm water usually helps remove impacted cerumen, particularly if it is not tightly packed in the external auditory canal. For successful removal, the water stream must flow behind the obstructing cerumen to move it first laterally and then out of the canal. To prevent injury, the lowest effective pressure should be used. However, if the eardrum behind the impaction is perforated, water can enter the middle ear, producing acute vertigo and infection. If irrigation is unsuccessful, direct visual, mechanical removal can be performed by a trained health care provider on a patient who is cooperative.

Nursing Alert: Warm water (never cold or hot) and gentle (not forceful) irrigation should be used to remove cerumen. Irrigation that is too forceful can cause perforation of the tympanic membrane, and ice water causes vomiting.

Instilling a few drops of warmed glycerin, mineral oil, or half-strength hydrogen peroxide into the ear canal for 30 minutes prior to irrigation can soften cerumen before its removal. Ceruminolytic agents, such as peroxide in glyceryl (Debrox), are available. The use of any softening solution two or three times a day for several days is generally sufficient. If the cerumen cannot be dislodged by these methods, instruments, such as a cerumen curette, aural suction, and a binocular microscope for magnification, can be used.

Foreign Bodies

Some objects are inserted intentionally into the ear by adults who may have been trying to clean the external canal or relieve itching, or by children who introduce peas, beans, pebbles, toys, and beads. Insects may also enter the ear canal. In either case, the effects may range from no symptoms to profound pain and decreased hearing.

Management

Removing a foreign body from the external auditory canal can be quite challenging. The three standard methods for removing foreign bodies are the same as those for removing cerumen: irrigation, suction, and instrumentation. The contraindications for irrigation are also the same. Foreign vegetable bodies and insects tend to swell; thus, irrigation is contraindicated. Usually, an insect can be dislodged by instilling mineral oil, which will kill the insect and allow it to be removed.

Attempts to remove a foreign body from the external canal may be dangerous in unskilled hands. The object may be pushed completely into the bony portion of the canal, lacerating the skin and perforating the tympanic membrane. In rare circumstances,

the foreign body may have to be extracted in the operating room with the patient under general anesthesia.

External Otitis (Otitis Externa)

External otitis (i.e., otitis externa), refers to an inflammation of the external auditory canal. Causes include water in the ear canal (swimmer's ear); trauma to the skin of the ear canal, permitting entrance of organisms into the tissues; and systemic conditions, such as vitamin deficiency and endocrine disorders. Bacterial or fungal infections are most frequently encountered. The most common bacterial pathogens associated with external otitis are *Staphylococcus aureus* and *Pseudomonas* species. The most common fungus isolated in both normal and infected ears is *Aspergillus* (Grossman & Porth, 2014). External otitis is often caused by a dermatosis such as psoriasis, eczema, or seborrheic dermatitis. Even allergic reactions to hair spray, hair dye, and permanent wave lotions can cause dermatitis, which clears when the offending agent is removed.

Clinical Manifestations

Patients usually report pain; discharge from the external auditory canal; aural tenderness (usually not present in middle ear infections); and occasionally fever, cellulitis, and lymphadenopathy. Other symptoms may include pruritus and hearing loss or a feeling of fullness in the ear. On otoscopic examination, the ear canal is erythematous and edematous. Discharge may be yellow or green and foul smelling. In fungal infections, hairlike black spores may be visible.

Medical Management

The principles of therapy are aimed at relieving the discomfort, reducing the swelling of the ear canal, and eradicating the infection. Patients may require analgesic medications for the first 48 to 96 hours. Treatment most often includes antimicrobial or antifungal otic medications given by dropper at room temperature. In bacterial infection, a combination antibiotic and corticosteroid agent may be used to soothe the inflamed tissues (Grossman & Porth, 2014).

Nursing Management

Nurses should instruct patients not to clean the external auditory canal with cotton-tipped applicators and to avoid events that traumatize the external canal, such as scratching the canal with the fingernail or other objects. Trauma may lead to infection of the canal. Patients should also avoid getting the canal wet when swimming or shampooing the hair. A cotton ball or lamb's wool can be covered in a water-insoluble gel such as petrolatum jelly and placed in the ear as a barrier to the canal getting wet. Infection can be prevented by using antiseptic otic preparations after swimming (e.g., Swim-Ear, Ear Dry), unless there is a history of tympanic membrane perforation or a current ear infection (see Chart 41-6).

Malignant External Otitis

A more serious, although rare, external ear infection is malignant external otitis (temporal bone osteomyelitis). This is a progressive, debilitating, and occasionally fatal infection of the external auditory canal, the surrounding tissue, and the base of the skull. *Pseudomonas aeruginosa* is usually the infecting organism in patients with low resistance to infection (e.g., patients with acquired immune deficiency virus). Successful treatment includes administration of antibiotics (usually intravenously [IV]), and aggressive local wound care. Standard parenteral antibiotic treatment includes the combination of an antipseudomonal agent and an aminoglycoside, both of which have potentially serious side effects. Because aminoglycosides are nephrotoxic and ototoxic, serum aminoglycoside levels and kidney and auditory function must be monitored during therapy. Local wound care includes limited débridement of the infected tissue, including bone and cartilage, depending on the extent of the infection.

Chart 41-6 PATIENT EDUCATION

Prevention of Otitis Externa

The nurse instructs the patient to:

- Protect the external canal when swimming, showering, or washing hair. Use ear plugs or place a cotton ball covered in petrolatum jelly in the ear, and wear a swim cap. The external canal may be dried afterward with a hair dryer on low heat.
- Place alcohol drops in the external canal to act as an astringent to help prevent infection after water exposure.
- Prevent trauma to the external canal. Procedures, foreign objects (e.g., bobby pin), scratching, or any other trauma to the canal that breaks the skin integrity may cause infection.
- Be aware that if otitis externa is diagnosed, refrain from any water sport activity for approximately 7–10 days to allow the canal to heal completely. Recurrence is highly likely unless you allow the external canal to heal completely.

Masses of the External Ear

Exostoses are small, hard, bony protrusions found in the lower posterior bony portion of the ear canal; they usually occur bilaterally. The skin covering the exostosis is normal. It is believed that exostoses are caused by an exposure to cold water, as in scuba diving or surfing. The usual treatment, if any, is surgical excision.

Malignant tumors also may occur in the external ear. Most common are basal cell carcinomas on the pinna and squamous cell carcinomas in the ear canal. If untreated, squamous cell carcinoma may spread through the temporal bone, causing facial nerve paralysis and hearing loss. Carcinomas must be treated surgically.

Deformities of the External Ear

External ear or auricle gathers the sound waves and directs it toward the ear drum for better hearing and differentiation of voices. Other than that it also gives an esthetic appeal to the face. Babies born with external ear abnormality experience psychological distress.

Deformities of the external ear are either due to total absence or malformation of the skin and cartilaginous tissue of the auricle. Hearing loss may be present along with external ear deformities.

Following are some of the defects in external ear:

- **Anotia:** Absence of external ear.
- **Microtia:** It is a condition in which ear lobe is underdeveloped and there is absence of skin or cartilage. It may be associated with middle ear abnormality leading to hearing loss (Bhatti et al., 2021). It may also be associated

with vertebral abnormality, oral cleft, facial asymmetry, renal or cardiac defects, microphthalmia, etc.

- **Cryptotia:** It is otherwise known as hidden ear. The superior one-third of the cartilage may be malformed and gets buried underneath the skin.
- **Stahl ear:** There may be presence of additional abnormal vertical cartilage band crossing the scaphoid fossa giving the ear a pointed appearance. It gives an elflike appearance.
- **Constricted ear:** The superior one-third of the cartilage is developed with deformity. There are four different types namely lidded ear, lop ear, canoe ear, and cockle shell ear (Bhatti et al., 2021).
- **Prominent ear:** The external ear may project more than 2 cm from the side of the head with large surface area. Underdeveloped antihelix or overdeveloped conchal bowl or both can lead to prominent ear.
- **Preauricular anomalies:** They are ear anomalies with remnant ectopic cartilage or sinus. The sinus or ectopic cartilage does not have any functional problem. These anomalies have esthetic implication as the cartilage does not regress over time. The sinus may get infected at times which warrants antibiotic treatment or surgical repair.

Management

If recognized early, the abnormalities can be corrected with surgery or repositioning. For some conditions, moulds may be used.

CONDITIONS OF THE MIDDLE EAR

Tympanic Membrane Perforation

Perforation of the tympanic membrane is usually caused by infection or trauma. Sources of trauma include skull fracture, injury from explosion, or a severe blow to the ear. Less frequently, perforation is caused by foreign objects (e.g., cotton-tipped applicators, hairpins, keys) that have been pushed too far into the external auditory canal. In addition to tympanic membrane perforation, injury to the ossicles and even the inner ear may result from this type of trauma. During infection, the tympanic membrane can rupture if the pressure in the middle ear exceeds the atmospheric pressure in the external auditory canal.

Medical Management

Although most tympanic membrane perforations heal spontaneously within weeks after rupture, some may take several months to heal. Some perforations persist because scar tissue grows over the edges of the perforation, preventing extension of the epithelial cells across the margins and final healing. In the case of a head injury or temporal bone fracture, a patient is observed for evidence of cerebrospinal fluid otorrhea or rhinorrhea—a clear, watery drainage from the ear or nose, respectively. While healing, the ear must be protected from water getting into the ear canal.

Surgical Management

Perforations that do not heal on their own may require surgery. The decision to perform a tympanoplasty (see later section in this chapter) is usually based on the need to prevent potential infection from water entering the ear or the desire to improve the patient's hearing. Performed on an outpatient basis, tympanoplasty may involve a variety of surgical techniques. In all techniques, tissue (commonly from the temporalis fascia) is placed across the perforation to allow healing. Surgery is usually successful in closing the perforation permanently and improving hearing.

Acute Otitis Media

Ear infections can occur at any age; however, they are most commonly seen in children. Acute otitis media (AOM) is an acute infection of the middle ear, lasting less than 6 weeks. Pathogens that cause AOM are usually bacterial or viral and enter the middle ear after eustachian tube dysfunction caused by obstruction related to upper respiratory infections, inflammation of surrounding structures (e.g., rhinosinusitis, adenoid hypertrophy), or allergic reactions (e.g., allergic rhinitis) (Grossman & Porth, 2014). Bacteria can enter the eustachian tube from contaminated secretions in the nasopharynx and the middle ear from a tympanic membrane perforation. A purulent exudate is usually present in the middle ear, resulting in a conductive hearing loss.

Clinical Manifestations

Symptoms of otitis media vary with the severity of the infection. The condition, usually unilateral in adults, may be accompanied by otalgia. The pain is relieved after spontaneous perforation or therapeutic incision of the tympanic membrane. Other symptoms may include drainage from the ear, fever, and hearing loss. Table 41-3 differentiates acute otitis externa from AOM. Risk factors for AOM include younger age, chronic upper respiratory infections, medical conditions that predispose the patient to ear infections (e.g., Down syndrome, cystic fibrosis, cleft palate), and chronic exposure to secondhand cigarette smoke.

Medical Management

The outcome of AOM depends on the efficacy of therapy (the prescribed dose of an oral antibiotic and the duration of therapy), the virulence of the bacteria, and the physical status of the patient. With early and appropriate broad-spectrum antibiotic therapy, otitis media may resolve with no serious sequelae. If drainage occurs, an antibiotic otic preparation is usually prescribed. The condition may become subacute (lasting 2 weeks to 3 months),

TABLE 41-3 Clinical Features of Otitis

Feature	Acute Otitis Externa	Acute Otitis Media
Otorrhea	May or may not be present	Present if tympanic membrane perforates; discharge is profuse.
Otalgia	Persistent; may awaken patient at night	Relieved if tympanic membrane ruptures
Aural tenderness	Present on palpation of auricle	Usually absent
Systemic symptoms	Absent	Fever, upper respiratory infection, rhinitis
Edema of external auditory canal	Present	Absent
Tympanic membrane	May appear normal	Erythema, bulging, may be perforated
Hearing loss	Conductive type	Conductive type

with persistent purulent discharge from the ear. Rarely does permanent hearing loss occur. Secondary complications involving the mastoid and other serious intracranial complications, such as meningitis or brain abscess, although rare, can occur.

Surgical Management

A myringotomy (i.e., tympanotomy) is an incision in the tympanic membrane. The tympanic membrane is numbed with a local anesthetic agent such as phenol or by iontophoresis (i.e., in which electrical current flows through a lidocaine and epinephrine solution to numb the ear canal and tympanic membrane). The procedure is painless and takes less than 15 minutes. Under microscopic guidance, an incision is made through the tympanic membrane to relieve pressure and to drain serous or purulent fluid from the middle ear.

Normally, this procedure is unnecessary for treating AOM, but it may be performed if pain persists. Myringotomy also allows the drainage to be analyzed (by culture and sensitivity testing) so that the infecting organism can be identified and appropriate antibiotic therapy prescribed. The incision heals within 24 to 72 hours.

If AOM recurs and there is no contraindication, a ventilating, or pressure-equalizing, tube may be inserted. The ventilating tube, which temporarily takes the place of the eustachian tube in equalizing pressure, is retained for 6 to 18 months. The ventilating tube is then extruded with normal skin migration of the tympanic membrane, with the hole healing in nearly every case. Ventilating tubes are used to treat recurrent episodes of AOM.

Serous Otitis Media

Serous otitis media is one of the important cause of deafness among Indians contributing for 3% of people with deafness (Varshney, 2016). Middle ear effusion, or serous otitis media, involves the presence of fluid, without evidence of active infection, in the middle ear. In theory, this fluid results from a negative pressure in the middle ear caused by eustachian tube obstruction. When this condition occurs in adults, an underlying cause for the eustachian tube dysfunction must be sought. Middle ear effusion is frequently seen in patients after radiation therapy or barotrauma and in patients with eustachian tube dysfunction from a concurrent upper respiratory infection or allergy. Barotrauma results from sudden pressure changes in the middle ear caused by changes in barometric pressure, as in scuba diving or airplane descent. A carcinoma (e.g., nasopharyngeal cancer) obstructing the eustachian tube should be ruled out in adults with persistent unilateral serous otitis media.

Clinical Manifestations

Patients may complain of hearing loss, fullness in the ear or a sensation of congestion, or popping and crackling noises that occur as the eustachian tube attempts to open. The tympanic membrane appears dull on otoscopy, and air bubbles may be visualized in the middle ear. Usually, the audiogram shows a conductive hearing loss.

Management

Serous otitis media need not be treated medically unless infection (i.e., AOM) occurs. If the hearing loss associated with middle ear effusion is significant, a myringotomy can be performed, and a tube may be placed to keep the middle ear ventilated. Corticosteroids in small doses may decrease the edema of the eustachian tube in cases of barotrauma. Decongestants have not proved to be effective. A Valsalva maneuver, which forcibly opens the eustachian tube by increasing nasopharyngeal pressure, may be cautiously performed; this maneuver may cause worsening pain or perforation of the tympanic membrane.

Chronic Otitis Media

Chronic otitis media ranks third as the cause of deafness among Indian population (Varshney, 2016). Chronic otitis media is recurrent AOM that causes irreversible tissue pathology. Chronic infections of the middle ear damage the tympanic membrane, destroy the ossicles, and involve the mastoid but are rare in developed countries.

Clinical Manifestations

Symptoms may be minimal, with varying degrees of hearing loss and a persistent or intermittent, foul-smelling otorrhea. Pain is not usually experienced, except in cases of acute mastoiditis, when the postauricular area is tender and may be erythematous and edematous. Otoscopic examination may show a perforation, and cholesteatoma can be identified as a white mass behind the tympanic membrane or coming through to the external canal from a perforation.

Cholesteatoma is a tumor of the external layer of the eardrum into the middle ear. It is generally caused by a chronic retraction pocket of the tympanic membrane, creating a persistently high negative pressure of the middle ear. The skin forms a sac that fills with degenerated skin and sebaceous materials. The sac can attach to the structures of the middle ear, mastoid, or both.

Chronic otitis media can cause chronic mastoiditis and lead to the formation of cholesteatoma. It can occur in the middle ear, mastoid cavity, or both, often dictating the type of surgery to be performed. If untreated, cholesteatoma will continue to enlarge, possibly causing damage to the facial nerve and horizontal canal and destruction of other surrounding structures.

Cholesteatomas are cystlike lesions of the inner ear (Grossman & Porth, 2014). They usually do not cause pain; however, if treatment or surgery is delayed, they may burst or destroy the mastoid bone. These fast-growing lesions may cause severe sequelae such as hearing loss. Cholesteatomas found in older adult patients generally develop in the external canal.

Cholesteatomas may be asymptomatic, or they may cause hearing loss, facial pain and paralysis, tinnitus, or vertigo. Audiometric tests often show a conductive or mixed hearing loss. Based on presenting symptoms, diagnosis may be made by visual examination or by computed tomography (CT) or MRI scan. Therapy includes treatment of the acute infection and surgical removal of the mass to restore hearing.

Medical Management

Local treatment for chronic otitis media consists of careful suctioning of the ear under otoscopic guidance. Instillation of antibiotic drops or application of antibiotic powder is used to treat purulent discharge. Systemic antibiotic agents are prescribed only in cases of acute infection.

Surgical Management

Surgical procedures, including tympanoplasty, ossiculoplasty, and mastoidectomy, are used if medical treatments are ineffective.

Tympanoplasty

The most common surgical procedure for chronic otitis media is tympanoplasty, or surgical reconstruction of the tympanic membrane. Reconstruction of the ossicles may also be required. The purposes of a tympanoplasty are to reestablish middle ear function, close the perforation, prevent recurrent infection, and improve hearing.

There are five types of tympanoplasties. The simplest surgical procedure, type I (myringoplasty), is designed to close a perforation in the tympanic membrane. The other procedures, types II through V, involve more extensive repair of middle ear structures. The structures and the degree of involvement can differ, but all tympanoplasty procedures include restoring the continuity of the sound conduction mechanism.

Tympanoplasty is performed through the external auditory canal with a transcanal approach or through a postauricular incision. The contents of the middle ear are carefully inspected, and the ossicular chain (malleus and incus unit) is evaluated. Ossicular interruption is most frequent in chronic otitis media, but problems of reconstruction can also occur with malformations of the middle ear and ossicular dislocations due to head injuries. Dramatic improvement in hearing can result from closure of a perforation and reestablishment of the ossicles. Surgery is usually performed in an outpatient facility under moderate sedation or general anesthesia.

Ossiculoplasty

Ossiculoplasty is the surgical reconstruction of the middle ear bones to restore hearing. Prostheses made of materials such as Teflon, stainless steel, and hydroxyapatite are used to reconnect the ossicles, thereby reestablishing the sound conduction mechanism. However, the greater the damage, the lower the success rate for restoring normal hearing.

Mastoidectomy

The objectives of mastoid surgery are to remove the cholesteatoma, gain access to diseased structures, and create a dry (noninfected) and healthy ear. If possible, the ossicles are reconstructed during the initial surgical procedure. Occasionally, extensive disease or damage dictates that this be performed as part of a two-stage operation.

A mastoidectomy is usually performed through a postauricular incision. Infection is eliminated by removing the mastoid air cells. A second mastoidectomy may be necessary to check for recurrent or residual cholesteatoma. The hearing mechanism may be reconstructed at this time. The success rate for correcting this conductive hearing loss is approximately 75%. Surgery is usually performed in an outpatient setting. The patient has a mastoid pressure dressing, which can be removed 24 to 48 hours after surgery. Although infrequently injured, the facial nerve, which runs through the middle ear and mastoid, is at some risk for injury during mastoid surgery. As the patient awakens from anesthesia, any evidence of facial paresis should be reported to the primary provider.

NURSING PROCESS

The Patient Undergoing Mastoid Surgery

Although several otologic surgical procedures are performed under moderate sedation, mastoid surgery is performed using general anesthesia.

Assessment

The health history includes a complete description of the ear disorder, including infection, otalgia, otorrhea, hearing loss, and vertigo. Data are collected about the duration and intensity of the disorder, its causes, and previous treatments. Information is obtained about other health problems and all medications that the patient is taking. Medication allergies and family history of ear disease also should be obtained.

Physical assessment addresses erythema, edema, otorrhea, lesions, and characteristics such as odor and color of discharge. The results of the audiogram are reviewed.

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Anxiety related to surgical procedure, potential loss of hearing, potential taste disturbance, and potential loss of facial movement
- Acute pain related to mastoid surgery
- Risk for infection related to mastoidectomy; placement of grafts, prostheses, and electrodes; and surgical trauma to surrounding tissues and structures
- Impaired verbal communication related to ear disorder, surgery, or packing
- Risk for injury related to impaired balance or vertigo during the immediate postoperative period, dislodgment of the graft or prosthesis, or injury to facial nerve (cranial nerve VII) and chorda tympani nerve
- Deficient knowledge about mastoid disease, surgical procedure, and postoperative care and expectations

Planning and Goals

The major goals of caring for a patient undergoing mastoidectomy include reduction of anxiety; freedom from pain and discomfort; prevention of infection; stable or improved hearing and communication; absence of vertigo and related injury; and increased knowledge regarding the disease, surgical procedure, and postoperative care.

Nursing Interventions

Reducing Anxiety

The nurse reinforces the information discussed by the otologic surgeon with the patient, including anesthesia, the location of the incision (postauricular), and expected surgical results (e.g., hearing, balance, taste, facial movement). The patient also is encouraged to discuss any anxieties and concerns about the surgery.

Relieving Pain

Although most patients complain very little about incisional pain after mastoid surgery, they do have some ear discomfort. Aural fullness or pressure after surgery is caused by residual blood or fluid in the middle ear. The prescribed analgesic medication may be taken for the first 24 hours after surgery and then only as needed.

A wick or external auditory canal packing is used if tympanoplasty was performed at the time of the mastoidectomy. For the next 2 to 3 weeks after surgery, the patient may experience sharp, shooting pains intermittently as the eustachian tube opens and allows air to enter the middle ear. Constant, throbbing pain accompanied by fever may indicate infection and should be reported to the primary provider.

Preventing Infection

Measures are initiated to prevent infection in the operated ear. The external auditory canal wick, or packing, may be impregnated with an antibiotic solution before instillation. Prophylactic antibiotic agents are given as prescribed, and the patient is instructed to prevent water from entering the external auditory canal for 6 weeks. A cotton ball or lamb's wool covered with a water-insoluble substance (e.g., petrolatum jelly) and placed loosely in the ear canal usually prevents water from entering the ear canal and should be used when the patient showers or washes their hair, or in any situations in which water may enter the ear canal. The postauricular incision should be kept dry for the first 2 days. Signs of infection such as an elevated temperature and purulent drainage should be reported. Some serosanguineous drainage from the external auditory canal is normal after surgery.

Improving Hearing and Communication

Hearing in the operated ear may be reduced for several weeks because of edema, accumulation of blood and tissue fluid in the middle ear, and dressings or packing. Measures are initiated to improve hearing and communication, such as reducing environmental noise, facing the patient when speaking, speaking clearly and distinctly without shouting, providing good lighting if the patient relies on speech reading, and using nonverbal clues (e.g., facial expression, pointing, gestures) and other forms of communication. Family members or significant others are instructed about effective ways to communicate with the patient. If the patient uses assistive hearing devices, one can be used in the unaffected ear.

Preventing Injury

Vertigo may occur after mastoid surgery if the semicircular canals or other areas of the inner ear are traumatized. Antiemetic or antivertiginous medications (e.g., antihistamines) can be prescribed if a balance disturbance or vertigo occurs. Safety measures such as assisted ambulation are implemented to prevent falls and injury. The patient is instructed to avoid heavy lifting, straining, exertion, and nose blowing for 2 to 3 weeks after surgery to prevent dislodging the tympanic membrane graft or ossicular prosthesis.

Facial nerve injury is a potential, although rare, complication of mastoid surgery. The patient is instructed to report immediately any evidence of facial nerve (cranial nerve VII) weakness, such as drooping of the mouth on the operated side, slurred speech, decreased sensation, and difficulty swallowing. A more frequent occurrence is a temporary disturbance in the chorda tympani nerve, which is a small branch of the facial nerve that runs through the middle ear. Patients experience a taste disturbance and dry mouth on the side of surgery for several months until the nerve regenerates.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Patients require education about medication therapy, such as analgesic and antivertiginous agents (e.g., antihistamines) prescribed for balance disturbance. Education includes information about the expected effects and potential side effects of the medication. Patients also need instruction about any activity restrictions. Possible complications such as infection, facial nerve weakness, or taste disturbances, including the signs and symptoms to report immediately, are included (see Chart 41-7).

Continuing and Transitional Care. Some patients, particularly older adult patients, who have had mastoid surgery may require the services of a home, community-based, or transitional care nurse for a few days after returning home. However, most people find that assistance from a family member or a friend is sufficient. The caregiver and patient are cautioned that the patient may experience some vertigo and will therefore require help with ambulation to avoid falling. Any symptoms of complications are to be reported promptly to the primary provider. The importance of scheduling and keeping follow-up appointments is also stressed.

Chart 41-7 PATIENT EDUCATION

Self-Care After Middle Ear or Mastoid Surgery

Postoperative instructions for patients who have had middle ear and mastoid surgery may vary among otolaryngologists. The nurse instructs the patient in the following general guidelines:

- Take antibiotics and other medications as prescribed.
- Avoid nose blowing for 2–3 weeks after surgery.
- Sneeze and cough with the mouth open for a few weeks after surgery.
- Avoid heavy lifting (>4.5 kg), straining, and bending over for a few weeks after surgery.
- Be aware that popping and crackling sensations in the operative ear are normal for approximately 3–5 weeks after surgery.
- Note that temporary hearing loss is normal in the operative ear due to fluid, blood, or packing in the ear.
- Report excessive or purulent ear drainage to the physician.
- Avoid getting water in the operative ear for 2 weeks after surgery. You may shampoo the hair 2–3 days postoperatively if the ear is protected from water by saturating a cotton ball with petrolatum jelly (or some other water-insoluble substance) and loosely placing it in the ear. If the postauricular suture line becomes wet, pat (not rub) the area and cover it with a thin layer of antibiotic ointment.

Evaluation

Expected patient outcomes may include:

1. Demonstrates reduced anxiety about surgical procedure
   a. Verbalizes and exhibits less stress, tension, and irritability
   b. Verbalizes acceptance of the results of surgery and adjustment to possible hearing impairment
2. Remains free of discomfort or pain
   a. Exhibits no facial grimacing, moaning, or crying, and reports absence of pain
   b. Uses analgesic agents appropriately
3. Demonstrates no signs or symptoms of infection
   a. Has normal vital signs, including temperature
   b. Demonstrates absence of purulent drainage from the external auditory canal
   c. Describes method for preventing water from contaminating packing
4. Exhibits signs that communication and hearing have stabilized or improved
   a. Describes surgical goal for hearing and judges whether the goal has been met
   b. Verbalizes that hearing has improved
5. Remains free of injury and trauma
   a. Reports absence of vertigo or balance disturbance
   b. Experiences no injury or fall
   c. Avoids activities that can cause dislodgement of graft or prosthesis
   d. Reports no taste disturbance, mouth dryness, or facial weakness

6. Verbalizes the reasons for and methods of care and treatment
   a. Discusses the discharge plan formulated with the nurse with regard to rest periods, medication, and activities permitted and restricted
   b. Lists symptoms that should be reported to the primary provider
   c. Keeps follow-up appointments

Otosclerosis

Otosclerosis involves the stapes and is thought to result from the formation of new, abnormal spongy bone, especially around the oval window, with resulting fixation of the stapes (Grossman & Porth, 2014). The efficient transmission of sound is prevented because the stapes cannot vibrate and carry the sound as conducted from the malleus and incus to the inner ear. Otosclerosis is more common in women, is a familial condition, and can progress to complete deafness (Eliopoulos, 2018); (Grossman & Porth, 2014).

Clinical Manifestations

Otosclerosis may involve one or both ears and manifests as a progressive conductive or mixed hearing loss. The patient may or may not complain of tinnitus. Otoscopic examination usually reveals a normal tympanic membrane. Bone conduction is better than air conduction on Rinne testing. The audiogram confirms conductive hearing loss or mixed loss, especially in the low frequencies.

Medical Management

The management of otosclerosis can be surgical or medical. Amplification with a hearing aid may help (Grossman & Porth, 2014).

Surgical Management

One of two surgical procedures may be performed: the stapedectomy or the stapedotomy. A stapedectomy involves removing the stapes superstructure and part of the footplate and inserting a tissue graft and a suitable prosthesis (see Fig. 41-6). In a stapedotomy, the surgeon drills a small hole into the stapes, instead of removing it, to hold a prosthesis. In both procedures, the prosthesis bridges the gap between the incus and the inner ear, providing better sound conduction. The majority of patients experience resolution of conductive hearing loss following stapes surgery. The use of sodium fluoride in the postoperative period increases the success rate and hearing ability postoperatively (Grossman & Porth, 2014). Balance disturbance or true vertigo may occur during the postoperative period for several days. Long-term balance disorders are rare.

Middle Ear Masses

Other than cholesteatoma, masses in the middle ear are rare. Glomus tympanicum is a tumor that arises from (in the temporal bone of the skull) and remains limited to the middle ear. On otoscopy, a red blemish on or behind the tympanic membrane is seen. Glomus jugulare tumors are rarely malignant; however,

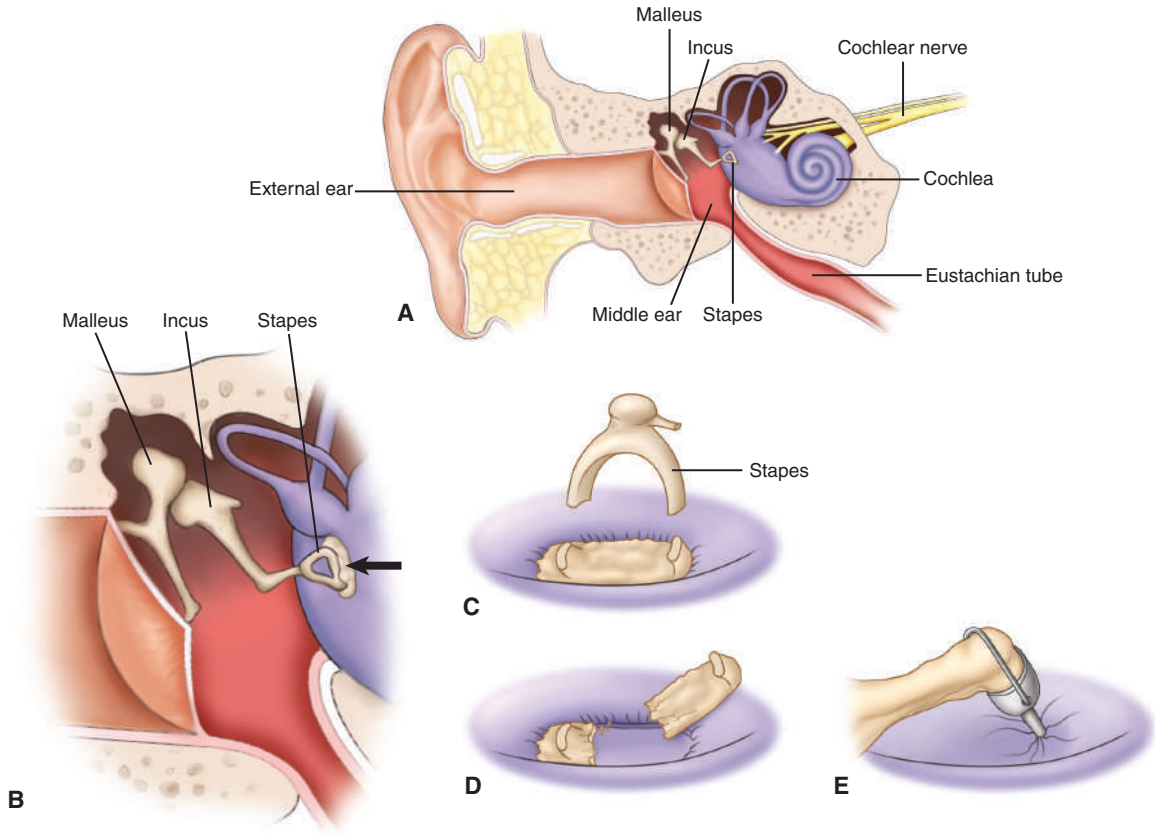

Figure 41-6 • Stapedectomy for otosclerosis. **A**. Normal anatomy. **B**. *Arrow* points to sclerotic process at the foot of the stapes. **C**. Stapes broken away surgically from its diseased base. The hole in the footplate provides an area where an instrument can grasp the plate. **D**. The footplate is removed from its base. Some otosclerotic tissue may remain, and tissue is placed over it. **E**. Robinson stainless steel prosthesis in position.

because of their location, treatment may be necessary to relieve symptoms. The treatment is surgical excision, except in patients who are poor surgical candidates, in whom radiation therapy is used.

A facial nerve neuroma is a tumor on cranial nerve VII. These types of tumors are usually not visible on otoscopic examination but are suspected when a patient presents with a facial nerve paresis. X-ray evaluation is used to identify the site of the tumor along the facial nerve. The treatment is surgical removal.

CONDITIONS OF THE INNER EAR

Disorders of balance are common (NIDCD, 2015a), and dizziness may increase the risk of falls. The term dizziness is used frequently by patients and health care providers to describe any altered sensation of orientation in space and is more commonly referred to as lightheadedness (Weber & Kelley, 2014). Vertigo is the misperception or illusion of motion of the person or the surroundings. Most patients with vertigo describe a spinning sensation or say they feel as though objects are moving around them. Ataxia is a failure of muscular coordination and may be present in patients with vestibular disease. Syncope, fainting, and loss of consciousness are not forms of vertigo and usually indicate disease in the cardiovascular system.

Nystagmus is an involuntary rhythmic movement of the eyes. Nystagmus occurs normally when a person watches a rapidly moving object (e.g., through the side window of a moving car or train). However, pathologically, it is an ocular disorder associated with vestibular dysfunction. Nystagmus can be horizontal, vertical, or rotary and can be caused by a disorder in the central or peripheral nervous system.

Motion Sickness

Motion sickness is a disturbance of equilibrium caused by constant motion. For example, it can occur aboard a ship, while riding on a merry-go-round or swing, or in a car (Brainard & Gresham, 2014).

Clinical Manifestations

The syndrome manifests itself in sweating, pallor, nausea, and vomiting caused by vestibular overstimulation. These manifestations may persist for several hours after the stimulation stops.

Management

Over-the-counter antihistamines such as dimenhydrinate (Dramamine) or meclizine (Antivert) may provide some relief of nausea and vomiting by blocking the conduction of the vestibular pathway of the inner ear. Anticholinergic medications, such as scopolamine patches (Transderm Scop), may also be effective because they antagonize the histamine response. These must be applied several hours before exposure to motion and replaced every 3 days (Brainard & Gresham, 2014). Side effects such as dry mouth and drowsiness may occur. Potentially hazardous activities such as driving a car or operating heavy machinery should be avoided if drowsiness occurs.

Ménière Disease

Ménière disease is an abnormality in inner ear fluid balance caused by a malabsorption in the endolymphatic sac or a blockage in the endolymphatic duct (NIDCD, 2015b). Endolymphatic hydrops (dilation of the endolymphatic space) develops, and either increased pressure in the system or rupture of the inner ear membrane occurs, producing symptoms of Ménière disease (Hansson & Brattmo, 2013).

Ménière disease affects 10 to 12 of 1000 people in the United States. It is estimated that there are 615,000 cases in the United States, with approximately 45,500 new cases diagnosed annually (NIDCD, 2015b). More than 500,000 people are affected by Meniere's disease in India (Business online india.com, 2016).

More common in adults, onset is generally seen when adults reach their 40s, with symptoms usually beginning between the ages of 20 and 60 years. Ménière disease appears to be equally common in men and women, and is usually bilateral (Grossman & Porth, 2014).

Clinical Manifestations

Ménière disease is characterized by a triad of symptoms: episodic vertigo, tinnitus (unwanted noises in the head or ear), and fluctuating sensorineural hearing loss. It may also include a feeling of pressure or fullness in the ear and incapacitating vertigo, often accompanied by nausea and vomiting (Hansson & Brattmo, 2013); (NIDCD, 2015b). These symptoms range in severity from a minor nuisance to extreme disability, especially if the attacks of vertigo are severe. At the onset of the disease, usually only one or two of the symptoms are manifested.

Some characterize the disease into two subsets: cochlear and vestibular. Cochlear Ménière disease is recognized as a fluctuating, progressive sensorineural hearing loss associated with tinnitus and aural pressure in the absence of vestibular symptoms or findings. Vestibular Ménière disease is characterized as the occurrence of episodic vertigo associated with aural pressure but no cochlear symptoms. Patients may experience either cochlear or vestibular disease symptoms; however, eventually all of these symptoms develop.

Assessment and Diagnostic Findings

Vertigo is usually the most troublesome complaint related to Ménière disease. A careful history is taken to determine the frequency, duration, severity, and character of the vertigo attacks. Vertigo may last minutes to hours, possibly accompanied by nausea or vomiting. Diaphoresis and a persistent feeling of imbalance or disequilibrium may awaken patients at night. Some patients report that these feelings last for days. However, they usually feel well between attacks. Hearing loss may fluctuate, with tinnitus and aural pressure waxing and waning with changes in hearing. These feelings may occur during or before attacks, or they may be constant.

Physical examination findings are usually normal, with the exception of those of cranial nerve VIII. Sounds from a tuning fork (Weber test) may lateralize to the ear opposite the hearing loss, the one affected with Ménière disease. An audiogram typically reveals a sensorineural hearing loss in the affected ear. This can be in the form of a "Pike's Peak" pattern, which looks like a hill or mountain. A sensorineural loss in the low frequencies occurs as the disease progresses. The electronystagmogram may be normal or may show reduced vestibular response.

Medical Management

Most patients with Ménière disease can be successfully treated with diet and medication. Many patients can control their

Chart 41-8 PATIENT EDUCATION

Dietary Guidelines for Patients with Ménière Disease

The nurse instructs the patient to:

- Limit foods high in salt or sugar. Be aware of foods with hidden salts and sugars.
- Eat meals and snacks at regular intervals to stay hydrated. Missing meals or snacks may alter the fluid level in the inner ear.
- Eat fresh fruits, vegetables, and whole grains. Limit the amount of canned, frozen, or processed foods with high sodium content.
- Drink plenty of fluids daily. Water, milk, and low-sugar fruit juices are recommended. Limit intake of coffee, tea, and soft drinks. Avoid caffeine because of its diuretic effect.
- Limit alcohol intake. Alcohol may change the volume and concentration of the inner ear fluid and may worsen symptoms.
- Avoid monosodium glutamate (MSG), which may increase symptoms.
- Pay attention to the intake of foods containing potassium (e.g., bananas, tomatoes, oranges) if taking a diuretic that causes potassium loss.
- Avoid aspirin and aspirin-containing medications. Aspirin may increase tinnitus and dizziness.

Adapted from National Institute on Deafness and Other Communication Disorders (NIDCD). (2015b). Ménière's disease. Retrieved on 6/12/2012 at: www.nidcd.nih.gov//health/balance/meniere.html

symptoms by adhering to a low-sodium (1000 to 1500 mg/day or less) diet. Chart 41-8 describes dietary guidelines that may be useful in Ménière disease. The amount of sodium is one of many factors that regulate the balance of fluid within the body. Sodium and fluid retention disrupts the delicate balance between endolymph and perilymph in the inner ear. Psychological evaluation and cognitive therapy may be indicated if a patient is anxious, uncertain, fearful, or depressed (NIDCD, 2015b).

Pharmacologic Therapy

Pharmacologic therapy for Ménière disease consists of antihistamines, such as meclizine, which shortens the attack (NIDCD, 2015b). Tranquilizers such as diazepam (Valium) may be used in acute instances to help control vertigo. Antiemetic agents such as promethazine (Phenergan) suppositories help control the nausea and vomiting and the vertigo because of their antihistamine effect. Diuretic therapy (e.g., hydrochlorothiazide [Dyazide], triamterene, spironolactone) may relieve symptoms by lowering the pressure in the endolymphatic system (Grossman & Porth, 2014). Intratympanic injection of gentamicin (Garamycin) is used to cause ablation of the vestibular hair cells; however, the risk of significant hearing loss is high (NIDCD, 2015b).

Surgical Management

Although most patients respond well to conservative therapy, some continue to have disabling attacks of vertigo. If these attacks reduce their quality of life, patients may elect to undergo surgery for relief. Surgical procedures include endolymphatic sac procedures and vestibular nerve section (NIDCD, 2015b). However, hearing loss, tinnitus, and aural fullness may continue, because the surgical treatment of Ménière disease is aimed at eliminating the attacks of vertigo.

Endolymphatic Sac Decompression

Endolymphatic sac decompression, or shunting, theoretically equalizes the pressure in the endolymphatic space. A shunt or drain is inserted in the endolymphatic sac through a postauricular incision. This procedure is favored by many otolaryngologists as a first-line surgical approach to treat the vertigo of Ménière disease because it is relatively simple and safe and can be performed on an outpatient basis.

Vestibular Nerve Sectioning

Vestibular nerve sectioning provides the greatest success rate (approximately 98%) in eliminating the attacks of vertigo. It can be performed by a translabyrinthine approach (i.e., through the hearing mechanism) or in a manner that can conserve hearing (i.e., suboccipital or middle cranial fossa), depending on the degree of hearing loss. Most patients with incapacitating Ménière disease have little or no effective hearing. Cutting the nerve prevents the brain from receiving input from the semicircular canals. This procedure may require a brief hospital stay. A plan of nursing care for the patient with vertigo is presented in Chart 41-9.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo is a brief period of incapacitating vertigo that occurs when the position of the patient's head is changed with respect to gravity, typically by placing the head back with the affected ear turned down (Hansson & Brattmo, 2013); (NIDCD, 2015b). The onset is sudden and followed by a predisposition for positional vertigo, usually for hours to weeks but occasionally for months or years.

Benign paroxysmal positional vertigo is thought to be due to the disruption of debris within the semicircular canal. This debris is formed from small crystals of calcium carbonate from the inner ear structure (the utricle). This is frequently stimulated by head trauma, infection, or other events. In severe cases, vertigo may easily be induced by any head movement. The vertigo is usually accompanied by nausea and vomiting; however, hearing impairment does not generally occur.

Bed rest is recommended for patients with acute symptoms. Repositioning techniques can be used to treat vertigo. The canalith repositioning procedure, also known as the Epley maneuver, is commonly used (Hansson & Brattmo, 2013). This noninvasive procedure, which involves quick movements of the body, rearranges the debris in the canal. The procedure is performed by placing the patient in a sitting position, turning the head to a 45-degree angle on the affected side, and then quickly moving the patient to the supine position. The procedure is safe, inexpensive, and easy to perform.

Patients with acute vertigo may be treated with meclizine for 1 to 2 weeks. After this time, the meclizine is stopped and the patient is reassessed. Patients who continue to have severe positional vertigo may be premedicated with prochlorperazine (Compazine) 1 hour before the canalith repositioning procedure is performed.

Vestibular rehabilitation can be used in the management of vestibular disorders. This strategy promotes active use of the vestibular system through an interdisciplinary team approach, including medical and nursing care, stress management, biofeedback, vocational rehabilitation, and physical therapy. A physical therapist prescribes balance exercises that help the brain compensate for the impairment to the balance system.

Tinnitus

Tinnitus is a symptom of an underlying disorder of the ear that is associated with hearing loss. A decade long epidemiological study done among South Indians showed a prevalence of 29.3%

Chart 41-9 PLAN OF NURSING CARE

Care of the Patient with Vertigo

Nursing Diagnosis: Risk for injury related to altered mobility because of gait disturbance and vertigo
Goal: Remains free of any injuries associated with imbalance and/or falls

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for vertigo, including history, onset, description of attacks, duration, frequency, and any associated ear symptoms (hearing loss, tinnitus, aural fullness).	1. Health history provides basis for interventions.	• Experiences no falls due to balance disturbance • Fear and anxiety are reduced • Performs exercises as prescribed • Takes prescribed medications appropriately • Assumes safe position when vertigo is present • Keeps head still when vertigo is present • Identifies a characteristic fullness or sense of pressure in the ear as occurring before an attack occurs • Reports measures that help reduce vertigo
2. Assess extent of disability in relation to activities of daily living.	2. Extent of disability indicates risk of falling.	
3. Instruct or reinforce vestibular/balance therapy as prescribed.	3. Exercises hasten labyrinthine compensation, which may decrease vertigo and gait disturbance.	
4. Administer, or educate about administration of, antivertiginous medications and/or vestibular sedation medication; instruct patient about side effects.	4. Alleviates acute symptoms of vertigo.	
5. Encourage patient to sit down and restrict activity when dizzy.	5. Decreases possibility of falling and injury.	
6. Place pillow on each side of head to restrict movement.	6. Movement aggravates vertigo.	
7. Assist patient in identifying aura that suggests an impending attack.	7. Recognition of aura may trigger the need to take medication before an attack occurs, thereby minimizing the severity of effects.	
8. Recommend that the patient keep eyes open and stare straight ahead when lying down and experiencing vertigo.	8. Sensation of vertigo decreases and motion decelerates if eyes are kept in a fixed position.	

Nursing Diagnosis: Risk-prone health behavior related to disability requiring change in lifestyle due to unpredictability of vertigo
Goal: Modifies lifestyle to decrease disability and exert maximum control and independence within limits posed by chronic vertigo

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage patient to identify personal strengths and roles that can still be fulfilled.	1. Maximizes sense of regaining control and independence.	• Exerts maximum control of environment and independence within limits imposed by vertigo • Is informed about condition • Family and significant others are included in rehabilitation process • Uses strengths and potentials to engage in the most independent and constructive lifestyle
2. Provide information about vertigo and what to expect.	2. Reduces fear and anxiety.	
3. Include family and significant others in rehabilitative process.	3. Perceived beliefs of significant others are important for patient's adherence to medical regimen.	
4. Encourage patient to maintain sense of control by making decisions and assuming more responsibility for care.	4. Reinforces positive psychological and social outcomes.	

Nursing Diagnosis: Risk for deficient fluid volume related to increased fluid output, altered intake, and medications
Goal: Maintains normal fluid and electrolyte balance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess, or have patient assess, intake and output (including emesis, liquid stools, urine, and diaphoresis). Monitor laboratory values of electrolytes.	1. Accurate records provide basis for fluid replacement.	• Laboratory values within normal limits • Alert and oriented; vital signs within normal limits, skin turgor normal; electrolytes normal • Mucous membranes are moist • Vomiting has stopped; usual oral intake is resumed
2. Assess indicators of dehydration, including blood pressure (orthostasis), pulse, skin turgor, mucous membranes, and level of consciousness.	2. Prompt recognition of dehydration allows early intervention.	
3. Encourage oral fluids as tolerated; discourage beverages containing caffeine (a vestibular stimulant).	3. Oral replacement is begun as soon as possible to replace losses.	

(Continued)

(Continued)

4. Administer, or educate about administration of, antiemetic medications as prescribed and needed. Educate patient about side effects.	4. Antiemetic medications reduce nausea and vomiting, reducing fluid losses and improving oral intake.

Nursing Diagnosis: Anxiety related to threat of, or change in, health status and disability effects of vertigo
Goal: Experiences less or no anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of anxiety. Help patient identify coping skills used successfully in the past.	1. Guides therapeutic interventions and participation in self-care. Past coping skills can relieve anxiety.	• Fear and anxiety about attacks of vertigo reduced or eliminated • Acquires knowledge and skills to deal with vertigo • Feels less tension, apprehension, and uncertainty • Uses stress management techniques when needed • Avoids upsetting encounters • Repeats instructions given and verbalizes understanding of treatments
2. Provide information about vertigo and its treatment.	2. Increased knowledge helps to decrease anxiety.	
3. Encourage patient to discuss anxieties and explore concerns about vertigo attacks.	3. Promotes awareness and understanding of relationship between anxiety level and behavior.	
4. Educate patient about stress management techniques or make appropriate referral.	4. Improved stress management can reduce the frequency and severity of some vertiginous attacks.	
5. Provide comfort measures, and avoid stress-producing activities.	5. Stressful situations may exacerbate symptoms of the condition.	
6. Instruct patient in aspects of treatment regimen.	6. Patient knowledge helps to decrease anxiety.	

Nursing Diagnosis: Risk for trauma related to impaired balance
Goal: Reduces the risk of trauma by adapting the home environment and by using assistive devices as necessary

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for balance disturbance and/or vertigo by taking history and by examination for nystagmus, positive Romberg, and inability to perform tandem Romberg.	1. Peripheral vestibular disorders cause these signs and symptoms.	• Has adapted home environment or uses rehabilitative devices to reduce risk of falling • Ambulates with needed assistance • Visual and proprioceptive risks identified • Activity level increased • Home environment free of hazards
2. Assist with ambulation when indicated.	2. Abnormal gait can predispose patient to unsteadiness and falls.	
3. Assess for visual acuity and proprioceptive deficits.	3. Balance depends on visual, vestibular, and proprioceptive systems.	
4. Encourage increased activity level with or without use of assistive devices.	4. Increased activity may help retrain balance system.	
5. Help identify hazards in home environment.	5. Adaptation of home environment can reduce risk of falls during rehabilitative process.	

Nursing Diagnosis: Self-care deficit: feeding, bathing/hygiene, dressing/grooming, toileting, related to labyrinth dysfunction and episodes of vertigo
Goal: Able to care for self

Nursing Interventions	Rationale	Expected Outcomes
1. Administer, or educate about administration of, antiemetic and other prescribed medications to relieve nausea and vomiting associated with vertigo.	1. Antiemetic and sedative-type medications depress stimuli in the cerebellum.	• Carries out necessary functions during symptom-free periods and takes medications to relieve nausea, vomiting, or vertigo • Carries out daily activities • Accepts dietary plan and reports its effectiveness • Drinks fluids in sufficient amounts
2. Encourage patient to perform self-care when free of vertigo.	2. Spacing activities is important because episodes of vertigo vary in occurrence.	
3. Review diet with patient and caregivers. Offer fluids as necessary.	3. Sodium restriction helps improve an inner ear fluid imbalance in some patients, thereby decreasing vertigo. Fluids help prevent dehydration.	

(Continued)

(Continued)

Nursing Diagnosis: Powerlessness related to illness regimen and being helpless in certain situations due to vertigo/balance disturbance
Goal: Experiences increased sense of control over life and activities despite vertigo/balance disturbance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's needs, values, attitudes, and readiness to initiate activities.	1. Involving patient in planning activities and care enhances potential for mastery.	• Does not restrict activities unnecessarily due to vertigo • Verbalizes positive feelings about own ability to achieve a sense of power and control • Identifies previous successful coping behaviors
2. Provide opportunities for patient to express feelings about self and illness.	2. Expressing feelings increases understanding of individual coping styles and defense mechanisms.	
3. Help patient identify previous coping behaviors that were successful.	3. Awareness increases understanding of stressors that trigger feeling of powerlessness. Awareness of past successes enhances self-confidence.	

Chart 41-10

Selected Ototoxic Substances

- **Aminoglycoside antibiotic agents**: amikacin, gentamicin, kanamycin, netilmicin, neomycin, streptomycin, tobramycin
- **Anti-inflammatory agents**: salicylates (aspirin), indomethacin
- **Antimalarial agents**: quinine, chloroquine
- **Chemicals**: alcohol, arsenic
- **Chemotherapeutic (antineoplastic) agents**: cisplatin, nitrogen mustard, carboplatin
- **Loop diuretic agents**: ethacrynic acid, furosemide, acetazolamide
- **Metals:** gold, mercury, lead
- **Other antibiotic agents:** erythromycin, minocycline, polymyxin B, vancomycin

Adapted from Mudd, P. (2016). Ototoxicity. Medscape. Retrieved on 9/12/2016 at: emedicine.medscape.com/article/857679-overview

tinnitus (Manchea, Madhavi, Meganandha. et al., 2016). The severity of tinnitus may range from mild to severe. Patients describe tinnitus as a roaring, buzzing, or hissing sound in one or both ears. Numerous factors may contribute to the development of tinnitus, including several ototoxic substances (see Chart 41-10). Underlying disorders that contribute to tinnitus may include cardiovascular disease, thyroid disease, hyperlipidemia, vitamin B_{12} deficiency, psychological disorders (e.g., depression, anxiety), fibromyalgia, otologic disorders (Ménière disease, acoustic neuroma), and neurologic disorders (head injury, multiple sclerosis).

A physical examination should be performed to determine the cause of tinnitus. Diagnostic testing determines if hearing loss is present. An audiograph speech discrimination test or a tympanogram may be used to help determine the cause. Some forms of tinnitus are irreversible; therefore, patients may need education and counseling about ways of adjusting to their treatment and dealing with tinnitus in the future.

Labyrinthitis

Labyrinthitis, an inflammation of the labyrinth of the inner ear, can be bacterial or viral in origin. Bacterial labyrinthitis is rare because of antibiotic therapy, but it sometimes occurs as a complication of otitis media. The infection can spread to the inner ear by penetrating the membranes of the oval or round windows. Viral labyrinthitis is a common diagnosis, but little is known about this disorder, which affects hearing and balance. The most common viral causes are mumps, rubella, rubeola, and influenza. Viral illnesses of the upper respiratory tract and herpetiform disorders of the facial and acoustic nerves (i.e., Ramsay Hunt syndrome) also cause labyrinthitis.

Clinical Manifestations

Labyrinthitis is characterized by a sudden onset of incapacitating vertigo, usually with nausea and vomiting, various degrees of hearing loss, and possibly tinnitus. The first episode is usually the worst; subsequent attacks, which usually occur over a period of several weeks to months, are less severe.

Management

Treatment of bacterial labyrinthitis includes IV antibiotic therapy, fluid replacement, and administration of an antihistamine (e.g., meclizine) and antiemetic medications. Treatment of viral labyrinthitis is based on the patient's symptoms.

Ototoxicity

A variety of medications may have adverse effects on the cochlea, vestibular apparatus, or cranial nerve VIII. All but a few, such as aspirin and quinine, cause irreversible hearing loss. Aspirin toxicity can produce bilateral tinnitus. IV medications, especially the aminoglycosides, are a common cause of ototoxicity, because they destroy the hair cells in the organ of Corti (see Chart 41-10). Antineoplastic agents also cause hair cell death in the cochlea, which can lead to hearing loss (Mudd, 2016). These medications can be found in the body several months later; side effects are dose dependent, with higher doses causing increased ototoxicity. Therefore, hearing loss may occur at any time, even several months after the last dose of the medication was given.

To prevent loss of hearing or balance, patients receiving potentially ototoxic medications should be counseled about their side effects (Lewis, McMillan, Hutter, et al., 2014) (see Chart 41-11). These medications should be used with caution in patients who are at high risk for complications, such as children, older adults, patients who are pregnant, patients with kidney or liver problems, and patients with current hearing disorders. Blood levels of the medications should be monitored, and patients receiving long-term IV antibiotics should be monitored with an audiogram twice each week during therapy.

Chart 41-11 NURSING RESEARCH PROFILE

Does Interferon Beta-1a Contribute to Hearing Loss in Patients with Multiple Sclerosis (MS)?

Lewis, M. S., McMillan, G. P., Hutter, M., et al. (2014). Does Interferon Beta-1a impact pure-tone hearing sensitivity among individuals with multiple sclerosis? Journal of Neuroscience Nursing, 46(6), 352–359.

Purpose

Previous studies reported that interferon medications, commonly used to treat multiple sclerosis (MS), might contribute to hearing loss. The purpose of this study was to assess participants with MS taking intramuscular interferon beta-1a and who have significantly poorer hearing compared to those not currently using any disease-modifying therapies.

Design

The design of this study was a secondary analysis of data that had been collected during two other large studies that evaluated hearing in those with MS. A linear mixed model was fit to the hearing thresholds of participants. The model included interferon use, MS subtype, gender, age, test frequency, MS duration in years and a disability score.

Findings

With all participants included (N = 52), there was insufficient evidence to infer that intramuscular interferon-beta 1a was not ototoxic compared to nonuse of a disease-modifying therapy at all frequencies at which participants had their hearing tested. After removing two participants who were outliers, the results indicated that there was support for no ototoxic effect of intramuscular interferon beta-1a at test frequencies from 250 to 6000 Hz. There was insufficient evidence, however, to rule out an ototoxic effect at 8000 Hz.

Nursing Implications

More research is needed to evaluate the ototoxic effects of interferon on hearing in patients with MS. Nurses should be aware of the potential for ototoxicity with interferon use and remind patients with MS to have their hearing evaluated on a regular basis throughout the course of treatment.

Acoustic Neuroma

Acoustic neuromas, also referred to as vestibular schwannomas, are slow-growing, benign tumors of cranial nerve VIII, usually arising from the Schwan cells of the vestibular portion of the nerve. Most acoustic tumors arise within the internal auditory canal and extend into the cerebellopontine angle to press on the brain stem, possibly destroying the vestibular nerve (Bader, Littlejohns, & Olson, 2016). Most acoustic neuromas are unilateral, except in von Recklinghausen disease (neurofibromatosis type 2), in which bilateral tumors occur (Grossman & Porth, 2014).

Acoustic neuromas develop in 1 of every 100,000 people per year. These neuromas account for 6% of all intracranial tumors and seem to occur with equal frequency in men and women at any age, although most occur during middle age (Hio, Kitahara, Uno, et al., 2013).

Assessment and Diagnostic Findings

The most common assessment findings of patients with acoustic neuromas are unilateral tinnitus and hearing loss with or without vertigo or balance disturbance. It is important to identify asymmetry in audiovestibular test results so that further workup can be performed to rule out an acoustic neuroma. Although conflicting data exist, the only known risk factor for acoustic neuroma is cell phone usage (Park, Vernick, & Ramakrishna, 2015). An MRI scan with a contrast agent (i.e., gadolinium or gadopentetate [Magnevist]) is the imaging study of choice. If the patient is claustrophobic or cannot undergo an MRI scan for other reasons, or if the scan is unavailable, a CT scan with contrast dye is performed. However, MRI is more sensitive than CT in delineating a small tumor.

Management

Conservative treatment is recommended for patients with tumors less than 1.5 cm and in those who are older. In addition, routine monitoring is recommended for these patients. For patients who are at low risk, surgical removal of the acoustic tumor is the treatment of choice because these tumors do not respond well to radiation or chemotherapy. Because treatment of acoustic tumors crosses several specialties, the interdisciplinary treatment approach involves a neurologist and a neurosurgeon. The objective of the surgery is to remove the tumor while preserving facial nerve function. Most acoustic tumors have damaged the cochlear portion of cranial nerve VIII, and hearing is impaired. In these patients, the surgery is performed using a translabyrinthine approach, and the hearing mechanism is destroyed. If hearing is still good before surgery, a suboccipital or middle cranial fossa approach to removing the tumor may be used. This procedure exposes the lateral third of the internal auditory canal and preserves hearing (Park et al., 2015).

Potential complications of surgery include facial nerve paralysis, cerebrospinal fluid leakage, meningitis, and cerebral edema. Death from acoustic neuroma surgery is rare (Park et al., 2015).

AURAL REHABILITATION

If hearing loss is permanent or cannot be treated by medical or surgical means or if the patient elects not to undergo surgery, aural rehabilitation may be beneficial. The purpose of aural rehabilitation is to maximize the communication skills of the person with hearing impairment. Aural rehabilitation includes auditory training, speech reading, speech training, and the use of hearing aids.

Auditory training emphasizes listening skills, so the person who is hearing impaired concentrates on the speaker. Speech reading (also known as lip reading) can help fill the gaps left by missed or misheard words. The goals of speech training are to conserve, develop, and prevent deterioration of current communication skills.

It is important to identify the type of hearing impairment a person has so that rehabilitative efforts can be directed at their particular need. Surgical correction may be all that is necessary to treat and improve a conductive hearing loss by eliminating the cause of the hearing loss. With advances in hearing aid technology, amplification for patients with sensorineural hearing loss is more helpful than ever.

Hearing Aids

A hearing aid is a device through which speech and environmental sounds are received by a microphone, converted to electrical signals, amplified, and reconverted to acoustic signals. Many aids available for sensorineural hearing loss depress the low frequencies, or tones, and enhance hearing for the high frequencies. A general guideline for assessing the patient's need for a hearing aid is a hearing loss exceeding 30 dB in the range of 500 to 2000 Hz in the better-hearing ear.

A hearing aid makes sounds louder, but it does not improve a patient's ability to discriminate words or understand speech. People who have low discrimination scores (i.e., 20%) on audiograms may derive little benefit from a hearing aid. Hearing aids amplify all sounds, including background noise, which may be particularly disturbing to the first-time wearer. Chart 41-12 identifies additional problems associated with hearing aid use. Computerized hearing aids are available to compensate for background noise or allow amplification at certain programmed frequencies rather than at all frequencies. Occasionally, depending on the type of hearing loss, binaural aids (i.e., one for each ear) may be indicated. Chart 41-13 provides tips for hearing aid care.

A hearing aid should be fitted according to the patient's needs (e.g., type of hearing loss, manual dexterity, and preferences), rather than the brand name, by a certified audiologist licensed to dispense hearing aids.

The evolution in technology has led to the availability of many smaller and more effective devices as well as different options and features of hearing aids (FDA, 2014) (see Chart 41-14). The majority of hearing aids sold today are behind-the-ear, in-the-ear, or in-the-canal types (see Table 41-4). One model is the Lyric, which is placed in the ear canal just 4 mm from the tympanic membrane. Its volume is controlled by a magnet, and when its batteries no longer function (1 to 4 months), a physician can remove it with the magnet and reinsert a new device. This device does not have many of the problems (e.g., feedback noise, overamplification of background noise) associated with other hearing aids, and it does not involve the expense and uncertainty of surgical procedures. However, it is not an option for a person whose ear canal is too narrow to accommodate it.

Chart 41-12

Hearing Aid Problems

Whistling Noise

- Loose ear mold
- Improperly made
- Improperly worn
- Worn out

Improper Aid Selection

- Too much power required in aid, with inadequate separation between microphone and receiver
- Open mold used inappropriately
- Inadequate amplification
- Dead batteries
- Cerumen in ear
- Cerumen or other material in mold
- Wires or tubing disconnected from aid
- Aid turned off or volume too low
- Improper mold
- Improper aid for degree of loss

Pain from Mold

- Improperly fitted mold
- Ear skin or cartilage infection
- Middle ear infection
- Ear tumor
- Unrelated conditions of the temporomandibular joint, throat, or larynx

Implanted Hearing Devices

There are several types of implanted hearing devices, ranging from implantable to semi-implantable devices (FDA, 2015).

Bone conduction devices, which transmit sound through the skull to the inner ear, are used in patients with a conductive

Chart 41-13 PATIENT EDUCATION

Tips for Hearing Aid Care

The nurse instructs the patient how to clean a hearing aid, check for malfunctions, and recognize complications:

Cleaning

- Keep in mind that the ear mold is the only part of the hearing aid that may be washed frequently.
- Wash the ear mold daily with soap and water.
- Allow the ear mold to dry completely before it is snapped into the receiver.
- Clean the cannula with a small pipe cleaner–like device.
- Note that properly caring for the ear device and keeping the ear canal clean and dry can prevent complications.

Checking for Malfunctions

- Be aware that inadequate amplification, a whistling noise, or pain from the mold can occur when a hearing aid is not functioning properly.
- Check for malfunctions:
  - Is the switch on properly?
  - Are the batteries charged and positioned correctly?
  - Is the ear mold clogged with cerumen? Ear wax can be easily removed with pin, pipe cleaner, or wax loop.
- Notify the hearing aid dealer if the hearing aid is still not working properly.
- Keep in mind that if the unit requires extended time for repair, the dealer may lend you a hearing aid until the repair can be accomplished.

Recognizing Complications

- Understand that common medical complications include external otitis media and pressure ulcers in the external auditory canal. Signs and symptoms of these infections include painful ear, especially when the external ear is touched; canal swelling; redness; difficulty hearing; pain radiating to the jaw area; and fever.
- Notify your health care provider for evaluation if any of these symptoms are present. You may need medication to treat infection, pain, or both.

Chart 41-14

Options and Features of Hearing Aids to Consider

- *T-Coil*: May improve hearing on the telephone by switching the settings from normal to telephone setting. This feature also assists in amplifying voices when the patient is in larger areas, such as theaters, auditoriums, and gymnasiums. Background noise may be toned down to adequately hear close conversation.
- *Directional Microphone*: Useful in environments with a lot of background noise and activity. The microphone may be directed toward the speaker and amplifies conversation while diminishing background noise.
- *Direct Audio Input*: Directly plugs into another device, such as a computer, television, or stereo, that is attached with an extension cord.
- *Feedback Suppression*: Suppresses whistling feedback noise.

Adapted from U.S. Food and Drug Administration. (2014). Medical devices: Types of hearing aids. Retrieved on 8/19/2016 at: www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/HomeHealthandConsumer/ConsumerProducts/HearingAids/ucm181470.htm

hearing loss if a hearing aid is contraindicated (e.g., those with chronic infection). The device is implanted postauricularly under the skin into the skull, and an external device—worn above the ear, not in the canal—transmits the sound through the skin. There are two types of implantable hearing aids. The bone-anchored hearing aid (BAHA) is implanted behind the ear in the mastoid area. The middle ear implantation (MEI) is implanted in the middle ear cavity. The BAHA is used for conductive or mixed hearing loss, whereas the MEI is used for sensorineural hearing loss (FDA, 2015).

The implantable middle ear hearing device (IMEHD) comes in two styles: piezoelectric and electromagnetic, which are partially or totally implanted. Patients must be 18 years or older, must be diagnosed with mild to severe sensorineural loss, and must have tried other conventional devices but achieved poor results to be considered candidates for this type of device. The implantable device has several advantages—for example, it may eliminate feedback, achieve good cosmetic results, and allow the patient to perform most preferred leisure activities (e.g., dancing, swimming). Disadvantages are that this device is expensive, necessitates surgery, requires periodic recharging of batteries, and has unpredictable power output (FDA, 2015).

The FDA has also approved the semi-implantable Vibrant Soundbridge (electromagnetic) and the total implantable Envoy Esteem (piezoelectric) devices. The Vibrant Soundbridge has an external device attached to the postauricular bone that transmits sound to the magnet in the middle ear that is attached to the long process of the incus. The magnet surrounds the long axis of the stapes, which in turn vibrates and sound is heard. The Envoy Esteem works similarly to the natural ear. The piezoelectric transducer is located at the head of the incus, which sends a signal that is amplified, filtered, and then converted back to a vibration signal. This vibration is delivered by the driver (piezoelectric transducer) and attached to the stapes capitulum; then, via the stapes bone, the inner ear receives the signal and is converted into a nerve impulse and translated into sound by the brain. The incus is removed prior to insertion of this device to prevent feedback from the sensor. It is estimated that sound is amplified up to 110 dB with this device (Shohet & Myers, 2011).

A cochlear implant is an auditory prosthesis used for people with profound sensorineural hearing loss bilaterally who do not benefit from conventional hearing aids. The cochlear implant directly stimulates the auditory nerve and has made it possible for people who are severely hearing impaired or who are deaf to hear sound (NIDCD, 2016). The hearing loss may be congenital or acquired. An implant does not restore normal hearing; rather, it helps the person detect medium to loud environmental sounds and conversation. The implant provides stimulation directly to the auditory nerve, bypassing the nonfunctioning hair cells of the inner ear. The microphone and signal processor, worn outside the body, transmit electrical stimuli to the implanted electrodes. The electrical signals stimulate the auditory nerve fibers and then the brain, where they are interpreted.

Worldwide, more than 324,200 people have received cochlear implants. In India, 25000 people have received cochlear implants (Kumar & Kameswaran, 2017). Studies report that older adult patients with cochlear implants experience improved understanding of speech and better cognition. Patients with cochlear implants were also noted to have more social interactions with others and improved quality of life. Research has reported that hearing improvement with a cochlear implant delays the occurrence as well as the progression of dementia (Mosnier, Bebear, Marx, et al., 2015). Candidates for a cochlear implant, who are usually at least 1 year of age, are selected after careful

TABLE 41-4 Hearing Aids

Site (Range of Hearing Loss)	Advantages	Disadvantages
Body, usually on the trunk (mild–profound)	Separation of receiver and microphone prevents acoustic feedback, allowing high amplification; generally used in a school setting	Bulky; requires long wire, which may be cosmetically displeasing; some loss of high-frequency response
Behind the ear (mild–profound)	Economical; powerful, with no long wires; easily used by children—adapts easily as the child grows, with only the ear mold needing replacement	Large size
In the ear (mild–moderately severe)	One-piece custom fit to contour of ear; no tubes or cords; miniature microphone located in the ear, which is a more natural placement; more cosmetically appealing due to easy concealment	Smaller size limits output; patients who have arthritis or cannot perform tasks requiring good manual dexterity may have difficulty with the small size of aid and/or battery; can require more repair than the behind-the-ear aid.
In the canal (mild–moderately severe)	Same as in-the-ear aids; less visible, so more cosmetically pleasing	Even smaller than in-the-ear aids; requires good manual dexterity and good vision

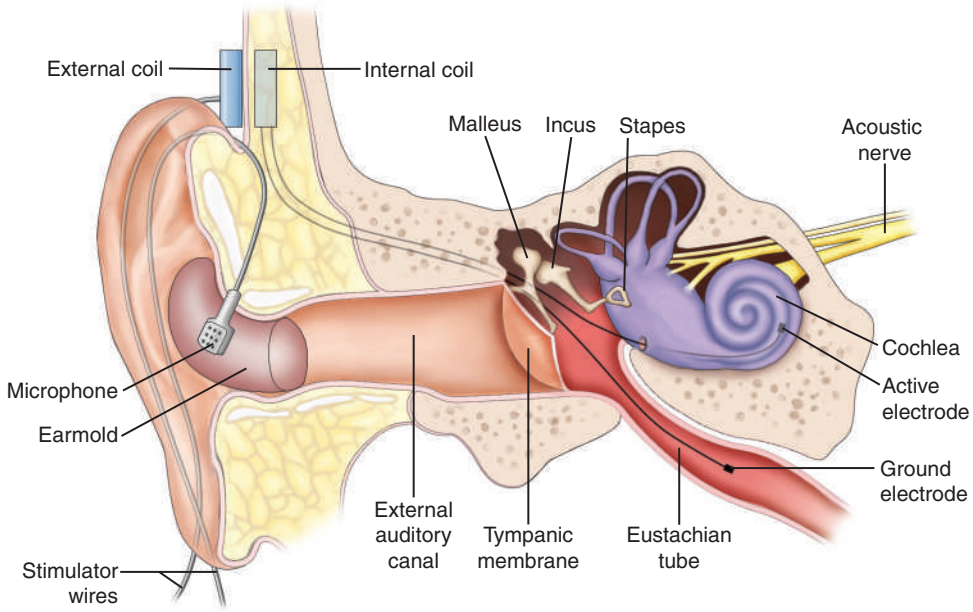

Figure 41-7 • The cochlear implant. The internal coil has a stranded electrode lead. The electrode is inserted through the round window into the scala tympani of the cochlea. The external coil (the transmitter) is held in alignment with the internal coil (the receiver) by a magnet. The microphone receives the sound. The stimulator wire receives the signal after it has been filtered, adjusted, and modified so that the sound is at a comfortable level for the patient. Sound is passed by the external transmitter to the inner coil receiver by magnetic conduction and is then carried by the electrode to the cochlea.

screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing. Criteria for choosing adults who may benefit from a cochlear implant include:

- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids
- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life

The surgery involves implanting a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear (see Fig. 41-7). The microphone and transmitter are worn on an external unit. The patient undergoes extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist. Several months may be needed to learn to interpret the sounds heard. Children and adults who lost their hearing before they learned to speak take much longer to acquire speech. There are wide variations of success with cochlear implants, and there is also controversy about their use, especially among the deaf community. Patients who have had a cochlear implant are cautioned that an MRI scan will inactivate the implant; MRI should be used only when there is no other diagnostic option.

CRITICAL THINKING EXERCISES

1. A 45-year-old patient who has been swimming frequently in the local pool has recently been diagnosed with otitis externa. Devise an evidence-based education plan for this patient, with consideration to the diagnosis, possible medical management and treatment options, and home care instructions. Identify evidence-based techniques that the patient should perform to prevent future infections.
2. A 91-year-old female has complained of hearing loss that has gradually worsened over the past few months. She has difficulty with hearing when carrying on a conversation with others, difficulty hearing the television, and having a telephone conversation. She has seen the primary provider today and has been diagnosed with cerumen impaction. Discuss how you will educate the patient about the diagnosis of cerumen impaction. What treatments will you plan to discuss and perform in the clinic? List treatments that the patient will need to perform at home. Should she expect to regain her previous hearing ability? What measures can she use to prevent cerumen impaction in the future?
3. You are providing home care for a 55-year-old patient with hypertension, diabetes, and a new diagnosis of vertigo. Identify the priorities, approach, and techniques you would use to provide nursing care to this patient. How would your priorities, approach, and techniques change if the patient was 85 years old and lived alone?

CHAPTER 42

Assessment and Management of Patients with Eye and Vision Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Identify the major structures and function of the eye.
2. Specify assessment and diagnostic findings used in the evaluation of ocular disorders.
3. Describe assessment and management strategies for patients with low vision and blindness.
4. List the pharmacologic actions and nursing management of common ophthalmic medications.
5. Recognize the clinical features, assessment and diagnostic findings, and medical or surgical management of glaucoma, cataracts, and other ocular disorders.
6. Explain the nursing management of patients with glaucoma, cataracts, and ocular trauma.
7. Discuss general discharge education for patients after ocular surgery.

GLOSSARY

anterior chamber: aqueous-containing space in the eye between the posterior (endothelial) cornea and the anterior iris and pupil
aqueous humor: transparent nutrient-containing fluid that fills the anterior and posterior chambers of the eye
astigmatism: refractive error due to an irregularity in the curvature of the cornea
binocular vision: normal ability of both eyes to focus on one object and fuse the two images into one
blindness: inability to see, defined as corrected visual acuity of 20/400 or less, or a visual field of no more than 20 degrees in the better eye
cataract: progressive opacity of the lens of the eye
chemosis: edema of the conjunctiva
diplopia: seeing one object as two; double vision
ectropion: turning out of the lower eyelid
emmetropia: normal refractive condition resulting in clear focus on retina; no optical defects
endophthalmitis: intraocular infection
entropion: turning in of the lower eyelid
enucleation: removal of the eyeball and part of the optic nerve
evisceration: removal of the intraocular contents through a corneal or scleral incision; the optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact
exenteration: surgical removal of the entire contents of the orbit, surrounding soft tissue, and most or all of the eyelids
glaucoma: group of conditions characterized by increased intraocular pressure
hyperemia: red eyes resulting from dilation of the vasculature of the conjunctiva
hyperopia: farsightedness; light rays focus behind the retina
hyphema: blood in the anterior chamber
hypopyon: collection of inflammatory cells in the anterior chamber of the eye
injection: congestion of blood vessels
keratoconus: cone-shaped deformity of the cornea
myopia: nearsightedness; light rays focus in front of the retina
neovascularization: growth of abnormal new blood vessels
nystagmus: involuntary oscillation of the eyeball
papilledema: swelling of the optic disc usually due to increased intracranial pressure
photophobia: ocular pain on exposure to light
presbyopia: the loss of accommodative power in the lens due to age
proptosis or exophthalmos: abnormal protrusion of the eyeball
ptosis: drooping eyelid
refraction: determination of the refractive errors of the eye for the purpose of vision correction
scotomas: blind or partially blind areas in the visual field
sympathetic ophthalmia: an inflammatory condition created in the fellow eye by the affected eye
trachoma: an infectious disease caused by the bacterium *Chlamydia trachomatis*—the leading cause of preventable blindness in the world
trichiasis: turning in of the eyelashes
vitreous humor: transparent, colorless gelatinous material that fills the vitreous chamber behind the lens

Note: Common abbreviations related to vision and eye health are OD (oculus dexter, right eye), OS (oculus sinister, left eye), and OU (oculus uterque, both eyes).

Introduction

The eye is a sensitive, highly specialized sense organ subject to various disorders, many of which can lead to impaired vision. Impaired vision may affect individuals in many ways, including their independence in self-care, sense of self-esteem, safety, and overall quality of life. Many of the leading causes of visual impairment are associated with aging (e.g., cataracts, glaucoma, and macular degeneration). Younger people are also at risk for eye disorders, particularly traumatic injuries.

Although most people with eye disorders are treated in an ambulatory care setting, various eye disorders are seen in many settings. In addition to understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings assess visual acuity in patients at risk (e.g., older adults, those with hypertension, diabetes or acquired immune deficiency syndrome [AIDS]), refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

ASSESSMENT OF THE EYE

Anatomic and Physiologic Overview

Unlike most organs of the body, the eye is available for external examination, and its anatomy is more easily assessed than other body parts (see Fig. 42-1). The eyeball, or globe, sits in the bony protective orbit (Hogan, 2014). Lined with muscle and connective and adipose tissues, the orbit is shaped like a four-sided pyramid, surrounded on three sides by the sinuses: ethmoid (medially), frontal (superiorly), and maxillary (inferiorly). The optic nerve and the ophthalmic artery enter the orbit at its apex through the optic foramen. The eyeball is moved through all fields of gaze by the extraocular muscles. The four rectus muscles and two oblique muscles (see Fig. 42-2) are innervated by cranial nerves (CNs) III, IV, and VI. Normally, the movements of the two eyes are coordinated and the brain perceives a single image.

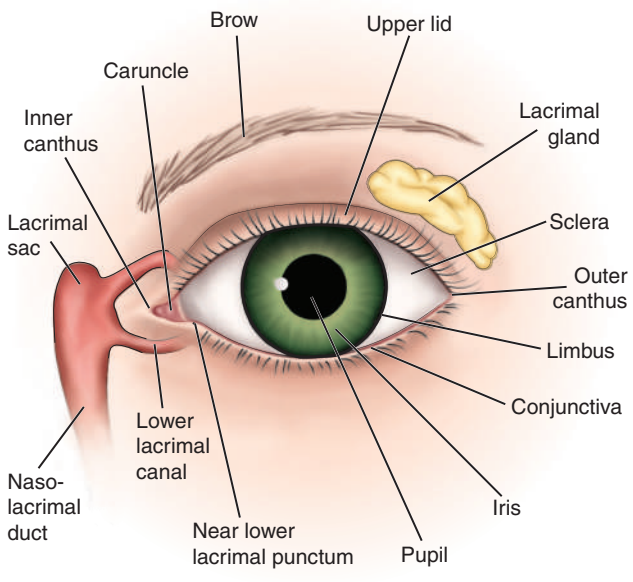

Figure 42-1 • External structures of the eye and position of the lacrimal structures.

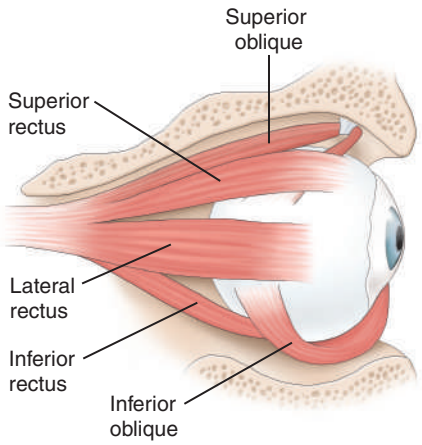

Figure 42-2 • The extraocular muscles responsible for eye movement. The medial rectus muscle (not shown) is responsible for opposing the movement of the lateral rectus muscle.

The eyelids are composed of thin, elastic skin that covers striated and smooth muscles and protect the anterior portion of the eye. The eyelids contain multiple glands (sebaceous, sweat, and lacrimal). The upper lid normally covers the uppermost portion of the iris and is innervated by the oculomotor nerve (CN III). The lid margins contain meibomian glands, the inferior and superior puncta, and the eyelashes. The triangular spaces formed by the junction of the eyelids are known as the inner or medial canthus and the outer or lateral canthus. With every blink, the eyelids wash the cornea and conjunctiva with tears.

Tears are vital to eye health. Formed by the lacrimal gland and the accessory lacrimal glands, tears are secreted in response to reflex or emotional stimuli. A healthy tear is composed of three layers: lipoid, aqueous, and mucoid. These layers nourish the cornea and create a smooth optical surface of the cornea and conjunctival epithelium. If there is a defect in the composition of any of these layers, the integrity of the cornea may be compromised.

The conjunctiva, a thin transparent mucous membrane, provides a barrier to the external environment extending under the eyelids (palpebral conjunctiva) and over the sclera (bulbar conjunctiva). The junction of the two portions is known as the fornix. The conjunctiva meets the cornea at the limbus on the outermost edge of the iris.

The eyeball is composed of the following three layers:

- The outer dense fibrous layer, including the sclera and transparent cornea
- The middle vascular layer, containing the iris, ciliary body, and choroid
- The inner neural layer, including the retina, optic nerve, and visual pathway

The eyeball is divided anatomically into two segments. The anterior segment is between the anterior cornea and posterior iris, including the anterior and posterior chamber. The posterior segment is between the posterior lens and the retina, including the vitreous chamber. The eyeball also has three fluid-containing chambers. The aqueous-filled anterior chamber lies between the posterior cornea and the anterior iris and pupil. The posterior chamber is a small aqueous containing space between the posterior iris and pupil and anterior lens. The vitreous chamber, containing clear gelatinous vitreous fluid, is the largest chamber in the ocular fundus between the lens and retina (see Fig. 42-3).

The aqueous humor (transparent nutrient-containing fluid that fills the anterior and posterior chambers of the eye) is produced in the posterior chamber by the ciliary body (Grossman & Porth, 2014). It flows through the pupil into the anterior chamber and drains through the trabecular meshwork into the canal of Schlemm. Production of aqueous humor is related to the intraocular pressure (IOP). Normal IOP is less than 21 mm Hg (Eldaly, Bunce, El Sheikha, et al., 2014). Vitreous humor, which is composed mostly of water and encapsulated by a hyaloid membrane, helps maintain the shape of the eye. The vitreous is attached to the retina by scattered collagenous filaments. The vitreous shrinks and shifts with age. Through this degenerative process, the gel-like characteristics liquefy, causing stringy debris known as floaters.

The sclera is the white avascular dense fibrous structure that helps maintain the shape of the eyeball and protects the intraocular contents. Scleral thinning and changes of the scleral collagen fibers can cause the underlying uveal pigment

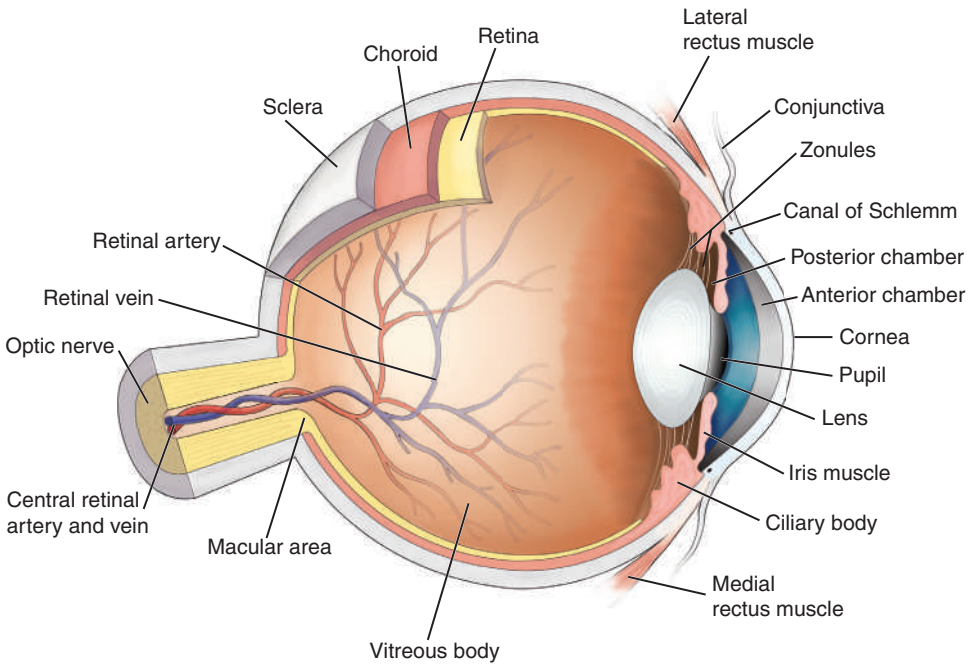

Figure 42-3 • Three-dimensional cross-section of the eye.

to be seen, resulting in a blue or gray sclera. The episclera is a vascularized loose elastic tissue that overlies the sclera supplying nutritional support and reacting to inflammation.

The cornea, a vulnerable transparent avascular domelike structure, forms the most anterior portion of the eyeball and is the main refracting surface of the eye. It is composed of five layers: the epithelium, Bowman membrane, stroma, Descemet membrane, and endothelium. It contains high concentrations of nerve fibers and is extremely sensitive to pain. The epithelium, the outermost protective layer, absorbs oxygen and nutrients from the tear film nourishing the cornea. The epithelial cells readily regenerate, unlike the innermost endothelial cells, which do not regenerate and result in corneal edema when injured.

The uveal tract is the vascular middle layer of the eye consisting of the iris, ciliary body, and the choroid.

The iris surrounding the pupil is a highly vascularized pigmented collection of fibers that give the eye color. The dilator and sphincter muscles of the iris control pupil size. The dilator muscles are controlled by the sympathetic nervous system. The sphincter muscles are controlled by the parasympathetic nervous system.

The ciliary body consists of ciliary processes, ciliary muscles, and zonular fibers (ligaments) that work together to form aqueous fluid and control focusing through the zonular fibers that suspend the crystalline lens.

The choroid lies between the retina and the sclera, supplying blood and oxygen to the outer retina. Pigmented cells containing melanocytes in the choroid assist to absorb scattered light.

Directly behind the pupil and iris lies the lens, an avascular and almost completely transparent biconvex structure held in position by zonular fibers in the ciliary body. The lens enables focusing for near and distance vision through accommodation, the process by which the lens of the eye adjusts the focal length to focus a clear image on the retina. With aging and certain conditions (e.g., diabetes or trauma), the lens loses its transparency and ability to focus due to formation of a cataract (see later discussion).

The retina—the innermost surface of the fundus composed of neural tissue—is an extension of the optic nerve. Viewed through the pupil, the landmarks of the retina are the optic disc, the retinal vessels, and the macula. The point of entrance of the optic nerve into the retina is the optic disc. The optic disc is pink, either oval or circular in shape, and has sharp margins. In the disc, a physiologic depression or cup is present centrally, with the retinal blood vessels emerging from it. The retinal tissues arise from the optic disc and line the inner surface of the vitreous chamber. The retinal vessels enter the eye through the optic disc, branching out through the retina and forming superior and inferior branches. The macula is the area of the retina responsible for central vision. The rest of the retina is responsible for peripheral vision. In the center of the macula is the most sensitive area—the fovea—which is avascular and surrounded by the superior and inferior vascular arcades. Two important layers of the retina are the retinal pigment epithelium (RPE) and the sensory retina. A single layer of cells constitutes the RPE. These cells have numerous functions, including the absorption of light. The sensory retina contains the photoreceptor cells: rods and cones. The rods are responsible for night or low light vision. The cones are retinal photoreceptor cells essential for visual acuity, color discrimination, and fine detail. Cones are distributed throughout the retina, with their greatest concentration in the fovea. Rods are absent in the fovea.

Visual acuity depends on a healthy functioning eye and an intact visual pathway. This pathway is made up of the retina, optic nerve, optic chiasm, optic tracks, lateral geniculate bodies, optic radiations, and the visual cortex area of the brain. The visual pathway is part of the central nervous system (see Fig. 42-4).

The optic nerve (CN II) transmits impulses from the retina to the occipital lobe of the brain. The optic nerve head, or optic disc, is the physiologic blind spot in each eye. The optic nerve leaves the eye and then meets the optic nerve from the other eye at the optic chiasm. The chiasm is the anatomic point at which the nasal fibers from the nasal retina of each eye cross to the opposite side of the brain. The nerve fibers from the temporal

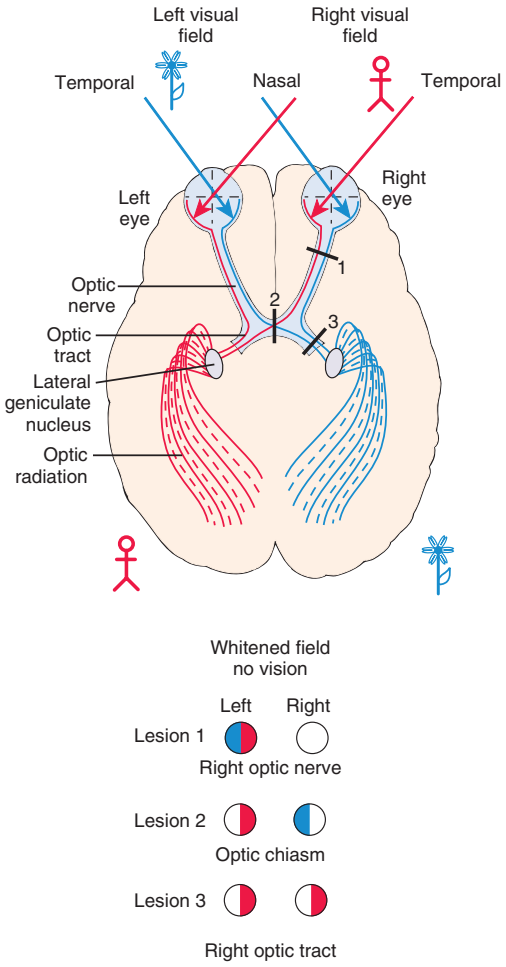

Figure 42-4 • Diagram of optic pathways. The *red* lines indicate the right visual field and the *blue* lines the left visual field. Note the crossing of the fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous) with loss of vision from half of each field (hemianopia). Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

retina of each eye remain uncrossed. Fibers from the right half of each eye, which would be the left visual field, carry impulses to the right occipital lobe. Fibers from the left half of each eye, or the right visual field, carry impulses to the left occipital lobe. Beyond the chiasm, these fibers are known as the optic tract. The optic tract continues on to the lateral geniculate body. The lateral geniculate body is connected by the optic radiations to the cortex of the occipital lobe of the brain.

Assessment

Ocular History

The nurse, through careful questioning, elicits the necessary information that can assist in diagnosis of an ophthalmic condition. Pertinent questions to ask when taking an ocular history are presented in Chart 42-1. Genetics plays a role in many eye and vision disorders (Lee & Garg, 2015) (see Chart 42-2).

Visual Acuity

Following the health history, the patient's visual acuity is assessed. This is an essential part of the eye examination and a measure against which all therapeutic outcomes are based.

Visual acuity is tested for both near (14 inches away) and distance (20 feet away) vision and is performed on each eye separately with a standardized Snellen chart for distance and a Rosenbaum pocket screener for near vision. A tumbling "E," "illiterate E," number, or regional language alphabet chart or picture chart is used if the person is illiterate (Weber & Kelley, 2014).

The Snellen chart is composed of a series of progressively smaller rows of letters; the person is asked to read the lowest line possible. The fraction 20/20 is considered the standard of normal vision. Most people can see the letters on the line designated as 20/20. The patient should be encouraged to read every letter possible.

Visual acuity is then recorded. The following would be an example of visual acuity documentation: A patient reads all five letters from the 20/20 line on the Snellen chart with the right eye (OD) and three of the five letters on the 20/30 line with the left eye (OS); the visual acuity is documented as OD: 20/20 and OS: 20/30 (Weber & Kelley, 2014).

If the patient cannot see the big "E" at the top of the Snellen chart, the examiner should determine next if the patient can count fingers ("CF" in documentation). Initially, the examiner

Chart 42-1 ASSESSMENT

Taking a History of Patients with Eye and Vision Disorders

- What does the patient perceive to be the problem?
- Is visual acuity diminished?
- Does the patient experience blurred, double, or distorted vision?
- Is there pain? Is it sharp or dull? Is it worse when blinking?
- Is the discomfort an itching sensation or more of a foreign-body sensation?
- Are both eyes affected?
- Is there a history of discharge? If so, inquire about color, consistency, and odor.
- Describe the onset of the problem (sudden, gradual). Is it worsening?
- What is the duration of the problem?
- Is this a recurrence of a previous condition?
- How has the patient self-treated?
- What makes the symptoms improve or worsen?
- Has the condition affected performance of activities of daily living?
- Are there any systemic diseases? What medications are used in their treatment?
- What other eye conditions does the patient have?
- Is there a history of eye surgery?
- Have other family members had the same symptoms or condition?

Adapted from Weber, J., & Kelley, J. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Chart 42-2 GENETICS IN NURSING PRACTICE

Eye and Vision Disorders

Several eye and vision disorders are associated with genetic abnormalities. Some examples include:

Autosomal dominant:
- Aniridia
- Vitelliform macular dystrophy

Autosomal recessive:
- Achromatopsia
- Homocystinuria
- Leber congenital amaurosis

X linked:
- Choroideremia
- Color blindness

Mitochondrial inheritance:
- Leber hereditary optic neuropathy

Multiple inheritance patterns identified:
- Glaucoma
- Macular degeneration
- Retinitis pigmentosa

Other genetic illness that will impact vision:
- Albinism
- Isolated familial congenital cataracts
- Marfan syndrome
- Stickler syndrome
- Tay–Sachs disease
- Usher syndrome

Nursing Assessments

Family History Assessment Specific to Vision

- Assess history of family members in the past three generations with glaucoma, cataracts, night blindness (retinitis pigmentosa), color blindness, or other vision impairment.
- Inquire about the age of onset of symptoms (the onset of Leber congenital amaurosis is in childhood, whereas the onset of Leber hereditary optic neuropathy is in young adulthood).
- Inquire about family members with other disorders that may include visual impairment, such as cutaneous, metabolic, or connective tissue disorders and hearing loss.

Patient Assessment Specific to Vision

- Assess for other systemic and/or clinical features such as cutaneous or skeletal conditions, or hearing loss.
- Look for color and clarity of iris.
- Assess for presence of strabismus (cross-eyes), amblyopia (lazy eye), nystagmus, astigmatism, and near- or far-sightedness.
- Assess for changes in visual acuity.
- Assess field of vision.
- Inquire about photophobia, night blindness, or double vision.

Genetics Resources

National Opthalmic Disease Genotyping Network, https://eyegene.nih.gov

stands 5 feet from the person, holds up a random number of fingers, and then asks the patient to count the number of fingers seen. If the patient is unable to count fingers at 5 feet, the examiner keeps moving a foot closer until either 1 foot away or the person can correctly count fingers. If the patient correctly counts the number of fingers at 3 feet, for example, the examiner would record vision as CF/3 ft.

If the patient cannot count fingers, the examiner raises one hand up and down or moves it side to side and asks in which direction the hand is moving. This level of vision is known as hand motion. A patient who can perceive only light is described as having light perception. The vision of a patient who cannot perceive light is described as no light perception.

External Eye Examination

The nurse uses a systematic approach to perform an external eye examination by first assessing for symmetry and placement of eyelids, pupils, and muscles. CNs III, IV, and VI control movement and pupil size. The eyelids should rest just above and below the corneal limbus without exposure of the sclera. The nurse observes for ptosis (drooping of the eyelid), ectropion (turning out of the lower eyelid), or entropion (turning in of the lower eyelid). Entropion may involve trichiasis (turning in of the eyelashes). Eyelids and lashes should be free of drainage or scaling.

The room should be darkened so that the pupils can be examined. The pupillary response is checked with a penlight to determine if the pupils are equally reactive and regular. A normal pupil is black. An irregular pupil may result from trauma, previous surgery, or a disease process.

The patient's eyes are observed in primary or direct gaze, and any head tilt is noted. A head tilt may indicate cranial nerve palsy. The patient is asked to stare at a target; each eye is covered and uncovered quickly while the examiner looks for any shift in gaze. The examiner observes for nystagmus (involuntary oscillating movement of the eyeball). The extraocular movements of the eyes are tested by having the patient follow the examiner's finger, pencil, or a hand light through the six cardinal directions of gaze (i.e., up, down, right, left, and both diagonals). This is especially important when screening patients for ocular trauma or for neurologic disorders such as stroke or myasthenia gravis (Hickey, 2014).

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with eye disorders. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should be aware of contraindications, potential complications, and trends in results. Trends provide information about disease progression as well as the patient's response to therapy.

Direct Ophthalmoscopy

A direct ophthalmoscope is a handheld instrument with various plus and minus lenses (Weber & Kelley, 2014). The lenses can be rotated into place, enabling the examiner to bring the cornea, lens, and retina into focus sequentially. The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. The examiner switches to the left hand and left eye when examining the patient's left eye. During this examination, the room should be darkened, and the patient's eye should be on the same level as the examiner's eye. The patient and the examiner should be comfortable, and both should breathe normally. The patient is given a target to gaze at and is encouraged to keep both eyes open and steady.

When the fundus is examined, the vasculature comes into focus first. The veins are larger in diameter than the arteries. The examiner focuses on a large vessel and then follows it toward the midline of the body, which leads to the optic nerve. The central depression in the disc is known as the cup. The normal cup is about one third the size of the diameter of the disc. The size of the physiologic optic cup should be estimated and the disc margins described as sharp or blurred. A silvery or coppery appearance, which indicates arteriolosclerosis, should be noted. The periphery of the retina is examined by having the patient shift their gaze. The last area of the fundus to be examined is the macula, because this area is the most sensitive to light. The retina of a young person often has a glistening effect, sometimes referred to as a cellophane reflex.

The healthy fundus should be free of any lesions. The examiner looks for intraretinal hemorrhages, which may appear as red smudges, and, if the patient has hypertension, they may be somewhat flame shaped. Lipid with a yellowish appearance may be present in the retina of patients with hypercholesterolemia or diabetes. Soft exudates that have a fuzzy, white appearance (cotton-wool spots) should be noted. The examiner looks for microaneurysms, which look like little red dots, and nevi. Drusen (small, hyaline, globular deposits), commonly found in macular degeneration, appear as yellowish areas with indistinct edges. Small drusen have a more distinct edge. The examiner should sketch the fundus and document any abnormalities.

Indirect Ophthalmoscopy

The indirect ophthalmoscope is an instrument commonly used by the ophthalmologist to see larger areas of the retina, although in an unmagnified state. It produces a bright and intense light. The light source is affixed with a pair of binocular lenses mounted on the examiner's head. The ophthalmoscope is used with a handheld, 20-diopter lens.

Slit-Lamp Examination

The slit lamp is a binocular microscope mounted on a table. This instrument enables the user to examine the eye with magnification of 10 to 40 times the real image. The illumination can be varied from a broad to a narrow beam of light for different parts of the eye. For example, by varying the width and intensity of the light, the anterior chamber can be examined for signs of inflammation. Cataracts may be evaluated by changing the angle of the light. When a handheld contact lens, such as a three-mirror lens, is used with the slit lamp, the angle of the anterior chamber may be examined, as may the ocular fundus.

Tonometry

Tonometry is an essential part of a diagnostic evaluation; it measures IOP to screen for and manage glaucoma. The device used for measuring IOP is an accurately calibrated applanation tonometer, which measures the pressure needed to flatten the cornea. Because the probe or prism touches the highly sensitive cornea, a topical anesthetic is given prior to measurement (Hogan, 2014).

Nursing Interventions

Providing patient education prior to tonometry helps avoid possible errors in IOP measurement. Patients are cautioned to avoid squeezing the eyelids, holding their breath, or performing a Valsalva maneuver, because these may result in abnormally increased IOP.

Color Vision Testing

The ability to differentiate colors has a dramatic effect on the activities of daily living (ADLs). For example, the inability to differentiate between red and green can compromise traffic safety. Some careers (e.g., commercial artist, [color] photographer, airline pilot, and electrician) may be closed to people with significant color deficiencies. The photoreceptor cells responsible for color vision are the cones, and the greatest area of color sensitivity is in the macula—the area of densest cone concentration.

A screening test, such as the polychromatic plates discussed in the next paragraph, can be used to establish whether a person's color vision is within normal range. Color vision deficits can be inherited. For example, red–green color deficiencies are inherited in an X-linked manner, affecting approximately 8% of men and 0.5% of women (Colour Blind Awareness, 2016). Acquired color vision losses may be caused by medications (e.g., digitalis) or pathology (e.g., cataracts). A simple test, such as asking a patient if the red top on a bottle of eye drops appears redder to one eye than the other, can be an effective tool. A difference in the perception of the intensity of the color red between the two eyes can be a symptom of a neurologic problem and may provide information about the location of the lesion.

Because alteration in color vision sometimes indicates conditions of the optic nerve, color vision testing is often performed in a neuro-ophthalmologic workup. The most common color vision test is performed using Ishihara polychromatic plates. These plates are bound together in a booklet. On each plate of this booklet are dots of primary colors that are integrated into a background of secondary colors. The dots are arranged in simple patterns, such as numbers or geometric shapes. Patients with diminished color vision may be unable to identify the hidden shapes. Patients with central vision conditions (e.g., macular degeneration) have more difficulty identifying colors than those with peripheral vision conditions (e.g., glaucoma) because central vision identifies color.

Amsler Grid

The Amsler grid is a test often used for patients with macular problems, such as macular degeneration. It consists of a geometric grid of identical squares with a central fixation point. The grid should be viewed by the patient wearing normal reading glasses. Each eye is tested separately. The patient is instructed to stare at the central fixation spot on the grid and report any distortion in the squares of the grid itself. For patients with macular problems, some of the squares may look faded, or the lines may be wavy. Patients with age-related macular degeneration (AMD) are commonly given these Amsler grids to take home. The patient is encouraged to check the grids frequently, as often as daily, to monitor macular function for early detection of changes requiring immediate attention (Gerstenblith & Rabinowitz, 2017); (Weber & Kelley, 2014).

Ultrasonography

Lesions in the globe or the orbit may not be directly visible and are evaluated by ultrasonography. Ultrasonography is a valuable diagnostic technique, especially when the view of the retina is obscured by opaque media such as cataract or hemorrhage. An ultrasonography B-scan identifies pathology such as orbital tumors, retinal detachment, and vitreous hemorrhage. Ultrasonography A-scans are used to measure the

axial length for implants prior to cataract surgery (Gerstenblith & Rabinowitz, 2017).

Optical Coherence Tomography

Optical coherence tomography is a technology that involves low-coherence interferometry (Boyd, 2015); (Gerstenblith & Rabinowitz, 2017). Light is used to evaluate retinal and macular diseases as well as anterior segment conditions. This method is noninvasive and involves no physical contact with the eye.

Fundus Photography

Fundus photography is used to detect and document retinal lesions. The patient's pupils are usually widely dilated before the procedure. The resulting fundus photographs can be viewed stereoscopically so that elevations such as macular edema can be identified.

Laser Scanning

Various scanning techniques use laser light in the diagnostic evaluation of eye disorders. Confocal laser scanning ophthalmoscopy provides a three-dimensional image of the optic nerve topography and is used alone or in conjunction with fundus photography to provide comparative data for suspected optic nerve disease such as glaucoma and papilledema (swelling of the optic disc due to increased intracranial pressure) (Gerstenblith & Rabinowitz, 2017). Laser scanning polarimetry is used to measure nerve fiber layer thickness and is an important indicator of glaucoma progression.

Angiography

Angiography is done using fluorescein or indocyanine green as contrast agents. Fluorescein angiography is used to evaluate clinically significant macular edema, document macular capillary nonperfusion, and identify retinal and choroidal neovascularization (growth of abnormal new blood vessels) in AMD. It is an invasive procedure in which fluorescein dye is injected, usually into an antecubital vein. Within 10 to 15 seconds, this dye can be seen coursing through the retinal vessels. Over a 10-minute period, serial black-and-white photographs are taken of the retinal vasculature.

Indocyanine green angiography is used to evaluate abnormalities in the choroidal vasculature, which often are seen in macular degeneration. Indocyanine green dye is injected intravenously (IV), and multiple images are captured using digital video angiography over a period of 30 seconds to 20 minutes.

Nursing Interventions

Prior to the angiography, the patient's blood urea nitrogen and creatinine should be checked to ensure that the kidneys will excrete the contrast agent (Fischbach & Dunning, 2015). The patient should be well hydrated, and clear liquids are usually permitted up to the time of the test. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

Nursing care after angiography includes observation of the injection site (usually the antecubital vein) for bleeding or hematoma formation (a localized collection of blood). Fluorescein may impart a gold tone to the skin in some patients, and urine may turn deep yellow or orange. This discoloration usually disappears in 24 hours. Indocyanine green dye is generally well tolerated, but some patients experience nausea and vomiting. Allergic reactions are rare; however, indocyanine green angiography is contraindicated in patients with a history of iodide reactions. Fluids are encouraged following the procedure to facilitate excretion of the contrast agent (Fischbach & Dunning, 2015).

Perimetry Testing

Perimetry testing evaluates the field of vision. Visual field testing (i.e., perimetry) helps identify which parts of the patient's central and peripheral visual fields have useful vision. It is most helpful in detecting central scotomas (blind or partially blind areas in the visual field) in macular degeneration and the peripheral field defects in glaucoma and retinitis pigmentosa. Visual field evaluation and optic nerve assessment are major components of monitoring and detecting glaucoma progression.

IMPAIRED VISION

Refractive Errors

In refractive errors, vision is impaired because a shortened or elongated eyeball prevents light rays from focusing sharply on the retina. Blurred vision from refractive error can be corrected with eyeglasses or contact lenses. Ophthalmic refraction is the determination of the refractive errors of the eye for the purpose of vision correction and consists of placing various types of lenses in front of the patient's eyes to determine which lens best improves the patient's vision.

The depth of the eyeball is important in determining refractive error (see Fig. 42-5). Patients for whom the visual image focuses precisely on the macula and who do not need eyeglasses or

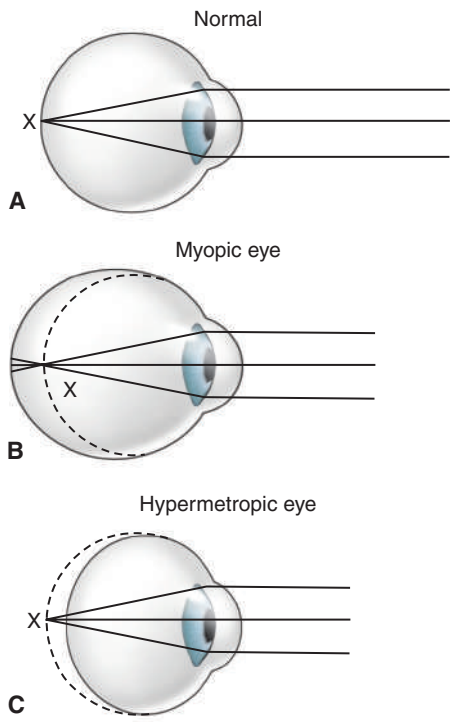

Figure 42-5 • Eyeball shape determines visual acuity in refractive errors. **A**. Normal eye. **B**. Myopic eye. **C**. Hypermetropic eye.

contact lenses are said to have emmetropia, a normal refractive condition resulting in clear focus on retina with no optical defects (normal vision). Some people have deeper eyeballs, in which case the distant visual image focuses in front of, or short of, the retina; those with myopia are said to be nearsighted and have blurred distance vision. Other people have shallower eyeballs, in which case the visual image focuses beyond the retina; those with hyperopia are said to be farsighted and have excellent distance vision but blurry near vision (Weber & Kelley, 2014).

Wavefront technology to measure unique refractive imperfections of the cornea or higher aberrations (i.e., myopia, hyperopia, astigmatism) can be used to customize laser-assisted in situ keratomileusis (LASIK) procedures. These procedures are described later in this chapter.

Vision Impairment and Blindness

Vision impairment is defined as having best corrected visual acuity of 20/40 or worse in the better-seeing eye. *Low vision* describes visual impairment that requires the use of devices and strategies to perform visual tasks.

Blindness is having best corrected visual acuity that can range from 20/400 to no light perception. The clinical definition of absolute blindness is the absence of light perception. Legal blindness is a condition of impaired vision in which a person has best corrected visual acuity that does not exceed 20/200 in the better eye or whose widest visual field diameter is 20 degrees or less (Prevent Blindness America, 2012). This definition neither equates with functional ability nor classifies the degrees of visual impairment. Legal blindness ranges from an inability to perceive light to having some vision remaining. A person who meets the criteria for legal blindness may be eligible for government financial assistance through disability.

Assessment and Diagnostic Testing

Assessment of vision impairment includes a thorough history and examination of distance and near visual acuity, visual field, contrast sensitivity, glare, color perception, and refraction. Specially designed, low vision visual acuity charts are used to evaluate patients.

Patient Interview

During history taking, the cause and duration of the patient's visual impairment are identified. Patients with retinitis pigmentosa, for example, have a genetic abnormality. Patients with diabetic macular edema typically have fluctuating visual acuity. Patients with macular degeneration have central acuity problems that cause difficulty in performing activities that require finer vision, such as reading. People with peripheral field defects have more difficulties with mobility. The patient's customary ADLs, medication regimen, habits (e.g., smoking), acceptance of the physical limitations brought about by the visual impairment, and realistic expectations of low vision aids are identified and included in the plan of care, as well as provision of guidelines for safety and referrals to social services.

Contrast-Sensitivity Testing and Glare Testing

Contrast-sensitivity testing measures visual acuity in different degrees of light and dark contrast to determine visual function. Glare testing is also used to determine visual function. Glare can reduce a person's ability to see, especially in patients with cataracts. Those affected by loss of contrast sensitivity and glare have difficulty functioning in low light, or driving at night or in foggy conditions. People with a loss of contrast sensitivity may benefit from better illumination.

Gerontologic Considerations

Approximately half of all individuals who are identified as legally blind each year are 65 years of age or older (Eliopoulos, 2018). With aging, structural and functional changes occur in the eye. Presbyopia, the loss of accommodative power in the lens, interferes with the ability to adequately focus and is the factor responsible for most older adults requiring some form of corrective lenses (Eliopoulos, 2018). Age-related changes in the eye are summarized in Table 42-1.

Impaired vision is often accompanied by difficulty in performing functional activities. People with visual acuity of 20/80 to 20/100 with a visual field restriction of 60 degrees to greater than 20 degrees can read at a nearly normal level with optical aids. Their visual orientation is near normal but requires increased scanning of the environment (i.e., systematic use of

TABLE 42-1 Age-Related Changes in the Eye

External Eye	Structural Change	Functional Change	History and Physical Findings
Eyelids and lacrimal structures	Loss of skin elasticity and orbital fat, decreased muscle tone; wrinkles develop	Lid margins turn in, causing entropion; or lid margins turn out, resulting in ectropion.	Reports of burning, foreign-body sensation, epiphora; injection, inflammation, and ulceration may occur.
Refractive changes; presbyopia	Loss of accommodative power in the lens with age	Reading materials must be held at increasing distance in order to focus.	Patient reports, "Arms are too short!"; need for increased light; reading glasses or bifocals needed.
Cataract	Opacities in the normally crystalline lens	Interference with the focus of a sharp image on the retina.	Patients report increased glare, decreased vision, changes in color values (blue and yellow especially affected).
Posterior vitreous detachment	Liquefaction and shrinkage of vitreous body	May lead to retinal tears and detachment.	Reports light flashes, cobwebs, floaters.
Age-related macular degeneration (AMD)	Drusen (yellowish aging spots in the retina) appear and coalesce in the macula. Abnormal choroidal blood vessels may lead to formation of fibrotic disciform scars in the macula	Central vision is affected; onset is more gradual in dry AMD, more rapid in wet AMD; distortion and loss of central vision may occur.	Reading vision is affected; words may be missing letters, faded areas appear on the page, straight lines may appear wavy; drusen, pigmentary changes in retina; abnormal submacular choroidal vessels.

head and eye movements). In a visual acuity range of 20/200 to 20/400 with a 20-degree to greater than 10-degree visual field restriction, the person can read slowly with optical aids.

The most common causes of blindness and visual impairment among adults 40 years and older are diabetic retinopathy, macular degeneration, glaucoma, and cataracts (Prevent Blindness America, 2012). Macular degeneration is more prevalent among Caucasians, whereas glaucoma is more prevalent among African Americans (Eliopoulos, 2018). The number of blind people in India is 8.8 million (Mascarenhas, 2017). Preventable conditions such as cataract and refractory errors are the major contributors (82.4%) of blindness.

Medical Management

Managing vision impairment involves magnification and image enhancement through the use of low vision aids and strategies, as well as referrals to social services and community agencies. The goals are to optimize the patient's remaining vision and assist the patient to perform customary activities. Table 42-2 presents low vision aids. Medications are prescribed for glaucoma. Ongoing research suggests that gene therapy may replace or be an adjunct to pharmacologic or surgical treatment for ocular disorders in the near future (Lee & Garg, 2015).

Nursing Management

Nurses need to increase their sensitivity to the challenges faced by patients with visual impairments. Coping with blindness involves emotional, physical, and social adaptation. The emotional adjustment to blindness or severe visual impairment determines the success of the physical and social adjustments of the patient. Successful emotional adjustment means acceptance of blindness or severe visual impairment.

Promoting Coping

Effective coping may not occur until the patient recognizes the permanence of the low vision or blindness. A patient who is newly visually impaired and their family members undergo the various steps of grieving: denial and shock, anger and protest, restitution, loss resolution, and acceptance. The ability to accept the changes that must come with visual loss and willingness to adapt to those changes influence the successful rehabilitation of the patient with vision loss. Additional aspects to consider are value changes, independence–dependence conflicts, coping with stigma, and learning to function in social settings without visual cues and landmarks.

Promoting Spatial Orientation and Mobility

A person who is blind or severely visually impaired requires strategies for adapting to the environment. ADLs, such as walking to a chair from a bed, require spatial concepts. The person needs to know where he or she is in relation to the rest of the room, to understand the changes that may occur, and to know how to approach the desired location safely. This requires a collaborative effort between the patient and the responsible adult who serves as the sighted guide. The nurse must assess the degree of physical assistance the person with vision loss requires and communicate this to other health care personnel.

The nurse should be aware of the importance of techniques in providing physical assistance, encouraging independence, and ensuring safety. Strategies for interacting with the patient with vision loss are presented in Chart 42-3. Research supports

TABLE 42-2 Activities Affected by Visual Impairment and Suggestions for Low Vision Aids

Activity	Optical Aids	Nonoptical Aids
Shopping	Hand magnifier	Lighting, color cues
Fixing a snack	Bifocals	Color cues; consistent food storage plan
Eating out	Hand magnifier	Flashlight, portable lamp
Identifying money	Bifocals, hand magnifier	Arrange paper money in wallet compartments
Reading print	High-power spectacle, bifocals, hand magnifier, stand magnifier, closed-circuit television	Lighting, high-contrast print, large print, reading slit
Writing	Hand magnifier	Lighting, bold-tip pen, black ink
Using a telephone	Hand magnifier	Large-print buttons, hand-printed directory Braille phones, picture/photo phones, and talking phones
Crossing streets	Lightweight handheld monoscopes/telescopes	Cane; ask directions
Finding taxis and bus signs	Lightweight handheld monoscopes/telescopes	Ask for assistance
Reading medication labels	Hand magnifier	Color codes, large print
Reading stove dials	Hand magnifier	Color codes, raised dots
Adjusting the thermostat	Hand magnifier	Enlarged-print model
Using a computer	Spectacles	High-contrast color, large-print program. Screen-reader programs convert text on the computer screen to synthesized speech
Reading signs	Spectacles	Move closer
Watching sporting event	Lightweight handheld monoscopes/telescopes	Sit in front rows

Chart 42-3

Strategies for Interacting with People who are Blind or have Low Vision

- Remember that the only difference between you and people who are blind or have low vision is that they are not able to see through their eyes what you are able to see through yours.
- Do not be uncomfortable when in the company of a person who is blind or has low vision. Talk with the person as you would talk with any other individual, honestly and without pity; do not be concerned about using words like "see" and "look." There is no need to raise your voice unless the person asks you to do so.
- Identify yourself as you approach the person and before you make physical contact. Tell the person your name and your role. If another person approaches, introduce him or her. When you leave the room, be sure to tell the person that you are leaving and if anyone else remains in the room.
- Keep in mind that it is often appropriate to touch the person's hand or arm lightly to indicate that you are about to speak.
- When talking, face the person and speak directly to him or her using a normal tone of voice.
- Be specific when communicating direction. Mention a specific distance or use clock cues when possible (e.g., walk left about 2 yards; walk about 20 feet to the right; the telephone is at 2 o'clock). Avoid using phrases such as "over there."
- When you offer to assist someone, allow the person to hold on to your arm just above the elbow and to walk a half-step behind you.
- When offering the person a seat, place the person's hand on the back or the arm of the seat.
- When you are about to go up or down a flight of stairs, tell the person and place their hand on the banister.
- Make sure that the environment is free of obstacles; close doors and cabinets so that they are not in the path.
- Offer to read written information, such as a menu.
- If you serve food to the person, use clock cues to specify where everything is on the plate.
- When the person who is blind or has low vision is a patient in a health care facility:
  - Make sure all objects the person will need are close at hand.
  - Identify the location of objects that the person may need (e.g., "The call light is near your right hand"; "The telephone is on the table on the left side of your bed.")
  - Remove obstacles that may be in the person's pathway and could cause a fall.
  - Place all assistive devices that the person uses close at hand; let the person feel the devices so that he or she knows their location.
- Ask the person, "How can I help you?" At some times, the person needs help; at other times, help may not be needed.

Adapted from Pagliuca, L. M., Macedo-Costa, K. N., Reboucas, G. B., et al. (2014). Validation of the general guidelines of communication between the nurse and the blind. Reviews Bras Enferm, 67(5), 715–725.

the use of a validated protocol to educate staff to perform therapeutic communication, deliver services, and minimize communication barriers with patients who are blind (Pagliuca, Macedo-Costa, Reboucas, et al., 2014). The readiness of the patient and family to learn must be assessed before initiating orientation and mobility training.

Promoting Home, Community-Based, and Transitional Care

The nurse, social worker, family, and others collaborate to assess the patient's home condition and support system. A low vision specialist or occupational therapist should be consulted, particularly for patients for whom identifying and administering medications pose challenges. Referral for vision rehabilitation should be provided for appropriate patients (American Academy of Ophthalmology Vision Rehabilitation Committee, 2012).

Other interventions that are appropriate for some people with visual impairment or blindness include Braille and. There has been an ever-increasing reliance on print magnification technology as well as computer-assisted speech output. However, although the use of Braille may be less important for adults who have already learned language and grammar skills, educators and low vision specialists have continued to advocate that children who are legally blind be given the opportunity to learn Braille.

OCULAR MEDICATION ADMINISTRATION

Because medications are often prescribed to treat ocular disorders, nurses must understand the actions of the commonly used medications and effective administration. The main objective of ocular medication delivery is to maximize the amount of medication that reaches the ocular site of action in sufficient concentration to produce a beneficial therapeutic effect. This is determined by the dynamics of ocular pharmacokinetics: absorption, distribution, metabolism, and excretion.

Ocular absorption involves the entry of a medication into the aqueous humor through the different routes of ocular medication administration. The rate and extent of aqueous humor absorption are determined by the characteristics of the medication and the anatomy and physiology of the eye. Natural barriers of absorption that diminish the efficacy of ocular medications include the following:

- *Limited size of the conjunctival sac.* The conjunctival sac can hold only 50 mcL, and any excess is wasted. The volume of one eye drop from commercial topical ocular solutions typically ranges from 20 to 35 mcL.
- *Corneal membrane barriers.* The epithelial, stromal, and endothelial layers are barriers to absorption.
- *Blood–ocular barriers.* Blood–ocular barriers prevent high ocular tissue concentration of most ophthalmic medications because they separate the bloodstream from the ocular tissues and keep foreign substances from entering the eye, thereby limiting a medication's efficacy.
- *Tearing, blinking, and drainage.* Increased tear production and drainage due to ocular irritation or an ocular condition may dilute or wash out an instilled eye drop; blinking expels an instilled eye drop from the conjunctival sac.

Distribution of an ocular medication into the various ocular tissues varies by tissue type—the conjunctiva, cornea, lens, iris, ciliary body, and choroids absorb medications to varying degrees. Medications penetrate the corneal epithelium by diffusion by passing through the cells (intracellular) or by passing between the cells (intercellular). Water-soluble (hydrophilic) medications diffuse through the intracellular route, and fat-soluble (lipophilic) medications diffuse through the intercellular route. Topical administration usually does not reach the retina in significant concentrations. Because the space

between the ciliary process and the lens is small, medication diffusion in the vitreous is slow. When high concentrations of medication in the vitreous are required, intraocular injection is often chosen to bypass the natural ocular anatomic and physiologic barriers (American Society of Ophthalmic Registered Nurses [ASORN], 2013).

Aqueous solutions are most commonly used for the eye. They are the least expensive medications and interfere the least with vision. However, corneal contact time is brief because tears dilute the medication. Ophthalmic ointments have extended retention time in the conjunctival sac and provide a higher concentration than eye drops. The major disadvantage of ointments is the blurred vision that results after application. In general, eyelids and eyelid margins are best treated with ointments. The conjunctiva, limbus, cornea, and anterior chamber are treated most effectively with instilled solutions or suspensions. Subconjunctival injection may be necessary for better absorption in the anterior chamber. If high medication concentrations are required in the posterior chamber, intravitreal injections or systemically absorbed medications are considered. Contact lenses and collagen shields soaked in antibiotic agents are alternative delivery methods for treating corneal infections.

Of all these delivery methods, the topical route of administration—instilled eye drops and applied ointments—remains the most common (ASORN, 2013). Topical instillation, which is the least invasive method, permits self-administration of medication and produces fewer side effects.

Preservatives are commonly used in ocular medications. Benzalkonium chloride, for example, prevents the growth of organisms and enhances the corneal permeability of most medications; however, some patients are allergic to this preservative. This may be suspected even if the patient had never before experienced an allergic reaction to systemic use of the medication in question. Eye drops without preservatives can be prepared by pharmacists.

Common Ocular Medications

Common ocular medications include topical anesthetic, mydriatic, and cycloplegic agents that reduce IOP; anti-infective medications; corticosteroids; nonsteroidal anti-inflammatory drugs (NSAIDs); antiallergy medications; eye irrigants; and lubricants.

Topical Anesthetic Agents

One or two drops of proparacaine hydrochloride (Ophthaine 0.5%) and tetracaine hydrochloride (Pontocaine 0.5%) are instilled before diagnostic procedures such as tonometry and minor ocular procedures such as removal of sutures or conjunctival or corneal scrapings. Topical anesthetic agents are also used for severe eye pain to allow the patient to open their eyes for examination or treatment (e.g., eye irrigation for chemical burns). Anesthesia occurs within 20 seconds to 1 minute and lasts 10 to 20 minutes. The nurse must educate the patient not to rub the eyes while anesthetized because this may result in corneal damage.

Mydriatic and Cycloplegic Agents

Mydriasis, or pupil dilation, is the main objective of the administration of mydriatics and cycloplegics (see Table 42-3). These two types of medications function differently and are used in combination to achieve the maximal dilation that is needed during surgery and fundus examinations to give the ophthalmologist a better view of the internal eye structures. Mydriatics potentiate alpha-adrenergic sympathetic effects that result in the relaxation of the ciliary muscle. This causes the pupil to dilate. However, this sympathetic action alone is not enough to sustain mydriasis because of its short duration of action. The strong light used during an eye examination also stimulates miosis (i.e., pupillary contraction). Cycloplegic medications are given to paralyze the iris sphincter.

TABLE 42-3 Mydriatics and Cycloplegics

Medication	Available Preparation/ Concentration	Indication/Dosage	Peak		Recovery Time	
			Mydriasis (Minutes)	Cycloplegia (Minutes)	Mydriasis	Cycloplegia
Phenylephrine (Neo-Synephrine)	Solutions (2.5%, 10%)	Given with cycloplegics in pupillary dilation for ophthalmoscopy and surgical procedures every 5–10 minutes × 3 or until the pupils are fully dilated	10–60	—	3–6 hours	—
Atropine (Isopto Ophthalmic)	Ointment (0.5–2%) Solutions (0.5–3%)	In uveitis, or after surgery, 2–4 × daily	30–40	60–180	7–10 days	6–12 days
Scopolamine (Isopto Hyoscine Ophthalmic)	Solution (0.25%)	Same as atropine	20–30	30–60	3–7 days	3–7 days
Homatropine (Homatropine HBr)	Solution (5–2.5%)	Same as atropine and scopolamine	40–60	30–60	1–3 days	1–3 days
Cyclopentolate (AK-Pentolate)	Solution (0.5–2%)	Given with mydriatics every 5–10 minutes × 3 or until the pupils are fully dilated for ophthalmoscopy and surgical procedures	30–60	25–75	1 day	6–24 hours
Tropicamide (Myrdal)	Solution (0.25–1%)		20–40	20–35	6 hours	<6 hours

Adapted from Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer.

The patient is educated about the temporary effects of mydriasis on vision, such as glare and the inability to focus properly. The patient may have difficulty reading. The effects of the various mydriatics and cycloplegics can last 3 hours to several days. The patient is advised to wear sunglasses (most eye clinics provide protective sunglasses). The ability to drive depends on the person's age, vision, and comfort level. Some patients can drive safely with the use of sunglasses, whereas others may need to be driven home.

Mydriatic and cycloplegic agents affect the central nervous system. Their effects are most prominent in younger and older adult patients; these patients must be assessed closely for symptoms, such as increased blood pressure, tachycardia, dizziness, ataxia, confusion, disorientation, incoherent speech, and hallucination. These medications are contraindicated in patients with narrow angles or shallow anterior chambers and in patients taking monoamine oxidase inhibitors or tricyclic antidepressants.

Medications Used to Treat Glaucoma

Therapeutic medications for glaucoma are used to lower IOP by decreasing aqueous production or increasing aqueous outflow. Because glaucoma calls for lifetime therapy, the patient must be educated with regard to both the ocular and systemic side effects of the medications. See section on glaucoma later in this chapter.

Anti-Infective Medications

Anti-infective medications include antibiotic, antifungal, and antiviral agents. Most are available as drops, ointments, or subconjunctival or intravitreal injections. Antibiotics include penicillin, cephalosporins, aminoglycosides, and fluoroquinolones. The main antifungal agent is amphotericin B. Side effects of amphotericin are serious and include severe pain, conjunctival necrosis, iritis, and retinal toxicity. Antiviral medications include acyclovir (Zovirax) and ganciclovir (Cytovene). They are used to treat ocular infections associated with herpes virus and cytomegalovirus (CMV). Patients receiving ocular anti-infective agents are subject to the same side effects and adverse reactions as those receiving oral or parenteral medications.

Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs

Topical preparations of corticosteroids are commonly used in inflammatory conditions of the eyelids, conjunctiva, cornea, anterior chamber, lens, and uvea. In posterior segment diseases that involve the posterior sclera, retina, and optic nerve, topical agents are less effective and parenteral and oral routes are preferred. When a suspension is prescribed, the patient is instructed to shake the bottle several times to promote mixture of the medication and maximize its therapeutic effect. The most common ocular side effects of long-term topical corticosteroid administration are glaucoma, cataracts, susceptibility to infection, impaired wound healing, mydriasis, and ptosis. High IOP may develop, which is reversible after corticosteroid use is discontinued. To avoid the side effects of corticosteroids, NSAIDs are used as an alternative in controlling inflammatory eye conditions and postoperatively to reduce inflammation.

Antiallergy Medications

Ocular hypersensitivity reactions, such as allergic conjunctivitis, are extremely common. These conditions result primarily from responses to environmental allergens. Most allergens are airborne or carried to the eye by the hand or by other means, although allergic reactions may also be drug induced. Corticosteroids are commonly used as anti-inflammatory and immunosuppressive agents to control ocular hypersensitivity reactions.

Ocular Irrigants and Lubricants

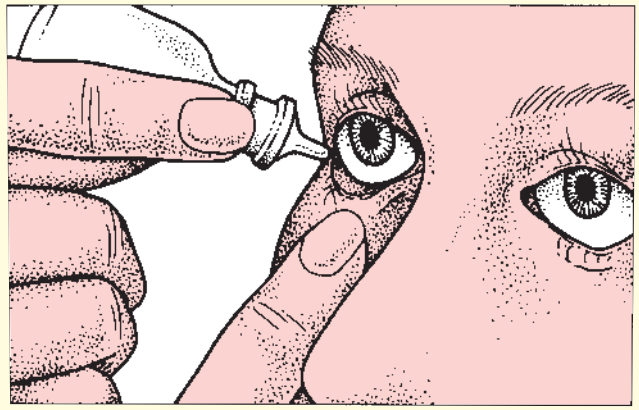
Most irrigating solutions are used to cleanse the external lids to maintain lid hygiene, to irrigate the external corneal surface to regain normal pH (e.g., in chemical burns), to irrigate the corneal surface to eliminate debris, or to inflate the globe intraoperatively. These solutions have various compositions that include sodium, potassium, magnesium, calcium, bicarbonate, glucose, and glutathione (i.e., substance found in the aqueous humor). Sterile irrigating solutions, such as Dacriose, for lid hygiene are available. Irrigating solutions are safe to use with an intact corneal surface; however, the corneal surface should not be irrigated in cases of threatened corneal perforation. For patients with severe corneal ulcer, specific instructions from the ophthalmologist must be obtained regarding whether it is safe to irrigate the corneal surface or just to cleanse the external lids. Although it is good practice to promote hygiene, prevention of complications must be the primary concern. Normal saline solutions are commonly used to irrigate the corneal surface when chemical burns occur.

Lubricants, such as artificial tears, help alleviate corneal irritation, such as dry eye syndrome. Artificial tears are topical preparations of carboxymethylcellulose or hydroxypropyl methylcellulose that are prepared as eye drop solutions, ointments, or ocular inserts (inserted at the lower conjunctival cul-de-sac once each day). The eye drops can be instilled as often as every hour, depending on the severity of symptoms.

Nursing Management

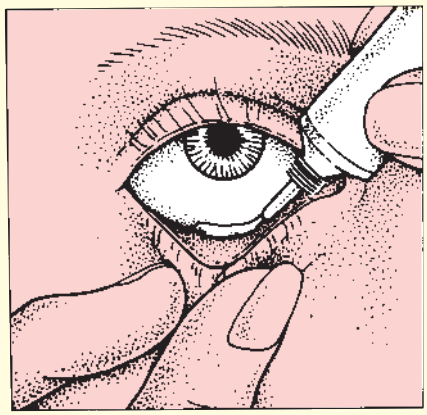
The objectives in administering ocular medications are to ensure proper administration to maximize the therapeutic effects and to ensure the safety of the patient by monitoring for systemic and local side effects (ASORN, 2013). Absorption of eye drops by the nasolacrimal duct is undesirable because of the potential systemic side effects of ocular medications. To diminish systemic absorption and minimize the side effects, it is important to occlude the puncta (see Chart 42-4). This is especially important for patients who are most vulnerable to medication overdose, including older adults; women who are pregnant or lactating; and patients with cardiac, pulmonary, hepatic, or kidney disease. A 5-minute interval between instillation of different types of ocular drops is recommended.

Before the administration of ocular medications, the nurse warns the patient that blurred vision, stinging, and a burning sensation are symptoms that ordinarily occur after instillation and are temporary. Risk for interactions of the ocular medication with other ocular and systemic medications must be emphasized; therefore, a careful patient interview regarding the medications being taken must be obtained.



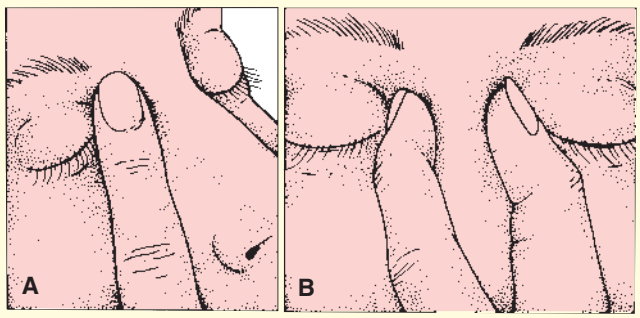
Nursing Alert: To prevent infection, meticulous hand hygiene before and after medication instillation is crucial. In addition, the tip of the eye drop bottle or the ointment tube must never touch any part of the eye, and the medication must be recapped immediately after each use.

Chart 42-4 PATIENT EDUCATION



Instilling Eye Medications

The nurse instructs the patient to:



- Never use eye solutions that have changed colors.
- Perform hand hygiene before and after the procedure.
- Ensure adequate lighting.
- Read the label of the eye medication to verify that it is the correct medication.
- Remove contact lens as needed.
- Assume a comfortable position.
- Avoid touching the tip of the medication container to any part of the eye or face.
- Hold the lower lid down; do not press on the eyeball. Apply gentle pressure to the cheekbone to anchor the finger holding the lid.

- Instill eye drops before applying ointments.
- Apply a 0.25–0.5-inch ribbon of ointment to the lower conjunctival sac.

- Keep the eyelids closed, and apply gentle pressure on the inner canthus (punctal occlusion) near the bridge of the nose for 1 or 2 minutes immediately after instilling eye drops.
- Use a clean tissue to gently pat skin to absorb excess eye drops that run onto the cheeks.
- Wait 5 minutes before instilling another eye drop and 10 minutes before instilling another ointment.
- Reinsert contact lens if applicable.

Adapted from American Society of Ophthalmic Registered Nurses (ASORN). (2013). Recommended practice for registered nurses–Use of multi-dose medications. San Francisco, CA: Author; Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer.

If a patient who instills their own medications cannot feel the eye drops when they are instilled, the eye medication may be refrigerated, because a cold drop is easier to detect. A 5-minute interval between successive administrations allows adequate drug retention and absorption. The patient or the caregiver at home should be asked to demonstrate actual eye drop or ointment instillation and punctal occlusion.

GLAUCOMA

The term glaucoma is used to refer to a group of ocular conditions characterized by elevated IOP (Eldaly et al., 2014). If left untreated, the increased IOP damages the optic nerve and nerve fiber layer, but the degree of harm is highly variable (Eliopoulos, 2018). The optic nerve damage is related to the IOP caused by congestion of aqueous humor in the eye. A range of IOPs are considered "normal," but these may also be associated with vision loss in some patients.

Glaucoma is estimated to affect 3 million Americans, approximately 50% of whom are undiagnosed (Grossman & Porth, 2014). Glaucoma is more prevalent in people older than 40 years, and it is the third most common age-related eye disease in the United States. Chart 42-5 presents the risk factors for glaucoma. There is no cure for glaucoma, but the disease can be controlled (Glaucoma Research Foundation, 2016). Prevalence of glaucoma in people aged 40 plus in India varies between urban and rural population. Among urban population, the prevalence is about 3.23% and among rural Indians it is 2.7% (Paul, et al., 2016). The estimated number of people affected by glaucoma is 12 million in India (Saxena, Singh, & Vashist, 2013). Glaucoma is the third leading cause of blindness in India (5.8%).

Chart 42-5 RISK FACTORS

Glaucoma

Physiology

Aqueous humor flows between the iris and the lens, nourishing the cornea and lens. Most (90%) of the fluid then flows out of the anterior chamber, draining through the spongy trabecular meshwork into the canal of Schlemm and the episcleral veins (see Fig. 42-6). About 10% of the aqueous fluid exits through the ciliary body into the suprachoroidal space and then drains into the venous circulation of the ciliary body, choroid, and sclera (Grossman & Porth, 2014). Unimpeded outflow of aqueous fluid depends on an intact drainage system and an open angle (about 45 degrees) between the iris and the cornea. A narrower angle places the iris closer to the trabecular meshwork, diminishing the angle. The amount of aqueous humor produced tends to decrease with age, in systemic diseases such as diabetes, and in ocular inflammatory conditions.

IOP is determined by the rate of aqueous production, the resistance encountered by the aqueous humor as it flows out of the passages, and the venous pressure of the episcleral veins that drain into the anterior ciliary vein. When aqueous fluid production and drainage are in balance, the IOP is between 10 and 21 mm Hg. When aqueous fluid is inhibited from flowing out, pressure builds up within the eye. Fluctuations in IOP occur with time of day, exertion, diet, and medications. IOP tends to increase with blinking, tight lid squeezing, and upward gazing. Systemic conditions such as diabetes and intraocular conditions such as uveitis and retinal detachment have been associated with elevated IOP. Glaucoma may not be recognized in people with thin corneas because measurement of the IOP may be falsely low as a result of this thinness.

Pathophysiology

There are two theories regarding how increased IOP damages the optic nerve in glaucoma. The direct mechanical theory suggests that high IOP damages the retinal layer as it passes through the optic nerve head. The indirect ischemic theory suggests that high IOP compresses the microcirculation in the optic nerve head, resulting in cell injury and death. Some glaucomas appear as exclusively mechanical, and some are exclusively ischemic types. Typically, most cases are a combination of both. Pathophysiological sequence of events of glaucoma is presented in Figure 42-7.

Classification of Glaucoma

There are several types of glaucoma. Forms of glaucoma are identified as wide-angle glaucoma; narrow-angle glaucoma;

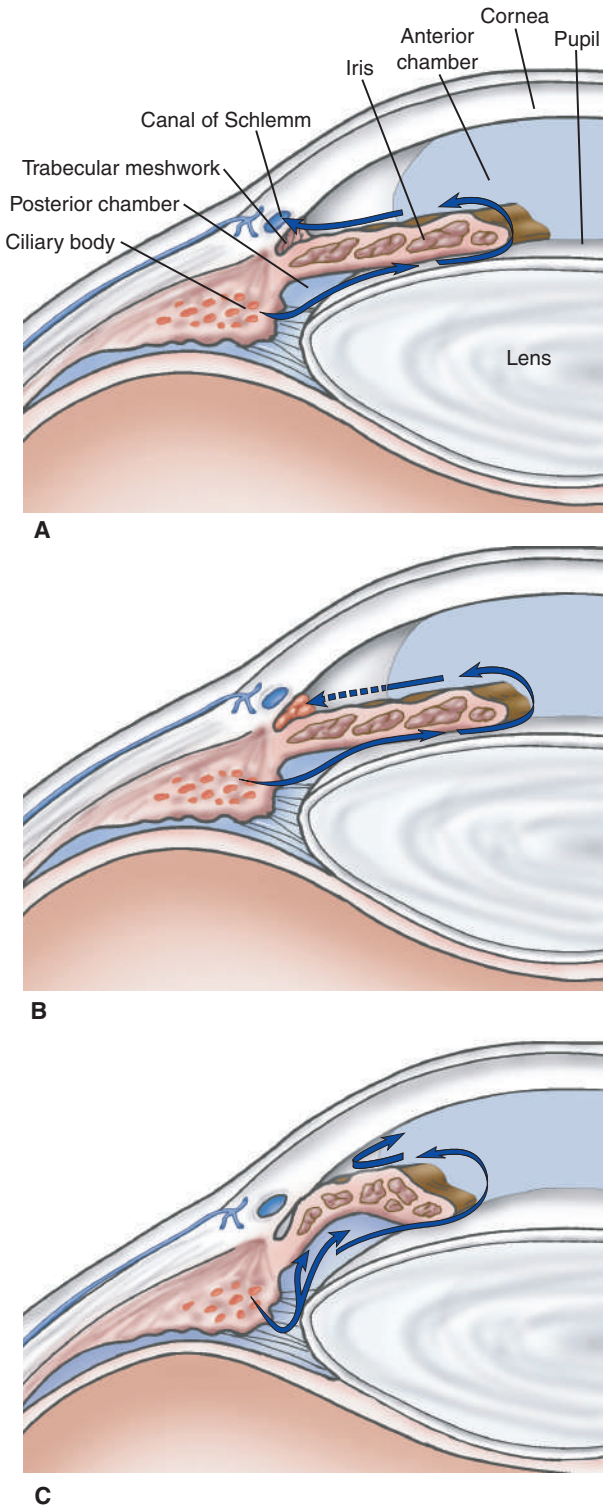

Figure 42-6 • A. Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. **B.** In wide-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. **C.** In narrow-angle glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris so that the iris blocks the trabecular meshwork. Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Porth's pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

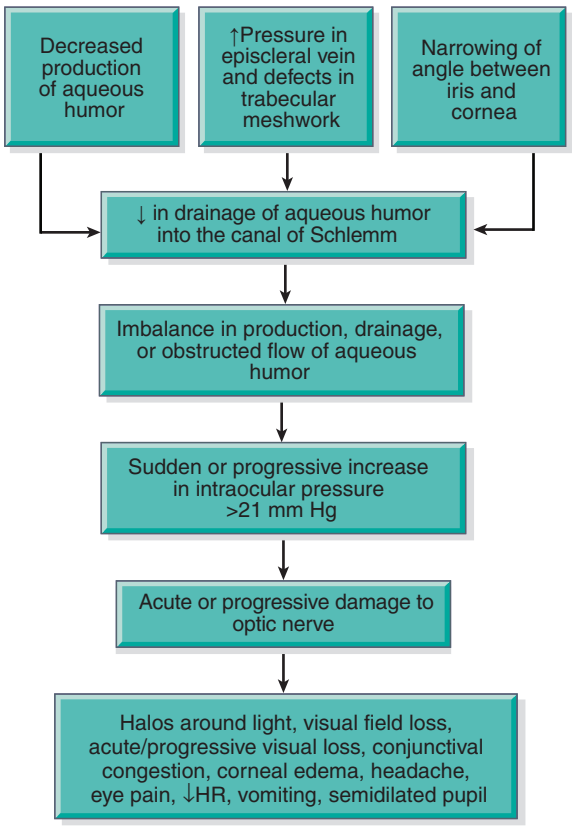

Figure 42-7 • Pathophysiological sequence of events in glaucoma.

congenital glaucoma; and glaucoma associated with other conditions, such as developmental anomalies or corticosteroid use. Glaucoma can be primary or secondary, depending on whether associated factors contribute to the rise in IOP. The two common clinical forms of glaucoma in adults are wide- and narrow-angle glaucoma, which are differentiated by the mechanisms that cause impaired aqueous outflow (Grossman & Porth, 2014). Table 42-4 summarizes the characteristics of the different types of adult glaucoma.

Clinical Manifestation

Glaucoma is often called the "silent thief of sight" because most patients are unaware that they have the disease until they have experienced visual changes and vision loss. The patient may not seek health care until he or she experiences blurred vision or "halos" around lights, difficulty focusing, difficulty adjusting eyes in low lighting, loss of peripheral vision, aching or discomfort around the eyes, and headache.

Assessment and Diagnostic Findings

The purpose of a glaucoma workup is to establish the diagnostic category, assess the optic nerve damage, and formulate a treatment plan. The patient's ocular and medical history must be detailed to investigate the history of predisposing factors. The types of examinations used in glaucoma include tonometry to measure the IOP, ophthalmoscopy to inspect the optic nerve, and central visual field testing (Glaucoma Research Foundation, 2016); (Grossman & Porth, 2014).

TABLE 42-4 Selected Glaucoma Types, Clinical Manifestation, and Treatment

Types of Glaucoma	Clinical Manifestations	Treatment
Wide Angle		
Usually bilateral, but one eye may be more severely affected than the other. In wide-angle glaucoma, the anterior chamber angle is open and appears normal.		
Normal tension glaucoma	IOP ≤21 mmHg. Optic nerve damage, visual field defects.	If medical treatment is unsuccessful, LT can decrease IOP by 20%. Glaucoma filtering surgery if continued optic nerve damage despite medication therapy and LT.
Ocular hypertension	Elevated IOP. Possible ocular pain or headache.	The best management for normal tension glaucoma management is yet to be established. Goal is to lower the IOP by at least 30%.
Narrow Angle		
Obstruction in aqueous humor outflow due to the complete or partial closure of the angle from the forward shift of the peripheral iris to the trabecula. The obstruction results in an increased IOP.		
Acute angle–closure glaucoma	Rapidly progressive visual impairment, periocular pain, conjunctival hyperemia, and congestion. Pain may be associated with nausea, vomiting, bradycardia, and profuse sweating. Reduced central visual acuity, severely elevated IOP, corneal edema. Pupil is vertically oval, fixed in a semidilated position, and unreactive to light and accommodation.	Ocular emergency; administration of hyperosmotics, acetazolamide, and topical ocular hypotensive agents, such as pilocarpine and beta-blockers (betaxolol). Possible laser incision in the iris (iridotomy) to release blocked aqueous and reduce IOP. Other eye is also treated with pilocarpine eye drops and/or surgical management to avoid a similar spontaneous attack.
Subacute angle–closure glaucoma	Transient blurring of vision, halos around lights; temporal headaches and/or ocular pain; pupil may be semidilated.	Prophylactic peripheral laser iridotomy. Can lead to acute or chronic angle–closure glaucoma if untreated.
Chronic angle–closure glaucoma	Progression of glaucomatous cupping and significant visual field loss; IOP may be normal or elevated; ocular pain and headache.	Management includes laser iridotomy and medications.

IOP, intraocular pressure; LT, laser trabeculoplasty.

Cochrane Database of Systematic Reviews, (2), CD007059. Grossman, S. C., & Porth, C. M. (2014). Porth's Pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Figure 42-8 • Visual changes associated with glaucoma. Photo courtesy of the National Eye Institute, National Institutes of Health.

The changes in the optic nerve related to glaucoma are pallor and cupping of the optic nerve disc. The pallor of the optic nerve is caused by a lack of blood supply. Cupping is characterized by exaggerated bending of the blood vessels as they cross the optic disc, resulting in an enlarged optic cup that appears more basin like compared with a normal cup. The progression of cupping in glaucoma is caused by the gradual loss of retinal nerve fibers and the loss of blood supply.

As the optic nerve damage increases, visual perception decreases. The localized areas of visual loss (i.e., scotomas) represent loss of retinal sensitivity and nerve fiber damage and are measured and mapped on a graph. In patients with glaucoma, the graph has a distinct pattern that is different from other ocular diseases and is useful in establishing the diagnosis. Figure 42-8 shows the visual changes caused by glaucoma.

Medical Management

The aim of all glaucoma treatment is prevention of optic nerve damage. Lifelong therapy is necessary because glaucoma cannot be cured. Treatment focuses on pharmacologic therapy, laser procedures, surgery, or a combination of these approaches, all of which have potential complications and side effects. The object is to achieve the greatest benefit at the least risk, cost, and inconvenience to the patient. Although treatment cannot reverse optic nerve damage, further damage can be controlled. The goal is to maintain an IOP within a range unlikely to cause further damage (Eldaly et al., 2014).

The initial target for IOP among patients with elevated IOP and those with low-tension glaucoma with progressive visual field loss is typically set at 30% lower than the current pressure. The patient is monitored for changes in the appearance of the optic nerve. If there is evidence of progressive damage, the target IOP is again lowered until the optic nerve shows stability.

Pharmacologic Therapy

Medical management of glaucoma relies on systemic and topical ocular medications that lower IOP. Periodic follow-up examinations are essential to monitor IOP, the appearance of the optic nerve, the visual fields, and side effects of medications. Therapy takes into account the patient's health and stage of glaucoma. Comfort, affordability, convenience, lifestyle, and functional ability are factors to consider in the patient's adherence to the medical regimen (Eliopoulos, 2018).

The patient is usually started on the lowest dose of topical medication and then advanced to increased concentrations until the desired IOP level is reached and maintained. Beta-blockers are the preferred initial topical medications because of their efficacy, minimal dosing (can be used once each day), and low cost. One eye is treated first, with the other eye used as a control in determining the efficacy of the medication; once efficacy has been established, treatment of the other eye is started. If the IOP is elevated in both eyes, both are treated. When results are not satisfactory, a new medication is substituted. The main markers of the efficacy of the medication in glaucoma control are lowering of the IOP to the target pressure, stable appearance of the optic nerve head, and the visual field.

Many ocular medications are used to treat glaucoma (see Table 42-5), including miotics, beta-blockers, alpha$_2$-agonists (i.e., adrenergic agents), carbonic anhydrase inhibitors, and prostaglandins. Cholinergics (i.e., miotics) increase the outflow of the aqueous humor by affecting ciliary muscle contraction and pupil constriction, allowing flow through a larger opening between the iris and the trabecular meshwork. Beta-blockers and carbonic anhydrase inhibitors decrease aqueous production. Prostaglandin analogs reduce IOP by increasing aqueous humor outflow (Comerford, 2015); (Grossman & Porth, 2014).

Surgical Management

Surgery is reserved for patients in whom pharmacologic treatment has not controlled the IOP. This minimally invasive procedure is specifically designed to improve fluid drainage from the eye to balance IOP. By restoring the eye's natural fluid balance, trabeculectomy surgery stabilizes the optic nerve and minimizes further visual field damage (Eldaly et al., 2014). The surgery is performed through a small incision and does not require creation of a permanent hole in the eye wall or an external filtering bleb or an implant.

In laser trabeculoplasty for glaucoma, a laser beam is applied to the inner surface of the trabecular meshwork to open the intratrabecular spaces and widen the canal of Schlemm, promoting outflow of aqueous humor and decreasing IOP. The procedure is indicated when IOP is inadequately controlled by medications, and it is contraindicated when the trabecular meshwork cannot be fully visualized because of a narrow angle.

In peripheral iridotomy for pupillary block glaucoma, an opening is made in the iris to eliminate the pupillary blockage. Laser iridotomy is contraindicated in patients with corneal edema, which interferes with laser targeting and strength. Potential complications include burns to the cornea, lens, or retina; transient elevated IOP; closure of the iridotomy; uveitis; and blurring.

Filtering procedures for glaucoma are used to create an opening or fistula in the trabecular meshwork to drain aqueous humor from the anterior chamber to the subconjunctival space into a bleb (fluid collection on the outside of the eye), thereby bypassing the usual drainage structures. This allows the aqueous humor to flow and exit by different routes (i.e., absorption by the conjunctival vessels or mixing with tears). Trabeculectomy is the standard filtering technique used to remove part of the trabecular meshwork (Eldaly et al., 2014). Complications include hemorrhage, an extremely low (hypotony) or extremely elevated IOP, uveitis, cataracts, bleb failure, bleb leak, and endophthalmitis (i.e., intraocular infection).

Drainage implants or *shunts* are tubes implanted in the anterior chamber to shunt aqueous humor to the episcleral plate in the conjunctival space. Implants are used when failure

TABLE 42-5 Medications Used in the Management of Glaucoma

Medication	Action	Side Effects	Nursing Implications
Cholinergics (miotics) (pilocarpine, carbachol)	Increase aqueous fluid outflow by contracting the ciliary muscle and causing miosis (constriction of the pupil) and opening of trabecular meshwork	Periorbital pain, blurry vision, difficulty seeing in the dark	Caution patients about diminished vision in dimly lit areas. Pilocarpine can be stored at room temperature for up to 8 weeks and then should be discarded.
Beta-blockers (timolol maleate)	Decrease aqueous humor production	Can have systemic effects, including bradycardia, exacerbation of pulmonary disease, and hypotension	Contraindicated in patients with asthma, chronic obstructive pulmonary disease, 2nd- or 3rd-degree heart block, bradycardia, or cardiac failure; educate patients about punctal occlusion to limit systemic effects (see Chart 42-4).
Alpha-adrenergic agonists (apraclonidine, brimonidine)	Decrease aqueous humor production	Eye redness, dry mouth and nasal passages	Educate patients about punctal occlusion to limit systemic effects (see Chart 42-4).
Carbonic anhydrase inhibitors (acetazolamide, dorzolamide)	Decrease aqueous humor production	Oral medications (acetazolamide) are associated with serious side effects, including anaphylactic reactions, electrolyte loss, depression, lethargy, gastrointestinal upset, impotence, and weight loss; side effects of topical form (dorzolamide) include topical allergy	Do not administer to patients with sulfa allergies; monitor electrolyte levels.
Prostaglandin analogs (latanoprost, bimatoprost)	Increase uveoscleral outflow	Darkening of the iris, conjunctival redness, possible rash	Instruct patients to report any side effects.

Adapted from Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer.

has occurred with one or more trabeculectomies in which antifibrotic agents were used. A fibrous capsule develops around the episcleral plate and filters the aqueous humor, thereby regulating the outflow and controlling IOP.

Nursing Management

Nurses in all settings encounter patients with glaucoma. Even patients with long-standing disease and those with glaucoma as a secondary diagnosis should be assessed for knowledge level and adherence to their prescribed therapeutic regimen.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

The medical and surgical management of glaucoma slows the progression of the disease but does not cure it. The lifelong therapeutic regimen mandates patient education. The nature of the disease and the importance of strict adherence to the medication regimen must be included in an individualized education plan. A structured self-management program may increase adherence to the treatment regime. A thorough discussion of the medication program, particularly the interactions of glaucoma-control medications with other medications, is essential. For example, the diuretic effect of acetazolamide (Diamox) may have an additive effect on the diuretic effects of other antihypertensive medications (Comerford, 2015). The effects of glaucoma-control medications on vision must also be explained. Miotics and sympathomimetics result in altered focus; therefore, patients need to be cautious in navigating their surroundings. Chart 42-4 presents patient education about instilling eye medications and preventing systemic absorption with punctal occlusion. Chart 42-6 contains additional educational information to review with patients with glaucoma.

Continuing and Transitional Care

Patients with severe glaucoma and impaired function may need referral to home, community-based or transitional services that provide assistance in the home. The loss of peripheral vision impairs mobility the most. These patients also benefit from a referral for low vision and rehabilitation services. Patients who meet the criteria for legal blindness should be offered referrals to agencies that can assist them in obtaining government assistance.

Reassurance and emotional support are important aspects of care. A lifelong disease involving possible loss of sight has psychological, physical, social, and vocational ramifications. The family must be integrated into the plan of care, and because the disease has a familial tendency, family members should be encouraged to undergo examinations at least once every 2 years to detect glaucoma early.

CATARACTS

A cataract is a lens opacity or cloudiness (see Fig. 42-9). Cataracts are responsible for visual disability in 18 million people worldwide (Grossman & Porth, 2014). By 80 years of age, more than half of all Americans have cataracts. Cataracts are a leading cause of blindness in the world (Prevent Blindness America, 2012). Cataract is the leading cause of blindness in India (62.7%) (National Program for Control of Blindness, 2018).

Chart 42-6 PATIENT EDUCATION

Managing Glaucoma

The nurse instructs the patient to:

- Know your intraocular pressure measurement and the desired range.
- Be informed about the extent of your vision loss and optic nerve damage.
- Keep a record of your eye pressure measurements and visual field test results to monitor your own progress.
- Review all of your medications (including over-the-counter and herbal medications) with your ophthalmologist, and mention any side effects each time you visit.
- Ask about potential side effects and drug interactions of your eye medications.
- Ask whether generic or less costly forms of your eye medications are available.
- Review the dosing schedule with your ophthalmologist, and inform him or her if you have trouble following the schedule.
- Participate in the decision-making process. Let your primary provider know what dosing schedule works for you and other preferences regarding your eye care.
- Have the nurse observe you instilling eye medication to determine whether you are administering it properly (see Chart 42-4).
- Be aware that glaucoma medications can cause adverse effects if used inappropriately. Eye drops are to be given as prescribed, not when eyes feel irritated.
- Ask your ophthalmologist to send a report to your primary provider after each appointment.
- Keep all follow-up appointments.

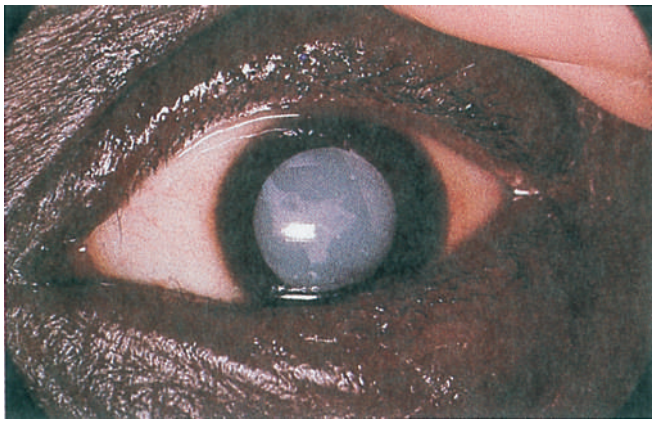

Figure 42-9 • A cataract is a cloudy or opaque lens. On visual inspection, the lens appears gray or milky. Reprinted with permission from Rubin, R., Strayer, D. S., & Rubin, E. (2012). Rubin's pathology: Clinicopathologic foundations of medicine (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Pathophysiology

Cataracts can develop in one or both eyes at any age. The three most common types are traumatic, congenital, or senile cataract (Grossman & Porth, 2014). There are a variety of risk factors, the most common one being age (see Chart 42-7).

Clinical Manifestations

Painless, blurry vision is characteristic of cataracts. The person perceives that surroundings are dimmer, as if their glasses need cleaning. Light scattering is common, and the person experiences reduced contrast sensitivity, sensitivity to glare, and reduced visual acuity. Other effects include myopic shift (return of ability to do close work [e.g., reading fine print] without eyeglasses), astigmatism (refractive error due to an irregularity in the curvature of the cornea), monocular diplopia (double vision), and color changes as lens becomes more brown in color (Cash & Glass, 2016); (Eliopoulos, 2018).

Assessment and Diagnostic Findings

Decreased visual acuity is directly proportionate to cataract density. The Snellen visual acuity test, ophthalmoscopy, and slit-lamp biomicroscopic examination are used to establish the degree of cataract formation. The degree of lens opacity does not always correlate with the patient's functional status. Some patients can perform normal activities despite clinically significant cataracts. Others with less lens opacification have a disproportionate decrease in visual acuity; hence, visual acuity is an imperfect measure of visual impairment.

Medical Management

No nonsurgical treatment (e.g., medications, eye drops, eyeglasses) cures cataracts or prevents age-related cataracts. Optimal medical management is prevention. Patients should be educated by primary providers about risk reduction strategies such as smoking cessation, weight reduction, optimal blood sugar control for patients with diabetes, and should be advised to wear sunglasses outdoors to prevent early cataract formation (Cash & Glass, 2016).

Surgical Management

In general, if reduced vision from cataract does not interfere with normal activities, surgery may not be needed. In deciding when cataract surgery is to be performed, the patient's functional and visual status should be a primary consideration (Eliopoulos, 2018). Cataract removal is common (Prevent Blindness America, 2012). Under the National Program for Control of Blindness, 6,324,490 cataract surgeries were performed in 2017–2018. Surgery is performed on an outpatient basis and usually takes less than 1 hour, with the patient being discharged in 30 minutes or less afterward. Although complications from cataract surgery are uncommon, they can have significant effects on vision (see Table 42-6). Restoration of visual function through a safe and minimally invasive procedure is the surgical goal, which is achieved with advances in topical anesthesia, smaller wound incision (i.e., clear cornea incision), and lens design (i.e., foldable and more accurate intraocular lens [IOL] measurements).

Injection-free topical and intraocular anesthesia, such as 1% lidocaine gel applied to the surface of the eye, eliminates the hazards of regional (retrobulbar and peribulbar) anesthesia, such as ocular perforation, retrobulbar hemorrhage, optic injuries, diplopia, and ptosis, and is ideal for patients receiving anticoagulants. Furthermore, patients can communicate and

Chart 42-7 RISK FACTORS

Cataract Formation

Aging

- Accumulation of a yellow-brown pigment due to the breakdown of lens protein
- Clumping or aggregation of lens protein (which leads to light scattering)
- Decreased oxygen uptake
- Decrease in levels of vitamin C, protein, and glutathione (an antioxidant)
- Increase in sodium and calcium
- Loss of lens transparency

Associated Ocular Conditions

- Infection (e.g., herpes zoster, uveitis)
- Myopia
- Retinal detachment and retinal surgery
- Retinitis pigmentosa

Toxic Factors

- Alkaline chemical eye burns, poisoning
- Aspirin use
- Calcium, copper, iron, gold, silver, and mercury, which tend to deposit in the pupillary area of the lens
- Cigarette smoking
- Corticosteroids, especially at high doses and in long-term use
- Ionizing radiation

Nutritional Factors

- Obesity
- Poor nutrition
- Reduced levels of antioxidants

Physical Factors

- Blunt trauma, perforation of the lens with a sharp object or foreign body, electric shock
- Dehydration associated with chronic diarrhea, the use of purgatives in anorexia nervosa, and the use of hyperbaric oxygenation
- Ultraviolet radiation in sunlight and x-ray

Systemic Diseases and Syndromes

- Diabetes
- Disorders related to lipid metabolism
- Down syndrome
- Musculoskeletal disorders
- Renal disorders

Adapted from Grossman, S. C., & Porth, C. M. (2014). Porth's Pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Kumar, C. M., Seet, E., Eke, T., et al. (2016). Glycaemic control during cataract surgery under loco-regional anesthesia: A growing problem and we are none the wiser. British Journal of Anesthesia, 117(6), 687–691.

cooperate during surgery. IV moderate sedation may be used to minimize anxiety and discomfort.

When both eyes have cataracts, one eye is treated first, with at least several weeks, preferably months, separating the two procedures. Because cataract surgery is performed to improve visual functioning, the delay for the other eye gives time for the patient and the surgeon to evaluate whether the results from the first surgery are adequate to preclude the need for a second operation. The delay also provides time for the first eye to recover; if there are any complications, the surgeon may decide to perform the second procedure differently.

Phacoemulsification

In this method of extracapsular cataract surgery, a portion of the anterior capsule is removed, allowing extraction of the lens nucleus and cortex while the posterior capsule and zonular support are left intact. An ultrasonic device is used to liquefy the nucleus and cortex, which are then suctioned out through a tube. An intact zonular–capsular diaphragm provides the needed safe anchor for the posterior chamber IOL. The pupil is dilated to 7 mm or greater (Peng, Fong, Phaik, et al., 2012). The surgeon makes a small incision on the upper edge of the cornea and a viscoelastic substance (clear gel) is injected into the space between the cornea and the lens. This prevents the space from collapsing and facilitates insertion of the IOL. Because the incision is smaller than the manual extracapsular cataract extraction, the wound heals more rapidly, and there is early stabilization of refractive error and less astigmatism.

Lens Replacement

After removal of the crystalline lens, the patient is referred to as aphakic (i.e., without lens). The lens, which focuses light on the retina, must be replaced for the patient to see clearly. There are three lens replacement options: aphakic eyeglasses, contact lenses, and IOL implants.

Aphakic glasses, although effective, are rarely used. Objects are magnified by 25%, making them appear closer than they actually are. This magnification creates distortion. Peripheral vision is also limited, and binocular vision (i.e., ability of both eyes to focus on one object and fuse the two images into one) is impossible if the other eye is aphakic (without a natural lens).

Contact lenses provide patients with almost normal vision, but because contact lenses need to be removed occasionally, the patient also needs a pair of aphakic glasses. Contact lenses are not advised for patients who have difficulty inserting, removing, and cleaning them. Frequent handling and improper disinfection increase the risk of infection.

Insertion of IOLs during cataract surgery is the most common approach to lens replacement (Eliopoulos, 2018). After cataract extraction, or phacoemulsification, the surgeon implants an IOL. Cataract extraction and posterior chamber IOLs are associated with a relatively low incidence of complications (e.g., eye infection, loss of vitreous humor, and slipping of the implant) (Eliopoulos, 2018). IOL implantation is contraindicated in patients with recurrent uveitis, proliferative diabetic retinopathy, neovascular glaucoma, or rubeosis iridis.

Nursing Management

Providing Preoperative Care

The patient with cataracts receives the usual preoperative care for ambulatory surgical patients undergoing eye surgery. The standard battery of preoperative tests (e.g., complete blood

TABLE 42-6 Potential Complications of Cataract Surgery

Complication	Effects	Management and Outcome
Immediate Preoperative		
Retrobulbar hemorrhage—can result from retrobulbar infiltration of anesthetic agents if the short ciliary artery is located by the injectia	Increased IOP, proptosis, lid tightness, and subconjunctival hemorrhage with or without edema	Emergent lateral canthotomy (slitting of the canthus) is performed to stop central retinal perfusion when the IOP is dangerously elevated. If this procedure fails to reduce IOP, a puncture of the anterior chamber with removal of fluid is considered. The patient must be closely monitored for at least a few hours. Postponement of cataract surgery for 2–4 weeks is advised. Complications such as iris prolapse, vitreous loss, and choroidal hemorrhage could result in a catastrophic visual outcome.
Intraoperative		
Rupture of the posterior capsule	May result in loss of vitreous	Anterior vitrectomy is required if vitreous loss occurs.
Suprachoroidal (expulsive) hemorrhage—profuse bleeding into the suprachoroidal space	Extrusion of intraocular contents from the eye or opposition of retinal surfaces	Closure of the incision and administration of a hyperosmotic agent to reduce IOP or corticosteroids to reduce intraocular inflammation. Vitrectomy is performed 1–2 weeks later. Visual prognosis is poor; some useful vision may be salvaged on rare occasions.
Early Postoperative		
Acute bacterial endophthalmitis—devastating complication that occurs in about 1 in 1000 cases; the most common causative organisms are *Staphylococcus epidermidis, Staphylococcus aureus, Pseudomonas,* and *Proteus* species	Characterized by marked visual loss, pain, lid edema, hypopyon, corneal haze, and chemosis	Managed by aggressive antibiotic therapy. Broad-spectrum antibiotics are given while awaiting culture and sensitivity results. Once results are obtained, the appropriate antibiotics are given via intravitreal injection. Corticosteroid therapy is also given.
Toxic anterior segment syndrome—noninfectious inflammation that is a complication of anterior chamber surgery; caused by a toxic agent such as an agent used to sterilize surgical instruments	Corneal edema occurs <24 hours after surgery; symptoms include reduced visual acuity and pain	If there is no growth of microorganisms, the treatment is topical steroids alone.
Late Postoperative		
Suture-related problems	Toxic reactions or mechanical injury from broken or loose sutures	Suture removal relieves the symptoms. Topical corticosteroids are used when the incision is not healed and sutures cannot be removed.
Malposition of the IOL	Results in astigmatism, sensitivity to glare, or appearance of halos	Miotics are used for mild cases, whereas IOL removal and replacement is necessary for severe cases.
Chronic endophthalmitis	Persistent, low-grade inflammation, and granuloma	Corticosteroids and antibiotics are given systemically. If the condition persists, removal of the IOL and capsular bag, vitrectomy, and intravitreal injection of antibiotics are required.
Opacification of the posterior capsule—most common late complication of extracapsular cataract extraction	Visual acuity is diminished	Nd:YAG laser is used to create a hole in the posterior capsule. Blurred vision is cleared immediately.

IOL, intraocular lens; IOP, intraocular pressure; Nd:YAG, Neodymium: yttrium aluminum garnet.

count, electrocardiogram, and urinalysis) commonly performed for most surgeries is prescribed only if indicated by the patient's medical history.

Alpha-antagonists (particularly tamsulosin [Flomax], which is used for treatment of enlarged prostate) are known to cause a condition called *intraoperative floppy iris syndrome.* Alpha-antagonists can interfere with pupil dilation during the surgical procedure, resulting in miosis and iris prolapse and leading to complications. Intraoperative floppy iris syndrome can occur even though a patient has stopped taking the drug. The nurse needs to ask patients about a history of taking alpha-antagonists. Surgical team members are then alerted to the risk of this complication (Comerford, 2015).

Dilating drops are given prior to surgery. Nurses in the ambulatory surgery setting begin patient education about eye medications (antibiotic, corticosteroid, and anti-inflammatory drops) that will need to be self-administered to prevent postoperative infection and inflammation.

Providing Postoperative Care

Before discharge, the patient receives verbal and written education regarding eye protection, administration of medications, recognition of complications, activities to avoid, and obtaining emergency care (see Chart 42-8). An eye shield is usually worn at night for the first week to avoid injury. The nurse also explains that there should be minimal discomfort

Chart 42-8 HOME CARE CHECKLIST

Intraocular Lens Implant

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Describe ongoing postoperative therapeutic regimen and activities to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Wear glasses or eye shield following surgery as instructed.
  - Always wash hands before touching or cleaning the postoperative eye.
  - Clean postoperative eye with a clean tissue; wipe the closed eye with a single gesture from the inner canthus outward.
  - When bathing or showering, shampoo hair cautiously or seek assistance.
  - Avoid lying on the side of the affected eye the night after surgery.
  - Keep activity light (e.g., walking, reading, watching television). Resume the following activities only as directed by the ophthalmologist: driving, sexual activity, unusually strenuous activity.
  - Avoid lifting, pushing, or pulling objects heavier than 6 kg.
  - Avoid bending or stooping for an extended period.
  - Be careful when climbing or descending stairs.
- Describe signs and symptoms of complications (e.g., vision change, continuous flashing lights appear to the affected eye, redness, swelling or increased pain near the eye, change in amount or type of eye drainage, any eye injury, significant pain not relieved by prescribed analgesia).
- Relate how to reach ophthalmologist with questions or complications.
- State time and date of follow-up appointments.
- Identify sources of assistance (e.g., meals, transportation) and support (e.g., friends, relatives, faith community).
- Identify the need for health promotion, disease prevention, and screening activities

ADL, activities of daily living; IADL, independent activities of daily living.

after surgery and educates the patient about taking a mild analgesic agent, such as acetaminophen/paracetamol, as needed. Antibiotic, anti-inflammatory, and corticosteroid eye drops or ointments are prescribed postoperatively. Patients prescribed anti-inflammatory or corticosteroid eye drops are monitored for possible increases in IOP (Kusne, Kang, & Fintelmann, 2016).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

To prevent accidental rubbing or poking of the eye, the patient wears a protective eye patch for about the first 24 hours after surgery, followed by eyeglasses worn during the day and an eye shield at night. The nurse educates the patient and family about applying and caring for the eye shield, if one is recommended. Sunglasses should be worn while outdoors during the day because the eye is sensitive to light.

Slight morning discharge, some redness, and a scratchy feeling may be expected for a few days. A clean, damp washcloth may be used to remove slight morning eye discharge. Because cataract surgery increases the risk of retinal detachment, the patient must know to notify the surgeon if new floaters (dots) in vision, flashing lights, decrease in vision, pain, or increase in redness occurs.

Continuing and Transitional Care

If an eye patch is worn, it is removed after the first follow-up appointment, which should occur within 48 hours of surgery. Nurses should educate patients about the importance of keeping their follow-up appointments, because monitoring of visual status and prompt intervention of postoperative complications enhance good visual outcome. Vision is stabilized when the eye is completely healed, usually within 6 to 12 weeks, when final corrective prescription is completed. Visual correction may still be needed for any remaining refractive errors. Patients who choose multifocal IOLs should be aware that there may be increased night glare and contrast sensitivity.

CORNEAL DISORDERS

Corneal Dystrophies

Corneal dystrophies are inherited as autosomal dominant traits and manifest when the person is about 20 years of age. They are characterized by deposits in the corneal layers. Decreased vision is caused by the irregular corneal surface and corneal deposits. Corneal endothelial decomposition leads to corneal edema and blurring of vision. Persistent edema leads to bullous keratopathy or the formation of blisters that cause pain and discomfort on rupturing. The two main types are keratoconus and Fuchs endothelial dystrophy.

Keratoconus

Keratoconus, the most common type of corneal dystrophy, is characterized by a conical protuberance of the cornea with progressive thinning on protrusion and irregular astigmatism. This hereditary condition has a higher incidence among women. Onset occurs at puberty; the condition may progress for more than 20 years and is bilateral. Corneal scarring occurs in severe cases. Blurred vision is a prominent symptom. Rigid, gas-permeable contact lenses correct irregular astigmatism and improve vision. Advances in contact lens design have reduced the need for surgery. Penetrating keratoplasty (PKP) is indicated when contact lens correction is no longer effective.

Fuchs Endothelial Dystrophy

Fuchs (pronounced *Fooks*) dystrophy is manifested by a slow death of cells in the endothelial cornea. It affects women more than men and is usually not noted until 50 years of age. Corneal endothelial cell death leads to corneal edema and blurring of vision. Persistent edema leads to bullous keratopathy. A bandage contact lens is used to flatten the bullae, protect the exposed corneal nerve endings, and relieve discomfort. Symptomatic treatments, such as hypertonic drops or ointment (5% sodium chloride), may reduce

epithelial edema. Currently, the only cure is a corneal transplant (Dickman, Peeters, Van Den Biggelaar, et al., 2016).

Corneal Surgeries

Among the surgical procedures used to treat diseased corneal tissue are phototherapeutic keratectomy (PTK), PKP and corneal endothelial transplantation, and Descemet's stripping endothelial keratoplasty (DSEK).

Phototherapeutic Keratectomy

PTK is a laser procedure that is used to treat diseased corneal tissue by removing or reducing corneal opacities and smoothing the anterior corneal surface to improve functional vision. PTK is contraindicated in patients with active herpetic keratitis because the ultraviolet rays may reactivate latent virus. Common side effects are induced hyperopia and stromal haze. Complications are delayed re-epithelialization (particularly in patients with diabetes) and bacterial keratitis. Postoperative management consists of oral analgesic agents for eye pain. Re-epithelialization is promoted with a pressure patch or therapeutic soft contact lens. Antibiotic and corticosteroid ointments and NSAIDs are prescribed postoperatively. Follow-up examinations are required for up to 2 years.

Penetrating Keratoplasty

PKP (corneal transplantation or corneal grafting) involves replacing abnormal host tissue with healthy donor (cadaver) corneal tissue. Common indications are keratoconus, corneal scarring from herpes simplex, keratitis, and chemical burns.

Several factors affect the success of the graft: the condition of the ocular structures (e.g., lids, conjunctiva), quality of the tears, adequacy of blinking, and viability of the donor endothelium. Contraindications for the use of donor tissue are outlined in Chart 42-9.

In PKP, the surgeon determines the graft size before the procedure, and the appropriate size is marked on the surface of the cornea. The surgeon prepares the donor cornea and the recipient bed, removes the diseased cornea, places the donor cornea on the recipient bed, and sutures it in place. Sutures remain in place for 12 to 18 months and are then removed. Potential complications include early graft failure due to poor quality of donor tissue, surgical trauma, acute infection, and persistently increased IOP and late graft failure due to rejection.

Postoperatively, the patient receives mydriatics for 2 weeks and topical corticosteroids for 12 months (daily doses for 6 months and tapered doses thereafter). These mydriatics and corticosteroid drops should be preservative free to prevent a reactive inflammation. Patients typically describe a sensation of postoperative eye discomfort rather than acute pain.

Additional Keratoplasty Surgeries

For many years, PKP was the standard of care for patients with corneal endothelial failure but with poor refractive results. Subsequently, other techniques have been developed. Anterior lamellar keratoplasty (ALK) involves a partial-thickness graft for disorders such as anterior corneal dystrophies or scarring not involving the endothelial portion of the cornea. Deep anterior lamellar keratoplasty (DALK) involves replacement of only anterior corneal layers and not Descemet's membrane or endothelial layers for disorders such as keratoconus. Posterior lamellar keratoplasty (PLK or EK) and DSEK (which replaces only the endothelial layer of the cornea) are procedures indicated for conditions such as Fuchs endothelial dystrophy or bullous keratopathy (Dickman, et al., 2016). In DSEK, layers of the cornea are dissected and selectively replaced by donor cornea tissue. DSEK offers several advantages, such as less postoperative astigmatism, faster visual recovery, and stronger wound integrity. Theoretically, the risk of rejection is less because less of the patient's tissue is replaced.

Chart 42-9

Contraindications to the Use of Donor Tissue for Corneal Transplantation: Donor Characteristics

Systemic Disorders

- Death from unknown cause
- History or suspected history of the following:
  - Acquired immune deficiency syndrome or high-risk for human immune deficiency virus infection
  - Creutzfeldt–Jakob disease
  - Eye infection
  - Hepatitis
  - Rabies
  - Systemic infection

Intrinsic Eye Disease

- Disorders of the conjunctiva or corneal surface involving the optical zone of the cornea
- Malignant tumors of anterior segment
- Ocular inflammation
- Retinoblastoma

Other

- Corneal scars
- History of eye trauma
- Previous surgical eye procedures such as corneal graft or LASIK eye surgery

Keratoprosthesis

An additional therapeutic option for patients with multiple graft failures or severe corneal disease is keratoprosthesis (artificial cornea; e.g., U.S. Food and Drug Administration [FDA]-approved Boston Keratoprosthesis [KPro] and AlphaCor). The design of the keratoprosthesis consists of a central optic core and an outer rim that secures the prosthesis. This procedure has serious potential complications (e.g., glaucoma, endophthalmitis) and requires close follow-up and monitoring (Patel, Moster, Kishfy, et al., 2016).

Nursing Management

For corneal surgeries, the nurse reinforces instructions regarding visual rehabilitation and visual improvement. A technically successful graft may initially produce disappointing results because the procedure has produced a new optical surface. Only after several months do patients start seeing the natural and true colors of their environment. Correction of a resultant refractive error with eyeglasses or contact lenses determines the final visual outcome. The nurse assesses the patient's support system and their ability to comply with long-term follow-up, which includes frequent clinic visits for several months for tapering of topical corticosteroid therapy, selective suture removal, and ongoing evaluation of the graft site and visual acuity. The nurse also initiates appropriate referrals to community services as indicated.

Because graft failure is an ophthalmic emergency that can occur at any time, the primary goal of nursing care is to educate the patient to identify signs and symptoms of graft failure. The early symptoms are blurred vision, discomfort, tearing, or redness of the eye. Decreased vision results after graft destruction. The patient must contact the ophthalmologist as soon as symptoms occur. Treatment of graft rejection usually involves prompt administration of hourly topical corticosteroids and periocular corticosteroid injections. Systemic immunosuppressive agents may be necessary for severe, resistant cases.

Refractive Surgeries

Refractive surgeries are elective procedures performed to correct refractive errors (myopia or hyperopia) and astigmatism by reshaping the cornea (Li, Zhan, Li, et al., 2016). Laser vision correction alters the major optical function of the eye and carries risks. Refractive surgery does not alter the normal aging process of the eye. If the reason for the procedure is to meet vision requirements for the patient's occupation, the results must satisfy both the patient and the employer. Precise visual outcome cannot be guaranteed.

The corneal structure must be normal, and the refractive error must be stable. The patient is required to discontinue using contact lenses for a period before the procedure (2 to 3 weeks for soft lenses and 4 weeks for hard lenses). Patients with conditions that are likely to adversely affect corneal wound healing (e.g., corticosteroid use, immunosuppression, elevated IOP) are not good candidates for the procedure. Any superficial eye disease must be diagnosed and fully treated before a refractive procedure.

Patient satisfaction is the ultimate goal; therefore, patient education and counseling about potential risks, complications, and postoperative follow-up are critical. Minimal postoperative care includes topical corticosteroid or NSAID and antibiotic drops.

Laser Vision Correction Photorefractive Keratectomy

Photorefractive keratectomy (PRK) is used to treat myopia and hyperopia with or without astigmatism (Li et al., 2016). The excimer laser is applied directly to the cornea according to carefully calculated measurements. For myopia, the relative curvature is decreased; for hyperopia, the relative curvature is increased. A bandage contact lens is placed over the cornea to promote epithelial healing and reduce pain, which is similar to that of a severe corneal abrasion.

Laser-Assisted In Situ Keratomileusis

LASIK involves flattening the anterior curvature of the cornea by removing a stromal lamella or layer. The surgeon creates a corneal flap with a microkeratome, which is an automatic corneal shaper. The surgeon retracts a flap of corneal tissue less than one third the thickness of a human hair to access the corneal stroma and then uses the excimer laser on the stromal bed to reshape the cornea according to calculated measurements (see Fig. 42-10). Data are insufficient to determine whether LASIK or PRK is better at correcting near-sightedness (Li et al., 2016). There are few adverse outcomes of either procedure.

Perioperative Complications

Surgically Induced Abnormalities

Corneal surface irregularities can occur after LASIK treatment. These include central islands (central areas of stiffness or elevation), decentered ablations resulting from misalignment of the laser treatment or from involuntary eye movement during laser treatment, and forms of irregular astigmatism. Symptoms of central islands and decentered ablations include monocular diplopia or ghost images, halos, glare, and decreased visual acuity.

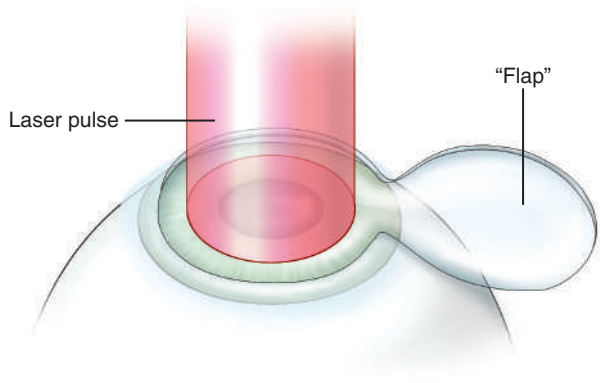

Figure 42-10 • LASIK combines delicate surgical procedures and laser treatment. A flap is surgically created and lifted to one side. A laser is then applied to the cornea to reshape it. With permission from the Wilmer Laser Vision Center, Lutherville, MD.

Phakic Intraocular Lenses

Increasingly, phakic IOL implantation has been used for patients with moderate to severe myopia (Barsam & Allan, 2014). Phakic IOLs may be used in either the anterior or posterior chamber. The implantation of such devices is reversible because the natural lens is left in place and the normal architecture of the cornea is preserved. This procedure provides more predictable refractive results than procedures that alter the corneal curvature, is safer, and has higher patient satisfaction scores (Barsam & Allan, 2014). Potential complications include cataract, iritis or uveitis, endothelial cell loss, and increased IOP.

Conductive Keratoplasty

Another innovation in refractive surgery for the correction of low to mild hyperopia uses the principles of thermal keratoplasty by applying radiofrequency current to the peripheral cornea using a thin, handheld probe. It does not involve the removal of cornea tissue.

RETINAL DISORDERS

Although the retina is composed of multiple microscopic layers, the two innermost layers—the sensory retina and the RPE—are most commonly implicated in retinal disorders (Grossman & Porth, 2014).

Retinal Detachment

Retinal detachment refers to the separation of the RPE from the neurosensory layer (Grossman & Porth, 2014). The four types of retinal detachment are rhegmatogenous, traction, a combination of rhegmatogenous and traction, and exudative. *Rhegmatogenous detachment* is the most common form. In this condition, a hole or tear develops in the sensory retina, allowing some of the liquid vitreous to seep through the sensory retina and detach it from the RPE (see Fig. 42-11). People at risk for

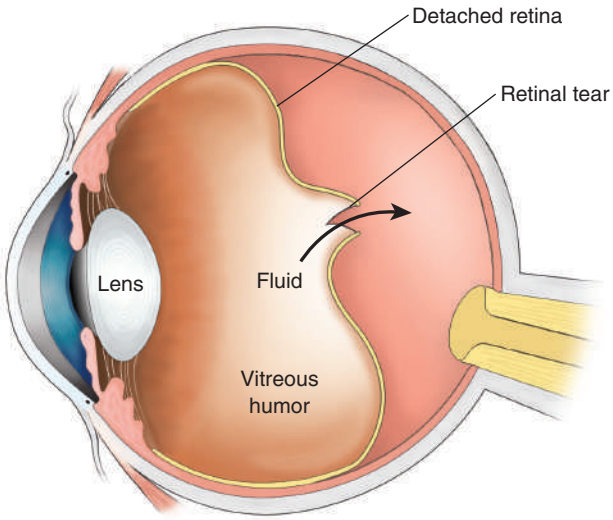

Figure 42-11 • Retinal detachment.

this type of detachment include those with high myopia or those who have aphakia (absence of the natural lens) after cataract surgery. Trauma may also play a role in rhegmatogenous retinal detachment. Between 5% and 10% of all rhegmatogenous retinal detachments are associated with proliferative retinopathy—a retinopathy associated with diabetic neovascularization (see Chapter 31).

Tension, or a pulling force, is responsible for *traction retinal detachment*. An ophthalmologist must ascertain all of the areas of retinal break and identify and release the scars or bands of fibrous material providing traction on the retina. In general, patients with this condition have developed fibrous scar tissue from conditions such as diabetic retinopathy, vitreous hemorrhage, or the retinopathy of prematurity. The hemorrhages and fibrous proliferation associated with these conditions exert a pulling force on the delicate retina.

Patients can have both rhegmatogenous and traction retinal detachment. *Exudative retinal detachments* are the result of the production of a serous fluid under the retina from the choroid. Conditions such as uveitis and macular degeneration may cause the production of this serous fluid.

Clinical Manifestations

Patients may report the sensation of a shade or curtain coming across the vision of one eye, cobwebs, bright flashing lights, or the sudden onset of a great number of floaters. Patients do not complain of pain but retinal detachment is an ocular emergency, requiring immediate surgical intervention for optimal outcomes.

Assessment and Diagnostic Findings

After visual acuity is determined, the patient must have a dilated fundus examination using an indirect ophthalmoscope as well as slit-lamp biomicroscopy. Stereo fundus photography and fluorescein angiography are commonly used during the evaluation.

Increasingly, optical coherence tomography and ultrasound are used for the complete retinal assessment, especially if the view is obscured by a dense cataract or vitreal hemorrhage. All retinal breaks, all fibrous bands that may be causing traction on the retina, and all degenerative changes must be identified.

Surgical Management

In rhegmatogenous detachment, an attempt is made to surgically reattach the sensory retina to the RPE. In traction retinal detachment, the source of traction must be removed and the sensory retina reattached. The most commonly used surgical interventions are the scleral buckle and vitrectomy (Boyd, 2016).

Scleral Buckle

The retinal surgeon compresses the sclera (often with a scleral buckle [see Fig. 42-12] or a silicone band) to indent the scleral wall from the outside of the eye and bring the two retinal layers in contact with each other (Boyd, 2016).

Vitrectomy

A vitrectomy is an intraocular procedure that allows the introduction of a light source through an incision; a second incision serves as the portal for the vitrectomy instrument. The surgeon dissects preretinal membranes under direct visualization while the retina is stabilized by an intraoperative vitreous substitute.

Traction on the retina may be relieved through vitrectomy and may be combined with scleral buckling to repair retinal detachments. A gas bubble, silicone oil, or perfluorocarbon and liquids may be injected into the vitreous cavity to help push the sensory retina up against the RPE. Argon laser photocoagulation or cryotherapy is also used to hold the retina in place (Boyd, 2016).

Nursing Management

Nursing management consists of educating the patient and providing supportive care. Postoperative positioning of the patient is critical when a gas bubble is used because the injected bubble must remain in position overlying the area of detachment, providing consistent pressure to reattach the sensory retina. The patient must maintain a prone position that would allow the gas bubble to act as a tamponade for the retinal break (Boyd, 2016). Patients and family members should be made aware of these needs beforehand so that the patient can be made as comfortable as possible.

In most cases, vitreoretinal procedures are performed on an outpatient basis, and the patient is seen the next day for a follow-up examination. Postoperative complications may

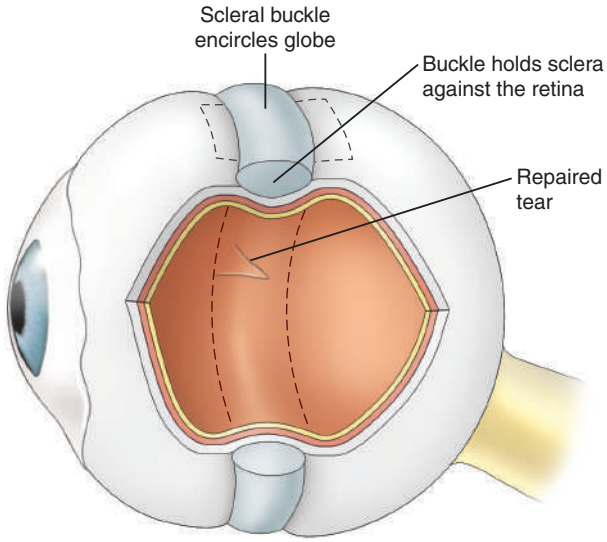

Figure 42-12 • Scleral buckle.

include increased IOP, endophthalmitis, retinal detachment, and development of cataracts. Patients must be educated about the signs and symptoms of complications, particularly of increasing IOP and postoperative infection. Contact details for the ophthalmic team are provided and the patient is encouraged to call immediately if complications occur.

Retinal Vascular Disorders

Loss of vision can occur from occlusion of a retinal artery or vein. Such occlusions may result from atherosclerosis, valvular heart disease, venous stasis, hypertension, or increased blood viscosity. Associated risk factors include diabetes, glaucoma, and aging.

Central Retinal Vein Occlusion

Blood supply to and from the ocular fundus is provided by the central retinal artery and vein. Central retinal vein occlusions (CRVOs) are found most often in people older than 50 years. Patients who suffer a CRVO report decreased visual acuity ranging from mild blurring to severely limited.

Direct ophthalmoscopy of the retina shows optic disc swelling, venous dilation and tortuousness, retinal hemorrhages, cotton-wool spots, and a bloody appearance of the retina. The better the initial visual acuity, the better the general prognosis.

Fluorescein angiography may show extensive areas of capillary closure. The patient should be monitored carefully over the ensuing several months for signs of neovascularization and neovascular glaucoma. Laser panretinal photocoagulation may be necessary to treat the abnormal neovascularization. Neovascularization of the iris may cause neovascular glaucoma. Macular edema, macular nonperfusion, and vitreous hemorrhage from the neovascularization are among the potential complications of CRVO.

Branch Retinal Vein Occlusion

Some patients with branch retinal vein occlusion (BRVO) are symptom free, whereas others complain of a sudden loss of vision if the macular area is involved. A more gradual loss of vision may occur if macular edema associated with BRVO develops.

On examination, the ocular fundus appears similar to that found in CRVO. The occlusions generally occur at the arteriovenous crossings. The diagnostic evaluation and follow-up assessments and complications are the same as for CRVO. Associated conditions include glaucoma, systemic hypertension, diabetes, and hyperlipidemia.

Central Retinal Artery Occlusion

Patients with central retinal artery occlusion, a relatively rare disorder that accounts for approximately 1 in 10,000 ophthalmologic visits, present with a sudden loss of vision. Visual acuity is reduced to being able to count the examiner's fingers, or the field of vision is tremendously restricted. A relative afferent pupillary defect is present. Examination of the ocular fundus reveals a pale retina with a cherry-red spot at the fovea. The retinal arteries are thin, and emboli are occasionally seen in the central retinal artery or its branches. Central retinal artery occlusion is a true ocular emergency. Various treatments are used: ocular massage, anterior chamber paracentesis, IV administration of hyperosmotic agents such as acetazolamide (Diamox), and high concentrations of oxygen. An aggressive stepwise approach may be beneficial, depending on the underlying cause of the occlusion and the amount of time from onset of occlusion to treatment. Most visual loss associated with central retinal artery occlusion is severe and permanent.

Age-Related Macular Degeneration

AMD accounts for 54% of all blindness in older adults (Centers for Disease Control [CDC], 2016). AMD is characterized by tiny, yellowish spots called *drusen* beneath the retina (see Fig. 42-13). Most people older than 60 years have at least a few small drusen, which are clusters of debris or waste material. When drusen are located in the macular area, they can affect vision. Patients with AMD have a wide range of visual loss, but only a small portion experience total blindness. Central vision is generally the most affected, with most patients retaining peripheral vision (see Fig. 42-14). There are two types of AMD: the dry type and the wet type (CDC, 2016).

Between 85% and 90% of people with AMD have the dry (nonneovascular, nonexudative) type of the condition, in which the outer layers of the retina slowly break down. With this breakdown comes the appearance of drusen. When the drusen occur outside of the macular area, patients generally have no symptoms. When the drusen occur within the macula, however, there is a gradual blurring of vision that patients may notice when they try to read.

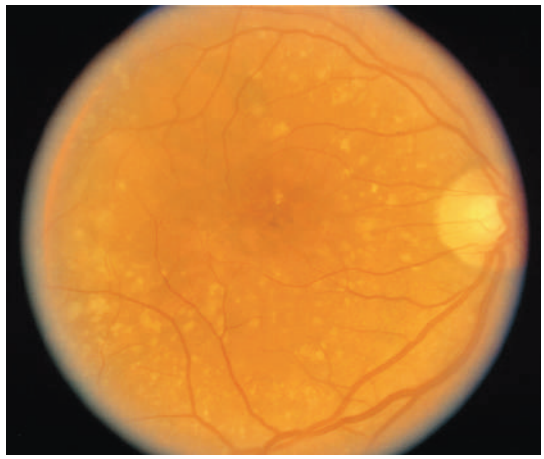

Figure 42-13 • Retina showing drusen and age-related macular degeneration.

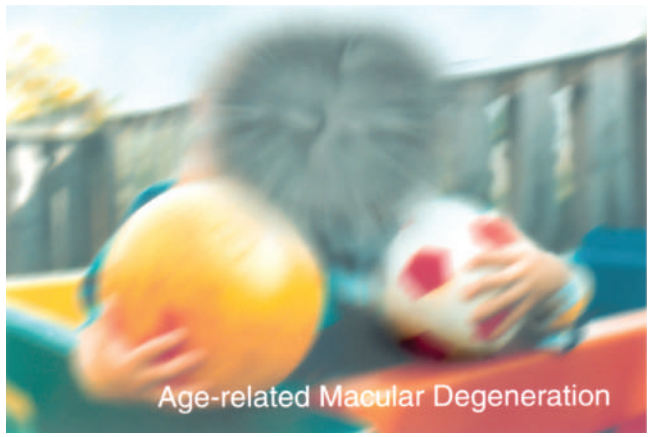

Figure 42-14 • Visual changes resulting from age-related macular degeneration. Photo courtesy of the National Eye Institute, National Institutes of Health.

The second type of AMD, the wet (neovascular, exudative) type, may have an abrupt onset and is more damaging to the vision (CDC, 2016). Patients report that straight lines appear crooked and distorted or that letters in words appear broken. This effect results from proliferation of abnormal blood vessels growing under the retina, within the choroid layer of the eye, a condition known as choroidal neovascularization. The affected vessels can leak fluid and blood, elevating the retina. Some patients can be treated with laser therapy to stop leakage from these vessels.

Medical Management

There is no known effective therapy for the dry (nonneovascular, nonexudative) type of AMD (Grossman & Porth, 2014).

An important component of treatment of wet (neovascular, exudative) AMD targets development and progression of angiogenesis (abnormal blood vessel formation). Vasoproliferation in wet AMD is believed to be caused by an underlying angiogenic stimulus known as vascular endothelial growth factor (VEGF) (Grossman & Porth, 2014). Examples of VEGF inhibitors given by intravitreal injection include ranibizumab (Lucentis) and bevacizumab (Avastin) (Comerford, 2015); (Grossman & Porth, 2014).

Nursing Management

Amsler grids are given to patients to use in their homes to monitor for a sudden onset or distortion of vision. These may provide the earliest sign that macular degeneration is getting worse. Patients should be encouraged to look at these grids, one eye at a time, several times each week with glasses on if needed for corrected near vision. If there is a change in the way the grid appears to the patient (e.g., if the lines or squares appear distorted or faded), the patient should notify the ophthalmologist immediately and should arrange to be seen promptly.

Orbital and Ocular Trauma

Whether affecting the eye or the orbit, trauma to the eye and surrounding structures may have devastating consequences for vision. It is preferable to prevent injury rather than treat it. Chart 42-10 details measures to prevent eye injuries.

Orbital Trauma

Injury to the orbit is usually associated with a head injury; hence, the patient's general medical condition must first be stabilized before conducting an ocular examination (Hickey, 2014). Only then is the globe assessed for soft tissue injury. During inspection, the face is meticulously assessed for underlying fractures, which should always be suspected in cases of blunt trauma. To establish the extent of ocular injury, visual acuity is assessed as soon as possible, even if it is only a rough estimate. Soft tissue orbital injuries often result in damage to the optic nerve. Major ocular injuries indicated by a soft globe, prolapsing tissue, ruptured globe, and hemorrhage require immediate surgical attention.

Chart 42-10 PATIENT EDUCATION

Education for Patients About Preventing Eye Injuries

The nurse instructs the patient in the following measures to prevent eye injuries:

In and Around the House

- Make sure that all spray nozzles are directed away from yourself before pressing down on the handle.
- Read instructions carefully before using cleaning fluids, detergents, ammonia, or harsh chemicals, and wash hands thoroughly after use.
- Use grease shields on frying pans to decrease spattering.
- Use opaque goggles to avoid burns from sunlamps.
- Wear special goggles to shield the eyes from fumes and splashes when using powerful chemicals.

In the Workshop

- Protect the eyes from flying fragments, fumes, dust particles, sparks, and splashed chemicals by wearing safety glasses.
- Read instructions thoroughly before using tools and chemicals, and follow precautions for their use.

Around Children

- Educate children about the correct way to handle potentially dangerous items, such as scissors and pencils.
- Pay attention to age and maturity level of a child when selecting toys and games, and avoid projectile toys, such as darts and pellet guns.
- Supervise children when they are playing with toys or games that can be dangerous.

In the Garden

- Avoid letting anyone stand at the side of or in front of a moving lawn mower.
- Avoid low-hanging branches.
- Direct pesticide spray can nozzles away from the face.
- Pick up rocks and stones before going over them with the lawn mower (stones can be hurled out of the rotary blades and rebound off curbs or walls, causing severe injury to the eye).

Around the Car

- Put out all smoking materials and matches before opening the hood of the car.
- Take standard safety precautions when using jumper cables (wear goggles; make sure the cars are not touching one another; make sure the jumper cable clamps never touch each other; never lean over the battery when attaching cables; and never attach a cable to the negative terminal of a dead battery).
- Use a flashlight, not a match or lighter, to look at the battery at night.
- Wear goggles when grinding metal or striking metal against metal while performing auto body repair.

In Sports

- Wear protective caps, helmets, or face protectors when appropriate, especially for sports such as ice hockey.
- Wear protective safety glasses, especially for sports such as racquetball, squash, tennis, baseball, and basketball.

Around Fireworks

- Avoid explosive fireworks.
- Avoid standing near others when lighting fireworks.
- Douse firework duds in water instead of attempting to relight them.
- Never allow children to ignite fireworks.
- Wear eyeglasses or safety goggles.

Soft Tissue Injury and Hemorrhage

The signs and symptoms of soft tissue injury from blunt or penetrating trauma include tenderness, ecchymosis, lid swelling, proptosis or exophthalmos (abnormal protrusion of the eyeball), and hemorrhage. Closed injuries lead to contusions with subconjunctival hemorrhage, commonly known as a black eye. Blood accumulates in the tissues of the conjunctiva. Hemorrhage may be caused by a soft tissue injury to the eyelid or by an underlying fracture.

Management of soft tissue hemorrhage that does not threaten vision is usually conservative and consists of thorough inspection, cleansing, and repair of wounds. Cold compresses are used in the early phase, followed by warm compresses. Hematomas that appear as swollen, fluctuating areas may be surgically drained or aspirated; if they are causing significant orbital pressure, they may be surgically evacuated.

Orbital Fractures

Orbital fractures are detected by facial x-rays. Depending on the orbital structures involved, orbital fractures can be classified as blowout, zygomatic or tripod, maxillary, midfacial, orbital apex, and orbital roof fractures. Blowout fractures result from compression of soft tissue and the sudden increase in orbital pressure when the force is transmitted to the orbital floor, which is the area of least resistance (Hickey, 2014).

The inferior rectus and inferior oblique muscles, with their fat and fascial attachments, or the nerve that courses along the inferior oblique muscle may become entrapped, and the globe may be displaced inward (i.e., enophthalmos). Computed tomography (CT) scanning can identify the muscle and its auxiliary structures that are entrapped. These fractures are usually caused by the blunt force from a fist or baseball (Hickey, 2014).

Orbital roof fractures are dangerous because of potential complications to the brain. Surgical management of these fractures requires a neurosurgeon and an ophthalmologist. The most common indications for surgical intervention are displacement of bone fragments disfiguring the normal facial contours, interference with normal binocular vision caused by extraocular muscle entrapment, interference with mastication in zygomatic fracture, and obstruction of the nasolacrimal duct. Surgery is usually nonemergent, and a period of 10 to 14 days gives the ophthalmologist time to assess ocular function, especially the extraocular muscles and the nasolacrimal duct. Emergency surgical repair is usually not performed unless the globe is displaced into the maxillary sinus. Surgical repair is primarily directed at freeing the entrapped ocular structures and restoring the integrity of the orbital floor.

Foreign Bodies

Foreign bodies that enter the orbit are usually tolerated, except for copper, iron, and vegetable materials such as those from plants or trees, which may cause purulent infection. X-rays and CT scans are used to identify the foreign body. A careful history is important, especially if the foreign body has been in the orbit for a period of time and the incident forgotten. It is important to identify metallic foreign bodies because they prohibit the use of magnetic resonance imaging (MRI) as a diagnostic tool.

After the extent of the orbital damage is assessed, the decision to use conservative treatment or surgical removal is made. In general, orbital foreign bodies are removed if they are superficial and anterior in location; have sharp edges that may affect adjacent orbital structures; or are composed of copper, iron, or vegetable material. Surgical intervention is directed at preventing further ocular injury and maintaining the integrity of the affected areas. Cultures are usually obtained, and the patient is placed on prophylactic IV antibiotic medications that are later changed to an oral route.

Ocular Trauma

Ocular trauma is a leading cause of blindness among children and young adults, especially male trauma victims. Ocular trauma occurs with occupational injuries (e.g., construction industry), contact sports, weapons (e.g., air guns, BB guns), assaults, motor vehicle crashes (e.g., broken windshields), and explosions (e.g., blast fragments).

There are two types of ocular trauma in which the first response is critical: chemical burn and foreign object in the eye. With a chemical burn, the eye should be immediately irrigated with tap water or normal saline. With a foreign body, no attempt should be made to remove the foreign object. The object should be protected from jarring or movement to prevent further ocular damage. No pressure or patch should be applied to the affected eye. All other traumatic eye injuries should be protected using a patch or shield if available or a stiff paper cup until medical treatment can be obtained (see Fig. 42-15).

Assessment and Diagnostic Findings

A thorough history is obtained, particularly assessing the patient's ocular history, such as pre-injury vision in the affected eye or past ocular surgery. Details related to the injury that help in the diagnosis and assessment of the need for further tests include the nature of the ocular injury (i.e., blunt or penetrating trauma); the type of activity that caused the injury to determine the nature of the force striking the eye; and whether onset of vision loss was sudden, slow, or progressive. For chemical eye burns, the chemical agent must be identified and tested for pH if the agent is available. The corneal surface is examined for foreign bodies, wounds, and abrasions, after which the other external structures of the eye are examined. Pupil size, shape, and light reaction of the pupil of the affected eye are compared with the other eye. Ocular motility (ability of the eyes to move synchronously up, down, right, and left) is also assessed.

Medical Management

Splash Injuries

Splash injuries are irrigated with normal saline solution before further evaluation occurs. In cases of a ruptured globe,

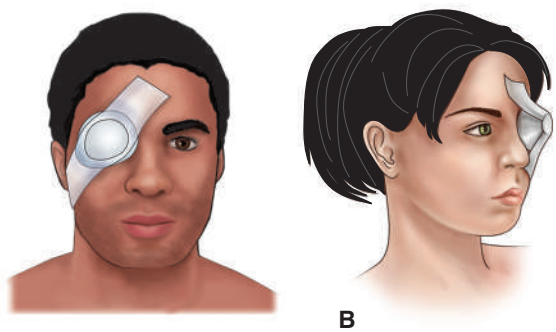

Figure 42-15 • Two kinds of eye patches. **A.** Aluminum shield. **B.** Stiff paper cup shield (innovative substitute when aluminum shield is unavailable).

cycloplegic agents (agents that paralyze the ciliary muscle) or topical antibiotics must be deferred because of potential toxicity to exposed intraocular tissues. Further manipulation of the eye must be avoided until the patient is under general anesthesia. Parenteral, broad-spectrum antibiotics are initiated. Tetanus antitoxin is given, if indicated, as well as analgesic agents. (Tetanus prophylaxis is recommended for full-thickness ocular and skin wounds.) Any topical ophthalmic medication (e.g., anesthetic, dyes) must be sterile.

Foreign Bodies and Corneal Abrasions

After removal of a foreign body from the surface of the eye, an antibiotic ointment is applied and the eye is patched. The eye is examined daily for evidence of infection until the wound is completely healed.

Contact lens wear is a common cause of corneal abrasion. The patient experiences severe pain and photophobia (ocular pain on exposure to light). Corneal epithelial defects are treated with antibiotic ointment and, in some instances, a pressure patch to immobilize the eyelids. Topical anesthetic eye drops must not be given to the patient to take home for repeated use after corneal injury because their effects mask further damage, delay healing, and can lead to corneal scarring.

Penetrating Injuries and Contusions of the Eyeball

Sharp penetrating injury or blunt contusion force can rupture the eyeball. When the globe, cornea, and sclera rupture, rapid decompression or herniation of the orbital contents into adjacent sinuses can occur. Blunt traumatic injuries (with an increased incidence of retinal detachment, intraocular tissue avulsion, and herniation) have a worse prognosis than penetrating injuries. Most penetrating injuries result in marked loss of vision with the following signs: hemorrhagic chemosis (edema of the conjunctiva), conjunctival laceration, shallow anterior chamber with or without an eccentrically placed pupil, hyphema (blood within the anterior chamber), or vitreous hemorrhage.

Hyphema is caused by contusion forces that tear the vessels of the iris and damage the anterior chamber angle. Preventing rebleeding and prolonged increased IOP are the goals of treatment for hyphema. In severe cases, the patient is hospitalized with moderate activity restriction. An eye shield is applied. Topical corticosteroids are prescribed to reduce inflammation. An antifibrinolytic agent (aminocaproic acid [Amicar]) stabilizes clot formation at the site of hemorrhage. Aspirin is contraindicated. A ruptured globe and severe injuries with intraocular hemorrhage require surgical intervention. Vitrectomy is performed for traumatic retinal detachments (Boyd, 2016). Primary enucleation (complete removal of the eyeball and part of the optic nerve) is considered only if the globe is irreparable and has no light perception. It is a general rule that enucleation is performed within 2 weeks of the initial injury (in an eye that has no useful vision after sustaining penetrating injury) to prevent the risk of sympathetic ophthalmia (an inflammation created in the uninjured eye by the affected eye that can result in blindness of the uninjured eye).

Intraocular Foreign Bodies

A patient who complains of blurred vision and discomfort should be questioned carefully about recent injuries and exposures. Patients may be injured in a number of different situations and experience an intraocular foreign body (IOFB). Precipitating circumstances can include working in construction, striking metal against metal, being involved in a motor vehicle crash with facial injury, a gunshot wound, grinding-wheel work, and explosions.

IOFB is diagnosed and localized by slit-lamp biomicroscopy and indirect ophthalmoscopy, as well as CT or ultrasonography scanning. MRI is contraindicated because most foreign bodies are metallic and magnetic. It is important to determine the composition, size, and location of the IOFB and affected eye structures. Every effort should be made to identify the type of IOFB and whether it is magnetic. Iron, steel, copper, and vegetable matter may cause intense inflammatory reactions. The incidence of endophthalmitis is high. Surgical excision of the foreign body depends on its location and composition and associated ocular injuries. Specially designed IOFB forceps and magnets are used to grasp and remove the foreign body. Any damaged area of the retina is treated to prevent retinal detachment.

Ocular Burns

Alkali, acid, and other chemically active organic substances, such as Mace and tear gas, cause chemical burns. Alkali burns (e.g., lye, ammonia) result in the most severe injury because they penetrate the ocular tissues rapidly and continue to cause long-term damage. Increased IOP also occurs. Acids (e.g., bleach, car batteries, refrigerant) generally cause less damage because the precipitated necrotic tissue proteins form a barrier to further penetration and damage. Chemical burns may appear as superficial punctate keratopathy (i.e., spotty damage to the cornea), subconjunctival hemorrhage, or complete marbleizing of the cornea.

In treating chemical burns, every minute counts. Immediate irrigation with tap water should be started on site before transport of the patient to an emergency department. A brief history and examination are performed. Critical information, if available, is the name of the substance that went into the eye (the actual container is best). Material safety data sheets (MSDS) should be accessed for reference (see Chapter 61). The corneal surfaces and conjunctival fornices are immediately and copiously irrigated with normal saline or any neutral solution. A local anesthetic is instilled, and a lid speculum is applied to overcome blepharospasm (i.e., spasms of the eyelid muscles that result in closure of the lids). Particulate matter must be removed from the fornices using moistened, cotton-tipped applicators and minimal pressure on the globe. Irrigation continues until the conjunctival pH normalizes (between 7.3 and 7.6). The pH of the corneal surface is checked by placing a pH paper strip in the fornix. Antibiotic agents are instilled, and the eye usually is patched.

The goal of intermediate treatment is to prevent tissue ulceration and promote re-epithelialization of the cornea. Intense lubrication using artificial tears without preservatives (to avoid allergic reactions) is essential. Patching or therapeutic soft lenses may also be used to promote corneal healing, and the patient is closely monitored. Prognosis depends on the type of injury and adequacy of the irrigation immediately after exposure. Long-term treatment consists of two phases: restoration of the ocular surface through grafting procedures and surgical restoration of corneal integrity and optical clarity.

Thermal injury is caused by exposure to a hot object (e.g., curling iron, tobacco, ash), whereas photochemical injury results from ultraviolet irradiation or infrared exposure (e.g., exposure to the reflections from snow, sun gazing, viewing an eclipse of the sun without an adequate filter). These injuries can cause corneal epithelial defect, corneal opacity, conjunctival chemosis and injection (congestion of blood vessels), and burns

of the eyelids and periocular region. Antibiotic agents and a patch for 24 hours constitute the treatment of mild injuries.

INFECTIOUS AND INFLAMMATORY CONDITIONS

Inflammation and infections of eye structures are common. Table 42-7 summarizes selected common infections and their treatment.

Dry Eyes

Dry eyes can be caused by decreased tear production or increased tear evaporation, which can be episodic or chronic (Grossman & Porth, 2014). Decreased tear production (aqueous deficiency) can be caused by systemic disease (Sjögren syndrome, connective tissue disease), lacrimal gland obstruction, and systemic drugs (e.g., diuretics, antihistamines, psychotropic drugs). Increased tear evaporation (evaporative dry eye) can be caused by meibomian gland deficiency, lid aperture disorder, vitamin A deficiency, reduced lid blinking rate, preservatives from topical drugs, ocular surface disease (allergy), and contact lens wear. Risk factors include increasing age, smoking, recent refractive surgery, and postmenopausal status (in women). An increase in the intake of omega-3 fatty acids may be beneficial in reducing the risk (Grossman & Porth, 2014).

Clinical Manifestations

The most common complaints are photophobia, foreign-body sensation, burning and stinging, redness, and decreased tearing.

Assessment and Diagnostic Findings

Chronic dry eyes may result in chronic conjunctival and corneal irritation that can lead to corneal erosion, scarring, ulceration, thinning, or perforation that can seriously threaten vision. Secondary bacterial infection can occur.

Management

Management of dry eyes requires the cooperation of the patient with a regimen that needs to be followed at home for a long period; otherwise, complete relief of symptoms is unlikely. Instillation of artificial tears during the day and an ointment at night is the usual regimen to hydrate and lubricate the eye and preserve a moist ocular surface. Cyclosporine ophthalmic emulsion (Restasis) is an effective agent that increases tear production and is used once daily. Anti-inflammatory medications are also used, and moisture chambers (e.g., moisture chamber spectacles, swim goggles) may provide additional relief.

Patients may become hypersensitive to chemical preservatives such as benzalkonium chloride and thimerosal. For these patients, preservative-free ophthalmic solutions are used. Management of dry eyes also includes the concurrent treatment of infections, such as chronic blepharitis and acne rosacea, and treating the underlying systemic disease, such as Sjögren syndrome (an autoimmune disease).

Surgical treatment includes punctal occlusion, grafting procedures, and lateral tarsorrhaphy (uniting the edges of the lids). Punctal plugs are made of silicone material for the temporary or permanent occlusion of the puncta. These help to preserve the volume of natural tears and prolong the effects of artificial tears (Grossman & Porth, 2014).

Conjunctivitis

Conjunctivitis (inflammation of the conjunctiva) is a common ocular disorder worldwide. It is characterized by a pink appearance (hence the common term *pink eye*) because of subconjunctival blood vessel congestion.

Clinical Manifestations

General symptoms include foreign-body sensation, scratching or burning sensation, itching, and photophobia. Conjunctivitis

TABLE 42-7 Common Infections and Inflammatory Disorders of Eye Structures

Disorder	Description	Management
Hordeolum (stye)	Acute suppurative infection of the glands of the eyelids caused by *Staphylococcus aureus.* The lid is red and edematous with a small collection of pus in the form of an abscess. There is considerable discomfort.	Warm compresses are applied directly to the affected lid area 3–4 times a day for 10–15 minutes. If the condition is not improved after 48 hours, incision and drainage may be indicated. Application of topical antibiotics may be prescribed thereafter.
Chalazion	Sterile inflammatory process involving chronic granulomatous inflammation of the meibomian glands; can appear as a single granuloma or multiple granulomas in the upper or lower eyelids.	Warm compresses applied 3–4 times a day for 10–15 minutes may resolve the inflammation in the early stages. Most often, however, surgical excision is indicated. Corticosteroid injection to the chalazion lesion may be used for smaller lesions.
Blepharitis	Chronic bilateral inflammation of the eyelid margins. There are 2 types: staphylococcal and seborrheic. Staphylococcal blepharitis is usually ulcerative and is more serious due to the involvement of the base of hair follicles. Permanent scarring can result.	The seborrheic type is chronic and is usually resistant to treatment, but the milder cases may respond to lid hygiene. Staphylococcal blepharitis requires topical antibiotic treatment. Instructions on lid hygiene (to keep the lid margins clean and free of exudates) are given to the patient.
Bacterial keratitis	Infection of the cornea by *S. aureus, Streptococcus pneumoniae,* and *Pseudomonas aeruginosa.*	Fortified (high-concentration) antibiotic eye drops are given every 30 minutes around the clock for the first few days, then every 1–2 hours. Systemic antibiotics may be given. Cycloplegics are given to reduce pain caused by ciliary spasm. Corticosteroid therapy and subconjunctival injections of antibiotics are controversial.
Herpes simplex keratitis	Symptoms are severe pain, tearing, and photophobia. The dendritic ulcer has a branching, linear pattern with feathery edges and terminal bulbs at its ends. Herpes simplex keratitis can lead to recurrent stromal keratitis and persist to 12 months with residual corneal scarring.	Many lesions heal without treatment and residual effects. The treatment goal is to minimize the damaging effect of the inflammatory response and eliminate viral replication within the cornea. Penetrating keratoplasty is indicated for corneal scarring and must be performed when the herpetic disease has been inactive for many months.

may be unilateral or bilateral, but the infection usually starts in one eye and then spreads to the other eye by hand contact.

Assessment and Diagnostic Findings

The four main clinical features important to evaluate are the type of discharge (watery, mucoid, purulent, or mucopurulent), type of conjunctival reaction (follicular or papillary), presence of pseudomembranes or true membranes, and presence or absence of lymphadenopathy (enlargement of the preauricular and submandibular lymph nodes where the eyelids drain). Pseudomembranes consist of coagulated exudate that adheres to the surface of the inflamed conjunctiva. True membranes form when the exudate adheres to the superficial layer of the conjunctiva, and removal results in bleeding. Follicles are multiple, slightly elevated lesions encircled by tiny blood vessels; they look like grains of rice. Papillae are hyperplastic conjunctival epithelium in numerous projections that are usually seen as a fine mosaic pattern under slit-lamp examination. Diagnosis is based on the distinctive characteristics of ocular signs, acute or chronic presentation, and identification of any precipitating events. Positive results of swab smear preparations and cultures confirm the diagnosis.

Types of Conjunctivitis

Conjunctivitis is classified according to its cause. The major causes are microbial infection, allergy, and irritating toxic stimuli. A wide spectrum of organisms can cause conjunctivitis, including bacteria (e.g., *Chlamydia*), viruses, fungus, and parasites. Conjunctivitis can also result from an existing ocular infection or can be a manifestation of a systemic disease.

Microbial Conjunctivitis

Bacterial Conjunctivitis

Bacterial conjunctivitis can be acute or chronic. The acute type can develop into a chronic condition. Signs and symptoms can vary from mild to severe. Chronic bacterial conjunctivitis is usually seen in patients with lacrimal duct obstruction, chronic dacryocystitis, and chronic blepharitis. The most common causative microorganisms are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Staphylococcus aureus.*

Bacterial conjunctivitis manifests with an acute onset of redness, burning, and discharge. There is papillary formation, conjunctival irritation, and injection in the fornices. The exudates are variable but are usually present on waking in the morning. The eyes may be difficult to open because of adhesions caused by the exudate. Purulent discharge occurs in severe acute bacterial infections, whereas mucopurulent discharge appears in mild cases. In gonococcal conjunctivitis, the symptoms are more acute. The exudate is profuse and purulent, and there is lymphadenopathy. Pseudomembranes may be present.

Trachoma is an infectious disease caused by the bacterium *Chlamydia trachomatis,* an ancient disease and the leading cause of preventable blindness in the world (Grossman & Porth, 2014). It is prevalent in areas with hot, dry, and dusty climates and in areas with poor living conditions. It is spread by direct contact or by carrier (e.g., insects such as flies and gnats). The onset of trachoma in children is usually insidious, but it can be acute or subacute in adults. The initial symptoms include red inflamed eyes, tearing, photophobia, ocular pain, purulent exudates, preauricular lymphadenopathy, and lid edema. Initial ocular signs include follicular and papillary formations. At the middle stage of the disease, there is an acute inflammation with papillary hypertrophy and follicular necrosis, after which trichiasis and entropion begin to develop. The lashes that are turned in rub against the cornea and, after prolonged irritation, cause corneal erosion and ulceration. The late stage of the disease is characterized by scarred conjunctiva, subepithelial keratitis, abnormal vascularization of the cornea (pannus), and residual scars from the follicles that look like depressions in the conjunctiva (Herbert pits). Severe corneal ulceration can lead to perforation and blindness.

Inclusion conjunctivitis affects sexually active people who have genital chlamydial infection. Transmission is by oral–genital sex or hand-to-eye transmission. Indirect transmission can occur in inadequately chlorinated swimming pools. The eye lesions usually appear a week after exposure and may be associated with a nonspecific urethritis or cervicitis. The discharge is mucopurulent, follicles are present, and there is lymphadenopathy.

Viral Conjunctivitis

Viral conjunctivitis can be acute and chronic. The discharge is watery, and follicles are prominent. Severe cases include pseudomembranes. The common causative organisms are adenovirus and herpes simplex virus. Conjunctivitis caused by adenovirus is highly contagious. The condition is usually preceded by symptoms of upper respiratory infection. Corneal involvement causes extreme photophobia. Symptoms include tearing, redness, and foreign-body sensation that can involve one or both eyes. There is lid edema, ptosis, and conjunctival hyperemia (red eyes caused by dilation of blood vessels) (see Fig. 42-16). These signs and symptoms vary from mild to severe. Viral conjunctivitis, although self-limited, tends to last longer than bacterial conjunctivitis.

Epidemic keratoconjunctivitis (EKC) is a highly contagious viral conjunctivitis that is easily transmitted from one person to another among household members, schoolchildren, and health care workers. The outbreak of epidemics is seasonal, especially during the summer when people use swimming pools. EKC is most often accompanied by preauricular lymphadenopathy and occasionally periorbital pain. There are marked follicular and papillary formations. This type of conjunctivitis can lead to keratopathy.

Allergic Conjunctivitis

Immunologic or allergic conjunctivitis is a hypersensitivity reaction that occurs as part of allergic rhinitis (hay fever), or it can be an independent allergic reaction. The patient usually has a

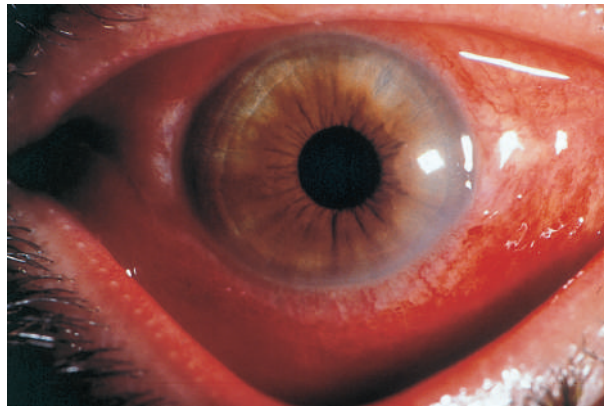

Figure 42-16 • Conjunctival hyperemia in viral conjunctivitis.

history of an allergy to pollens and other environmental allergens. There is extreme pruritus, epiphora (excessive secretion of tears), injection, and usually severe photophobia. The stringlike mucoid discharge is usually associated with rubbing the eyes because of severe pruritus. Vernal conjunctivitis is also known as seasonal conjunctivitis because it appears mostly during warm weather. There may be large formations of papillae that have a cobblestone appearance. It is more common in children and young adults. Most affected people have a history of asthma or eczema.

Toxic Conjunctivitis

Chemical conjunctivitis can be the result of medications; chlorine from swimming pools; exposure to toxic fumes among industrial workers; or exposure to other irritants such as smoke, hair sprays, acids, and alkalis.

Medical Management

The management of conjunctivitis depends on the type. Most types of mild and viral conjunctivitis are self-limiting, benign conditions that may not require treatment and laboratory procedures. For more severe cases, topical antibiotic agents, eye drops, or ointments are prescribed. Patients with gonococcal conjunctivitis require urgent antibiotic therapy. If left untreated, this ocular disease can lead to corneal perforation and blindness. The systemic complications can include meningitis and sepsis.

Bacterial Conjunctivitis

Acute bacterial conjunctivitis is almost always self-limiting, lasting 2 weeks if left untreated. If treated with antibiotics, it may last a few days, except for gonococcal and staphylococcal conjunctivitis.

For trachoma, usually broad-spectrum antibiotic agents are given topically and systemically. Surgical management includes the correction of trichiasis to prevent conjunctival scarring.

Adult inclusion conjunctivitis requires 1 week of antibiotics. Prevention of reinfection is important, and affected people and their sexual partners must seek treatment for sexually transmitted infection, if indicated.

Viral Conjunctivitis

Viral conjunctivitis is not responsive to any treatment. Cold compresses may alleviate some symptoms. Viral conjunctivitis, especially EKC, is highly contagious. Patients must be made aware of the contagious nature of the disease, and adequate education must be provided (see Chart 42-11).

Proper steps must be taken to avoid health care–associated infections. Frequent hand hygiene and procedures for environmental cleaning and disinfection of equipment used for eye examination must be strictly followed at all times. To prevent spread during outbreaks of conjunctivitis caused by adenovirus, health care facilities must set aside specified areas for treating patients diagnosed with or suspected of having conjunctivitis caused by adenovirus. All forms of tonometry must be avoided unless medically indicated. All multidose ophthalmic medications must be discarded at the end of each day or when contaminated. Employees who are infected and others must not be allowed to work or attend school until symptoms have resolved, which can take 3 to 7 days.

Allergic Conjunctivitis

Patients with allergic conjunctivitis, especially recurrent vernal or seasonal conjunctivitis, are usually given corticosteroids in ophthalmic preparations. Depending on the severity of the disease, they may be given oral preparations. The use of vasoconstrictors, such as topical epinephrine solution, cold compresses, ice packs, and cool ventilation usually provide comfort by decreasing swelling.

Chart 42-11 PATIENT EDUCATION

Education for Patients with Viral Conjunctivitis

Viral conjunctivitis is a highly contagious eye infection that can easily spread from one person to another. The symptoms can be alarming but are not serious.

The nurse instructs the patient about this eye condition and the following self-care strategies:

- Be aware that your eyes will look red and will have watery discharge, and your lids will be swollen for about a week.
- Expect to experience eye pain, a sandy sensation in your eye, and sensitivity to light.
- Keep in mind that symptoms will resolve after about 1 week.
- Use lightweight cold compresses over your eyes for about 10 minutes 4–5 times a day to soothe the pain.
- Use artificial tears for the sandy sensation in your eye and mild pain medications such as acetaminophen/paracetamol (Tylenol).
- Stay at home and not go outside. You may return to work or school after 7 days, when the redness and discharge have cleared. Obtain a note from your primary provider to return to work or school.
- Do not share towels, linens, makeup, or any items that have come in contact with your eyes.
- Wash your hands thoroughly with soap and water frequently, including before and after you apply artificial tears or cold compresses.
- Use a new tissue every time you wipe the discharge from your eye. Dampen the tissue with clean water to clean the outside of the eye.
- Wash your face and take a shower as you normally do.
- Discard all of your makeup articles and do not apply makeup until the infection has resolved.
- Wear dark glasses if bright lights bother you.
- Note if the discharge from your eye turns yellowish and purulent or if your vision changes and return to the primary provider for an examination.

Toxic Conjunctivitis

For conjunctivitis caused by chemical irritants, the eye must be irrigated immediately and profusely with saline or sterile water.

Uveitis

Inflammation of the uveal tract (uveitis) can affect the iris, the ciliary body, or the choroid. There are two types of uveitis: nongranulomatous and granulomatous.

The more common form of uveitis is the nongranulomatous type, which manifests as an acute condition with pain, photophobia, and a pattern of conjunctival injection, especially around the cornea. The pupil is small or irregular, and vision is blurred. There may be small, fine precipitates on the posterior corneal surface and cells in the aqueous humor (i.e., cell and flare). If the uveitis is severe, a hypopyon (accumulation of inflammatory cells in the anterior chamber of the eye) may develop. The condition may be unilateral or bilateral and may be recurrent. Repeated attacks of nongranulomatous anterior uveitis can cause anterior synechiae (peripheral iris adheres to the cornea and impedes outflow of aqueous humor). Posterior

synechiae (adherence of the iris and lens) block aqueous outflow from the posterior chamber. Secondary glaucoma can result from either anterior or posterior synechiae. Cataracts may also occur as a sequela to uveitis.

Granulomatous uveitis can have a more insidious onset and can involve any portion of the uveal tract. It tends to be chronic. Symptoms such as photophobia and pain may be minimal. Vision is markedly and adversely affected. Conjunctival injection is diffuse, and there may be vitreous clouding. In a severe posterior uveitis, such as chorioretinitis, there may be retinal and choroidal hemorrhages.

Medical Management

Because photophobia is a common symptom, patients should wear dark glasses outdoors. Ciliary spasm and synechia are best avoided through mydriasis; cyclopentolate (Cyclogyl) and atropine are commonly used. Local corticosteroid drops, such as Pred Forte 1% and Flarex 0.1%, instilled four to six times a day are also used to decrease inflammation.

If the uveitis is recurrent, a careful history should be initiated to discover any underlying causes. This evaluation should include a complete history, physical examination, and diagnostic tests, including a complete blood count, erythrocyte sedimentation rate, antinuclear antibodies, and Venereal Disease Research Laboratory (VDRL) and Lyme disease titers. Underlying causes include autoimmune disorders such as ankylosing spondylitis and sarcoidosis as well as toxoplasmosis, herpes zoster virus, ocular candidiasis, histoplasmosis, herpes simplex virus, tuberculosis, and syphilis.

Orbital Cellulitis

Orbital cellulitis is inflammation of the tissues surrounding the eye that may result from bacterial, fungal, or viral inflammatory conditions of contiguous structures, such as the face, oropharynx, dental structures, or intracranial structures. It can also result from foreign bodies and pre-existing ocular infection, such as dacryocystitis and panophthalmitis, or from sepsis. Infection of the sinuses is the most frequent cause. Infection originating in the sinuses can spread easily to the orbit through the thin bony walls and foramina or by means of the interconnecting venous system of the orbit and sinuses. The most common causative organisms are staphylococci and streptococci in adults. The symptoms include pain, eyelid swelling, conjunctival edema, proptosis, and decreased ocular motility. With such edema, optic nerve compression can occur and IOP may increase.

The severe intraorbital tension caused by abscess formation and the impairment of optic nerve function in orbital cellulitis can result in permanent visual loss. Because of the orbit's proximity to the brain, orbital cellulitis can lead to life-threatening complications, such as intracranial abscess and cavernous sinus thrombosis.

Medical Management

Immediate administration of high-dose, broad-spectrum, systemic antibiotics is indicated. Cultures and Gram-stained smears are obtained. Monitoring changes in visual acuity, degree of proptosis, central nervous system function (e.g., nausea, vomiting, fever, cognitive changes), displacement of the globe, extraocular movements, pupillary signs, and the fundus is extremely important. Consultation with an otolaryngologist is necessary, especially when rhinosinusitis is suspected. In the event of abscess formation or progressive loss of vision, surgical drainage of the abscess or sinus is performed. Sinusotomy and antibiotic irrigation are also performed.

ORBITAL AND OCULAR TUMORS

Benign Tumors of the Orbit

Benign tumors can develop from infancy and grow rapidly or slowly and present in later life. Some benign tumors are superficial and are easily identifiable by external presentation, palpation, and x-rays, but some are deep and may require a CT scan to diagnose. There can be significant proptosis, and visual function may be jeopardized. Benign tumors are masses characterized by the lack of infiltration in the surrounding tissues. Examples are cystic dermoid cysts and mucocele, hemangiomas, lymphangiomas, lacrimal tumors, and neurofibromas.

To prevent recurrence, benign masses are excised completely when possible. Excision may be difficult because of the involvement of some portions of the orbital bones, such as deep dermoid cysts, in which dissection of the bone is required. Subtotal resection may be indicated in deep benign tumors that intertwine with other orbital structures, such as optic nerve meningiomas. Complete removal of the tumor may endanger visual function.

Benign Tumors of the Eyelids

There are a wide variety of benign tumors that increase in frequency with age. Nevi may be unpigmented at birth and may enlarge and darken in adolescence or may never acquire any pigment at all. Hemangiomas are vascular capillary tumors that may be bright, superficial, red lesions (formerly known as strawberry angiomas) or bluish and purplish deeper lesions. Milia are small, white, slightly elevated cysts of the eyelid that may occur in multiples. Xanthelasma are yellowish, lipoid deposits on both lids that commonly appear as a result of the aging of the skin or a lipid disorder. Molluscum contagiosum lesions are flat, symmetric growths along the lid margin caused by a virus that can result in conjunctivitis and keratitis if the lesion grows into the conjunctival sac.

Treatment of benign congenital lid lesions is rarely indicated except when visual function is affected. Corticosteroid injection to the hemangioma lesion is usually effective, but surgical excision may be performed. Benign lid lesions usually present aesthetic problems rather than visual function problems. Surgical excision, or electrocautery, is primarily performed for cosmetic reasons, except for cases of molluscum contagiosum, for which surgical intervention is performed to prevent an infectious process that may ensue.

Benign Tumors of the Conjunctiva

Conjunctival nevus, a congenital benign neoplasm, is a flat, slightly elevated, brown spot that becomes pigmented during late childhood or adolescence. This should be differentiated from the pigmented lesion melanosis, which is acquired at middle age and may become melanoma. Keratin- and sebum-containing dermoid cysts are congenital and can be found

in the conjunctiva. Dermolipoma is a congenital tumor that manifests as a smooth, rounded growth in the conjunctiva near the lateral canthus. Papillomas are usually soft with irregular surfaces and appear on the lid margins. Treatment consists of surgical excision.

Malignant Tumors of the Orbit

Rhabdomyosarcoma is the most common malignant primary orbital tumor in childhood; it can also develop in older adults. The symptoms of rhabdomyosarcoma include sudden painless proptosis of one eye followed by lid swelling, conjunctival chemosis, and impairment of ocular motility. CT or MRI scans of these tumors establish the size, configuration, location, and stage of the disease; delineates the degree of bone destruction; and is useful in estimating the field for radiation therapy. The most common site of metastasis is the lung.

Management of these primary malignant orbital tumors involves three major therapeutic modalities: surgery, radiation therapy, and adjuvant chemotherapy. The degree of orbital destruction is important in planning the surgical approach. Resection often involves removal of the eyeball. The psychological needs of the patient and family are paramount in planning the management approach.

Malignant Tumors of the Eyelid

Basal cell carcinoma is the most common malignant tumor of the eyelid. Squamous cell carcinoma occurs less frequently but is considered the second most common malignant tumor. Melanoma is rare. Malignant eyelid tumors occur more frequently among people with a fair complexion who have a history of chronic exposure to the sun (Grossman & Porth, 2014).

Basal cell carcinoma appears as a painless nodule that may ulcerate. The lesion is invasive, spreads to the surrounding tissues, and grows slowly but does not metastasize. It usually appears on the lower lid margin near the inner canthus with a pearly white margin. Squamous cell carcinoma of the eyelids may resemble basal cell carcinoma initially because it also grows slowly and painlessly. It tends to ulcerate and invade the surrounding tissues, but it can metastasize to the regional lymph nodes. Melanoma may not be pigmented and can arise from nevi. It spreads to the surrounding tissues and metastasizes to other organs.

Complete excision of these carcinomas is followed by reconstruction with skin grafting if the surgical excision is extensive. The ocular postoperative site and the graft donor site are monitored for bleeding. Donor graft sites may include the buccal mucosa, the thigh, or the abdomen. The patient is referred to an oncologist for evaluation of the need for radiation therapy and monitoring for metastasis. Early diagnosis and surgical management are the basis of a good prognosis. These conditions have life-threatening consequences, and surgical excisions may result in facial disfigurement. Emotional support is an extremely important aspect of nursing management.

Malignant Tumors of the Conjunctiva

Conjunctival carcinoma most often grows in the exposed areas of the conjunctiva. The typical lesions are usually gelatinous and whitish due to keratin formation. They grow gradually, and deep invasion and metastasis are rare. Melanoma is rare but may arise from a pre-existing nevus or acquired melanosis during middle age. Squamous cell carcinoma is also rare but invasive.

The management is surgical incision. Some benign tumors and most malignant tumors recur. To avoid recurrences, patients usually undergo radiation therapy and cryotherapy after the excision of malignant tumors. Cosmetic disfigurement may result from extensive excision when deep invasion by the malignant tumor is involved.

Malignant Tumors of the Globe

Ocular melanoma is a rare malignant choroidal tumor sometimes discovered on a retinal examination. In its early stages, it could be mistaken for a nevus. In addition to a complete physical examination to discover any evidence of metastasis (to the liver, lung, and breast), retinal fundus photography, fluorescein angiography, and ultrasonography are performed. The diagnosis is confirmed at biopsy after enucleation.

Tumors are classified according to boundary lines (apical height and basal diameter) as small, medium, or large. Small tumors are generally monitored, whereas medium and large tumors require treatment. Treatment consists of radiation, enucleation, or both. Radiation therapy may be achieved by external beam performed in repeated episodes over several days or through the implantation of a small plaque that contains radioactive iodine (I-125) pellets over the tumor.

SURGICAL PROCEDURES AND ENUCLEATION

Orbital Surgeries

Orbital surgeries may be performed to repair fractures, remove a foreign body, or remove benign or malignant growths. Surgical procedures involving the orbit and lids affect facial appearance (cosmesis). The goals are to recover and preserve visual function and to maintain the anatomic relationship of the ocular structures to achieve cosmesis. During the repair of orbital fractures, the orbital bones are realigned to follow the anatomic positions of facial structures.

Orbital surgical procedures involve working around delicate structures of the eye, such as the optic nerve, retinal blood vessels, and ocular muscles. Complications of orbital surgical procedures may include blindness as a result of damage to the optic nerve and its blood supply. Sudden pain and loss of vision may indicate intraorbital hemorrhage or compression of the optic nerve. Ptosis and diplopia may result from trauma to the extraocular muscles during the surgical procedure, but these conditions typically resolve after a few weeks.

Prophylaxis with IV antibiotic agents is the usual postoperative regimen after orbital surgery, especially with repair of orbital fractures and intraorbital foreign-body removal. IV corticosteroids may be used if there is concern about optic nerve swelling. Topical ocular antibiotics are typically instilled, and antibiotic ointments are applied externally to the skin suture sites.

For the first 24 to 48 hours postoperatively, ice compresses are applied over the periocular area to decrease periorbital swelling, facial swelling, and hematoma. The head of the patient's bed should be elevated to a comfortable position (30 to 45 degrees).

Discharge education should include information about oral antibiotic agents, instillation of ophthalmic medications, and application of ocular compresses.

Enucleation

Enucleation is removal of the eyeball (globe) from the orbit, leaving the muscles and orbital contents intact. It may be surgically performed for the following conditions:

- Injury resulting in prolapse of uveal tissue or loss of light perception
- A blind, painful, deformed, or disfigured eye, usually caused by glaucoma, retinal detachment, or chronic inflammation
- An eye without useful vision that is producing or has produced sympathetic ophthalmia in the other eye
- Intraocular tumors that are untreatable by other means

The procedure for enucleation involves the separation and cutting of each of the ocular muscles and surrounding soft tissue and cutting of the optic nerve from the eyeball. The insertion of an orbital implant typically follows, and the conjunctiva is closed. A large pressure dressing is applied over the area.

Evisceration involves the removal of the intraocular contents through an incision or opening in the cornea or sclera. Evisceration may be surgically performed to treat severe ocular trauma with ruptured globe, severe ocular inflammation, or severe ocular infection. The optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact. The main advantage of evisceration over enucleation is that the final cosmetic result and motility after fitting the ocular prosthesis are enhanced.

Exenteration is the surgical removal of the entire contents of the orbit, surrounding soft tissue, and most or all of the eyelids. This surgery is indicated in malignancies of the orbit that are life threatening or when more conservative modalities of treatment have failed or are inappropriate. An example is squamous cell carcinoma of the paranasal sinuses, skin, and conjunctiva with deep orbital involvement. In its most extensive form, exenteration may include the removal of all orbital tissues and resection of the orbital bones.

Ocular Prostheses

Orbital implants and conformers (ocular prostheses usually made of silicone rubber) maintain the shape of the eye after enucleation or evisceration to prevent a contracted, sunken appearance. The temporary conformer is placed over the conjunctival closure after the implantation of an orbital implant. A conformer is placed after the enucleation or evisceration procedure to protect the suture line, maintain the fornices, prevent contracture of the socket in preparation for the ocular prosthesis, and promote the integrity of the eyelids.

All ocular prosthetics have limitations in their motility. There are two designs of eye prostheses. The anophthalmic ocular prostheses are used in the absence of the globe. Scleral shells look just like the anophthalmic prosthesis (see Fig. 42-17) but are thinner and fit over a globe with intact corneal sensation. An eye prosthesis usually lasts about 6 years, depending on the quality of fit, comfort, and cosmetic appearance. When the anophthalmic socket is completely healed, conformers are replaced with prosthetic eyes.

An ocularist is a specially trained and skilled professional who makes prosthetic eyes. After the ophthalmologist is satisfied that the anophthalmic socket is completely healed and is ready for prosthetic fitting, the patient is referred to an ocularist.

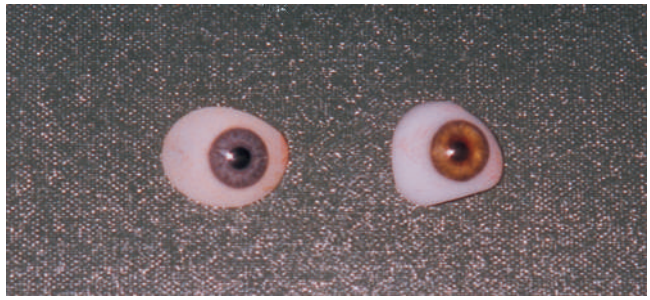

Figure 42-17 • Eye prostheses. (*Left*) Anophthalmic ocular prosthesis. (*Right*) Scleral shell.

The healing period is usually 6 to 8 weeks. It is advisable for the patient to have a consultation with the ocularist before the fitting. Obtaining accurate information and verbalizing concerns can lessen anxiety about wearing an ocular prosthesis.

Medical Management

Removal of an eye has physical, social, and psychological ramifications for any person. The significance of loss of the eye and vision must be addressed in the plan of care. The patient's preparation should include information about the surgical procedure and placement of orbital implants and conformers and the availability of ocular prosthetics to enhance cosmetic appearance. In some cases, patients may choose to see an ocularist before the surgery to discuss ocular prosthetics.

Nursing Management

Providing Education about Postsurgical and Prosthetic Care

Patients who undergo eye removal need to know that they will usually have a large ocular pressure dressing, which is typically removed after a week, and that an ophthalmic topical antibiotic ointment is applied in the socket three times daily.

After the removal of an eye, there is a loss of depth perception. Patients must be advised to take extra caution in their ambulation and movement to avoid miscalculations that may result in injury. It may take some time to adjust to monocular vision.

The patient must be advised that conformers may accidentally fall out of the socket. If this happens, the conformer must be washed, wiped dry, and placed back in the socket.

When surgical eye removal is unexpected, such as in severe ocular trauma, leaving no time for the patient and family to prepare for the loss, the nurse's role in providing emotional support is crucial.

Promoting Home, Community-Based, and Transitional Care

The patient with a new prosthetic eye may need referral to home, community-based or transitional services that provide assistance in the home. These patients also benefit from a referral for rehabilitation services.

Educating Patients about Self-Care

Patients need to be educated about how to insert, remove, and care for the prosthetic eye. Proper hand hygiene must be observed before inserting and removing an ocular prosthesis. A suction cup may be used if there are problems with manual dexterity. Precautions, such as draping a towel over the sink and closing the sink drain, must be taken to avoid loss of the

prosthesis. When instructing patients or family members, a return demonstration is important to assess the level of understanding and ability to perform the procedure.

Before insertion, the inner punctal or outer lateral aspects and the superior and inferior aspects of the prosthesis must be identified by locating the identifying marks, such as a reddish color in the inner punctal area. For people with low vision, other forms of identifying markers, such as dots or notches, are used. The upper lid is raised high enough to create a space and then the patient learns to slide the prosthesis up, underneath, and behind the upper eyelid. Meanwhile, the patient pulls the lower eyelid down to help put the prosthesis in place and to have its inferior edge fall back gradually to the lower eyelid. The lower eyelid is checked for correct positioning.

To remove the prosthesis, the patient cups one hand on the cheek to catch the prosthesis, places the forefinger of the free hand against the midportion of the lower eyelid, and gazes upward. Gazing upward brings the inferior edge of the prosthesis nearer the inferior eyelid margin. With the finger pushing inward, downward, and laterally against the lower eyelid, the prosthesis slides out into the cupped hand.

Continuing and Transitional Care

An eye prosthesis can be worn and left in place for several months. Hygiene and Pcomfort are usually maintained with daily irrigation of the prosthesis in place with normal saline solution, hard contact lens solution, or artificial tears. In the case of dry eye symptoms, the use of ophthalmic ointment lubricants or oil-based drops, such as vitamin E and mineral oil, can be helpful. Removing crusting and mucus discharge that accumulate overnight is performed with the prosthesis in place. Malpositions may occur when wiping or rubbing the prosthesis in the socket. The prosthesis can be repositioned with the use of clean fingers. Proper wiping of the prosthesis should be a gentle temporal-to-nasal motion to avoid malpositions.

The prosthesis needs to be removed and cleaned when it becomes uncomfortable and when there is increased mucus discharge. The socket should also be rendered free of mucus and inspected for any signs of infection. Any unusual discomfort, irritation, or redness of the globe or eyelids may indicate excessive wear, debris under the shell, or lack of proper hygiene. Any infection or irritation that does not resolve needs medical attention.

OCULAR CONSEQUENCES OF SYSTEMIC DISEASE

Diabetic Retinopathy

Advancements in the treatment of diabetes have enabled patients to have a relatively a normal lifespan, but many have complications of long-term diabetes. One of the most serious complications of diabetes is retinopathy. Patients with diabetes are also at higher risk of cataracts and best practices for glycemic control during cataract surgery are not known (Kumar, Seet, Eke, et al., 2016). See Chapter 31 for a detailed discussion of diabetic retinopathy.

Cytomegalovirus Retinitis

Many ophthalmic complications have been associated with AIDS, and CMV is the most common cause of retinal inflammation in patients with AIDS. Early symptoms of CMV retinitis vary from patient to patient. Some patients complain of floaters or a decrease in peripheral vision. Some have a paracentral or central scotoma, whereas others have fluctuations in vision from macular edema. The retina often becomes thin and atrophic and susceptible to retinal tears and breaks.

CMV retinitis generally takes one of three forms: hemorrhagic, brushfire, or granular. In the hemorrhagic type, large areas of white, necrotic retina may be associated with retinal hemorrhage. In the brushfire type, a yellow-white margin begins at the edge of burned-out atrophic retina. This retinitis expands and, if untreated, involves the entire retina. In the granular type, white granular lesions in the periphery of the retina gradually expand. The white, feathery infiltration of the retina destroys sensory retina and leads to necrosis, optic atrophy, and retinal detachment.

Medical Management

Management of CMV retinitis consists of prescribing the appropriate pharmacologic agent.

Pharmacologic Therapy

Pharmacologic agents available for the treatment of CMV retinitis include ganciclovir, foscarnet (Foscavir), and cidofovir (Vistide).

Ganciclovir is administered IV, orally, or intravitreously in the acute stage of CMV retinitis. The intravitreous form is available as a 4-mm intraocular implant or insert containing the medication embedded in a polymer-based system that slowly releases the medication. The insert is surgically placed in the posterior segment of the eye, and the medication diffuses locally to the site of the infection over a period of 5 to 8 months before the insert must be replaced. When given systemically, ganciclovir is a very potent medication; it can cause neutropenia, thrombocytopenia, anemia, and elevated serum creatinine levels. The surgically implanted sustained-release insert enables higher concentrations of ganciclovir to reach the CMV retinitis, but there are risks and complications associated with the inserts, including endophthalmitis, retinal detachment, and hypotony.

Foscarnet inhibits viral deoxyribonucleic acid (DNA) replication. It may be the medication of choice when ganciclovir is ineffective. It may be administered by IV or intravitreal injections. The combination of foscarnet and ganciclovir has been more effective than either medication alone. Nephrotoxicity may occur with systemic foscarnet, and renal function must be monitored carefully.

Cidofovir impedes CMV replication and is administered IV. Cidofovir has been shown to delay the progression of CMV retinitis significantly. Nephrotoxicity, proteinuria, and increased serum creatinine levels are significant side effects.

A nucleoside analog such as zidovudine (Retrovir) given in combination with one or more protease inhibitors such as ritonavir (Norvir) in the management of patients with AIDS has led to a suppression of human immune deficiency virus (HIV) replication for sustained periods. The immune system can then recover to a functional level. Some patients develop immune recovery uveitis, characterized by intraocular inflammation, cystoid macular edema, and the formation of epiretinal membranes. Immune recovery uveitis is managed by corticosteroids or by injection of corticosteroids into the sub-Tenon area of the eye.

Hypertension-Related Eye Changes

Long-standing hypertension is associated with atherosclerosis, and retinal changes are evidenced by the development of retinal arteriolar changes, such as tortuousness, narrowing, and a change in light reflex (Weber & Kelley, 2014). Funduscopic examination reveals a copper or silver coloration of the arterioles and venous compression (arteriovenous nicking) at the arteriolar and venous crossings. Intraretinal hemorrhages from hypertension appear flame shaped because they occur in the nerve fiber layer of the retina.

Hypertension can also occur as an acute consequence of conditions such as pheochromocytoma, acute kidney injury, and pregnancy-induced hypertension. The retinopathy associated with these crisis states is extensive, and the manifestations include cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often clustered around the macula (Weber & Kelley, 2014).

The choroid is also affected by the profound and abrupt rise in blood pressure and resulting vasoconstriction, and ischemia may result in serious retinal detachments and infarction of the RPE. Ischemic optic neuropathy and papilledema may also result. Blood pressure in these more severe stages should be lowered in a controlled gradual fashion to avoid ischemia of the optic nerve and brain secondary to a too-rapid fall in blood pressure. See Chapter 25 for further information about hypertension.

Eye Donation

Around 36 million people suffer due to blindness all over the world. In India alone, around 8.8 million people are accounted to be living with blindness. Corneal blindness is the fourth leading cause of blindness in India with glaucoma, cataract, and age-related macular degeneration leading the list. Corneal blind people are the most suitable candidates for corneal transplant. Sharma et al. (2019) asserted that 50% of the corneal blind people can get successful visual rehabilitation following corneal transplant. There is a huge demand–supply gap in corneal tissue availability in India. There is only 1 cornea is available for every 70 corneal demands (Priyambada, 2019). To improve the eye donation, National Eye Donation Fortnight is observed between 25 August and 8 September each year. Poor awareness and lack of motivation were found to be the causes of low eye donation rates.

Possible Donors

Eye donation refers to donation of corneal tissue following clinical death or brain death of an individual by the family members or the individual. Irrespective of age, sex, religion, etc., any motivated individual can pledge to donate his or her eyes. Those who had surgeries on the eye such as cataract and people with hypertension and diabetes also can donate their eye.

Contraindications for eye donation are given in Chart 42-9. People with a history of infections such as HIV, HBV, tuberculosis, leprosy, or rabies; any active infections of the eye at the time of death; cancers in the eye; active leukemia; death from unknown cause; septicemia; and certain neurological conditions such as encephalitis, multiple sclerosis, and dementia are not eligible to donate eyes.

How to Donate Eyes

The diseased person if he or she has pledged or family members who wish to donate eye need to contact the nearest government-approved eye bank immediately following death. Within 6 hours from the death, the cornea needs to be harvested. Before the team from the eye bank arrives, relatives or family need to do the following:

- Close the eyes of the prospective donor and switch off the fans directly above to prevent corneal drying.
- If possible/available, switch on the AC.
- Refrain from applying eye ointment.
- Keep ready the death certificate issued by competent authorities.
- The legal heir of the deceased must give written consent for the donation process.

The whole process of eye harvesting is performed by a qualified and certified team from the nearest eye bank. Blood specimen—10 mL—is taken for the laboratory testing. It takes 15 to 20 minutes and does not cause any disfigurement. Either the eyes are enucleated or the corneal tissue alone is harvested and transported in a prescribed medium and preserved.

Eye Banking

An eye bank plays a major role in the identification, harvesting, preservation, and appropriate utilization of the banked corneas. Eye banks must be established following the guidelines of eye banking and should be registered by the Government of India as per the Human Organ and Tissue Transplantation Act 1994 (Eye Banking Standards, Government of India, 2020). Creation of mass awareness and grievance counseling of the prospective donor are part of the other functioning of the eye bank. The standard operating procedures are provided for the functioning of the eye bank. The preserved eyes are distributed to the suitable donors based on the priority list. The quality of the donor cornea depends on the quality of the maintenance and preservation of the tissues. Human eyes of the younger age group (younger than 45 years) are found to be of excellent quality and can reduce the post-transplant complication and result in a better clinical outcome (Pereira et al., 2021). Adherence to meticulous infection control protocols is warranted in the process of harvesting and storing. Nurses play a crucial role in education and motivation of donors. They can offer counseling and emotional support to the grieving families. Misconception of disfigurement and undue delay in proceeding for funeral can be dispelled by the nurses.

Eye Transplant

Eyes harvested from the deceased donors can be transplanted to two people. The corneal transplant or keratoplasty is otherwise called an eye transplant. The corneal transplant can help restore vision in people with corneal scarring following injuries, keratoconus, and corneal infections. A full-thickness corneal transplant (or penetrating keratoplasty) or partial-thickness corneal transplant (or deep anterior lamellar keratoplasty) can be performed. In other patients, the thin layer of corneal endothelial tissues and Descemet membrane without the supportive tissues may be transplanted. The details of nursing concern are given in the previous section on corneal surgeries.

The most common postoperative complications are infection, rejection, glaucoma, swelling of the cornea, and retinal detachment. To avoid daily doses of steroids, intravitreal steroid implants are nowadays used (Aruljothi, Anandamoorthi, Balasundaram, et al., 2021). One of the important factors that lead to poor clinical outcome is noncompliance to therapy. Patients with corneal transplant may become depressed due

to prolonged therapy and poor outcome. Nurses are in a better position to educate and counsel the patients about the importance of compliance.

CRITICAL THINKING EXERCISES

1. You are making a home visit to a 75-year-old male who has a long history of diabetes and complains that recently he is having trouble with his vision. Describe what priority assessment data you would focus on obtaining during your initial visit. What are your priorities of care of this patient with low vision? How would your priorities change if the man were blind?
2. A 45-year-old woman presents to the emergency department with family members, complaining she has had progressive loss of vision of her right eye since this morning. What are your priority assessments for this patient? What focused questions would you ask her? How would you focus your physical assessment? What surgical interventions could be appropriate to treat her? How would you prepare the patient and her family members for possible surgery?
3. A 56-year-old patient reports to you that he has been diagnosed with glaucoma but it is "no big deal" since his vision is fine. Although prescribed ophthalmic medications to treat glaucoma, he has not been self-administering them. What is the strength of the evidence that prescriptive medications are useful in preventing glaucoma-related complications? Identify the risk he is taking by not adhering to his prescribed medication regimen. Describe how you would educate him to gain his adherence to his prescribed regimen.

Kidney and Urinary Tract Function

Chapter 43 Assessment of Kidney and Urinary Function 1369

Chapter 44 Management of Patients with Kidney Disorders. 1387

Chapter 45 Management of Patients with Urinary Disorders 1434

CHAPTER 43

Assessment of Kidney and Urinary Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the structure and function of the renal and urinary systems.
2. Explain the role of the kidneys in regulating fluid and electrolyte balance, acid–base balance, and blood pressure.
3. Identify the diagnostic studies used to determine upper and lower urinary tract function and related nursing implications.
4. Discriminate between normal and abnormal assessment findings of upper and lower urinary tract function.
5. Initiate education and preparation for patients undergoing assessment of the urinary system.

GLOSSARY

aldosterone: hormone synthesized and released by the adrenal cortex; causes the kidneys to reabsorb sodium
antidiuretic hormone (ADH): hormone secreted by the posterior pituitary gland; causes the kidneys to reabsorb more water; also called *vasopressin*
anuria: decreased urine output of less than 50 mL in 24 hours
bacteriuria: bacteria in the urine
creatinine: endogenous waste product of muscle energy metabolism
diuresis: increased urine volume
dysuria: painful or difficult urination
frequency: voiding more frequently than every 3 hours
glomerular filtration rate (GFR): amount of plasma filtered through the glomeruli per unit of time
glomerulus: tuft of capillaries forming part of the nephron through which filtration occurs
hematuria: red blood cells in the urine
micturition: urination or voiding
nephron: structural and functional unit of the kidney responsible for urine formation
nocturia: awakening at night to urinate
oliguria: urine output less than 0.5 mL/kg/hr
proteinuria: protein in the urine
pyuria: white blood cells in the urine
renal clearance: ability of the kidneys to clear solutes from the plasma
renal glycosuria: excretion of glucose in the urine
specific gravity: expression of the degree of concentration of the urine
urea nitrogen: end product of protein metabolism

Introduction

Function of the renal and urinary systems is essential to life. The primary purpose of the renal and urinary systems is to maintain the body's state of homeostasis by carefully regulating fluid and electrolytes, removing wastes, and providing other functions (see Chart 43-1). Dysfunction of the kidneys and lower urinary tract is common and may occur at any age and with varying degrees of severity. Assessment of upper and lower urinary tract function is part of every health examination and requires that the nurse have an understanding of the anatomy and physiology of the urinary system as well as the effects of changes in the system on other physiologic functions.

Chart 43-1

Functions of the Kidney

- Urine formation
- Excretion of waste products
- Regulation of electrolytes
- Regulation of acid–base balance
- Control of water balance
- Control of blood pressure
- Renal clearance
- Regulation of red blood cell production
- Synthesis of vitamin D to active form
- Secretion of prostaglandins

Anatomic and Physiologic Overview

Anatomy of the Kidney and Urinary Systems

The kidney and urinary systems include the kidneys, ureters, bladder, and urethra. Urine is formed by the kidney and flows through the other structures to be eliminated from the body.

Kidneys

The kidneys are a pair of bean-shaped, brownish-red structures located retroperitoneally (behind and outside the peritoneal cavity) on the posterior wall of the abdomen—from the 12th thoracic vertebra to the 3rd lumbar vertebra in the adult (see Fig. 43-1A). The center of the concave medial border of each kidney houses a deep vertical fissure called hilum. Each hilum is penetrated with blood vessels, nerves, and the ureter (Eaton & Pooler, 2013). The average adult kidney weighs approximately 113 to 170 g and is 10 to 12 cm long, 6 cm wide, and 2.5 cm thick (Eaton & Pooler, 2013); (Grossman & Porth, 2014). The right kidney is slightly lower than the left due to the location of the liver.

Externally, the kidneys are well protected by the ribs and by the muscles of the abdomen and back. Internally, fat deposits

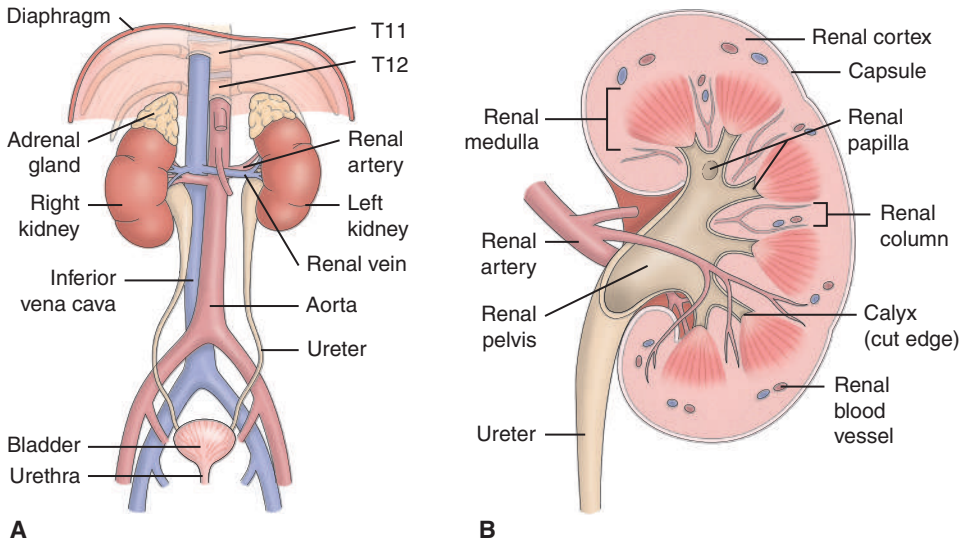

Figure 43-1 • A. Kidneys, ureters, and bladder. **B.** Internal structure of the kidney. Redrawn with permission from Porth, C. M., & Matfin, G. (2009). Pathophysiology: Concepts of altered health states (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

surround each kidney, providing protection against jarring. The kidneys and surrounding fat are suspended from the abdominal wall by renal fascia made of connective tissue which holds the kidney in place (Skorecki, Chertow, Marsden, 2015). The fibrous connective tissue, blood vessels, and lymphatics surrounding each kidney are known as the renal capsule. An adrenal gland lies on top of each kidney. The kidneys and adrenals are independent in function, blood supply, and innervation.

The renal parenchyma is divided into two parts: the cortex and the medulla (see Fig. 43-1B). The medulla, which is approximately 5 cm wide, is the inner portion of the kidney. It contains the loops of Henle, the vasa recta, and the collecting ducts of the juxtamedullary nephrons. The collecting ducts from both the juxtamedullary and the cortical nephrons connect to the renal pyramids, which are triangular and are situated with the base facing the concave surface of the kidney and the point (papilla) facing the hilum, or pelvis. Each kidney contains approximately 8 to 18 pyramids. The pyramids drain into minor calyces, which drain into major calyces that open directly into the renal pelvis. The tip of each pyramid is called a papilla and projects into the minor calyx (Eaton & Pooler, 2013). The renal pelvis is the beginning of the collecting system and is composed of structures that are designed to collect and transport urine. Once the urine leaves the renal pelvis, the composition or amount of urine does not change.

The cortex, which is approximately 1 cm wide, is located farthest from the center of the kidney and around the outermost edges. It contains the nephrons (the structural and functional units of the kidney responsible for urine formation), which are discussed later.

Blood Supply to the Kidneys

The hilum is the concave portion of the kidney through which the renal artery enters and the ureters and renal vein exit. The kidneys receive 20% to 25% of the total cardiac output, which means that all of the body's blood circulates through the kidneys approximately 12 times per hour (Grossman & Porth, 2014). The renal artery (arising from the abdominal aorta) divides into smaller and smaller vessels, eventually forming the afferent arterioles. Each afferent arteriole branches to form a glomerulus, which is the tuft of capillaries forming part of the nephron through which filtration occurs. Blood leaves the glomerulus through the efferent arteriole and flows back to the inferior vena cava through a network of capillaries and veins.

Nephrons

Each kidney has 1 million nephrons that are located within the renal parenchyma and are responsible for the formation of filtrate that will become urine (Eaton & Pooler, 2013). The large number of nephrons allows for adequate renal function even if the opposite kidney is damaged or becomes nonfunctional. If the total number of functioning nephrons is less than 20% of normal, renal replacement therapy needs to be considered.

There are two types of nephrons. The cortical nephrons (80% to 85%) are located in the outermost part of the cortex, and the juxtamedullary nephrons (15% to 20%) are located deeper in the cortex (Grossman & Porth, 2014). The juxtamedullary nephrons are distinguished by long loops of Henle and are surrounded by long capillary loops called *vasa recta* that dip into the medulla of the kidney. The length of the tubular component of the nephron is directly related to its ability to concentrate urine.

Nephrons are made up of two basic components: a filtering element composed of an enclosed capillary network (the glomerulus) and the attached tubule (see Fig. 43-2). The glomerulus is a unique network of capillaries suspended between the afferent and efferent blood vessels, which are enclosed in an epithelial structure called the *Bowman capsule.* The glomerular membrane is composed of three filtering layers: the capillary endothelium, the basement membrane, and the epithelium. This membrane normally allows filtration of fluid and small molecules yet limits passage of larger molecules, such as blood cells and albumin. Pressure changes and the permeability of the glomerular membrane of the Bowman capsule facilitate the passage of fluids and various substances from the blood vessels, filling the space within the Bowman capsule with this filtered solution.

The tubular component of the nephron begins in the Bowman capsule. The filtrate created in the Bowman capsule travels first into the proximal tubule, which is made up of epithelial cells resting on the basement membrane, then the loop of Henle, the distal tubule, and either the cortical or medullary collecting ducts

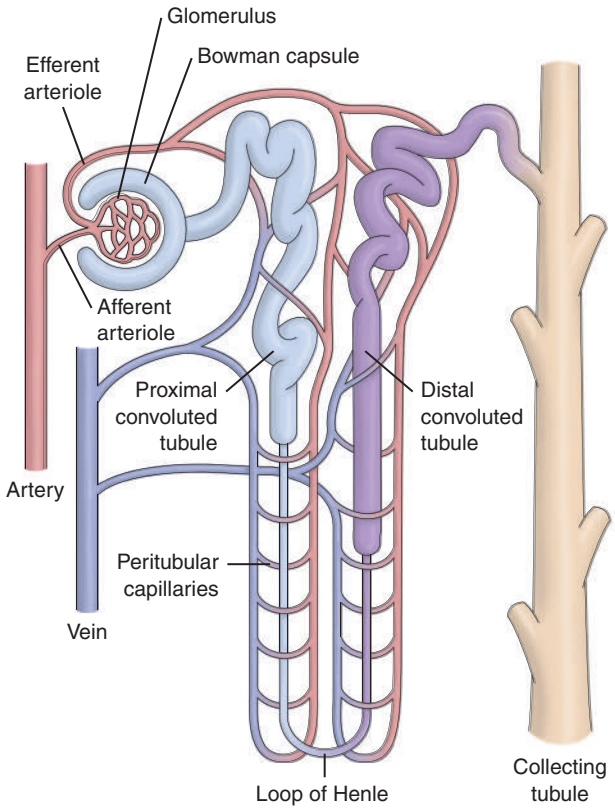

Figure 43-2 • Representation of a nephron. Each kidney has about 1 million nephrons of two types: cortical and juxtamedullary. Cortical nephrons are located in the cortex of the kidney; juxtamedullary nephrons are adjacent to the medulla.

(Eaton & Pooler, 2013). The structural arrangement of the tubule allows the distal tubule to lie in close proximity to where the afferent and efferent arterioles, respectively, enter and leave the glomerulus. The distal tubular cells located in this area, known as the macula densa, function with the adjacent afferent arteriole and create what is known as the juxtaglomerular apparatus. This is the site of renin production. Renin is a hormone directly involved in the control of arterial blood pressure; it is essential for proper functioning of the glomerulus (see later discussion).

The tubular component consists of the Bowman capsule, the proximal tubule, the descending and ascending limbs of the loop of Henle, and the cortical and medullary collecting ducts. This portion of the nephron is responsible for making adjustments in the filtrate based on the body's needs. Changes are continually made as the filtrate travels through the tubules until it enters the collecting system and is expelled from the body (see Fig. 43-2).

Ureters, Bladder, and Urethra

The urine formed in the nephrons flows through the renal calyces and then into the ureters, which are long fibromuscular tubes that connect each kidney to the bladder (Hall, 2016). These narrow tubes, each 24 to 30 cm long, originate at the lower portion of the renal pelvis and terminate in the trigone (tissue between the opening of the ureters and urethra) of the bladder wall.

The lining of the ureters is made up of transitional cell epithelium called *urothelium.* The urothelium prevents reabsorption of urine. The movement of urine from each renal pelvis through the ureter into the bladder is facilitated by peristaltic contraction of the smooth muscles in the ureter wall. Each ureter has three narrow areas that are prone to obstruction by renal calculi (kidney stones) or stricture. These three areas include the ureteropelvic junction, the ureteral segment near the sacroiliac junction, and the ureterovesical junction. Obstruction of the ureteropelvic junction is the most serious because of its close proximity to the kidney and the risk of associated kidney dysfunction.

The urinary bladder is a distensible muscular sac located just behind the pubic bone (Weber & Kelley, 2014). The usual capacity of the adult bladder is 400 to 500 mL, but it can distend to hold a larger volume. The bladder is characterized by its central, hollow area, called the *vesicle,* which has two inlets (the ureters) and one outlet (the urethra). The area surrounding the bladder neck is called the *urethrovesical junction.* The angling of the ureterovesical junction is the primary means of providing antegrade, or downward, movement of urine, also referred to as efflux of urine. This angling prevents vesicoureteral reflux (retrograde, or backward, movement of urine) from the bladder, up the ureter, toward the kidney.

The wall of the bladder contains four layers. The outermost layer is the adventitia, which is made up of connective tissue. Immediately beneath the adventitia is a smooth muscle layer known as the detrusor. Beneath the detrusor is a submucosal layer of loose connective tissue that serves as an interface between the detrusor and the innermost layer, a mucosal lining. The inner layer contains specialized transitional cell epithelium, a membrane that is impermeable to water and prevents reabsorption of urine stored in the bladder. The bladder neck contains bundles of involuntary smooth muscle that form a portion of the urethral sphincter known as the internal sphincter. An important portion of the sphincter mechanism that helps maintain continence is the external urinary sphincter at the anterior urethra, which is the segment most distal from the bladder (Grossman & Porth, 2014). During micturition (voiding or urination), increased intravesical pressure keeps the ureterovesical junction closed and urine within the ureters. As soon as micturition is completed, intravesical pressure returns to its normal low baseline value, allowing efflux of urine to resume. Therefore, the only time that the bladder is completely empty is in the last seconds of micturition, before efflux of urine resumes.

The urethra arises from the base of the bladder: In the male, it passes through the penis; in the female, it opens just anterior to the vagina. In the male, the prostate gland, which lies just below the bladder neck, surrounds the urethra posteriorly and laterally.

Function of the Kidney and Urinary Systems

Urine Formation

The healthy human body is composed of approximately 60% water. Water balance is regulated by the kidneys and results in the formation of urine. Urine is formed in the nephrons through a complex three-step process: glomerular filtration, tubular reabsorption, and tubular secretion (see Fig. 43-3). Each nephron functions independently from other nephrons because each has its own blood supply (Eaton & Pooler, 2013). The various substances normally filtered by the glomerulus, reabsorbed by the tubules, and excreted in the urine include sodium, chloride, bicarbonate, potassium, glucose, urea, creatinine, and uric acid. Within the tubule, some of these substances are selectively reabsorbed into the blood. Others are secreted from the blood into the filtrate as it travels down the tubule.

Amino acids and glucose are usually filtered at the level of the glomerulus and reabsorbed so that neither is excreted in the urine. Normally, glucose does not appear in the urine. However, renal glycosuria (excretion of glucose in the urine)

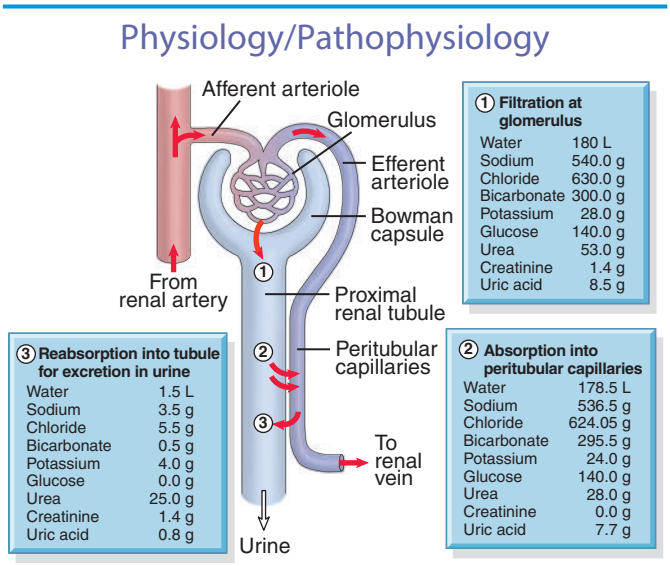

Figure 43-3 • Urine is formed in the nephrons in a three-step process: filtration, reabsorption, and secretion. Water, electrolytes, and other substances, such as glucose and creatinine, are filtered by the glomerulus; varying amounts of these substances are reabsorbed in the renal tubule or excreted in the urine. Approximate normal volumes of these substances during the steps of urine formation are shown at the top. Wide variations may occur in these values depending on diet.

occurs if the amount of glucose in the blood and glomerular filtrate exceeds the amount that the tubules are able to reabsorb. Renal glycosuria can occur on its own as a benign condition (Hall, 2016). It also occurs in poorly controlled diabetes—the most common condition that causes the blood glucose level to exceed the kidney's reabsorption capacity.

Protein molecules also are not usually found in the urine; however, low–molecular-weight proteins (globulins and albumin) may periodically be excreted in small amounts. Protein in the urine is referred to as proteinuria (Eaton & Pooler, 2013).

Glomerular Filtration

The normal blood flow through the kidneys is between 1000 and 1300 mL/min (Grossman & Porth, 2014). As blood flows into the glomerulus from an afferent arteriole, filtration occurs. The filtered fluid, also known as filtrate or ultrafiltrate, then enters the renal tubules. Under normal conditions, about 20% of the blood passing through the glomeruli is filtered into the nephron, amounting to about 180 L/day of filtrate (Eaton & Pooler, 2013). The filtrate normally consists of water, electrolytes, and other small molecules, because water and small molecules are allowed to pass, whereas larger molecules stay in the bloodstream. As blood enters the glomerulus from the afferent arteriole, filtration depends on adequate blood flow that maintains a consistent pressure through the glomerulus called hydrostatic pressure. Many factors can alter this blood flow and pressure, including hypotension, decreased oncotic pressure in the blood, and increased pressure in the renal tubules from an obstruction (Eaton & Pooler, 2013); (Grossman & Porth, 2014).

Tubular Reabsorption and Tubular Secretion

The second and third steps of urine formation occur in the renal tubules. In tubular reabsorption, a substance moves from the filtrate back into the peritubular capillaries or vasa recta. In tubular secretion, a substance moves from the peritubular capillaries or vasa recta into tubular filtrate. Of the 180 L of filtrate that the kidneys produce each day, 99% is reabsorbed into the bloodstream, resulting in the formation of 1 to 2 L of urine each day. Although most reabsorption occurs in the proximal tubule, reabsorption occurs along the entire tubule. Reabsorption and secretion in the tubule frequently involve passive and active transport and may require the use of energy. Tubular secretion occurs when substances move from the peritubular capillary blood plasma (blood) into the tubular lumen (filtrate). Tubular secretion helps with the elimination of potassium, hydrogen ions, ammonia, uric acid, some drugs, and other waste products (Headly, 2015). Filtrate becomes concentrated in the distal tubule and collecting ducts under hormonal influence and becomes urine, which then enters the renal pelvis. In the absence of tubular reabsorption, volume depletion would rapidly occur (Headly, 2015).

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as vasopressin, is a hormone that is secreted by the posterior portion of the pituitary gland in response to changes in osmolality of the blood. With decreased water intake, blood osmolality tends to increase, stimulating ADH release. ADH then acts on the kidney, increasing reabsorption of water and thereby returning the osmolality of the blood to normal. With excess water intake, the secretion of ADH by the pituitary is suppressed; therefore, less water is reabsorbed by the kidney tubule, leading to diuresis (increased urine volume).

A dilute urine with a fixed specific gravity (about 1.010) or fixed osmolality (about 300 mOsm/L) indicates an inability to concentrate and dilute the urine, which is a common early sign of kidney disease (Skorecki et al., 2015).

Osmolarity and Osmolality

Osmolarity refers to the ratio of solute to water. The regulation of salt and water is paramount for control of the extracellular volume and both serum and urine osmolarity. Controlling either the amount of water or the amount of solute can change osmolarity. Osmolarity and ionic composition are maintained by the body within very narrow limits. As little as a 1% to 2% change in the serum osmolarity can cause a conscious desire to drink and conservation of water by the kidneys (Skorecki et al., 2015).

The degree of dilution or concentration of the urine is also measured in terms of osmolality (the number of osmoles [the standard unit of osmotic pressure] dissolved per kilogram of solution). The filtrate in the glomerular capillary normally has the same osmolality as the blood—280 to 300 mOsm/kg. Serum and urine osmolality and osmolarity are discussed in more detail in Chapter 7.

Regulation of Water Excretion

Regulation of the amount of water excreted is an important function of the kidney. With high fluid intake, a large volume of dilute urine is excreted. Conversely, with a low fluid intake, a small volume of concentrated urine is excreted. A person normally ingests about 1300 mL of oral liquids and 1000 mL of water in food per day. Of the fluid ingested, approximately 900 mL is lost through the skin and lungs (called *insensible loss*), 50 mL through sweat, and 200 mL through feces. It is important to consider all fluid gained and lost when evaluating total fluid status. Daily weight measurements are a reliable means of determining overall fluid status.1 Kg weight gain approximately equals to 1000 mL, so a weight change of as little as 0.5 kg could suggest an overall fluid gain or loss of 500 mL (Grossman & Porth, 2014).

Regulation of Electrolyte Excretion

When the kidneys are functioning normally, the volume of electrolytes excreted per day is equal to the amount ingested. For example, the average Indian diet contains more than twice the WHO recommended sodium, approximately 10.98 g of salt. The consumption of salt ranges from 5.22 to 42.30 g/day. They eat e more of salt-cured items such as pickle, dried fish, and also add salt on the table. There is a great variation in sodium intake according to the region; people of southern and eastern states of India consume comparatively more salt than the people of Uttar Pradesh, Uttarakhand, Punjab, Haryana, Gujarat, and Maharashtra. With increase in the consumption of packed ready-to-eat items the mean salt consumption is likely to increase still more (Johnson. C., Praveen. D., Pope. A., et.al, 2017).

The regulation of sodium volume excreted depends on aldosterone, a hormone synthesized and released by the adrenal cortex. With increased aldosterone in the blood, less sodium is excreted in the urine, because aldosterone fosters renal reabsorption of sodium. Release of aldosterone from the adrenal cortex is largely under the control of angiotensin II. Angiotensin II levels are in turn controlled by renin, an enzyme that is released from specialized cells in the kidneys (see Fig. 43-4). This complex system is activated when pressure in the renal arterioles falls below normal levels, as occurs with shock, dehydration, or decreased sodium chloride delivery to the tubules. Activation of this system increases the retention of water and expansion of the intravascular fluid volume, thereby maintaining enough pressure within the glomerulus to ensure adequate filtration.

The regulation of serum sodium and potassium are discussed in detail in Chapter 7.

Regulation of Acid–Base Balance

The normal serum pH is about 7.35 to 7.45 and must be maintained within this narrow range for optimal physiologic function (Grossman & Porth, 2014). The kidney performs major functions to assist in this balance. One function is to reabsorb and return to the body's circulation any bicarbonate from the urinary filtrate; other functions are to excrete or reabsorb acid, synthesize ammonia, and excrete ammonium chloride (Headly, 2015). Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The renal tubules actively reabsorb most of the bicarbonate in the urinary filtrate. To replace any lost bicarbonate, the renal tubular cells generate new bicarbonate through a variety of chemical reactions. This newly generated bicarbonate is then reabsorbed by the tubules and returned to the body.

The body's acid production is the result of catabolism, or breakdown, of proteins, which produces acid compounds, particularly phosphoric and sulfuric acids. The normal daily diet also includes a certain amount of acid materials. Unlike carbon dioxide (CO_2), phosphoric and sulfuric acids cannot be eliminated by the lungs. Because accumulation of these acids in the blood lowers pH (making the blood more acidic) and inhibits cell function, they must be excreted in the urine. However, if the hydrogen ions are low, they will be reabsorbed. A person with normal kidney function excretes about 70 mEq of acid each day. The kidney is able to excrete some of this acid directly into the urine until the urine pH reaches 4.5, which is 1000 times more acidic than blood (Grossman & Porth, 2014).

However, more acid usually needs to be eliminated from the body than can be secreted directly as free acid in the urine. These excess acids are bound to chemical buffers so that they can be excreted in the urine. Two important chemical buffers are phosphate ions and ammonia (NH_3). When buffered with acid, ammonia becomes ammonium (NH_4^+). Phosphate is present in the glomerular filtrate, and ammonia is produced by the cells of the renal tubules and secreted into the tubular fluid. Through the buffering process, the kidney is able to excrete large quantities of acid in a bound form without further lowering the pH of the urine.

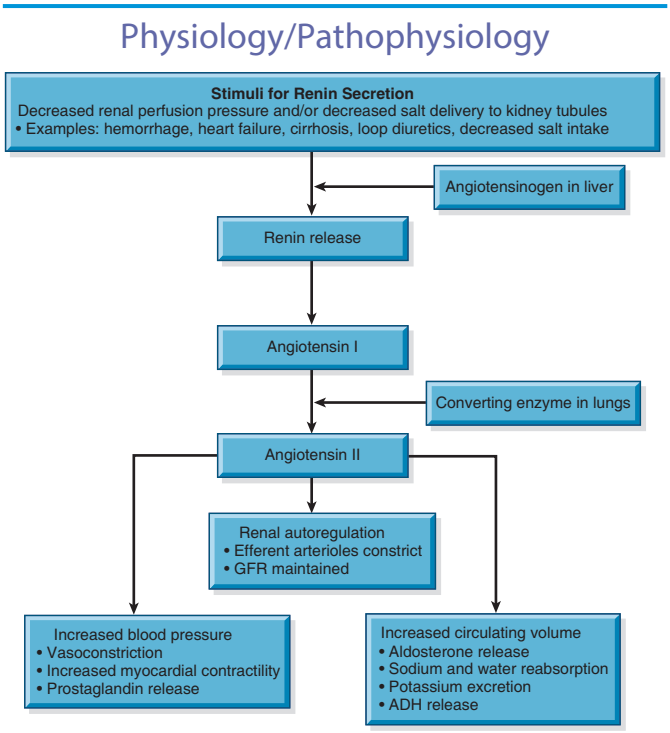

Figure 43-4 • The renin–angiotensin system. GFR, glomerular filtration rate; ADH, antidiuretic hormone.

Autoregulation of Blood Pressure

Regulation of blood pressure is an important function of the kidney. Specialized vessels of the kidney, called the *vasa recta,* constantly monitor blood pressure as blood begins its passage into the kidney. When the vasa recta detect a decrease in blood pressure, specialized juxtaglomerular cells near the afferent arteriole, distal tubule, and efferent arteriole, secrete the hormone renin. Renin converts angiotensinogen to angiotensin I, which is then converted to angiotensin II—the most powerful vasoconstrictor known; angiotensin II causes the blood pressure to increase (Hall, 2016). The adrenal cortex secretes aldosterone in response to stimulation by the pituitary gland, which occurs in response to poor perfusion or increasing serum osmolality. The result is an increase in blood pressure. When the vasa recta recognize the increase in blood pressure, renin secretion stops. Failure of this feedback mechanism is one of the primary causes of hypertension (see Fig. 43-4).

Renal Clearance

Renal clearance refers to the ability of the kidneys to clear solutes from the plasma. A 24-hour collection of urine is the primary test of renal clearance used to evaluate how well the kidney performs this important excretory function. Renal clearance depends on several factors: how quickly the substance is filtered across the glomerulus, how much of the substance is reabsorbed along the tubules, and how much of the substance is secreted into the tubules. It is possible to measure the renal clearance of

any substance, but the one measure that is particularly useful is the creatinine clearance.

Creatinine is an endogenous waste product of skeletal muscle that is filtered at the glomerulus, passed through the tubules with minimal change, and excreted in the urine. Hence, creatinine clearance is a good measure of the glomerular filtration rate (GFR), the amount of plasma filtered through the glomeruli per unit of time. To calculate creatinine clearance, a 24-hour urine specimen is collected. Midway through the collection, the serum creatinine level is measured. The following formula is then used to calculate the creatinine clearance:

$$\frac{(\text{Volume of urine [mL/min]} \times \text{Urine creatinine [mL/dL]})}{\text{Serum creatinine (mg/dL)}}$$

The adult GFR can vary from a normal of approximately 125 mL/min (1.67 to 2 mL/sec) to a high of 200 mL/min (Grossman & Porth, 2014). Creatinine clearance is the best approximation of renal function. As renal function declines, both creatinine clearance and renal clearance (the ability to excrete solutes) decrease.

Regulation of Red Blood Cell Production

When the kidneys detect a decrease in the oxygen tension in renal blood flow, because of anemia, arterial hypoxia, or inadequate blood flow, the juxtaglomerular apparatus releases erythropoietin. Erythropoietin is a glycoprotein from the kidney that stimulates the bone marrow to produce red blood cells (RBCs), which carry oxygen throughout the body (Eaton & Pooler, 2013).

Vitamin D Synthesis

The kidneys are also responsible for the final conversion of inactive vitamin D to its active form, 1,25-dihydroxycholecalciferol. Vitamin D is necessary for maintaining normal calcium balance in the body.

Secretion of Prostaglandins and other Substances

The kidneys also produce prostaglandin E and prostacyclin, thromboxanes and leukotrienes, which have vasoactive effects. These substances help the afferent and efferent arterioles maintain renal blood flow by causing selective vasodilation or vasoconstriction (Headly, 2015).

Excretion of Waste Products

The kidneys eliminate the body's metabolic waste products. The major waste product of protein metabolism is urea, of which about 25 to 30 g are produced and excreted daily (Grossman & Porth, 2014). All of this urea must be excreted in the urine; otherwise, it accumulates in body tissues. Other waste products of metabolism that must be excreted are creatinine, phosphates, and sulfates. Uric acid, formed as a waste product of purine metabolism, is also eliminated in the urine. The kidneys serve as the primary mechanism for excreting drug metabolites.

Urine Storage

The bladder is the reservoir for urine. Both filling and emptying of the bladder are mediated by coordinated sympathetic and parasympathetic nervous system control mechanisms involving the detrusor muscle and the bladder outlet. Conscious awareness of bladder filling occurs as a result of sympathetic neuronal pathways that travel via the spinal cord to the level of T10 through T12, where peripheral, hypogastric nerve innervation allows for continued bladder filling. As bladder filling continues, stretch receptors in the bladder wall are activated, coupled with the desire to void. This information from the detrusor muscle is relayed back to the cerebral cortex via the parasympathetic pelvic nerves at the level of S1 through S4 (Grossman & Porth, 2014). Overall bladder pressure remains low due to the bladder's compliance (ability to expand or collapse) as urine volume changes.

Bladder compliance is due in part to the smooth muscle lining of the bladder and collagen deposits within the wall of the bladder, as well as to neuronal mechanisms that inhibit the detrusor muscle from contracting (specifically, adrenergic receptors that mediate relaxation). To maintain adequate kidney filtration rates, bladder pressure during filling must remain lower than 40 cm water (H_2O). This low pressure allows the urine to freely leave the renal pelvis and enter the ureters. The sensation of bladder fullness is transmitted to the central nervous system when the bladder has reached about 150 to 200 mL in adults, and an initial desire to void occurs (Hall, 2016). A marked sense of fullness and discomfort with a strong desire to void usually occurs when the bladder reaches its functional capacity of 400 to 500 mL of urine. Neurologic changes to the bladder at the level of the supraspinal nerves, the spinal nerves, or the bladder wall itself can cause abnormally high volumes (up to 2000 mL) of urine to be stored due to a decreased or absent urge to void.

Under normal circumstances with average fluid intake of approximately 1 to 2 L/day, the bladder should be able to store urine for periods of 2 to 4 hours at a time during the day (Hall, 2016). At night, the release of vasopressin in response to decreased fluid intake causes a decrease in the production of urine and makes it more concentrated. This phenomenon usually allows the bladder to continue filling for periods of 6 to 8 hours in adolescents and adults, making them able to sleep for longer periods before needing to void. In older adults, decreasing bladder compliance and decreased vasopressin levels often cause nocturia (awakening during the night to urinate).

Bladder Emptying

Micturition normally occurs approximately eight times in a 24-hour period. It is activated via the micturition reflex arc within the sympathetic and parasympathetic nervous systems, which causes a coordinated sequence of events. Initiation of voiding occurs when the efferent pelvic nerve, which originates in the S1 to S4 area, stimulates the bladder to contract, resulting in complete relaxation of the striated urethral sphincter. This is followed by a decrease in urethral pressure, contraction of the detrusor muscle, opening of the vesicle neck and proximal urethra, and flow of urine. This coordinated effort by the parasympathetic system is mediated by muscarinic and, to a lesser extent, cholinergic receptors within the detrusor muscle. The pressure generated in the bladder during micturition is about 20 to 40 cm H_2O in females. It is somewhat higher and more variable in males 45 years and older due to the normal hyperplasia of the cells of the middle lobes of the prostate gland, which surround the proximal urethra. Any obstruction of the bladder outlet, such as in advanced benign prostatic hyperplasia (BPH), results in a high voiding pressure. High voiding pressures make it more difficult to start urine flow and maintain it.

If the spinal pathways from the brain to the urinary system are destroyed (e.g., after a spinal cord injury), reflex contraction of the bladder is maintained, but voluntary control over the process is lost. In both situations, the detrusor muscle can contract and expel urine, but the contractions are generally insufficient to empty the bladder completely, so residual urine (urine left in the bladder after voiding) remains. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2014).

Gerontologic Considerations

Upper and lower urinary tract function changes with age. The GFR decreases, starting between 35 and 40 years of age, and a yearly decline of about 1 mL/min continues thereafter. Older adults are more susceptible to acute and chronic kidney injury due to the structural and functional changes in the kidney. Examples include sclerosis of the glomerulus and renal vasculature, decreased blood flow, decreased GFR, altered tubular function, and acid–base imbalance. Although renal function usually remains adequate, renal reserve is decreased and may reduce the kidneys' ability to respond effectively to drastic or sudden physiologic changes. This steady decrease in glomerular filtration, combined with the use of multiple medications in which metabolites are cleared by the kidneys, puts the older person at higher risk for adverse drug effects and drug–drug interactions (Eliopoulos, 2018).

Older adults are more prone to develop hypernatremia and fluid volume deficit, because increasing age is also associated with diminished osmotic stimulation of thirst. Thirst is defined as one's awareness of the desire to drink. The sense of thirst is so protective that hypernatremia almost never occurs in adults younger than 60 years.

Structural or functional abnormalities that occur with aging may also prevent complete emptying of the bladder. This may be due to decreased bladder wall contractility; secondary to myogenic or neurogenic factors; or related to bladder outlet obstruction, such as in BPH or after prostatectomy. Vaginal and urethral tissues atrophy (become thinner) in aging women due to decreased estrogen levels. This causes decreased blood supply to the urogenital tissues, resulting in urethral and vaginal irritation and urinary incontinence.

Urinary incontinence is present in 15% to 30% of community-dwelling older adults, 50% of older adults who are institutionalized, and 30% of older adults who are hospitalized (Eliopoulos, 2018). Many older adults and their families are unaware that urinary incontinence stems from many causes. The nurse needs to inform the patient and family that with appropriate evaluation, urinary incontinence can often be managed at home, and in many cases it can be eliminated. Many treatments are available for urinary incontinence in older adults, including noninvasive, behavioral interventions that the patient or caregiver can carry out. Treatment modalities for urinary incontinence are described in further detail in Chapter 45.

Preparation of the older adult patient for diagnostic tests must be managed carefully to prevent dehydration, which might precipitate kidney disease in a patient with marginal renal function. Limitations in mobility may affect an older patient's ability to void adequately or to consume an adequate volume of fluids. The patient may limit fluid intake to minimize the frequency of voiding or the risk of incontinence.

Nursing Alert: Providing education about the dangers of an inadequate fluid intake is an important role of the nurse caring for the older patient. The nurse emphasizes the need to drink throughout the day even if the patient does not feel thirsty, because the thirst stimulation is decreased.

Older women often have incomplete emptying of the bladder and urinary stasis, which may result in urinary tract infection or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or chronic kidney disease (Eliopoulos, 2018). Urologic symptoms can mimic disorders such as appendicitis, peptic ulcer disease, and cholecystitis, which can make diagnosis difficult in older adults due to decreased neurologic innervation (Eliopoulos, 2018).

Assessment of the Kidney and Urinary Systems

Health History

Obtaining a urologic health history requires excellent communication skills, because many patients are embarrassed or uncomfortable discussing genitourinary function or symptoms (Weber & Kelley, 2014). It is important to use language the patient can understand and to avoid medical jargon. It is also important to review risk factors, particularly for those patients who are at high risk. For example, the nurse needs to be aware that multiparous women delivering their children vaginally have a high risk for stress urinary incontinence, which, if severe enough, can also lead to urge incontinence. People with neurologic disorders such as diabetic neuropathy, multiple sclerosis, or Parkinson disease often have incomplete emptying of the bladder and urinary stasis, which may result in urinary tract infection or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or chronic kidney disease (Eliopoulos, 2018). Risk factors for specific disorders and kidney and lower urinary tract dysfunction are summarized in Table 43-1 and discussed in Chapters 44 and 45.

When obtaining the health history, the nurse should inquire about the following:

- The patient's chief concern or reason for seeking health care, the onset of the problem, and its effect on the patient's quality of life
- The location, character, and duration of pain, if present, and its relationship to voiding; factors that precipitate pain, and those that relieve it
- History of urinary tract infections, including past treatment or hospitalization for urinary tract infection
- Fever or chills
- Previous renal or urinary diagnostic tests, surgeries or procedures; or the use of indwelling urinary catheters
- Dysuria (painful or difficult urination), as well as during voiding (i.e., at initiation or at termination of voiding) this occurs
- Hesitancy, straining, or pain during or after urination
- Urinary incontinence (stress incontinence, urge incontinence, overflow incontinence, or functional incontinence)
- Hematuria (RBCs in the urine) or change in color or volume of urine
- Nocturia and its date of onset
- Renal calculi (kidney stones), passage of stones or gravel in urine
- In female patients, the number and type (vaginal or cesarean) of deliveries; the use of forceps; vaginal infection, discharge, or irritation; contraceptive practices
- History of anuria (decreased urine production of less than 50 mL in 24 hours) or other kidney problem
- Presence or history of genital lesions or sexually transmitted infections
- The use of tobacco, alcohol, or recreational drugs
- Any prescription and over-the-counter medications (including those prescribed for renal or urinary problems)

TABLE 43-1 Risk Factors for Selected Renal or Urologic Disorders

Risk Factor	Possible Renal or Urologic Disorder
Advanced age	Incomplete emptying of bladder, leading to urinary tract infection and urosepsis
Benign prostatic hyperplasia	Obstruction to urine flow, leading to frequency, oliguria, anuria
Diabetes	Chronic kidney disease, neurogenic bladder
Gout, hyperparathyroidism, Crohn's disease, ileostomy	Kidney stone formation
Hypertension	Renal insufficiency, chronic kidney failure
Instrumentation of urinary tract, cystoscopy, catheterization	Urinary tract infection, incontinence
Immobilization	Kidney stone formation
Multiple sclerosis	Incontinence, neurogenic bladder, and other complications
Occupational, recreational, or environmental exposure to chemicals (plastics, pitch, tar, rubber)	Acute kidney failure
Obstetric injury, tumors	Incontinence
Parkinson disease	Incontinence and other complications
Pregnancy	Proteinuria, frequent voiding
Radiation therapy to pelvis	Cystitis, fibrosis of ureter, or fistula in urinary tract
Recent pelvic surgery	Inadvertent trauma to ureters or bladder
Sickle cell disease, multiple myeloma	Chronic kidney disease
Spinal cord injury	Neurogenic bladder, urinary tract infection, incontinence
Strep throat, impetigo, nephrotic syndrome	Chronic kidney disease
Systemic lupus erythematosus	Nephritis, chronic kidney disease

Common Symptoms

Dysfunction of the kidney can produce a complex array of symptoms throughout the body. Pain, changes in voiding, and gastrointestinal symptoms are particularly suggestive of urinary tract disease.

Pain

Genitourinary pain is usually caused by distention of some portion of the urinary tract as a result of obstructed urine flow or inflammation and swelling of tissues. Severity of pain is related to the sudden onset, rather than the extent of distention.

Table 43-2 lists the various types of genitourinary pain, characteristics of the pain, associated signs and symptoms, and possible causes. However, kidney disease does not always involve pain. It tends to be diagnosed because of other symptoms that cause a patient to seek health care, such as pedal edema, shortness of breath, and changes in urine elimination (Weber & Kelley, 2014).

Changes in Voiding

Micturition is normally a painless function that occurs approximately eight times in a 24-hour period. The average person voids 1 to 2 L of urine in 24 hours, although this amount varies depending on fluid intake, sweating, environmental temperature, vomiting, or diarrhea. Common problems associated with voiding include frequency (voiding more frequently than every 3 hours), urgency, dysuria, hesitancy, incontinence, enuresis, polyuria, oliguria, and hematuria. These problems and others are described in Table 43-3. Increased urinary urgency and frequency, coupled with decreasing urine volumes strongly suggest urine retention. Depending on the acuity of the onset of these symptoms, immediate bladder emptying via catheterization and evaluation may be necessary to prevent kidney dysfunction.

Gastrointestinal Symptoms

Gastrointestinal signs and symptoms are often associated with urologic conditions because of shared autonomic and sensory innervation and renointestinal reflexes (see Table 43-3). The proximity of the right kidney to the colon, duodenum, head of the pancreas, common bile duct, liver, and gallbladder may cause gastrointestinal disturbances. The proximity of the left kidney to the colon (splenic flexure), stomach, pancreas, and spleen may also result in intestinal symptoms. The most

TABLE 43-2 Identifying Characteristics of Genitourinary Pain

Type	Location	Characteristics	Associated Signs and Symptoms	Possible Etiology
Kidney	Costovertebral angle, may extend to umbilicus	Dull constant ache; if sudden distention of capsule, pain is severe, sharp, stabbing, and colicky in nature	Nausea and vomiting, diaphoresis, pallor, signs of shock	Acute obstruction, kidney stone, blood clot, acute pyelonephritis, trauma
Bladder	Suprapubic area	Dull, continuous pain that may be intense with voiding; may be severe if bladder full	Urgency, pain at end of voiding, painful straining	Overdistended bladder, infection, interstitial cystitis; tumor
Ureteral	Costovertebral angle, flank, lower abdominal area, testis, or labium	Severe, sharp, stabbing pain, colicky in nature	Nausea and vomiting, paralytic ileus	Ureteral stone, edema or stricture, blood clot
Prostatic	Perineum and rectum	Vague discomfort, feeling of fullness in perineum, vague back pain	Suprapubic tenderness, obstruction to urine flow; frequency, urgency, dysuria, nocturia	Prostatic cancer, acute or chronic prostatitis
Urethral	*Male*: Along penis to meatus *Female*: Urethra to meatus	Pain variable, most severe during and immediately after voiding	Frequency, urgency, dysuria, nocturia, urethral discharge	Irritation of bladder neck, infection of urethra, trauma, foreign body in lower urinary tract

TABLE 43-3 Problems Associated with Changes in Voiding

Problem	Definition	Possible Etiology
Anuria	Urine output <50 mL/day	Acute or chronic kidney injury (see Chapter 44), complete obstruction
Bacteriuria	Bacterial count >100,000 colonies/mL in the urine	Infection
Dysuria	Painful or difficult voiding	Lower urinary tract infection, inflammation of bladder or urethra, acute prostatitis, stones, foreign bodies, tumors in bladder
Enuresis	Involuntary voiding during sleep	Delay in functional maturation of central nervous system (bladder control usually achieved by 5 years of age), obstructive disease of lower urinary tract, genetic factors, failure to concentrate urine, urinary tract infection, psychological stress
Frequency	Frequent voiding—more than every 3 hours	Infection, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretic agents, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy
Hematuria	Red blood cells in the urine	Cancer of genitourinary tract, acute glomerulonephritis, renal stones, renal tuberculosis, blood dyscrasia, trauma, extreme exercise, rheumatic fever, hemophilia, leukemia, sickle cell trait or disease
Hesitancy	Delay, difficulty in initiating voiding	Benign prostatic hyperplasia, compression of urethra, outlet obstruction, neurogenic bladder
Incontinence	Involuntary loss of urine	External urinary sphincter injury, obstetric injury, lesions of bladder neck, detrusor dysfunction, infection, neurogenic bladder, medications, neurologic abnormalities
Nocturia	Awakening during the night to urinate	Decreased renal concentrating ability, heart failure, diabetes, incomplete bladder emptying, excessive fluid intake at bedtime, nephrotic syndrome, cirrhosis with ascites
Oliguria	Urine output <0.5 mL/kg/hr	Acute or chronic kidney failure (see Chapter 44), inadequate fluid intake
Polyuria	Increased volume of urine voided	Diabetes, diabetes insipidus, the use of diuretics, excess fluid intake, lithium toxicity, some forms of kidney disease (hypercalcemic and hypokalemic nephropathy)
Proteinuria	Protein in the urine	Acute and chronic kidney disease, nephrotic syndrome, vigorous exercise, heat stroke, severe heart failure, diabetic nephropathy, multiple myeloma
Urgency	Strong desire to void	Infection, chronic prostatitis, urethritis, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretic agents, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy

common signs and symptoms are nausea, vomiting, diarrhea, abdominal discomfort, and abdominal distention.

Unexplained Anemia

Gradual kidney dysfunction can be insidious in its presentation, although fatigue is a common symptom. Fatigue, shortness of breath, and exercise intolerance all result from the condition known as "anemia of chronic disease."

Past Health, Family, and Social History

Data collection about previous health problems or diseases provides the health care team with useful information for evaluating the patient's current urinary status. People with diabetes who have hypertension are at risk for renal dysfunction. Older men are at risk for prostatic enlargement, which causes urethral obstruction and can result in urinary tract infections and kidney disease. People with a family history of urinary tract problems are at increased risk for renal disorders. Genetics may also influence renal conditions (see Chart 43-2).

It is also important to assess the patient's psychosocial status, level of anxiety, perceived threats to body image, available support systems, and sociocultural patterns.

Physical Assessment

Several body systems can affect upper and lower urinary tract dysfunction, and conversely that dysfunction can affect several end organs; therefore, a head-to-toe assessment is indicated. Areas of emphasis include the abdomen, suprapubic region, genitalia, lower back, and lower extremities.

The kidneys are not usually palpable. However, palpation of the kidneys may detect an enlargement that could prove to be very important (Weber & Kelley, 2014). The correct technique for palpation is illustrated in Figure 43-5. It may be possible to palpate the smooth, rounded lower pole of the kidney between the hands. The right kidney is easier to detect, because it is somewhat lower than the left one. In patients who are obese, palpation of the kidneys is more difficult.

Renal dysfunction may produce tenderness over the costovertebral angle, which is the angle formed by the lower border of the 12th, or bottom, rib and the spine (see Fig. 43-6). The abdomen (just slightly to the right and left of the midline in both upper quadrants) is auscultated to assess for bruits (low-pitched murmurs that indicate renal artery stenosis or an aortic aneurysm). The abdomen is also assessed for the presence of ascites (accumulation of fluid in the peritoneal cavity), which may occur with kidney as well as liver dysfunction.

To check for residual urine, the bladder should be percussed after the patient voids. Percussion of the bladder begins at the midline just above the umbilicus and proceeds downward. The sound changes from tympanic to dull when percussing over the bladder. The bladder, which can be palpated only if it is moderately distended, feels like a smooth, firm, round mass rising out of the abdomen, usually at midline (see Fig. 43-7). Dullness to percussion of the bladder after voiding indicates incomplete bladder emptying (Weber & Kelley, 2014). Portable bladder ultrasonography is another method of detecting urinary retention. These devices provide a three-dimensional image of the bladder and should be used 10 minutes after voiding to detect urine retention (Davis, Chrisman, & Walden, 2012). See later discussion in bladder ultrasonography section.

In older men, BPH or prostatitis can cause difficulty with urination. Because the signs and symptoms of prostate cancer can mimic those of BPH, the prostate gland is palpated by digital rectal examination (DRE) as part of the yearly physical examination in men 40 years and older (see Chapter 46). In addition, a blood specimen is obtained to test the

Chart 43-2 GENETICS IN NURSING PRACTICE

Kidney and Urinary Disorders

Various conditions that affect the renal system and urinary tract function are influenced by genetic factors. Some examples of these genetic disorders are:

Autosomal Dominant:
- Familial Wilms tumor
- Polycystic kidney disease
- Renal cystic disease in tuberous sclerosis complex

X-Linked Recessive:
- Alport syndrome (primarily X-linked but autosomal dominant and recessive forms exist)

Congenital Kidney Disorders:
- Congenital absence of the vas deferens (caused by *CFTR* gene mutation for cystic fibrosis)
- Horseshoe kidney
- Multicystic dysplastic kidneys

Other Genetic Disorders that Impact the Renal System:
- Alpha-1 antitrypsin deficiency
- Anderson–Fabry disease
- Diabetes
- Coronary artery disease
- Pulmonary hypertension
- Von Hippel–Lindau syndrome

Nursing Assessments

Family History Specific to Kidney and Urinary Disorders

- Inquire about other family members with a history of renal and/or urinary tract malformations, kidney disease, or end-stage kidney disease and age of onset.
- Determine if other family members have diabetic kidney disease (clustering of this within the family could indicate genetic susceptibility).
- Identify family history of male infertility and cystic fibrosis (congenital absence of vas deferens).
- Be alert to family members with history of early-onset renal (Wilms tumor) or other cancers.

Physical Assessment Specific to Genetic Kidney and Urinary Disorders

- Be alert to signs and symptoms of kidney disease at an early age.
- Ascertain for presence and frequency of kidney stones or urinary tract infections.
- Assess for the presence and frequency of:
  - Abdominal pain or presence of an abdominal mass
  - Hematuria
  - Hypertension
  - Peripheral or orbital edema
  - Proteinuria
- Assess for clinical findings suggesting that kidney disease is a component of a genetic syndrome (e.g., seizures, intellectual disability, skin involvement).
- Assess for bleeding tendencies, abnormal clotting, or history of anemia.

The National Kidney Foundation (India) (NKFI), http://www.nkfi.in/

Figure 43-5 • The left kidney is palpated by reaching over to the patient's left side and placing the left hand beneath the patient's lower left rib. Push the hand on top forward as the patient inhales deeply.

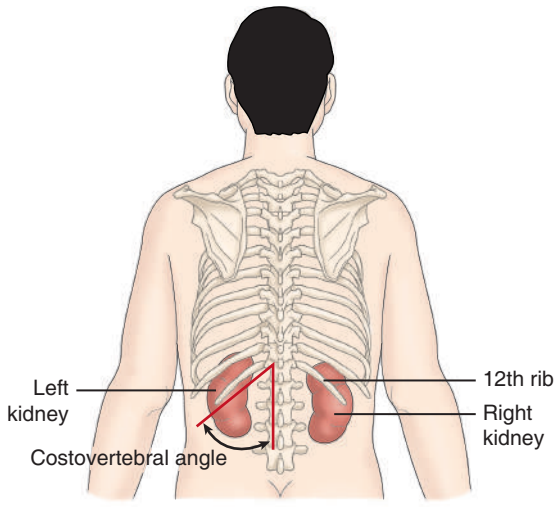

Figure 43-6 • Location of the costovertebral angle.

prostate-specific antigen (PSA) level annually; the results of the DRE and PSA are then correlated. Blood is drawn for PSA before the DRE, because manipulation of the prostate can cause the PSA level to increase temporarily. The inguinal area is examined for enlarged nodes, an inguinal or femoral hernia, and varicocele (varicose veins of the spermatic cord).

In women, the vulva, urethral meatus, and vagina are examined (Weber & Kelley, 2014). The urethra is palpated for diverticula, and the vagina is assessed for adequate estrogen effect and any of five types of herniation: urethrocele, cystocele, pelvic prolapse, enterocele, and rectocele. Urethrocele is the bulging of the anterior vaginal wall into the urethra. Cystocele is the herniation of the bladder wall into the vaginal vault. Pelvic prolapse is bulging of the cervix into the vaginal vault. Enterocele is herniation of the bowel into the posterior vaginal wall. Rectocele is herniation of the rectum into the vaginal wall. These prolapses are graded depending on the degree of herniation.

The woman is asked to cough and perform a Valsalva maneuver to assess the urethra's system of muscular and ligament support. If urine leakage occurs, the index and middle

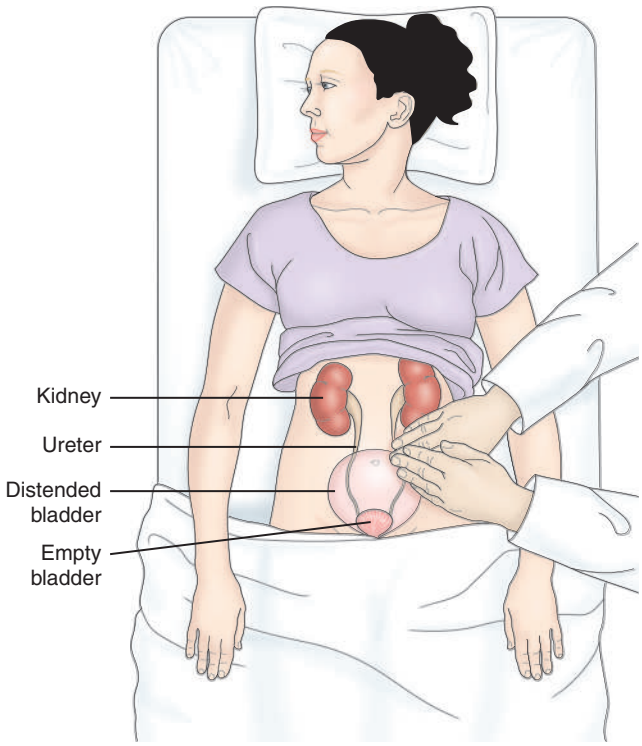

Figure 43-7 • Palpation of the bladder.

fingers of the examiner's gloved hand are used to support either side of the urethra as the woman is asked to repeat the Valsalva maneuver; this is called the *Marshall–Bonney maneuver.* If this produces urinary leakage, referral is suggested.

The patient is assessed for edema and changes in body weight. Edema may be observed, particularly in the face causing puffiness in the morning, which is an early symptom of renal dysfunction. Edema may be noted in the dependent parts of the body, such as the ankles and sacral areas, and suggests fluid retention. An increase in body weight commonly accompanies edema. A 1 kg weight gain equals approximately 1000 mL of fluid (Hall, 2016).

The deep tendon reflexes of the knee are examined for quality and symmetry. This is an important part of testing for neurologic causes of bladder dysfunction, because the sacral area, which innervates the lower extremities, is the same peripheral nerve area responsible for urinary continence. The gait pattern of the person with bladder dysfunction is also noted, as well as the patient's ability to walk toe to heel. These tests evaluate possible supra spinal causes for urinary incontinence.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with urinary conditions. A comprehensive health history is used to determine the appropriate laboratory and diagnostic tests. The following sections review some of the specific tests that might be used.

The nurse educates the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. The nurse should also note trends in results, because they provide information about disease progression as well as the patient's response to therapy.

Most patients undergoing urologic testing or imaging studies are apprehensive, even those who have had these tests in the past. Patients frequently feel discomfort and embarrassment about such a private and personal function as voiding. Voiding in the presence of others can frequently cause guarding, a natural reflex that inhibits voiding due to situational anxiety. Because the outcomes of these studies determine the plan of care, the nurse must help the patient relax by providing as much privacy and explanation about the procedure as possible (see Chart 43-3). In addition, Chart 43-4 provides a plan of care for patients undergoing diagnostic testing.

Urinalysis and Urine Culture

The urinalysis provides important clinical information about kidney function and helps diagnose other diseases, such as diabetes. The urine culture determines whether bacteria are present in the urine, as well as their strains and concentration. Urine culture and sensitivity also identify the antimicrobial

Chart 43-3 PATIENT EDUCATION

Before and After Urodynamic Testing

The nurse instructs the patient on what to expect before, during, and after the procedure:

Preprocedure

- A physician or nurse will conduct an in-depth interview. Questions related to the urologic symptoms and voiding habits will be asked.

During the Procedure

- You will be asked to describe sensations felt.
- You might be asked to change positions (e.g., from supine to sitting or standing).
- You may be asked to cough or perform the Valsalva maneuver (bear down).
- You will probably need to have one or two urethral catheters inserted so that bladder pressure and bladder filling can be measured. Another catheter may be placed in the rectum or vagina to measure abdominal pressure.
- You may also have electrodes (surface, wire, or needle) placed in the perianal area for electromyography. This may be uncomfortable initially during insertion and later during position changes.
- Your bladder will be filled through the urethral catheter one or more times.

After the Procedure

- You may experience urinary frequency, urgency, or dysuria from the urethral catheters. Avoid caffeinated, carbonated, and alcoholic beverages because they can further irritate the bladder. These symptoms usually decrease or subside by the day after the procedure.
- You might notice slight hematuria (blood-tinged urine) right after the procedure (especially in men with benign prostatic hyperplasia). Drinking fluids will help to clear the hematuria.
- If the urinary meatus is irritated, a warm sitz bath may be helpful.
- Be alert to signs of a urinary tract infection. Contact your primary provider if you experience fever, chills, lower back pain, or continued dysuria and hematuria.
- If you receive an antibiotic medication before the procedure, you should continue taking the complete course of medication after the procedure. This is a measure to prevent infection.

Chart 43-4 PLAN OF NURSING CARE

Care of the Patient Undergoing Diagnostic Testing of the Renal–Urologic System

NURSING DIAGNOSIS: Deficient knowledge about procedures and diagnostic tests
GOAL: Patient demonstrates increased understanding of the procedure and tests and expected behaviors

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's level of understanding of planned diagnostic tests	1. Provides basis for education and gives indication of patient's perception of tests	• States rationale for planned diagnostic tests and what tasks and behaviors are expected during the procedure
2. Provide a description of tests in language the patient can understand	2. Understanding what is expected enhances patient adherence and cooperation	• Adheres to prescribed urine collection, fluid modifications, or other procedures required for diagnostic evaluation
3. Assess patient's understanding of test results after their completion	3. Apprehension may interfere with patient's ability to understand information and results provided by health care team	• Restates in own words results of diagnostic tests
4. Reinforce information provided to patient about test results and implications for follow-up care	4. Provides opportunity for patient to clarify information and anticipate follow-up care	• Asks for clarification of terms and procedures • Explains rationale for follow-up care • Participates in follow-up care

NURSING DIAGNOSIS: Acute pain related to infection, edema, obstruction, or bleeding along urinary tract or related to invasive diagnostic tests
GOAL: Patient reports decrease in pain and absence of discomfort

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of pain: dysuria, burning on urination, abdominal or flank pain, bladder spasm	1. Provides baseline for evaluation of pain-relief strategies and progression of dysfunction	• Reports decreasing levels of pain • Reports absence of local symptoms
2. Encourage fluid intake (unless contraindicated)	2. Promotes dilute urine and flushing of the lower urinary tract	• States ability to start and stop urinary stream without discomfort • Consumes increased fluid intake if indicated
3. Encourage warm sitz baths	3. Relieves local discomfort and promotes relaxation	• Uses sitz bath as indicated
4. Report increased pain to primary provider	4. May indicate progression or recurrence of dysfunction, or untoward signs (e.g., bleeding, calculi)	• Identifies signs and symptoms to be reported to the primary provider • Takes medications as prescribed
5. Administer analgesic and antispasmodic agents for pain and spasm as prescribed	5. Prescribed to relieve pain or spasm	• Does not delay in emptying bladder • Uses appropriate hygienic measures, avoids bubble baths, uses appropriate hygiene after bowel movements
6. Assess voiding patterns and hygiene practices and provide instructions about recommended voiding patterns and hygienic practices	6. Delayed emptying of the bladder and poor hygiene may contribute to pain secondary to renal or urinary tract dysfunction	

NURSING DIAGNOSIS: Fear related to potential alteration in renal function and embarrassment secondary to discussion of urinary function and invasion of genitalia
GOAL: Patient appears relaxed and reports decreased fear and anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's level of fear and apprehension	1. A high level of fear or apprehension can interfere with learning and cooperation	• Appears relaxed with a low level of fear or apprehension
2. Explain all procedures and tests to patient	2. Knowledge about what is expected helps reduce fear and apprehension	• States rationale for tests and procedures in a calm, relaxed manner
3. Provide privacy and respect patient's modesty by closing doors and keeping patient covered. Keep urinal and bedpan covered and out of sight	3. Communicates that you are aware of and accept patient's need for privacy and modesty	• Maintains usual privacy and modesty • Discusses own urinary tract dysfunction using correct terminology without overt indications of embarrassment or discomfort
4. Use correct terminology in a factual manner when questioning patient about urinary tract dysfunction	4. Conveys that you are comfortable discussing patient's urinary dysfunction and symptoms with patient	• Relates fears and concerns
5. Assess patient's fears about perceived changes associated with tests and other procedures	5. May uncover fears and misconceptions of the patient that can be alleviated by correct understanding	• Demonstrates correct understanding of procedures and possible outcomes
6. Instruct patient in relaxation techniques	6. Promotes relaxation and assists patient in coping with uncertainty about outcomes	• Appears relaxed with low level of fear and apprehension

therapy that is best suited for the particular strains identified, taking into consideration the antibiotic agents that have the best rate of resolution in that particular geographic region. To get accurate results in urine culture test, the first morning sample collected from the midstream is the most valuable. Before collection of specimen the nurse needs to instruct the patient to clean the urinary meatus. The patient should be instructed to leave the first and last part of urine and collect the midportion without touching the lid or surface of the sterile urine collection container. Appropriate physical evaluation of urine for any abnormality can assist in detecting serious underlying diseases.

Components

Urine examination includes the following:

- Urine color (see Table 43-4)
- Urine clarity and odor
- Urine pH and specific gravity
- Tests to detect protein, glucose, and ketone bodies in the urine (proteinuria, renal glycosuria, and ketonuria, respectively)
- Microscopic examination of the urine sediment after centrifugation to detect RBCs (hematuria), white blood cells (pyuria), casts (cylindruria), crystals (crystalluria), and bacteria (bacteriuria) (see Table 43-3)

Researchers are working on additional noninvasive tests that can be performed on urine to detect conditions such as bladder cancer. For example, urine telomerase activity levels have been found to be sensitive and specific to detect bladder cancer in men (Lamarca & Barriuso, 2012).

Significance of Findings

Several abnormalities, such as hematuria and proteinuria, produce no symptoms but may be detected during a routine urinalysis using a dipstick. Normally, about 1 million RBCs pass into the urine daily, which is equivalent to one to three RBCs per high-power field. Hematuria (more than three RBCs per high-power field) can develop from an abnormality anywhere along the genitourinary tract and is more common in women than in men. Common causes include acute infection (cystitis, urethritis, or prostatitis), renal calculi, and neoplasm. Other causes include systemic disorders, such as bleeding disorders; malignant lesions; and medications, such as warfarin (Coumadin) and heparin. Although hematuria may initially be detected using a dipstick test, further evaluation is necessary with a 24-hour collection (Fischbach & Dunning, 2015).

Proteinuria may be a benign finding, or it may signify serious disease. Occasional loss of up to 150 mg/day of protein in the urine, primarily albumin and Tamm–Horsfall protein (also known as uromodulin), is considered normal and usually does not require further evaluation. A dipstick examination, which can detect from 30 to 1000 mg/dL of protein, should be used as a screening test only, because urine concentration, pH, hematuria, and radiocontrast materials all affect the results. Because dipstick analysis does not detect protein concentrations of less than 30 mg/dL, the test cannot be used for early detection of diabetic nephropathy. Microalbuminuria (excretion of 20 to 200 mg/dL of protein in the urine) is an early sign of diabetic nephropathy. Common benign causes of transient proteinuria are fever, strenuous exercise, and prolonged standing.

Causes of persistent proteinuria include glomerular diseases, malignancies, collagen diseases, diabetes, preeclampsia, hypothyroidism, heart failure, exposure to heavy metals, and the use of medications, such as nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors (Comerford, 2015).

TABLE 43-4 Changes in Urine Color and Possible Causes

Urine Color	Possible Cause
Colorless to pale yellow	Dilute urine due to diuretic agents, alcohol consumption, diabetes insipidus, glycosuria, excess fluid intake, kidney disease
Yellow to milky white	Pyuria, infection, vaginal cream
Bright yellow	Multiple vitamin preparations
Pink to red	Hemoglobin breakdown, red blood cells, gross blood, menses, bladder or prostate surgery, beets, blackberries, medications (phenytoin [Dilantin], rifampin [Rifadin], thioridazine [Mellaril], cascara sagrada, senna products)
Blue, blue green	Dyes, methylene blue, *Pseudomonas* species organisms, medications (amitriptyline HCl [Amitriptyline], triamterene [Dyrenium])
Orange to amber	Concentrated urine due to dehydration, fever, bile, excess bilirubin or carotene, medications (phenazopyridine hydrochloride [Pyridium], nitrofurantoin [Furadantin])
Brown to black	Old red blood cells, urobilinogen, bilirubin, melanin, porphyrin, extremely concentrated urine due to dehydration, medications (cascara sagrada, metronidazole [Flagyl], iron preparations, quinine sulfate [Qualaquin], senna products, methyldopa [Aldomet], nitrofurantoin)

Specific Gravity

Specific gravity is an expression of the degree of concentration of the urine that measures the density of a solution compared to the density of water, which is 1.000. Specific gravity is altered by the presence of blood, protein, and casts in the urine. The normal range of urine-specific gravity is 1.010 to 1.025 (Grossman & Porth, 2014).

Methods for determination of specific gravity include the following:

- Multiple-test dipstick (most common method), with a specific reagent area for specific gravity
- Urinometer (least accurate method), in which urine is placed in a small cylinder and the urinometer is floated in the urine; a specific gravity reading is obtained at the meniscus level of the urine
- Refractometer, an instrument used in a laboratory setting, which measures differences in the speed of light passing through air and the urine sample; this is the most accurate test

Urine-specific gravity depends largely on hydration status. When fluid intake decreases, specific gravity normally increases. With high fluid intake, specific gravity decreases. In patients with kidney disease, urine-specific gravity does not vary with fluid intake, and the patient's urine is said to have a fixed specific gravity. Disorders or conditions that cause decreased urine-specific gravity include diabetes insipidus, glomerulonephritis, and severe renal damage. Those that can cause increased specific gravity include diabetes, nephritis, and fluid deficit.

Osmolality

Osmolality is the most accurate measurement of the kidney's ability to dilute and concentrate urine. It measures the number of solute particles in a kilogram of water. Serum and

urine osmolality are measured simultaneously to assess the body's fluid status. In healthy adults, serum osmolality is 280 to 300 mOsm/kg, and normal urine osmolality is 200 to 800 mOsm/kg. For a 24-hour urine sample, the normal value is 300 to 900 mOsm/kg (Fischbach & Dunning, 2015).

Renal Function Tests

Renal function tests are used to evaluate the severity of kidney disease and to assess the status of the patient's kidney function. These tests also provide information about the effectiveness of the kidney in carrying out its excretory function. Renal function test results may be within normal limits until the GFR is reduced to less than 50% of normal. Renal function can be assessed most accurately if several tests are performed and their results are analyzed together. Common tests of renal function include renal concentration tests, creatinine clearance, and serum creatinine and blood urea nitrogen (end product of protein metabolism) levels (see Table 43-5).

Other tests for evaluating renal function that may be helpful include serum electrolyte levels as well as urinary biomarkers to detect acute kidney injury (Fallone & Cotton, 2015) (see Chapter 7).

Diagnostic Imaging

Kidney, Ureter, and Bladder Studies

An x-ray study of the abdomen or kidneys, ureters, and bladder (KUB) may be performed to delineate the size, shape, and position of the kidneys and to reveal urinary system abnormalities (Fischbach & Dunning, 2015).

General Ultrasonography

Ultrasonography is a noninvasive procedure that uses sound waves passed into the body through a transducer to detect abnormalities of internal tissues and organs. Abnormalities such as fluid accumulation, masses, congenital malformations, changes in organ size, and obstructions can be identified. During the test, the lower abdomen and genitalia may need to be exposed. Ultrasonography requires a full bladder; therefore, fluid intake is encouraged before the procedure.

Bladder Ultrasonography

Bladder ultrasonography is a noninvasive method of measuring urine volume in the bladder. It may be indicated for urinary frequency, inability to void after removal of an indwelling urinary catheter, measurement of postvoiding residual urine volume, inability to void postoperatively, or assessment of the need for catheterization during the initial stages of an intermittent catheterization training program. Portable, battery-operated devices are available for bedside use. The scan head is placed on the patient's abdomen and directed toward the bladder (see Fig. 43-8). The device automatically calculates and displays urine volume.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques that provide excellent cross-sectional views of the anatomy of the kidney and urinary tract. They are used to evaluate genitourinary masses, nephrolithiasis, chronic renal infections, renal or urinary tract trauma,

TABLE 43-5 Renal Function Tests

Test	Purpose	Normal Values
Renal Concentration		
Specific gravity	A measure of the degree of concentration of the urine.	1.010–1.025
Urine osmolality	Concentrating ability is lost early in kidney disease; hence, these test findings may disclose early defects in renal function.	250–900 mOsm/kg/24 hr, 50–1200 mOsm/kg random sample
24-Hour Urine		
Creatinine clearance	Detects and evaluates progression of kidney disease. Test measures volume of blood cleared of endogenous creatinine in 1 minute, which provides an approximation of the glomerular filtration rate. Sensitive indicator of kidney disease used to follow progression of kidney disease.	Measured in mL/min/1.73 m^2

Age (Years)	Male	Female
<30	88–146	81–134
30–40	82–140	75–128
40–50	75–133	69–122
50–60	68–126	64–116
60–70	61–120	58–110
70–80	55–113	52–105

Serum		
Creatinine level	Measures effectiveness of renal function. Creatinine is the end product of muscle energy metabolism. In normal function, the level of creatinine, which is regulated and excreted by the kidneys, remains fairly constant in the body.	0.6–1.2 mg/dL (50–110 mmol/L)
BUN	Serves as index of renal function. Urea is the nitrogenous end product of protein metabolism. Test values are affected by protein intake, tissue breakdown, and fluid volume changes.	7–18 mg/dL; patients >60 years: 8–20 mg/dL
BUN-to-creatinine ratio	Evaluates hydration status. An elevated ratio is seen in hypovolemia; a normal ratio with an elevated BUN and creatinine is seen with intrinsic kidney disease.	About 10:1

BUN, blood urea nitrogen.

Figure 43-8 • Bladder ultrasonography.

metastatic disease, and soft tissue abnormalities. Occasionally, an oral or intravenous (IV) radiopaque contrast agent is used in CT scanning to enhance visualization.

Nursing Interventions

Preparation includes educating the patient about relaxation techniques and explaining that they will be able to communicate with the staff by means of a microphone located inside the scanner. Many MRI suites provide headphones so that patients can listen to the music of their choice during the procedure. Nursing care guidelines for patient preparation and precautions for any imaging procedure that requires a contrast agent (contrast medium) are explained in Chart 43-5.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) are removed. This includes medication patches (e.g., nicotine and nitroglycerin) that have a metal backing, which can cause burns if they are not removed. No metal objects (e.g., oxygen tanks, ventilators, stethoscopes) may be brought into the MRI room. The magnetic field is so strong that any metal-containing items will be pulled toward the magnet, causing severe injury and possible death. A patient history is obtained to determine the presence of any metal objects (e.g., aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants are inactivated by MRI; therefore, other imaging procedures are considered. A sedative agent may be prescribed, because claustrophobia is a problem for some patients.

Chart 43-5

Patient Care During Urologic Testing with Contrast Agents

For some patients, contrast agents are nephrotoxic and allergenic. Emergency equipment and medications should be available in case of an anaphylactic reaction to the contrast agent. Emergency supplies include epinephrine, corticosteroids, vasopressors, oxygen, and airway and suction equipment.

The following guidelines can help the nurse respond quickly in the event of a problem.

Nursing Actions for Patient Preparation

- Obtain the patient's allergy history with emphasis on allergy to iodine, shellfish, and other seafood, because many contrast agents contain iodine.
- Notify primary provider and radiologist if the patient is allergic or suspected to be allergic to iodine.
- Obtain health history. Contrast agents should be used with great caution in older patients and in patients who have multiple myeloma, renal impairment, or volume depletion.
- Obtain medication history. Nephrotoxic medications such as vancomycin, amphotericin B, metformin, and nonsteroidal anti-inflammatory drugs should be discontinued before contrast media administration.
- The use of both nonionic low-osmolar contrast media (LOCM, e.g., iohexol) and ionic high-osmolar contrast media (HOCM, e.g., diatrizoate), is indicated in patients with renal impairment and other risk factors to prevent contrast-induced nephropathy.
- Check kidney function in at-risk patients. Patients should receive IV hydration prior to the procedure.
- Inform the patient that they may experience a temporary feeling of warmth, flushing of the face, and an unusual flavor (similar to that of seafood) in the mouth when the contrast agent is infused.

Nursing Actions During and Post Procedure

- Monitor patient closely for allergic reaction, and monitor urine output.
- Maintain hydration status.

Adapted from Andreucci, M., Solomon, R., & Tasanarong, A. (2014). Side effects of radiographic contrast media: Pathogenesis, risk factors, and prevention. Retrieved on 4/17/2016 at: www.hindawi.com/journals/bmri/2014/741018/; Rank, W. (2013). Preventing contrast media–induced nephrotoxicity. Nursing, 43(4), 48–51.

Prior to MRI of the urinary system, the patient needs to be informed to avoid alcohol, caffeine-containing beverages, and smoking for at least 2 hours and food for at least 1 hour prior to the scan. Patients should continue taking their usual medication, except for iron supplements, which can interfere with the imaging (Fischbach & Dunning, 2015).

Nuclear Scans

Nuclear scans require injection of a radioisotope (a technetium 99m–labeled compound or iodine 123 [^{123}I] hippurate) into the circulatory system; the isotope is then monitored as it moves through the blood vessels of the kidneys. A scintillation camera is placed behind the kidney with the patient in a supine, prone, or seated position. Hypersensitivity to the radioisotope is rare. The technetium scan provides information about kidney perfusion. The ^{123}I-hippurate renal scan provides information about kidney function, such as GFR.

Nuclear scans are used to evaluate acute and chronic kidney injury, renal masses, and blood flow before and after kidney transplantation. The radioisotope is injected at a specified time to achieve the proper concentration in the kidneys. After the

procedure is completed, the patient is encouraged to drink fluids to promote excretion of the radioisotope by the kidneys.

Intravenous Urography

IV urography includes various tests such as excretory urography, intravenous pyelography (IVP), and infusion drip pyelography. A radiopaque contrast agent is given IV. An IVP shows the kidneys, ureter, and bladder via x-ray imaging as the dye moves through the upper and then the lower urinary system. A nephrotomogram may be carried out as part of the study to visualize different layers of the kidney and the diffuse structures within each layer and to differentiate solid masses or lesions from cysts in the kidneys or urinary tract.

IV urography may be used as the initial assessment of many suspected urologic conditions, especially lesions in the kidneys and ureters. It also provides an approximate estimate of renal function. After the contrast agent (sodium diatrizoate or meglumine diatrizoate) is given IV, multiple x-rays are obtained to visualize drainage structures in the upper and lower urinary systems.

Infusion drip pyelography requires IV infusion of a large volume of a dilute contrast agent to opacify the renal parenchyma and fills the urinary tract. This examination method is useful when prolonged opacification of the drainage structures is desired so that tomograms (body-section radiography) can be made. Images are obtained at specified intervals after the start of the infusion. These images show the filled and distended collecting system. The patient preparation is the same as for excretory urography, except fluids are not restricted.

Retrograde Pyelography

In retrograde pyelography, catheters are advanced through the ureters into the renal pelvis by means of cystoscopy. A contrast agent is then injected. Retrograde pyelography is usually performed if IV urography provides inadequate visualization of the collecting systems. It may also be used before extracorporeal shock wave lithotripsy and in patients with urologic cancer who need follow-up and have an allergy to IV contrast agents. Possible complications include infection, hematuria, and perforation of the ureter. Retrograde pyelography is used infrequently because of improved techniques in excretory urography.

Cystography

Cystography aids in evaluating vesicoureteral reflux (backflow of urine from the bladder into one or both ureters) and in assessing for bladder injury. A catheter is inserted into the bladder, and a contrast agent is instilled to outline the bladder wall. The contrast agent may leak through a small bladder perforation stemming from bladder injury, but such leakage is usually harmless. Cystography can also be performed with simultaneous pressure recordings inside the bladder.

Voiding Cystourethrography

Voiding cystourethrography uses fluoroscopy to visualize the lower urinary tract and assess urine storage in the bladder. It is commonly used as a diagnostic tool to identify vesicoureteral reflux. A urethral catheter is inserted, and a contrast agent is instilled into the bladder. When the bladder is full and the patient feels the urge to void, the catheter is removed, and the patient voids.

Renal Angiography

A renal angiogram, or renal arteriogram, provides an image of the renal arteries. The femoral (or axillary) artery is pierced with a needle, and a catheter is threaded up through the femoral and iliac arteries into the aorta or renal artery. A contrast agent is injected to opacify the renal arterial supply. Angiography is used to evaluate renal blood flow in suspected renal trauma, to differentiate renal cysts from tumors, and to evaluate hypertension. It is used preoperatively for renal transplantation.

Nursing Interventions

Before the procedure, a laxative may be prescribed to evacuate the colon so that unobstructed x-rays can be obtained. Injection sites (groin for femoral approach or axilla for axillary approach) may be shaved. The peripheral pulse sites (radial, femoral, and dorsalis pedis) are marked for easy access during postprocedural assessment (Rank, 2013). See Chart 43-5 for considerations for the patient receiving a contrast agent.

After the procedure, vital signs are monitored until stable. If the axillary artery was the injection site, blood pressure measurements are taken on the opposite arm. The injection site is examined for swelling and hematoma. Peripheral pulses are palpated, and the color and temperature of the involved extremity are noted and compared with those of the uninvolved extremity. Cold compresses may be applied to the injection site to decrease edema and pain. Possible complications include hematoma formation, arterial thrombosis or dissection, false aneurysm formation, and altered renal function.

MAG3 Renogram

This scan is used to further evaluate kidney function in some centers by permitting visualization of renal clearance (Fischbach & Dunning, 2015). The patient is given an injection containing a small amount of radioactive material, which will show how the kidneys are functioning. The patient needs to lie still for about 35 minutes while special cameras take images (Fischbach & Dunning, 2015).

Urologic Endoscopic Procedures

Endourology, or urologic endoscopic procedures, can be performed in one of two ways: using a cystoscope inserted into the urethra, or percutaneously, through a small incision.

The cystoscopic examination is used to directly visualize the urethra and bladder. The cystoscope, which is inserted through the urethra into the bladder, has an optical lens system that provides a magnified, illuminated view of the bladder (see Fig. 43-9). The use of high-intensity light and interchangeable lenses allows excellent visualization and permits still and motion pictures to be taken. The cystoscope is manipulated to allow complete visualization of the urethra and bladder as well as the ureteral orifices and prostatic urethra. Small ureteral catheters can be passed through the cystoscope for assessment of the ureters and the pelvis of each kidney.

The cystoscope also allows the urologist to obtain a urine specimen from each kidney to evaluate its function. Cup forceps can be inserted through the cystoscope for biopsy. Calculi may be removed from the urethra, bladder, and ureter using cystoscopy. If a lower tract cystoscopy is performed, the patient is usually conscious, and the procedure is usually no more uncomfortable than a catheterization. To minimize posttest urethral discomfort, viscous lidocaine is given several minutes before the study. If the cystoscopy includes examination of the upper tracts, a sedative agent may be given before the procedure. General anesthesia is usually given to ensure that there are no involuntary muscle spasms when the scope is being passed through the ureters or kidneys.

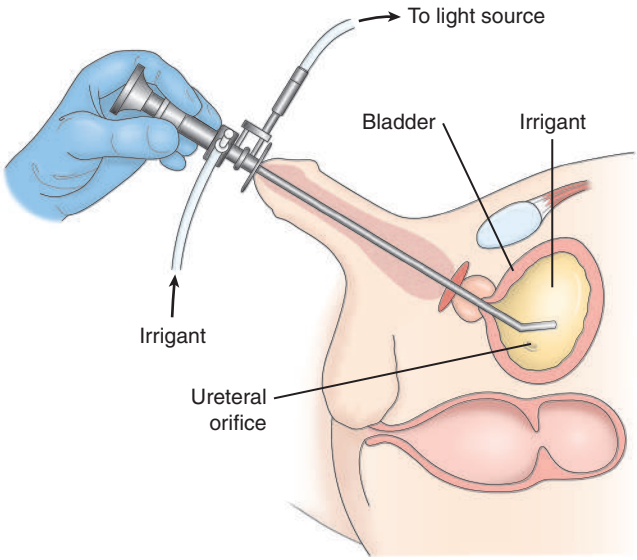

Figure 43-9 • Cystoscopic examination. A rigid or semirigid cystoscope is introduced into the bladder. The upper cord is an electric line for the light at the distal end of the cystoscope. The lower tubing leads from a reservoir of sterile irrigant that is used to inflate the bladder.

Nursing Interventions

The nurse describes the procedure to the patient and family to prepare them and to allay their fears. If an upper cystoscopy is to be performed, the patient is usually restricted to nothing by mouth (NPO) for several hours beforehand.

Postprocedural management is directed at relieving any discomfort resulting from the examination. Some burning on voiding, blood-tinged urine, and urinary frequency from trauma to the mucous membranes can be expected. Moist heat to the lower abdomen and warm sitz baths are helpful in relieving pain and relaxing the muscles.

After a cystoscopic examination, the patient with obstructive pathology may experience urine retention if the instruments used during the examination caused edema. The nurse carefully monitors the patient with prostatic hyperplasia for urine retention. Warm sitz baths and antispasmodic medication, such as flavoxate (Urispas), may be prescribed to relieve temporary urine retention caused by poor relaxation of the urinary sphincter; however, intermittent catheterization may be necessary for a few hours after the examination. The nurse monitors the patient for signs and symptoms of urinary tract infection. Because edema of the urethra secondary to local trauma may obstruct urine flow, the patient is also monitored for signs and symptoms of obstruction.

Biopsy

Renal and Ureteral Brush Biopsy

Brush biopsy techniques provide specific information when abnormal x-ray findings of the ureter or renal pelvis raise questions about whether a defect is a tumor, a stone, a blood clot, or an artifact. First, a cystoscopic examination is conducted. Then, a ureteral catheter is introduced, followed by a biopsy brush that is passed through the catheter. The suspected lesion is brushed back and forth to obtain cells and surface tissue fragments for histologic analysis.

Kidney Biopsy

Biopsy of the kidney is used to help diagnose and evaluate the extent of kidney disease. Indications for biopsy include unexplained acute kidney injury, persistent proteinuria or hematuria, transplant rejection, and glomerulopathies. A small section of renal cortex is obtained either percutaneously (needle biopsy) or by open biopsy through a small flank incision. Before the biopsy is carried out, coagulation studies are conducted to identify any risk of post biopsy bleeding. Contraindications to kidney biopsy include bleeding tendencies, uncontrolled hypertension, sepsis, a solitary kidney, large polycystic kidneys, kidney neoplasm, urinary tract infection, and morbid obesity (Doss-McQuitty, 2015).

The patient may be prescribed a fasting regimen 6 to 8 hours before the test. An IV line is established. A urine specimen is obtained and saved for comparison with the post biopsy specimen.

If a needle biopsy is to be performed, the patient is instructed to breathe in and hold that breath (to prevent the kidney from moving) while the needle is being inserted. The sedated patient is placed in a prone position with a sandbag under the abdomen. The skin at the biopsy site is infiltrated with a local anesthetic agent. The biopsy needle is introduced just inside the renal capsule of the outer quadrant of the kidney. The location of the needle may be confirmed by fluoroscopy or by ultrasound, in which case a special probe is used.

With open biopsy, a small incision is made over the kidney, allowing direct visualization. Preparation for an open biopsy is similar to that for any major abdominal surgery.

Nursing Interventions

After a biopsy procedure, nursing care includes monitoring vital signs for the first 24 hours to detect signs and symptoms of bleeding or infection. The nurse should assess for other signs and symptoms of internal bleeding such as pallor, dizziness, and flank or back pain. IV fluids may be given to help clear the kidneys and prevent clot formation. Urine may contain blood (usually clearing in 24 to 48 hours) from oozing at the site. Bed rest should be maintained and pressure dressings applied for prescribed periods of time to control bleeding. Puncture sites should be examined for signs and symptoms of infection. Analgesic agents should be given as prescribed and needed for pain (Doss-McQuitty, 2015).

CRITICAL THINKING EXERCISES

1. A patient you are caring for complains of urinary incontinence. Describe the assessment techniques appropriate to evaluate the patient. Review the possible causes and describe the actions you would take and the rationale for each action. Describe any differences in your assessments and possible action that are dependent on the gender of the patient.
2. A 30-year-old male is admitted to the emergency department for evaluation of urinary dysfunction and is scheduled for a renal angiography. The patient is now highly anxious. Describe your priorities for educating this patient about a kidney biopsy. What are your priority interventions for decreasing the patient's anxiety?
3. You make a home visit to a 70-year-old female who had a urologic examination with contrast. She complains of flu-like symptoms and reports that she thinks she notices swelling in her lower extremities. She has a history of renal impairment. Identify assessments and possible interventions that you would use to evaluate and manage the patient's symptoms. Identify the evidence for the assessments and nursing interventions you chose and the strength of that evidence.

CHAPTER 44

Management of Patients with Kidney Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the key factors associated with the development of kidney disorders.
2. Differentiate between the causes of chronic kidney disease (CKD) and acute kidney injury (AKI).
3. Explain the pathophysiology, clinical manifestations, medical management, and nursing management for patients with kidney disorders.
4. Understand the nursing management of patients with chronic kidney disease and acute kidney injury.
5. Compare and contrast the renal replacement therapies, including hemodialysis, peritoneal dialysis, continuous renal replacement therapies, and kidney transplantation.
6. Identify the nursing management of the patient on dialysis who is hospitalized.
7. Develop a postoperative plan of nursing care for the patient undergoing kidney surgery and transplantation.

GLOSSARY

arteriovenous graft: type of surgically created vascular access for dialysis by which a piece of biologic, semibiologic, or synthetic graft material connects the patient's artery to a vein
azotemia: abnormal concentration of nitrogenous waste products in the blood
chronic kidney disease: kidney damage or a decrease in the glomerular filtration rate lasting for 3 or more months
continuous ambulatory peritoneal dialysis (CAPD): method of peritoneal dialysis whereby a patient manually performs exchanges or cycles throughout the day
continuous cyclic peritoneal dialysis (CCPD): method of peritoneal dialysis in which a peritoneal dialysis machine (cycler) automatically performs exchanges, usually while the patient sleeps
continuous renal replacement therapy (CRRT): method used to replace normal kidney function in patients who are hemodynamically unstable by circulating the patient's blood through a hemofilter and returning it to the patient
dialysate: the electrolyte solution that circulates through the dialyzer in hemodialysis and through the peritoneal membrane in peritoneal dialysis
dialyzer: artificial kidney; contains a semipermeable membrane through which particles of a certain size can pass
diffusion: movement of solutes (waste products) from an area of higher concentration to an area of lower concentration
effluent: term used to describe the drained fluid from a peritoneal dialysis exchange
end-stage kidney disease (ESKD): final stage of chronic kidney disease that results in retention of uremic waste products and the need for renal replacement therapies
exchange: denotes a complete cycle including fill, dwell, and drain phases of peritoneal dialysis
glomerular filtration rate (GFR): amount of plasma filtered through the glomeruli per unit of time
glomerulonephritis: inflammation of the glomerular capillaries
hemodialysis: procedure during which a patient's blood is circulated through a dialyzer to remove waste products and excess fluid
interstitial nephritis: inflammation within the renal tissue
nephrosclerosis: hardening of the renal arteries
nephrotic syndrome: type of kidney disease with increased glomerular permeability and massive proteinuria
nephrotoxic: any substance, medication, or action that destroys kidney tissue
oliguria: urine output less than 0.5 mL/kg/hr
osmosis: movement of water through a semipermeable membrane from an area of lower solute concentration to an area of higher solute concentration
peritoneal dialysis: procedure that uses the lining of the patient's peritoneal cavity as the semipermeable membrane for exchange of fluid and solutes
peritonitis: inflammation of the peritoneal membrane (lining of the peritoneal cavity)
polyuria: excessive urine production
ultrafiltration: process whereby water is removed from the blood by means of a pressure gradient between the patient's blood and the dialysate
uremia: an excess of urea and other nitrogenous wastes in the blood
urinary casts: proteins secreted by damaged kidney tubules

Introduction

The kidneys and urinary system help regulate the body's internal environment and are essential for the maintenance of life. Nurses working in any clinical setting may encounter patients with various kidney injuries and diseases, and thus need to be knowledgeable about these disorders. This chapter provides an overview of electrolyte imbalances and systemic manifestations that are common in patients with kidney disorders. The main causes are discussed, together with management strategies to prevent damage and preserve renal function. Chronic kidney disease (CKD) and acute kidney injury (AKI) are discussed, as is the care of patients with other renal conditions requiring dialysis, continuous renal replacement therapies (CRRTs), transplantation, and kidney surgery.

FLUID AND ELECTROLYTE IMBALANCES IN KIDNEY DISORDERS

Patients with kidney disorders commonly experience fluid and electrolyte imbalances and require careful assessment and close

monitoring for signs of potential problems. The patient whose fluid intake exceeds the ability of the kidneys to excrete fluid is said to have fluid overload. If fluid intake is inadequate, the patient is said to be volume depleted and may show signs and symptoms of fluid volume deficit. The intake and output (I&O) record, a key monitoring tool, is used to document important fluid parameters, including the amount of fluid taken in (orally or parenterally), the volume of urine excreted, and other fluid losses (diarrhea, vomiting, diaphoresis). Patient weight is also important, and documenting trends in weight is a key assessment strategy essential for determining the daily fluid allowance and indicating signs of fluid volume excess or deficit.

Nursing Alert: The most accurate indicator of fluid loss or gain in patients who are acutely ill is weight. An accurate daily weight must be obtained and recorded. 1-kg weight gain is equal to 1000 mL of retained fluid.

Clinical Manifestations

The signs and symptoms of common fluid and electrolyte disturbances that can occur in patients with kidney disorders and general management strategies are listed in Table 44-1. The nurse continually assesses, monitors, and informs appropriate members of the health care team if the patient exhibits any of these signs. Management strategies for fluid and electrolyte disturbances in kidney disease are discussed in greater depth later in this chapter (see Chapter 7).

Gerontologic Considerations

With aging, the kidney is less able to respond to acute fluid and electrolyte changes. Older adult patients may develop atypical and nonspecific signs and symptoms of altered renal function and fluid and electrolyte imbalances. A fluid balance deficit in older adults can lead to constipation, falls, medication toxicity, urinary tract and respiratory tract infections, delirium, seizures, electrolyte imbalances, hyperthermia, and delayed wound

TABLE 44-1 Common Fluid and Electrolyte Disturbances in Kidney Disorders

Disturbance	Manifestations	General Management Strategies
Fluid volume deficit	Acute weight loss ≥5%, decreased skin turgor, dry mucous membranes, oliguria or anuria, increased hematocrit, BUN level increased out of proportion to creatinine level, hypothermia	Fluid challenge, fluid replacement orally or parenterally
Fluid volume excess	Acute weight gain ≥5%, edema, crackles, shortness of breath, decreased BUN, decreased hematocrit, distended neck veins	Fluid and sodium restriction, diuretic agents, dialysis
Sodium deficit	Nausea, malaise, lethargy, headache, abdominal cramps, apprehension, seizures	Diet, normal saline or hypertonic saline solutions
Sodium excess	Dry, sticky mucous membranes, thirst, rough dry tongue, fever, restlessness, weakness, disorientation	Fluids, diuretic agents, dietary restriction
Potassium deficit	Anorexia, abdominal distention, paralytic ileus, muscle weakness, ECG changes, dysrhythmias	Diet, oral or parenteral potassium replacement therapy
Potassium excess	Diarrhea, colic, nausea, irritability, muscle weakness, ECG changes	Dietary restriction, diuretics, IV glucose, insulin and sodium bicarbonate, cation-exchange resin, calcium gluconate, dialysis
Calcium deficit	Abdominal and muscle cramps, stridor, carpopedal spasm, hyperactive reflexes, tetany, positive Chvostek or Trousseau sign, tingling of fingers and around mouth, ECG changes	Diet, oral or parenteral calcium salt replacement
Calcium excess	Deep bone pain, flank pain, muscle weakness, depressed deep tendon reflexes, constipation, nausea and vomiting, confusion, impaired memory, polyuria, polydipsia, ECG changes	Fluid replacement, etidronate, pamidronate, mithramycin, calcitonin, glucocorticoids, phosphate salts
Bicarbonate deficit	Headache, confusion, drowsiness, increased respiratory rate and depth, nausea and vomiting, warm flushed skin	Bicarbonate replacement, dialysis
Bicarbonate excess	Depressed respirations, muscle hypertonicity, dizziness, tingling of fingers and toes	Fluid replacement if volume depleted; ensure adequate chloride
Protein deficit	Chronic weight loss, emotional depression, pallor, fatigue, soft flabby muscles	Diet, dietary supplements, hyperalimentation, albumin
Magnesium deficit	Dysphagia, muscle cramps, hyperactive reflexes, tetany, positive Chvostek or Trousseau sign, tingling of fingers, dysrhythmias, vertigo	Diet, oral or parenteral magnesium replacement therapy
Magnesium excess	Facial flushing, nausea and vomiting, sensation of warmth, drowsiness, depressed deep tendon reflexes, muscle weakness, respiratory depression, cardiac arrest	Calcium gluconate, mechanical ventilation, dialysis
Phosphorus deficit	Deep bone pain, flank pain, muscle weakness and pain, paresthesia, apprehension, confusion, seizures	Diet, oral or parenteral phosphorus supplementation therapy

BUN, blood urea nitrogen; ECG, electrocardiographic; IV, intravenous.

healing. Recognition of acute changes in fluid and electrolytes is further hampered by their association with pre-existing disorders and the misconception that they are normal changes of aging.

KIDNEY DISORDERS

Chronic Kidney Disease

Chronic kidney disease is an umbrella term that describes kidney damage or a decrease in the glomerular filtration rate (GFR) lasting for 3 or more months. CKD is associated with decreased quality of life, increased health care expenditures, and premature death. Untreated CKD can result in end-stage kidney disease (ESKD), which is the final stage of CKD. ESKD results in retention of uremic waste products and the need for renal replacement therapies, dialysis, or kidney transplantation. Risk factors include cardiovascular disease, diabetes, hypertension, and obesity. Recent research reported that 10% of the U.S. population aged 20 years and older has CKD (Centers for Disease Control and Prevention [CDC], 2014).

Diabetes is the primary cause of CKD. More than 35% of the U.S. population aged 20 years and older with diabetes have CKD (CDC, 2014). Diabetes is the leading cause of kidney disease in patients starting renal replacement therapy. The second leading cause is hypertension, followed by glomerulonephritis and pyelonephritis; polycystic, hereditary, or congenital disorders; and renal cancers (U.S. Renal Data System [USRDS], 2015). More than 20% of the U.S. population aged 20 years and older with hypertension have CKD (CDC, 2014). With the increasing prevalence of diabetes and hypertension among Indians there is a concomitant increase in the prevalence of chronic renal failure and it is approximately estimated to be 6.3% (Varma, 2015). In India, there has been an alarming increase in the death rate attributable to renal failure; it has increased from 1.94% in 2000 to 3.04% in 2015 (Jha & Modi, 2017).

Pathophysiology

In the early stages of CKD, there can be significant damage to the kidneys without signs or symptoms. The damage to the kidneys is thought to be caused by prolonged acute inflammation that is not organ specific and thus has subtle systemic manifestations. Reduction in functional nephrons leads to derangements in kidney functions. The pathophysiology of chronic kidney disease is presented in Figure 44-1.

Clinical Manifestations

- Increased blood urea and serum creatinine level
- Edema starting as puffiness of face in the early morning and later bilateral pedal edema
- Weight gain
- Reduction in urine output
- Hiccoughs, nausea, vomiting, anorexia
- Breathing difficulty due to fluid overload
- Electrolyte abnormalities: Pulmonary crackles, ECG changes pertaining to hyperkalemia
- Renal osteodystrophy—osteoporosis of bones
- Anemia
- Pruritus due to deposition of urea in the skin

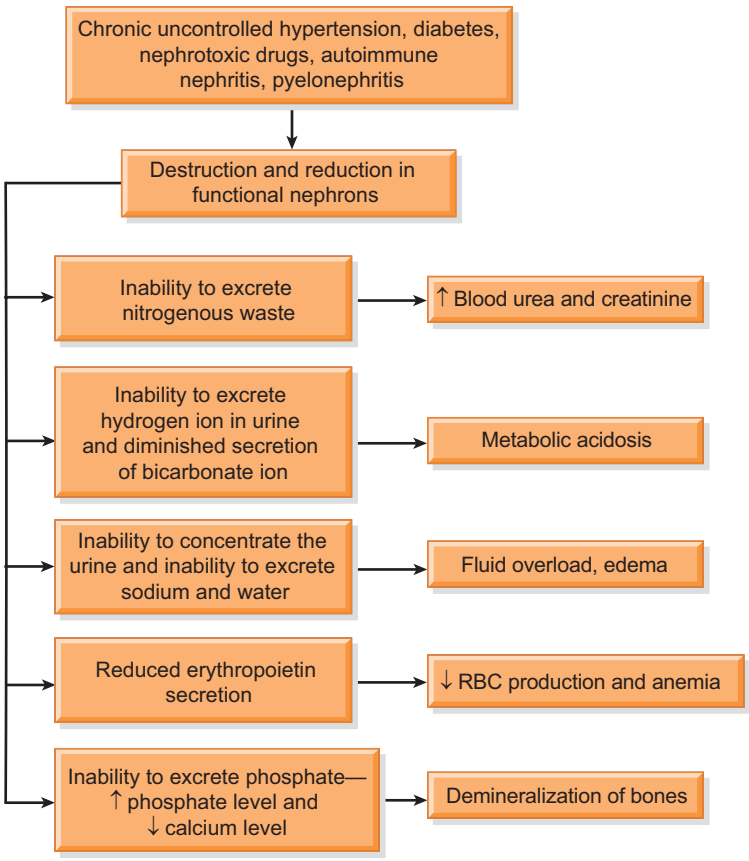

Figure 44-1 • Pathophysiology of chronic kidney disease.

Chart 44-1

Stages of Chronic Kidney Disease

Stages are based on the GFR. The normal GFR is 125 mL/min/1.73 m^2.

Stage 1

GFR ≥90 mL/min/1.73 m^2
Kidney damage with normal or increased GFR

Stage 2

GFR = 60–89 mL/min/1.73 m^2
Mild decrease in GFR

Stage 3

GFR = 30–59 mL/min/1.73 m^2
Moderate decrease in GFR

Stage 4

GFR = 15–29 mL/min/1.73 m^2
Severe decrease in GFR

Stage 5

GFR <15 mL/min/1.73 m^2
End-stage kidney disease or chronic kidney disease

GFR, glomerular filtration rate.

Adapted from Grossman, S. C., & Porth, C. M. (2014). Pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Stages of Chronic Kidney Disease

CKD has been classified into five stages by the National Kidney Foundation (NKF) (see Chart 44-1). Stage 5 results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions; thus, renal replacement therapies are required to sustain life. Screening and early intervention are important, because not all patients progress to stage 5 CKD. Patients with CKD are at increased risk for cardiovascular disease, which is the leading cause of morbidity and mortality (Kane-Gill, Sileanu, Murugan, et al., 2015). Treatment of hypertension, anemia, and hyperglycemia and detection of proteinuria all help to slow disease progression and improve patient outcomes (Lewis, 2013).

Assessment and Diagnostic Findings

The glomerular filtration rate (GFR) is the amount of plasma filtered through the glomeruli per unit of time. Creatinine clearance is a measure of the amount of creatinine the kidneys are able to clear in a 24-hour period. Normal values differ in men and women. Calculation of GFR, an important assessment parameter in CKD, is discussed in Chapter 43.

Medical Management

The management of patients with CKD includes treatment of the underlying causes. Regular clinical and laboratory assessment is important to keep the blood pressure below 130/80 mm Hg (Klein-Kauric, 2015). Medical management also includes early referral for initiation of renal replacement therapies as indicated by the patient's renal status. Prevention of complications is accomplished by controlling cardiovascular risk factors; treating hyperglycemia; managing anemia; smoking cessation, weight loss, and exercise programs as needed; and reduction in salt and alcohol intake.

Gerontologic Considerations

Changes in kidney function with normal aging increase the susceptibility of older patients to kidney dysfunction and kidney disease (Kane-Gill et al., 2015). As age advances, along with reduction of functional nephrons, tubulointerstitial changes and thickening of the basement membrane of the glomerular apparatus occurs (O'Sullivan et al., 2017). In addition, the incidence of systemic diseases, such as atherosclerosis, hypertension, heart failure, diabetes, and cancer, increases with advancing age, predisposing older adults to kidney disease associated with these disorders. Therefore, acute problems need to be prevented if possible or recognized and treated quickly to avoid kidney damage. Thus, nurses in all settings need to be alert to signs and symptoms of kidney dysfunction in older patients.

Older patients frequently take multiple prescription and over-the-counter medications. Because alterations in renal blood flow, glomerular filtration, and renal clearance increase the risk of medication-associated changes in renal function, precautions are indicated with all medications. When older patients undergo extensive diagnostic tests or when new medications (e.g., diuretic agents) are added, precautions must be taken to prevent dehydration, which can compromise marginal renal function and lead to kidney disease (Kane-Gill et al., 2015).

Nephrosclerosis

Nephrosclerosis (hardening of the renal arteries) is most often due to prolonged hypertension and diabetes. Nephrosclerosis is a major cause of CKD and ESKD secondary to many disorders.

Pathophysiology

There are two forms of nephrosclerosis: malignant (accelerated) and benign. Malignant nephrosclerosis is often associated with significant hypertension (diastolic blood pressure higher than 130 mm Hg). It usually occurs in young adults and twice as often in men compared to women (Klein-Kauric, 2015). Damage is caused by decreased blood flow to the kidney resulting in patchy necrosis of the renal parenchyma. Over time, fibrosis occurs and glomeruli are destroyed.

The disease process progresses rapidly. Without dialysis, more than half of patients die of uremia (an excess of urea and other nitrogenous waste products in the blood) in a few years. Benign nephrosclerosis can be found in older adults, associated with atherosclerosis and hypertension.

Assessment and Diagnostic Findings

Symptoms are rare early in the disease, even though the urine usually contains protein and occasional casts. Renal insufficiency and associated signs and symptoms occur late in the disease.

Medical Management

Treatment of nephrosclerosis is aggressive antihypertensive therapy. An angiotensin-converting enzyme (ACE) inhibitor, alone or in combination with other antihypertensive medications, significantly reduces its incidence. See Chapter 25 for additional information on hypertension.

Primary Glomerular Diseases

Diseases that destroy the glomerulus of the kidney are the third most common cause of stage 5 CKD. In these disorders, the glomerular capillaries are primarily involved. Antigen–antibody complexes form in the blood and become trapped in the glomerular capillaries (the filtering portion of the kidney), inducing an inflammatory response. Immunoglobulin G (IgG)—the major immunoglobulin (antibody) found in the blood—can be detected in the glomerular capillary walls. The major clinical manifestations of glomerular injury include proteinuria, hematuria, decreased GFR, decreased excretion of sodium, edema, and hypertension (see Chart 44-2).

Acute Nephritic Syndrome

Acute nephritic syndrome is a type of kidney disease with glomerular inflammation (Grossman & Porth, 2014). Glomerulonephritis is an inflammation of the glomerular capillaries that can occur in acute and chronic forms.

Pathophysiology

Primary glomerular diseases include postinfectious glomerulonephritis, rapidly progressive glomerulonephritis, membrane proliferative glomerulonephritis, and membranous glomerulonephritis. Postinfectious causes are group A beta-hemolytic streptococcal infection of the throat that precedes the onset of glomerulonephritis by 2 to 3 weeks (see Fig. 44-2). It may also follow impetigo (infection of the skin) and acute viral infections (upper respiratory tract infections, mumps, varicella zoster virus, Epstein–Barr virus, hepatitis B, and human immune deficiency virus [HIV] infection). In some patients, antigens outside the body (e.g., medications, foreign serum) initiate the process, resulting in antigen–antibody complexes being deposited in the glomeruli. In other patients, the kidney tissue itself serves as the inciting antigen.

Clinical Manifestations

The primary presenting features of an acute glomerular inflammation are hematuria, edema, azotemia (an abnormal concentration of nitrogenous wastes in the blood), and **proteinuria** (excess protein in the urine) (Grossman & Porth, 2014). The hematuria may be microscopic (identifiable only through microscopic examination) or macroscopic (visible to the eye). The urine may appear cola colored because of red blood cells (RBCs) and protein plugs or casts; RBC casts indicate glomerular injury. Glomerulonephritis may be mild and the hematuria discovered incidentally through a routine urinalysis, or the disease may be severe, with AKI and oliguria.

Some degree of edema and hypertension is present in most patients. Marked proteinuria due to the increased permeability of the glomerular membrane may also occur, with associated pitting edema, hypoalbuminemia, hyperlipidemia, and fatty casts in the urine. Blood urea nitrogen (BUN) and serum creatinine levels may increase as urine output decreases. In addition, anemia may be present.

In the more severe form of the disease, patients also complain of headache, malaise, and flank pain. Older patients may experience circulatory overload with dyspnea, engorged neck veins, cardiomegaly, and pulmonary edema. Atypical symptoms include confusion, somnolence, and seizures, which are often confused with the symptoms of a primary neurologic disorder.

Assessment and Diagnostic Findings

In acute nephritic syndrome, the kidneys become large, edematous, and congested. All renal tissues, including the glomeruli, tubules, and blood vessels, are affected to varying degrees. Patients with an immunoglobulin A (IgA) nephropathy have an elevated serum IgA and low to normal complement levels. Electron microscopy and immunofluorescent analysis help identify the nature of the lesion; however, a kidney biopsy may be needed for definitive diagnosis. See Chapter 43 for discussion of kidney biopsy.

If the patient improves, the amount of urine increases and the urinary protein and sediment diminish. The percentage of adults who recover is unknown. Some patients develop severe

Chart 44-2

Terms Typically Used When Describing Glomerular Disease

Primary: Disease is mainly in glomeruli
Secondary: Glomerular diseases that are the consequence of systemic disease
Idiopathic: Cause is unknown
Acute: Occurs over days or weeks
Chronic: Occurs over months or years
Rapidly progressing: Constant loss of renal function with minimal chance of recovery
Diffuse: Involves all glomeruli
Focal: Involves some glomeruli
Segmental: Involves portions of individual glomeruli
Membranous: Evidence of thickened glomerular capillary walls
Proliferative: Number of glomerular cells involved is increasing

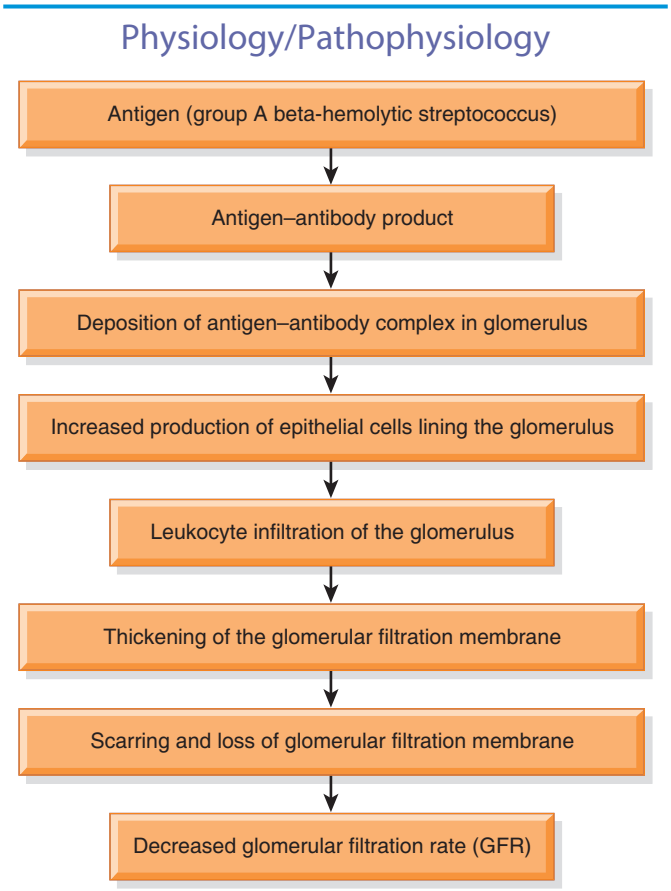

Figure 44-2 • Sequence of events in acute nephritic syndrome.

uremia (an excess of urea and other nitrogenous wastes in the blood) within weeks and require dialysis for survival. Others, after a period of apparent recovery, insidiously develop chronic glomerulonephritis.

Complications

Complications of acute glomerulonephritis include hypertensive encephalopathy, heart failure, and pulmonary edema. Hypertensive encephalopathy is a medical emergency, and therapy is directed toward reducing the blood pressure without impairing renal function. This can occur in acute nephritic syndrome or preeclampsia with chronic hypertension of greater than 140/90 mm Hg. Rapidly progressive glomerulonephritis is characterized by a rapid decline in renal function. Without treatment, ESKD develops in a matter of weeks or months. Signs and symptoms are similar to those of acute glomerulonephritis (hematuria and proteinuria), but the course of the disease is more severe and rapid. Crescent-shaped cells accumulate in Bowman space, disrupting the filtering surface. Plasma exchange (plasmapheresis) and treatment with high-dose corticosteroids and cytotoxic agents have been used to reduce the inflammatory response. Dialysis is initiated in acute glomerulonephritis if signs and symptoms of uremia are severe. The prognosis for patients with acute nephritic syndrome is excellent and rarely causes CKD (Grossman & Porth 2014).

Medical Management

Management consists primarily of treating symptoms, attempting to preserve kidney function, and treating complications promptly. Treatment may include prescribing corticosteroids, managing hypertension, and controlling proteinuria. Pharmacologic therapy depends on the cause of acute glomerulonephritis. If residual streptococcal infection is suspected, penicillin is the agent of choice; however, other antibiotic agents may be prescribed. Dietary protein is restricted when renal insufficiency and nitrogen retention (elevated BUN) develop. Sodium is restricted when the patient has hypertension, edema, and heart failure.

Nursing Management

Although most patients with acute uncomplicated glomerulonephritis are cared for as outpatients, nursing care is important in every setting.

Providing Care in the Hospital

In a hospital setting, carbohydrates are given liberally to provide energy and reduce the catabolism of protein. I&O is carefully measured and recorded. Fluids are given based on the patient's fluid losses and daily body weight. Insensible fluid loss through the lungs (300 mL) and skin (500 mL) is considered when estimating fluid loss (see Chapter 7; Table 7-2). If treatment is effective, diuresis will begin, resulting in decreased edema and blood pressure. Proteinuria and microscopic hematuria may persist for many months; in fact, 20% of patients have some degree of persistent proteinuria or decreased GFR 1 year after presentation (Grossman & Porth, 2014). Other nursing interventions focus on patient education about the disease process, explanations of laboratory and other diagnostic tests, and preparation for safe and effective self-care at home.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education is directed toward managing symptoms and monitoring for complications. Fluid and diet restrictions must be reviewed with the patient to avoid worsening of edema and hypertension. The patient is instructed verbally and in writing to notify the primary provider if symptoms of kidney disease occur (e.g., fatigue, nausea, vomiting, diminishing urine output) or at the first sign of any infection.

Continuing and Transitional Care

The importance of follow-up evaluations of blood pressure, urinalysis for protein, and BUN and serum creatinine levels to determine if the disease has progressed is stressed to the patient. A referral for transitional, home, or community-based care may be indicated. A home visit from a nurse provides an opportunity for careful assessment of the patient's progress and detection of early signs and symptoms of renal insufficiency. If corticosteroids, immunosuppressant agents, or antibiotic medications are prescribed, the nurse uses the opportunity to review the dosage, desired actions, and adverse effects of medications and the precautions to be taken.

Chronic Glomerulonephritis

Chronic glomerulonephritis may be due to repeated episodes of acute nephritic syndrome, hypertensive nephrosclerosis, hyperlipidemia, chronic tubulointerstitial injury, or hemodynamically mediated glomerular sclerosis. Secondary glomerular diseases that can have systemic effects include systemic lupus erythematosus, Goodpasture syndrome (caused by antibodies to the glomerular basement membrane), diabetic glomerulosclerosis, and amyloidosis.

Pathophysiology

The kidneys are reduced to as little as one fifth their normal size (consisting largely of fibrous tissue). The cortex layer shrinks to 1 to 2 mm in thickness or less. Bands of scar tissue distort the remaining cortex, making the surface of the kidney rough and irregular. Numerous glomeruli and their tubules become scarred, and the branches of the renal artery are thickened. The resulting severe glomerular damage can progress to stage 5 CKD and require a renal replacement therapy.

Clinical Manifestations

The symptoms of chronic glomerulonephritis vary. Some patients with severe disease have no symptoms at all for many years. The condition may be discovered when hypertension or elevated BUN and serum creatinine levels are detected. Most patients report general symptoms, such as loss of weight and strength, increasing irritability, and an increased need to urinate at night (nocturia). Headaches, dizziness, and digestive disturbances are also common.

As chronic glomerulonephritis progresses, signs and symptoms of CKD may develop. The patient appears poorly nourished, with a yellow-gray pigmentation of the skin and periorbital and peripheral (dependent) edema. Blood pressure may be normal or severely elevated. Retinal findings include hemorrhage, exudate, narrowed tortuous arterioles, and papilledema. Anemia causes pale mucous membranes. Cardiomegaly, a gallop rhythm, distended neck veins, and other signs and symptoms of heart failure may be present. Crackles can be heard in the bases of the lungs.

Peripheral neuropathy with diminished deep tendon reflexes and neurosensory changes occur late in the disease. The patient becomes confused and demonstrates a limited attention span. An additional late finding includes evidence of pericarditis with a pericardial friction rub and pulsus paradoxus (difference in

blood pressure during inspiration and expiration of greater than 10 mmHg).

Assessment and Diagnostic Findings

A number of laboratory abnormalities occur. Urinalysis reveals a fixed specific gravity of about 1.010, variable proteinuria, and urinary casts (proteins secreted by damaged kidney tubules). As kidney disease progresses and the GFR falls below 50 mL/min, the following changes occur:

- Hyperkalemia due to decreased potassium excretion, acidosis, catabolism, and excessive potassium intake from food and medications
- Metabolic acidosis from decreased acid secretion by the kidney and inability to regenerate bicarbonate
- Anemia secondary to decreased erythropoiesis (production of RBCs)
- Hypoalbuminemia with edema secondary to protein loss through the damaged glomerular membrane
- Increased serum phosphorus level due to decreased renal excretion of phosphorus
- Decreased serum calcium level (calcium binds to phosphorus to compensate for elevated serum phosphorus levels)
- Mental status changes
- Impaired nerve conduction due to electrolyte abnormalities and uremia

Chest x-rays may show cardiac enlargement and pulmonary edema. The electrocardiogram (ECG) may be normal or may indicate left ventricular hypertrophy associated with hypertension and signs of electrolyte disturbances, such as tall, tented (or peaked) T waves associated with hyperkalemia. Computed tomography (CT) and magnetic resonance imaging (MRI) scans show a decrease in the size of the renal cortex.

Medical Management

Management of symptoms guides the treatment. If the patient has hypertension, efforts are made to reduce the blood pressure with sodium and water restriction, antihypertensive agents, or both. Weight is monitored daily, and diuretic medications are prescribed to treat fluid overload. Proteins of high biologic value (dairy products, eggs, meats) are provided to promote good nutritional status. Adequate calories are provided to spare protein for tissue growth and repair. Urinary tract infections (UTIs) must be treated promptly to prevent further kidney damage.

Dialysis is initiated early in the course of the disease to keep the patient in optimal physical condition, prevent fluid and electrolyte imbalances, and minimize the risk of complications of kidney disease. The course of dialysis is smoother if treatment begins before the patient develops complications.

Nursing Management

Whether the patient is hospitalized or cared for in the home, the nurse observes the patient for common fluid and electrolyte disturbances in kidney disease (see Table 44-1). Changes in fluid and electrolyte status and in cardiac and neurologic status are reported promptly to the primary provider. Throughout the course of the disease and treatment, the nurse gives emotional support by providing opportunities for the patient and family to verbalize their concerns, have their questions answered, and explore their options (Ahmad & Al Nazly, 2015).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse has a major role in educating the patient and family about the prescribed treatment plan and the risks associated with noncompliance. Instructions to the patient include explanations and scheduling for follow-up evaluations: blood pressure, urinalysis for protein and casts, and laboratory studies of BUN and serum creatinine levels. If long-term dialysis is needed, the nurse educates the patient and family about the procedure, how to care for the access site, dietary restrictions, and other necessary lifestyle modifications.

Nurse educates about the changes to report to the primary provider such as worsening signs and symptoms of kidney disease, nausea, vomiting, and diminished urine output. Specific education may include explanations about recommended diet and fluid modifications and medications (purpose, desired effects, adverse effects, dosage, and administration schedule).

Continuing and Transitional Care

Periodic laboratory evaluations of creatinine clearance and BUN and serum creatinine levels are carried out to assess residual renal function and the need for dialysis or transplantation. If dialysis is initiated, the patient and family require considerable assistance and support in dealing with therapy and its long-term implications. The patient and family are reminded of the importance of participation in health promotion activities, including health screening. The patient is instructed to inform all health care providers about the diagnosis of glomerulonephritis so that all medical management, including pharmacologic therapy, is based on altered renal function.

Nephrotic Syndrome

Nephrotic syndrome is a type of kidney disease characterized by increased glomerular permeability and is manifested by massive proteinuria (Grossman & Porth, 2014). Clinical findings include a marked increase in protein (particularly albumin) in the urine (proteinuria), a decrease in albumin in the blood (hypoalbuminemia), diffuse edema, high serum cholesterol, and low-density lipoproteins (hyperlipidemia).

The syndrome is apparent in any condition that seriously damages the glomerular capillary membrane and results in increased glomerular permeability to plasma proteins. Although the liver is capable of increasing the production of albumin, it cannot keep up with the daily loss of albumin through the kidneys. Thus, hypoalbuminemia results (see Fig. 44-3).

Pathophysiology

Nephrotic syndrome occurs with many intrinsic kidney diseases and systemic diseases that cause glomerular damage. It is not a specific glomerular disease but a constellation of clinical findings that result from the glomerular damage.

Clinical Manifestations

The major manifestation of nephrotic syndrome is edema. It is usually soft and pitting and commonly occurs around the eyes (periorbital), in dependent areas (sacrum, ankles, and hands), and in the abdomen (ascites). Patients may also exhibit irritability, headache, and malaise.

Assessment and Diagnostic Findings

Proteinuria (predominately albumin) exceeding 3.5 g/day is the hallmark of the diagnosis of nephrotic syndrome. Protein electrophoresis and immunoelectrophoresis may be performed on the urine to categorize the type of proteinuria. The urine may also contain increased white blood cells (WBCs) as well as granular and epithelial casts. A needle biopsy of the kidney

Physiology/Pathophysiology

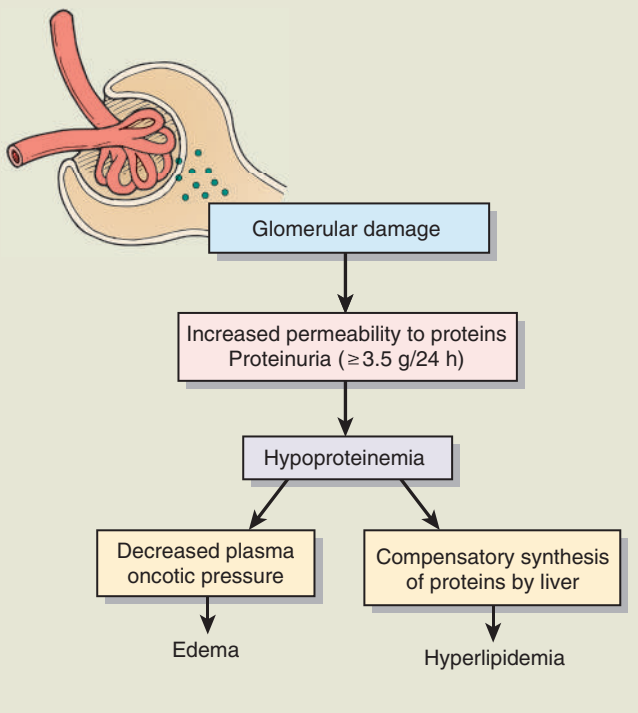

Figure 44-3 • Sequence of events in nephrotic syndrome. Reprinted with permission from Grossman, S. C., & Porth, C. M. (2014). Pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

may be performed for histologic examination of renal tissue to confirm the diagnosis.

Complications

Complications of nephrotic syndrome include infection (due to a deficient immune response), thromboembolism (especially of the renal vein), pulmonary embolism, AKI (due to hypovolemia), and accelerated atherosclerosis (due to hyperlipidemia).

Medical Management

Treatment is focused on addressing the underlying disease state causing proteinuria, slowing progression of CKD, and relieving symptoms. Typical treatment includes diuretic agents for edema, ACE inhibitors to reduce proteinuria, and lipid-lowering agents for hyperlipidemia.

Nursing Management

In the early stages of nephrotic syndrome, nursing management is similar to that of the patient with acute glomerulonephritis, but as the condition worsens, management is similar to that of the patient with ESKD.

Patients with nephrotic syndrome need adequate instruction about the importance of following all medication and dietary regimens so that their condition can remain stable as long as possible. Patients must be made aware of the importance of communicating any health-related change to their primary providers as soon as possible so that appropriate medication and dietary changes can be made before further changes occur within the glomeruli.

Polycystic Kidney Disease

Pathophysiology

Polycystic kidney disease (PKD) is a genetic disorder characterized by the growth of numerous fluid-filled cysts in the kidneys, which destroy the nephrons. PKD cysts can profoundly enlarge the kidneys while replacing much of the normal structure, resulting in reduced kidney function and leading to kidney failure.

PKD can also cause cysts in the liver and problems in other areas, such as blood vessels in the brain and heart. The number of cysts and the resulting complications help distinguish PKD from the usually harmless cysts that can form in the kidneys in later years of life. In India, PKD is the attributable cause of kidney failure in 2.5% of the kidney failure patients. The common type of PKD in India is the autosomal dominant one (Jha, 2013). Two major inherited forms of PKD exist:

- Autosomal dominant PKD is the most common inherited form. Symptoms usually develop between 30 and 40 years of age, but they can begin earlier, even in childhood. About 90% of all PKD cases are autosomal dominant PKD.
- Autosomal recessive PKD is a rare inherited form. Symptoms of autosomal recessive PKD begin in the earliest months of life or in utero.

When autosomal dominant PKD causes kidneys to fail, which usually happens after many years, the patient requires dialysis or kidney transplantation. Approximately one half of individuals with autosomal dominant PKD progress to stage 5 CKD, requiring renal replacement therapy.

Clinical Manifestations

Signs and symptoms of PKD result from loss of renal function and the increasing size of the kidneys as the cysts grow. Kidney damage can result in hematuria, polyuria (excessive urine production), hypertension, development of renal calculi and associated UTIs, and proteinuria. The growing cysts are noted with reports of abdominal fullness and flank pain (back and lower sides).

Assessment and Diagnostic Findings

PKD is a genetic disease; therefore, careful evaluation of family history is necessary. Palpation of the abdomen will often reveal enlarged cystic kidneys. Ultrasound imaging of the kidneys is the preferred technique for diagnosis (Grossman & Porth, 2014).

Medical Management

PKD has no cure, and treatment is largely supportive and includes blood pressure control, pain control, and antibiotic agents to resolve infections. Once the kidneys fail, renal replacement therapy is indicated (see later discussion in chapter). Genetic linkage studies and counseling may be indicated, particularly when screening family members for potential kidney donation (Grossman & Porth, 2014).

RENAL CANCER

Renal cancer accounts for about 3% of all cancers in the Indian adult populations and it is considered as one of the cancers which is related with advanced age. In contrast to the male female

Chart 44-3 RISK FACTORS

Renal Cancer

Gender—affects men more than women
Obesity
Occupational exposure to industrial chemicals, such as petroleum products, heavy metals, and asbestos
Polycystic kidney disease
Tobacco use
Unopposed estrogen therapy

Adapted from American Cancer Society (2015). Kidney cancer. Retrieved on 1/10/2015 at: www.cancer.org/cancer/kidneycancer/detailedguide/kidney-cancer-adult-key-statistics

ratio of 2:1 among Americans and rest of the developing world, it is 4:1 in Indian population (Yuvaraja et al., 2016). Tobacco use continues to be a significant risk factor (see Chart 44-3). Those presented with renal cancer at younger age (<39 years) tend to have higher mortality.

The most common type of renal carcinoma arises from the renal epithelium and accounts for more than 85% of all kidney tumors (ACS, 2015). These tumors may metastasize early to the lungs, bone, liver, brain, and contralateral kidney. One quarter of patients have metastatic disease at the time of diagnosis. Although enhanced imaging techniques account for improved detection of early-stage kidney cancer, it is unknown why the rate of late-stage kidney cancers is high.

Clinical Manifestations

Many renal tumors produce no symptoms and are discovered on a routine physical examination as a palpable abdominal mass. Signs and symptoms, which occur in only 10% of patients, include hematuria, pain, and a mass in the flank. The usual sign that first calls attention to the tumor is painless hematuria, which may be either intermittent and microscopic or continuous and gross. There may be a dull pain in the back from the pressure produced by compression of the ureter, extension of the tumor into the perirenal area, or hemorrhage into the kidney tissue. Colicky pains occur if a clot or mass of tumor cells passes down the ureter. Symptoms from metastasis may be the first manifestations of renal tumor and may include unexplained weight loss, increasing weakness, and anemia.

Assessment and Diagnostic Findings

The diagnosis of a renal tumor may require intravenous (IV) urography, cystoscopic examination, renal angiograms, ultrasonography, or a CT scan (see Chapter 43). These tests may be exhausting for patients already debilitated by the systemic effects of a tumor as well as for older patients and those who are anxious about the diagnosis and outcome. The nurse assists the patient to prepare physically and psychologically for these procedures and monitors carefully for signs and symptoms of dehydration and exhaustion.

Medical Management

The goal of medical management is to detect the tumor early and to eradicate slow-growing tumors before metastasis occurs. Treatment most often includes a combination of surgery and pharmacologic management. Radiation therapy may be used for palliation in patients who are not candidates for surgery or other treatments.

Surgical Management

Nephrectomy

A radical nephrectomy is the preferred treatment if the tumor can be removed. This includes removal of the kidney (and tumor), adrenal gland, surrounding perinephric fat and Gerota fascia, and lymph nodes. Laparoscopic nephrectomy can be performed for removal of the kidney with a small tumor. This procedure incurs less morbidity and a shorter recovery time. Radiation therapy, hormonal therapy, or chemotherapy may be used along with surgery. Immunotherapy may also be helpful. For patients with bilateral tumors or cancer of a functional single kidney, nephron-sparing surgery (partial nephrectomy) may be considered. Favorable results have been achieved in patients with small local tumors and a normal contralateral kidney.

Nephron-sparing surgery is increasingly being used to treat patients with solid renal lesions. The technical success rate of nephron-sparing surgery is excellent, and operative morbidity and mortality are low.

Patients with upper tract transitional cell carcinoma may benefit from laparoscopic nephroureterectomy. Although it is a lengthier surgical procedure, it has the same efficacy and is better tolerated by patients than open nephroureterectomy.

Renal Artery Embolization

In patients with metastatic renal carcinoma, the renal artery may be occluded to impede the blood supply to the tumor and thus kill the tumor cells. After angiographic studies are completed, a catheter is advanced into the renal artery, and embolizing materials (e.g., Gelfoam, autologous blood clot, steel coils) are injected into the artery and carried with the arterial blood flow to occlude the tumor vessels mechanically. This decreases the local blood supply, making removal of the kidney (nephrectomy) easier. It also stimulates an immune response because infarction of the renal cell carcinoma releases tumor-associated antigens that enhance the patient's response to metastatic lesions. The procedure may also reduce the number of tumor cells entering the venous circulation during surgical manipulation.

After renal artery embolization and tumor infarction, a characteristic symptom complex called postinfarction syndrome occurs, lasting 2 to 3 days. The patient has pain localized to the flank and abdomen, elevated temperature, and gastrointestinal (GI) symptoms. Pain is treated with parenteral analgesic agents, and acetaminophen/paracetamol (Tylenol) is given to control fever. Antiemetic medications, restriction of oral intake, and IV fluids are used to treat the GI symptoms.

Pharmacologic Therapy

Depending on the stage of the tumor, percutaneous partial or radical nephrectomy may be followed by treatment with chemotherapeutic agents. Treatment with biologic response modifiers such as interleukin 2 (IL-2) is effective. IL-2, a protein that regulates cell growth, is used alone or in combination with lymphokine-activated killer cells (WBCs that have been stimulated by IL-2 to increase their ability to kill cancer cells). Interferon, another biologic response modifier, appears to have a direct antiproliferative effect on renal tumors.

Another promising experimental approach to renal cell carcinoma is a vaccination to stimulate immune response, with autologous tumor cells with IL-2–, granulocyte-macrophage

stimulating factor–, and dendritic cell–type vaccines. If patients with renal cancer do not respond to immunotherapy, allogeneic stem cell transplantation may be indicated (see Chapter 58).

Nursing Management

The patient with a renal tumor usually undergoes extensive diagnostic and therapeutic procedures. Treatment includes surgery, radiation therapy, and medications. After surgery, the patient usually has catheters and drains in place to maintain a patent urinary tract, to remove drainage, and to permit accurate measurement of urine output. Because of the location of the surgical incision, the patient's position during surgery, and the nature of the surgical procedure, pain and muscle soreness are common. Pharmacologic management often includes immunosuppressant agents; therefore, patients are monitored for infection.

The patient requires frequent analgesia during the postoperative period and assistance with turning, coughing, the use of incentive spirometry, and deep breathing to prevent atelectasis and other pulmonary complications. The patient and family require assistance and support to cope with the diagnosis and uncertain prognosis. See discussion later in this chapter of postoperative care of the patient undergoing kidney surgery and Chapter 58 for discussion of care of the patient with cancer.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse educates the patient about how to inspect and care for the incision and to perform other general postoperative care including activity and lifting restrictions, driving, and pain management. Instructions are provided about when to notify the primary provider about problems (e.g., fever, respiratory difficulty, wound drainage, blood in the urine, pain or swelling of the legs).

The nurse encourages the patient to eat a healthy diet and to drink adequate liquids to avoid constipation and to maintain an adequate urine volume. Education and emotional support are provided related to the diagnosis, treatment, and continuing care because many patients are concerned about the loss of the other kidney, the possible need for dialysis, or the recurrence of cancer.

Continuing and Transitional Care

Follow-up care is essential to detect signs of metastases and to reassure the patient and family about the patient's status and well-being. The patient who has had surgery for renal carcinoma should have a yearly physical examination and chest x-ray, because late metastases are not uncommon. All subsequent symptoms should be evaluated with possible metastases in mind.

If follow-up chemotherapy is necessary, the patient and family are informed about the treatment plan or chemotherapy protocol, what to expect with each visit, and when to notify the primary provider. Evaluation of remaining renal function (creatinine clearance, BUN, and serum creatinine levels) may also be carried out periodically. A home care nurse may monitor the patient's physical status and psychological well-being and coordinate other indicated services and resources.

KIDNEY DISEASE

Kidney disease results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions. The substances normally eliminated in the urine accumulate in the body fluids as a result of impaired renal excretion, affecting endocrine and metabolic functions as well as fluid, electrolyte, and acid–base disturbances. Kidney disease is a systemic disease and a final common pathway of many different kidney and urinary tract diseases. Each year, the number of deaths from irreversible kidney disease increases (USRDS, 2015).

Acute Kidney Injury

Acute kidney injury (AKI) is a rapid loss of renal function due to damage to the kidneys. Incidence of acute kidney injury is 31.2% for Southeast Asian countries (Yang Li, 2016).

Common contributing causes of acute renal injury in India are diarrheal illness, malaria, snake bite. Contrarily, in Western countries, the main causative factors of acute renal injury are hemolytic uremic syndrome, major complicated surgeries, etc. (Inbanathan & Lavanya, 2016).

Depending on the duration and severity of AKI, a wide range of potentially life-threatening metabolic complications can occur, including metabolic acidosis as well as fluid and electrolyte imbalances (Vritis, 2013). Treatment is aimed at replacing renal function temporarily to minimize potentially lethal complications and reduce potential causes of increased kidney injury with the goal of minimizing long-term loss of renal function. AKI is a problem seen in patients who are hospitalized and those in outpatient settings. A widely accepted criterion for AKI is a 50% or greater increase in serum creatinine above baseline (normal creatinine is less than 1 mg/dL) (Vritis, 2013). Urine volume may be normal, or changes may occur. Possible changes include nonoliguria (greater than 800 mL/day), oliguria (less than 0.5 mL/kg/hr), or anuria (less than 50 mL/day) (Vritis, 2013).

Pathophysiology

In the pathogenesis of AKI and oliguria, many times there is a specific underlying cause. Pathophysiology of acute kidney injury is presented in Figure 44-4. Some of the factors may be reversible if identified and treated promptly, before kidney function is impaired. This is true of the following conditions that reduce blood flow to the kidney and impair kidney function: (1) hypovolemia; (2) hypotension; (3) reduced cardiac output and heart failure; (4) obstruction of the kidney or lower urinary tract by tumor, blood clot, or kidney stone; and (5) bilateral obstruction of the renal arteries or veins. If these conditions are treated and corrected before the kidneys are permanently damaged, the increased BUN and creatinine levels, oliguria, and other signs may be reversed.

Although renal stones are not a common cause of AKI, some types may increase the risk of AKI. Some hereditary stone diseases (see Chapter 45), primary struvite stones, and infection-related urolithiasis associated with anatomic and functional urinary tract anomalies and spinal cord injury may cause recurrent bouts of obstruction as well as crystal-specific damage to tubular epithelial cells and interstitial renal cells.

Classifications

The term acute kidney injury has replaced the term acute renal failure because it better describes this syndrome in patients, not only simply those who require renal replacement therapies but also those patients who experience minor changes in renal function. Classification criteria for AKI include assessment of

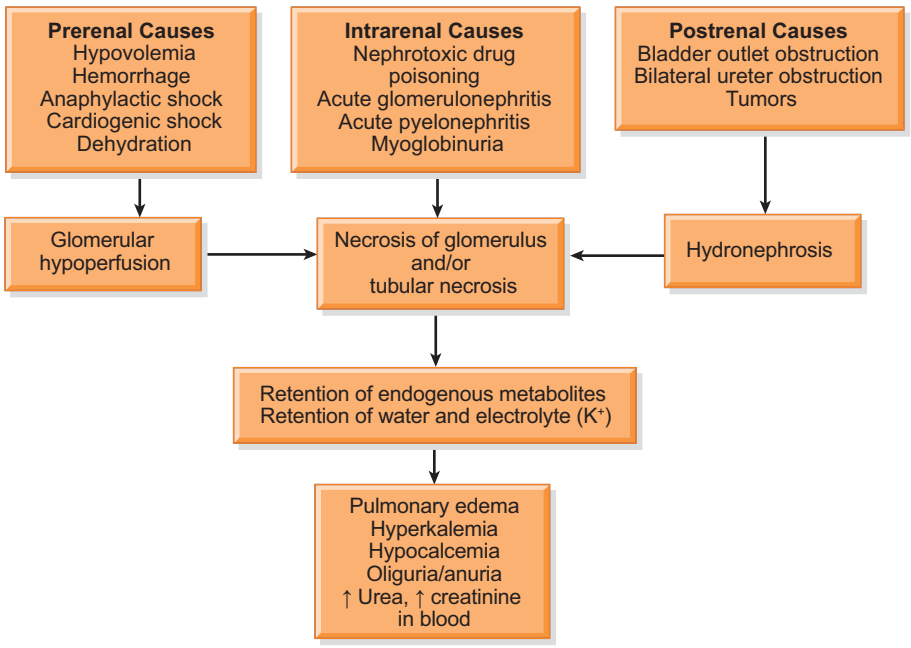

Figure 44-4 • Pathophysiology of acute kidney injury.

three grades of severity and two outcome-level classifications. This 5-point system is known as the RIFLE classification system (Davies & Leslie, 2012). RIFLE stands for risk, injury, failure, loss, and ESKD (Vrtis, 2013). Risk, injury, and failure are considered grades of AKI severity, whereas loss and ESKD are considered outcomes of loss that require some form of renal replacement therapy, at least temporarily (Dring & Hipkiss, 2015). Table 44-2 lists the classification criteria for the RIFLE system for AKI (Vritis, 2013). This classification system is used by health care professionals to identify kidney injury and improve patient outcomes.

TABLE 44-2 The RIFLE Classification for Acute Kidney Injury

Class	GFR Criteria	Urinary Output Criteria
R (Risk)	Increased serum creatinine 1.5 × baseline OR GFR decreased ≥25%	0.5 mL/kg/hr for 6 hours
I (Injury)	Increased serum creatinine 2 × baseline OR GFR decreased ≥50%	0.5 mL/kg/hr for 12 hours
F (Failure)	Increased serum creatinine 3 × baseline OR GFR decreased ≥75% OR Serum creatinine ≥354 mmol/L with an acute rise of at least 44 mmol/L	<0.3 mL/kg/hr for 24 hours OR Anuria for 12 hours
L (Loss)	Persistent acute kidney injury = complete loss of kidney function >4 weeks	
E (ESKD)	ESKD >3 months	

ESKD, end-stage kidney disease; GFR, glomerular filtration rate.
Adapted from Davies, H., & Leslie, G. (2012). Acute kidney injury and the critically ill patient. Dimensions of Critical Care Nursing, 31(3), 135–152.

Categories

The major categories of AKI are prerenal (hypoperfusion of kidney), intrarenal (actual damage to kidney tissue), and postrenal (obstruction to urine flow). Prerenal AKI, which occurs in 60% to 70% of cases, is the result of impaired blood flow that leads to hypoperfusion of the kidney commonly caused by volume depletion (burns, hemorrhage, GI losses), hypotension (sepsis, shock), and renal artery stenosis, ultimately leading to a decrease in the GFR (Vritis, 2013). Intrarenal AKI is the result of actual parenchymal damage to the glomeruli or kidney tubules. Acute tubular necrosis (ATN), or AKI in which there is damage to the kidney tubules, is the most common type of intrinsic AKI. Characteristics of ATN are intratubular obstruction, tubular back leak (abnormal reabsorption of filtrate and decreased urine flow through the tubule), vasoconstriction, and changes in glomerular permeability. These processes result in a decrease of GFR, progressive azotemia, and fluid and electrolyte imbalances. CKD, diabetes, heart failure, hypertension, and cirrhosis can lead to ATN. Postrenal AKI usually results from obstruction distal to the kidney by conditions such as renal calculi, strictures, blood clots, benign prostatic hypertrophy, malignancies, and pregnancy. Pressure rises in the kidney tubules, and eventually the GFR decreases. Common causes of each type of AKI are further summarized in Chart 44-4.

Phases

There are four phases of AKI: initiation, oliguria, diuresis, and recovery.

- The initiation period begins with the initial insult and ends when oliguria develops.
- The oliguria period is accompanied by an increase in the serum concentration of substances usually excreted by the kidneys (urea, creatinine, uric acid, organic acids, and the intracellular cations [potassium and magnesium]). The minimum amount of urine needed to rid the body of normal metabolic waste products is 400 mL in 24 hours or 0.5 mL/kg/hr. In this phase, uremic symptoms first appear and life-threatening conditions such as hyperkalemia develop.

Chart 44-4

Causes of Acute Kidney Injury

Prerenal Failure

- Volume depletion resulting from:
  - Gastrointestinal losses (vomiting, diarrhea, nasogastric suction)
  - Hemorrhage
  - Renal losses (diuretic agents, osmotic diuresis)
- Impaired cardiac efficiency resulting from:
  - Cardiogenic shock
  - Dysrhythmias
  - Heart failure
  - Myocardial infarction
- Vasodilation resulting from:
  - Anaphylaxis
  - Antihypertensive medications or other medications that cause vasodilation
  - Sepsis

Intrarenal Failure

- Prolonged renal ischemia resulting from:
  - Hemoglobinuria (transfusion reaction, hemolytic anemia)
  - Rhabdomyolysis/myoglobinuria (trauma, crush injuries, burns)
  - Pigment nephropathy (associated with the breakdown of blood cells containing pigments that in turn occlude kidney structures)
- Nephrotoxic agents such as:
  - Aminoglycoside antibiotics (gentamicin, tobramycin)
  - Angiotensin-converting enzyme inhibitors
  - Heavy metals (lead, mercury)
  - Nonsteroidal anti-inflammatory drugs
  - Radiopaque contrast agents
  - Solvents and chemicals (ethylene glycol, carbon tetrachloride, arsenic)
- Infectious processes such as:
  - Acute glomerulonephritis
  - Acute pyelonephritis

Postrenal Failure

- Urinary tract obstruction, including:
  - Benign prostatic hyperplasia
  - Blood clots
  - Calculi (stones)
  - Strictures
  - Tumors

- The diuresis period is marked by a gradual increase in urine output, which signals that glomerular filtration has started to recover. Laboratory values stabilize and eventually decrease. Although the volume of urinary output may reach normal or elevated levels, renal function may still be markedly abnormal. Because uremic symptoms may still be present, the need for expert medical and nursing management continues. The patient must be observed closely for dehydration during this phase; if dehydration occurs, the uremic symptoms are likely to increase.
- The recovery period signals the improvement of renal function and may take 3 to 12 months. Laboratory values return to the patient's normal level. Although a permanent 1% to 3% reduction in the GFR may occur, it is not clinically significant.

Some patients have decreased renal function with increasing nitrogen retention but actually excrete normal amounts of urine (1 to 2 L/day). This is the nonoliguric form of kidney injury and occurs predominantly after exposure of the patient to nephrotoxic agents (any substance, medication, or action that destroys kidney tissue), burns, traumatic injury, and the use of halogenated anesthetic agents.

Clinical Manifestations

Almost every system of the body is affected with failure of the normal renal regulatory mechanisms. The patient may appear critically ill and lethargic. The skin and mucous membranes are dry from dehydration. Central nervous system signs and symptoms include drowsiness, headache, muscle twitching, and seizures. Table 44-3 summarizes common clinical characteristics in all three categories of AKI.

Assessment and Diagnostic Findings

Assessment of the patient with AKI includes evaluation for changes in the urine, diagnostic tests that evaluate the kidney contour, and a variety of laboratory values. See Chapter 43 for information about the normal characteristics of urine, diagnostic findings, and laboratory values in the renal system.

In AKI, urine output varies from scanty to a normal volume, hematuria may be present, and the urine has a low specific gravity (compared with a normal value of 1.010 to 1.025). One of the earliest manifestations of tubular damage is the inability to concentrate the urine (Vritis, 2013). Patients with prerenal azotemia have a decreased amount of sodium in the urine (less than 20 mEq/L) and normal urinary sediment. Patients with

TABLE 44-3 Comparing Clinical Characteristics of Acute Kidney Injury

	Categories		
Characteristics	Prerenal	Intrarenal	Postrenal
Etiology	Hypoperfusion	Parenchymal damage	Obstruction
Blood urea nitrogen value	↑ (out of normal 20:1 proportion to creatinine)	↑	↑
Creatinine	↑	↑	↑
Urine output	↓	Varies, often ↓	Varies, may be ↓, or sudden anuria
Urine sodium	↓ to <20 mEq/L	↑ to >40 mEq/L	Varies, often ↓ to ≤20 mEq/L
Urinary sediment	Normal, few hyaline casts	Abnormal casts and debris	Usually normal
Urine osmolality	↑ to 500 mOsm	~350 mOsm, similar to serum	Varies, ↑ or equal to serum
Urine specific gravity	↑	Low normal	Varies

↑, increased; ↓, decreased.

intrarenal azotemia usually have urinary sodium levels greater than 40 mEq/L with **urinary casts** and other cellular debris.

Ultrasonography is a critical component of the evaluation of patients with kidney disease. A renal sonogram or a CT or MRI scan may show evidence of anatomic changes.

The BUN level increases steadily at a rate that depends on the degree of catabolism (breakdown of protein), renal perfusion, and protein intake. Serum creatinine levels are useful in monitoring kidney function and disease progression and increase with glomerular damage.

With a decline in the GFR, oliguria, and anuria, patients are at high risk for hyperkalemia. Protein catabolism results in the release of cellular potassium into the body fluids, causing severe hyperkalemia (high serum potassium levels). Hyperkalemia may lead to dysrhythmias, such as ventricular tachycardia and cardiac arrest. Sources of potassium include normal tissue catabolism, dietary intake, blood in the GI tract, or blood transfusion and other sources (e.g., IV infusions, potassium penicillin, and extracellular shift in response to metabolic acidosis).

Progressive metabolic acidosis occurs in kidney disease because patients cannot eliminate the daily metabolic load of acid-type substances produced by the normal metabolic processes. In addition, normal renal buffering mechanisms fail. This is reflected by decreased serum carbon dioxide (CO_2) and pH levels.

Blood phosphate concentrations may increase; calcium levels may be low due to decreased absorption of calcium from the intestine and as a compensatory mechanism for the elevated blood phosphate levels. Anemia is another common laboratory finding in AKI, as a result of reduced erythropoietin production, uremic GI lesions, reduced RBC lifespan, and blood loss from the GI tract.

Prevention

AKI has a high mortality rate that ranges from 40% to 90%. Factors that influence mortality include increased age, comorbid conditions, and pre-existing kidney and vascular diseases and respiratory failure (Vritis, 2013). Therefore, prevention of AKI is essential (see Chart 44-5).

A careful history is obtained to identify exposure to nephrotoxic agents or environmental toxins. The kidneys are susceptible to the adverse effects of medications because the metabolic by-products of most medications are excreted by the kidneys. Patients taking nephrotoxic medications (e.g., aminoglycosides, gentamicin [Garamycin], tobramycin, colistimethate [Coly-Mycin], polymyxin B, amphotericin B, vancomycin, amikacin [Amikin], cyclosporine [Neoral]) should be monitored closely for changes in renal function. Kidney function needs to be monitored prior to initiation of these medications and during therapy (Prentice, 2013).

Any agent that reduces renal blood flow (e.g., long-term analgesic use) may cause renal insufficiency. Chronic use of analgesic agents, particularly nonsteroidal anti-inflammatory drugs (NSAIDs), may cause interstitial nephritis (inflammation within the renal tissue) and papillary necrosis. Patients with heart failure or cirrhosis with ascites are at particular risk for NSAID-induced kidney disease. Increased age, pre-existing kidney disease, and the simultaneous administration of several nephrotoxic agents increase the risk of kidney damage.

Radiocontrast-induced nephropathy (CIN) is the third major cause of hospital-acquired AKI. Other most common causes of hospital-acquired AKI are hypovolemia and sepsis (Goswami, Vohra, Raju, et al., 2016). CIN is a potentially preventable condition. Baseline levels of creatinine greater than 2 mg/dL identify patients at high risk. Limiting the patient's exposure to contrast agents and nephrotoxic medications will reduce the risk of CIN (Rank, 2013). Administration of N-acetylcysteine and sodium bicarbonate before and during procedures reduces risk, but prehydration with saline is considered the most effective method to prevent CIN (Rank, 2013).

Chart 44-5

Preventing Acute Kidney Injury

- Continually assess renal function (urine output, laboratory values) when appropriate.
- Monitor central venous and arterial pressures and hourly urine output of critically ill patients to detect the onset of kidney disease as early as possible.
- Pay special attention to wounds, burns, and other precursors of sepsis.
- Prevent and treat infections promptly. Infections can produce progressive kidney damage.
- Prevent and treat shock promptly with blood and fluid replacement.
- Provide adequate hydration to patients at risk for dehydration, including:
  - Before, during, and after surgery
  - Patients undergoing intensive diagnostic studies requiring fluid restriction and contrast agents (e.g., barium enema, IV pyelograms), especially older patients who may have marginal renal reserve
  - Patients with neoplastic disorders or disorders of metabolism (e.g., gout) and those receiving chemotherapy
  - Patients with skeletal muscle injuries (e.g., crush injuries, compartment syndrome)
  - Patients with heat-induced illnesses (e.g., heat stroke, heat exhaustion)
- Take precautions to ensure that the appropriate blood is given to the correct patient in order to avoid severe transfusion reactions, which can precipitate kidney disease.
- To prevent infections from ascending in the urinary tract, give meticulous care to patients with indwelling catheters. Remove catheters as soon as possible.
- To prevent toxic drug effects, closely monitor dosage, duration of use, and blood levels of all medications metabolized or excreted by the kidneys.
- Treat hypotension promptly.

Gerontologic Considerations

About half of all patients who develop AKI during hospitalization are older than 60 years. The etiology of AKI in older adults includes prerenal causes such as dehydration, intrarenal causes such as nephrotoxic agents (e.g., medications, contrast agents), and complications of major surgery (Elliott, 2012). Suppression of thirst, enforced bed rest, lack of access to drinking water, and confusion all contribute to the older patient's failure to consume adequate fluids and may lead to dehydration, further compromising already decreased renal function.

AKI in older adults is also often seen in the community setting. Nurses in the ambulatory setting need to be aware of the risk. All medications need to be monitored for potential side effects that could result in damage to the kidney either through reduced circulation or nephrotoxicity. Outpatient procedures that require fasting or a bowel preparation may cause dehydration and therefore require careful monitoring.

Medical Management

The kidneys have a remarkable ability to recover from insult. The objectives of treatment for AKI are to restore normal chemical balance and prevent complications until repair of renal tissue and restoration of renal function can occur. Management includes eliminating the underlying cause; maintaining fluid balance; avoiding fluid excesses; and, when indicated, providing renal replacement therapy. Prerenal azotemia is treated by optimizing renal perfusion, whereas postrenal failure is treated by relieving the obstruction. Intrarenal azotemia is treated with supportive therapy, with removal of causative agents, aggressive management of prerenal and postrenal failure, and avoidance of associated risk factors. Shock and infection, if present, are treated promptly (see Chapter 8). The presence of myoglobin in the urine (i.e., myoglobinuria) in the patient who has had a crush injury, compartment syndrome, or heat-induced illness is treated for rhabdomyolysis (see Chapter 60).

Maintenance of fluid balance is based on daily body weight, serial measurements of central venous pressure, serum and urine concentrations, fluid losses, blood pressure, and the clinical status of the patient. The parenteral and oral intake and the output of urine, gastric drainage, stools, wound drainage, and perspiration are calculated and are used as the basis for fluid replacement. The insensible fluid produced through the normal metabolic processes and lost through the skin and lungs is also considered in fluid management.

Fluid excesses can be detected by the clinical findings of dyspnea, tachycardia, and distended neck veins. The patient's lungs are auscultated for moist crackles. Because pulmonary edema may be caused by excessive administration of parenteral fluids, extreme caution must be used to prevent fluid overload. The development of generalized edema is assessed by examining the presacral and pretibial areas several times daily. Mannitol (Osmitrol), furosemide (Lasix), or ethacrynic acid (Edecrin) may be prescribed to initiate diuresis (Walton, 2015).

Adequate renal blood flow in patients with prerenal causes of AKI may be restored by IV fluids or transfusions of blood products. If AKI is caused by hypovolemia secondary to hypoproteinemia, an infusion of albumin may be prescribed. Dialysis may be initiated to prevent complications of AKI, such as hyperkalemia, metabolic acidosis, pericarditis, and pulmonary edema. Dialysis corrects many biochemical abnormalities; allows for liberalization of fluid, protein, and sodium intake; diminishes bleeding tendencies; and promotes wound healing. Hemodialysis (a procedure that circulates the patient's blood through an artificial kidney [dialyzer] to remove waste products and excess fluid), peritoneal dialysis (PD; a procedure that uses the patient's peritoneal membrane [the lining of the peritoneal cavity] as the semipermeable membrane to exchange fluid and solutes), or a variety of continuous renal replacement therapies (CRRTs) (methods used to replace normal kidney function by circulating the patient's blood through a hemofilter) may be performed (Dirkes, 2014). These and other treatment modalities for patients with renal dysfunction are discussed later in this chapter.

Pharmacologic Therapy

Hyperkalemia is the most life threatening of the fluid and electrolyte changes that occur in patients with kidney disorders. Therefore, the patient is monitored for hyperkalemia through serial serum electrolyte levels (potassium value greater than 5.0 mEq/L [5 mmol/L]), ECG changes (tall, tented, or peaked T waves), and changes in clinical status (see Chapter 7). Other symptoms of hyperkalemia include irritability, abdominal cramping, diarrhea, paresthesia, and generalized muscle weakness. Muscle weakness may present as slurred speech, difficulty breathing, paresthesia, and paralysis. As the potassium level increases, both cardiac and other muscular function declines, making this a medical emergency.

The elevated potassium levels may be reduced by administering cation-exchange resins (sodium polystyrene sulfonate [Kayexalate]) orally or by retention enema. Kayexalate works by exchanging sodium ions for potassium ions in the intestinal tract. Sorbitol may be given in combination with Kayexalate to induce a diarrhea-type effect (it induces water loss in the GI tract). If a Kayexalate retention enema is given (the colon is the major site of potassium exchange), a rectal catheter with a balloon may be used to facilitate retention if necessary. The patient should retain the Kayexalate for at least 30 to 60 minutes (preferable 6 to 10 hours) to promote potassium removal (Comerford, 2015). Afterward, a cleansing enema may be prescribed to remove remaining medication as a precaution against fecal impaction.

If the patient is hemodynamically unstable (low blood pressure, changes in mental status, dysrhythmia), IV dextrose 50%, insulin, and calcium replacement may be given to shift potassium back into the cells. The shift of potassium into the intracellular space is temporary, so arrangements for dialysis need to be made on an emergent basis.

Many medications are eliminated through the kidneys; therefore, dosages must be reduced when a patient has AKI. Examples of commonly used agents that require adjustment are antibiotic medications (especially aminoglycosides), digoxin (Lanoxin), phenytoin (Dilantin), ACE inhibitors, and magnesium-containing agents.

In addition, many medications have been used in patients with AKI in an attempt to improve patient outcomes. Diuretic agents are often used to control fluid volume, but they have not been shown to improve recovery from AKI (Prentice, 2013).

In patients with severe acidosis, the arterial blood gases and serum bicarbonate levels (CO_2) must be monitored because the patient may require sodium bicarbonate therapy or dialysis. If respiratory problems develop, appropriate ventilatory measures must be instituted. The elevated serum phosphate level may be controlled with phosphate-binding agents (e.g., calcium or lanthanum carbonate) that help prevent a continuing rise in serum phosphate levels by decreasing the absorption of phosphate from the intestinal tract.

Nutritional Therapy

AKI causes severe nutritional imbalances (because nausea and vomiting contribute to inadequate dietary intake), impaired glucose use and protein synthesis, and increased tissue catabolism. The patient is weighed daily at the same time using the same scale and loses 0.2 to 0.5 kg daily if the nitrogen balance is negative (i.e., caloric intake falls below caloric requirements). If the patient gains or does not lose weight or develops hypertension, fluid retention should be suspected.

Nutritional support is based on the underlying cause of AKI, the catabolic response, the type and frequency of renal replacement therapy, comorbidities, and nutritional status. Replacement of dietary proteins is individualized to provide the maximum benefit and minimize uremic symptoms. Caloric requirements are met with high-carbohydrate meals, because carbohydrates have a protein-sparing effect (i.e., in a high-carbohydrate diet, protein is not used for meeting energy

requirements but is "spared" for growth and tissue healing). Foods and fluids containing potassium or phosphorus (e.g., bananas, citrus fruits and juices, coffee) are restricted.

The oliguric phase of AKI may last 10 to 14 days and is followed by the diuretic phase, at which time urine output begins to increase, signaling the patient is in the recovery phase (Prentice, 2013). Results of blood chemistry tests are used to determine the amounts of sodium, potassium, and water needed for replacement, along with assessment for over- or underhydration. Following the diuretic phase, the patient is placed on a high-protein, high-calorie diet and is encouraged to resume activities gradually.

Nursing Management

The nurse has an important role in caring for the patient with AKI. The nurse monitors for complications, participates in emergency treatment of fluid and electrolyte imbalances, assesses the patient's progress and response to treatment, and provides physical and emotional support. In addition, the nurse keeps family members informed about the patient's condition, helps them understand the treatments, and provides psychological support. Although the development of AKI may be the most serious problem, the nurse continues to provide nursing care indicated for the primary disorder (e.g., burns, shock, trauma, obstruction of the urinary tract).

Monitoring Fluid and Electrolyte Balance

Because of the serious fluid and electrolyte imbalances that can occur with AKI, the nurse monitors the patient's serum electrolyte levels and physical indicators of these complications during all phases of the disorder. IV solutions must be carefully selected based on the patient's fluid and electrolyte status. The patient's cardiac function and musculoskeletal status are monitored closely for signs of hyperkalemia.

Nursing Alert: Hyperkalemia is the most immediate life-threatening imbalance seen in AKI. Parenteral fluids, all oral intake, and all medications are screened carefully to ensure that sources of potassium are not inadvertently given or consumed.

The nurse monitors fluid status by paying careful attention to fluid intake (IV medications should be given in the smallest volume possible), urine output, apparent edema, distention of the jugular veins, alterations in heart sounds and breath sounds, and increasing difficulty in breathing. Accurate daily weights, as well as I&O records, are essential. Indicators of deteriorating fluid and electrolyte status are reported immediately to the primary provider, and preparation is made for emergency treatment. Severe fluid and electrolyte disturbances may be treated with hemodialysis, PD, or CRRT.

Reducing Metabolic Rate

The nurse takes steps to reduce the patient's metabolic rate. Bed rest may be indicated to reduce exertion and the metabolic rate during the most acute stage of the disorder. Fever and infection, both of which increase the metabolic rate and catabolism, are prevented or treated promptly.

Promoting Pulmonary Function

Attention is given to pulmonary function, and the patient is assisted to turn, cough, and take deep breaths frequently to prevent atelectasis and respiratory tract infection. Drowsiness and lethargy may prevent the patient from moving and turning without encouragement and assistance.

Preventing Infection

Asepsis is essential with invasive lines and catheters to minimize the risk of infection and increased metabolism. An indwelling urinary catheter is avoided whenever possible due to the high risk of UTI associated with its use but may be required to provide ongoing data required to accurately monitor fluid I&O.

Providing Skin Care

The skin may be dry or susceptible to breakdown as a result of edema; therefore, meticulous skin care is important. In addition, excoriation and itching of the skin may result from the deposit of irritating toxins in the patient's tissues. Bathing the patient with cool water, frequent turning, and keeping the skin clean and well moisturized and the fingernails trimmed to avoid excoriation are often comforting and prevent skin breakdown.

Providing Psychosocial Support

The patient with AKI may require treatment with hemodialysis, PD, or CRRT. The length of time that these treatments are necessary varies with the cause and extent of damage to the kidneys. The patient and family need assistance, explanation, and support during this period. The purpose of the treatment is explained to the patient and family by the primary provider. However, high levels of anxiety and fear may necessitate repeated explanation and clarification by the nurse. The family members may initially be afraid to touch and talk to the patient during these procedures but should be encouraged and assisted to do so.

In an intensive care setting, many of the nurse's functions are devoted to the technical aspects of patient care; however, it is essential that the psychological needs and other concerns of the patient and family be addressed. Continued assessment of the patient for complications of AKI and precipitating causes is essential (Davies & Leslie, 2012).

End-Stage Kidney Disease or Chronic Kidney Disease

When a patient has sustained enough kidney damage to require renal replacement therapy on a permanent basis, the patient has moved into the fifth or final stage of CKD, also referred to as ESKD.

Pathophysiology

As renal function declines, the end products of protein metabolism (normally excreted in urine) accumulate in the blood. Uremia develops and adversely affects every system in the body. The greater the buildup of waste products, the more pronounced the symptoms.

The rate of decline in renal function and progression of ESKD is related to the underlying disorder, the urinary excretion of protein, and the presence of hypertension. The disease tends to progress more rapidly in patients who excrete significant amounts of protein or have elevated blood pressure than in those without these conditions.

Clinical Manifestations

Because virtually every body system is affected in ESKD, patients exhibit a number of signs and symptoms. The severity of these signs and symptoms depends in part on the degree of

renal impairment, other underlying conditions, and the patient's age. Cardiovascular disease is the predominant cause of death in patients with ESKD (Walton, 2015). Peripheral neuropathy, a disorder of the peripheral nervous system, is present in some patients. Patients complain of severe pain and discomfort. Restless leg syndrome and burning feet can occur in the early stage of uremic peripheral neuropathy. The precise mechanisms for many of these systemic signs and symptoms have not been identified. However, it is generally thought that the accumulation of uremic waste products is the probable cause. Chart 44-6 summarizes the systemic signs and symptoms.

Assessment and Diagnostic Findings

Glomerular Filtration Rate

As the GFR decreases (due to nonfunctioning glomeruli), the creatinine clearance decreases, whereas the serum creatinine and BUN levels increase. Serum creatinine is a more sensitive indicator of renal function than BUN. The BUN is affected not only by kidney disease but also by protein intake in the diet, catabolism (tissue and RBC breakdown), parenteral nutrition, and medications such as corticosteroids.

Sodium and Water Retention

The kidney cannot concentrate or dilute the urine normally in ESKD. Appropriate responses by the kidney to changes in the daily intake of water and electrolytes, therefore, do not occur. Some patients retain sodium and water, increasing the risk for edema, heart failure, and hypertension. Hypertension may also result from activation of the renin–angiotensin–aldosterone axis and the concomitant increased aldosterone secretion. Other patients have a tendency to lose sodium and run the risk of developing hypotension and hypovolemia. Vomiting and diarrhea may cause sodium and water depletion, which worsens the uremic state.

Acidosis

Metabolic acidosis occurs in ESKD because the kidneys are unable to excrete increased loads of acid. Decreased acid secretion results from the inability of the kidney tubules to excrete ammonia (NH_3^-) and to reabsorb sodium bicarbonate (HCO_3^-). There is also decreased excretion of phosphates and other organic acids.

Anemia

Anemia develops as a result of inadequate erythropoietin production, the shortened lifespan of RBCs, nutritional

Chart 44-6 ASSESSMENT

Assessing for End-Stage Kidney Disease

Be alert to the following signs and symptoms:

Neurologic

- Asterixis
- Behavior changes
- Burning of soles of feet
- Confusion
- Disorientation
- Inability to concentrate
- Restlessness of legs
- Seizures
- Tremors
- Weakness and fatigue

Integumentary

- Coarse, thinning hair
- Dry, flaky skin
- Ecchymosis
- Gray-bronze skin color
- Pruritus
- Purpura
- Thin, brittle nails

Cardiovascular

- Engorged neck veins
- Hyperkalemia
- Hyperlipidemia
- Hypertension
- Pericardial effusion
- Pericardial friction rub
- Pericardial tamponade
- Pericarditis
- Periorbital edema
- Pitting edema (feet, hands, sacrum)

Pulmonary

- Crackles
- Depressed cough reflex
- Kussmaul-type respirations
- Pleuritic pain
- Shortness of breath
- Tachypnea
- Thick, tenacious sputum
- Uremic pneumonitis

Gastrointestinal

- Ammonia odor to breath ("uremic fetor")
- Anorexia, nausea, and vomiting
- Bleeding from gastrointestinal tract
- Constipation or diarrhea
- Hiccups
- Metallic taste
- Mouth ulcerations and bleeding

Hematologic

- Anemia
- Thrombocytopenia

Reproductive

- Amenorrhea
- Decreased libido
- Infertility
- Testicular atrophy

Musculoskeletal

- Bone fractures
- Bone pain
- Footdrop
- Loss of muscle strength
- Muscle cramps
- Renal osteodystrophy

deficiencies, and the patient's tendency to bleed, particularly from the GI tract. Erythropoietin, a substance normally produced by the kidneys, stimulates bone marrow to produce RBCs. In ESKD, erythropoietin production decreases and profound anemia results, producing fatigue, angina, and shortness of breath.

Calcium and Phosphorus Imbalance

Another abnormality seen in ESKD is a disorder in calcium and phosphorus metabolism. Serum calcium and phosphate levels have a reciprocal relationship in the body: As one increases, the other decreases. With a decrease in filtration through the glomerulus of the kidney, there is an increase in the serum phosphate level and a reciprocal or corresponding decrease in the serum calcium level. The decreased serum calcium level causes increased secretion of parathormone from the parathyroid glands. However, in kidney disease, the body does not respond normally to the increased secretion of parathormone; as a result, calcium leaves the bone, often producing bone changes and bone disease as well as calcification of major blood vessels in the body. In addition, the active metabolite of vitamin D (1,25-dihydroxycholecalciferol) normally manufactured by the kidney decreases as kidney disease progresses (Counts, 2015). Uremic bone disease, often called renal osteodystrophy, develops from the complex changes in calcium, phosphate, and parathormone balance. There is also evidence of calcification of blood vessels.

Complications

There are a number of potential complications of ESKD that necessitate a collaborative approach to care. These include the following:

- Anemia due to decreased erythropoietin production, decreased RBC lifespan, bleeding in the GI tract from irritating toxins and ulcer formation, and blood loss during hemodialysis
- Bone disease and metastatic and vascular calcifications due to retention of phosphorus, low serum calcium levels, abnormal vitamin D metabolism, and elevated aluminum levels
- Hyperkalemia due to decreased excretion, metabolic acidosis, catabolism, and excessive intake (diet, medications, fluids)
- Hypertension due to sodium and water retention and malfunction of the renin–angiotensin–aldosterone system
- Pericarditis, pericardial effusion, and pericardial tamponade due to retention of uremic waste products and inadequate dialysis

Medical Management

The goal of management is to maintain kidney function and homeostasis for as long as possible. All factors that contribute to ESKD and all factors that are reversible (e.g., obstruction) are identified and treated. Management is accomplished primarily with medications and diet therapy, although dialysis may also be needed to decrease the level of uremic waste products in the blood and to control electrolyte balance.

Pharmacologic Therapy

Complications can be prevented or delayed by administering prescribed phosphate-binding agents, calcium supplements, antihypertensive and cardiac medications, anticonvulsant medications, and recombinant human erythropoietin (epoetin alfa [Epogen]).

Calcium and Phosphorus Binders

Hyperphosphatemia and hypocalcemia are treated with medications that bind dietary phosphorus in the GI tract. Binders such as calcium carbonate (Os-Cal) or calcium acetate (PhosLo) are prescribed, but there is a risk of hypercalcemia. If calcium is high or the calcium–phosphorus product exceeds 55 mg/dL, a polymeric phosphate binder such as sevelamer hydrochloride (Renagel) may be prescribed (Walton, 2015). This medication binds dietary phosphorus in the intestinal tract; one to four tablets are given with food to be effective. Magnesium-based antacid agents are avoided to prevent magnesium toxicity.

Antihypertensive and Cardiovascular Agents

Hypertension is managed by intravascular volume control and a variety of antihypertensive agents (Weiner, Brunelli, Hunt, et al., 2014). Heart failure and pulmonary edema may also require treatment with fluid restriction, low-sodium diets, diuretic agents, inotropic agents such as digoxin or dobutamine (Dobutrex), and dialysis. The metabolic acidosis of ESKD usually produces no symptoms and requires no treatment; however, sodium bicarbonate supplements or dialysis may be needed to correct the acidosis if it causes symptoms.

Anticonvulsant Agents

Neurologic abnormalities may occur, so the patient must be observed for early evidence of slight twitching, headache, delirium, or seizure activity. If seizures occur, the onset of the seizure is recorded along with the type, duration, and general effect on the patient. The primary provider is notified immediately. IV diazepam (Valium) or phenytoin is usually given to control seizures. The side rails of the bed should be raised and padded to protect the patient. See Chapter 49 for discussion of nursing management for the patient with seizures.

Erythropoietin

Anemia associated with ESKD is treated with erythrocyte-stimulating agents (recombinant human erythropoietin). Patients with anemia (hematocrit less than 30%) present with nonspecific symptoms, such as malaise, general fatigability, and decreased activity tolerance. Erythrocyte stimulation therapy is initiated to achieve a hematocrit of 33% to 38% and a target hemoglobin of 12 g/dL, which generally alleviates the symptoms of anemia.

Epoetin alfa is administered IV or subcutaneously three times a week in ESKD. It may take 2 to 6 weeks for the hematocrit to increase; therefore, the medication is not indicated for patients who need immediate correction of severe anemia. Adverse effects seen with erythropoietin therapy include hypertension (especially during early stages of treatment), increased clotting of vascular access sites, seizures, and depletion of body iron stores (Arslanian, 2015).

Management involves adjustment of heparin to prevent clotting of the lines during hemodialysis treatments, frequent monitoring of hemoglobin and hematocrit, and periodic assessment of serum iron and transferrin levels. Because adequate stores of iron are necessary for an adequate response to epoetin alfa, supplementary iron may be prescribed. Common iron supplements include iron sucrose (Venofer), iron dextran (INFeD or Dexferrum), and ferric gluconate (Ferrlecit). In addition, the patient's blood pressure and serum potassium level are monitored to detect hypertension and increasing serum potassium levels, which may occur with therapy and the

increasing RBC mass. The occurrence of hypertension requires initiation or adjustment of the patient's antihypertensive therapy. Hypertension that cannot be controlled is a contraindication to recombinant erythropoietin therapy.

Patients who have received erythropoietin therapy have reported decreased levels of fatigue, increased feelings of well-being, better tolerance of dialysis, higher-energy levels, and improved exercise tolerance. In addition, this therapy has decreased the need for transfusion and its associated risks, including blood-borne infectious disease, antibody formation, and iron overload.

Nutritional Therapy

Dietary intervention is necessary with deterioration of renal function and includes careful regulation of protein intake, fluid intake to balance fluid losses, sodium intake to balance sodium losses, and some restriction of potassium. At the same time, adequate caloric intake and vitamin supplementation must be ensured. Protein is restricted because urea, uric acid, and organic acids—the breakdown products of dietary and tissue proteins—accumulate rapidly in the blood when there is impaired renal clearance. The allowed protein must be of high biologic value (dairy products, eggs, meats). High–biologic-value proteins are those that are complete proteins and supply the essential amino acids necessary for growth and cell repair.

Usually, the fluid allowance per day is 500 to 600 mL more than the previous day's 24-hour urine output. Calories are supplied by carbohydrates and fat to prevent wasting. Vitamin supplementation is necessary because a protein-restricted diet does not provide the necessary complement of vitamins. In addition, the patient on dialysis may lose water-soluble vitamins during the dialysis treatment.

Hyperkalemia is usually prevented by ensuring adequate dialysis treatments with potassium removal and careful monitoring of diet, medications, and fluids for their potassium content. Sodium polystyrene sulfonate (Kayexalate), a cation-exchange resin, may be needed for acute hyperkalemia.

Dialysis

The patient with increasing symptoms of kidney disease is referred to a dialysis and transplantation center early in the course of progressive kidney disease. Dialysis is usually initiated when the patient cannot maintain a reasonable lifestyle with conservative treatment.

Nursing Management

The patient with ESKD requires astute nursing care to avoid the complications of reduced renal function and the stresses and anxieties of dealing with a life-threatening illness.

Nursing care is directed toward assessing fluid status and identifying potential sources of imbalance, implementing a dietary program to ensure proper nutritional intake within the limits of the treatment regimen, and promoting positive feelings by encouraging increased self-care and greater independence. It is extremely important to provide explanations and information to the patient and family concerning ESKD, treatment options, and potential complications. A great deal of emotional support is needed by the patient and family because of the numerous changes experienced. Specific interventions, along with rationale and evaluation criteria, are presented in more detail in the plan of nursing care for the patient with ESKD (see Chart 44-7).

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse plays an important role in educating the patient with ESKD. Because of the extensive education needed, the home care nurse, dialysis nurse, and nurses in the hospital and outpatient settings all provide ongoing education and reinforcement while monitoring the patient's progress and compliance with the treatment regimen.

A referral to a nutritionist is made because of the dietary changes required. The patient is instructed to check the vascular access device for patency and to use appropriate precautions, such as avoiding venipuncture and blood pressure measurements on the arm with the access device.

In addition, the patient and family need to know what problems to report to the primary provider. These include the following:

- Worsening signs and symptoms of kidney disease (nausea, vomiting, change in usual urine output [if any], ammonia odor on breath)
- Signs and symptoms of hyperkalemia (muscle weakness, diarrhea, abdominal cramps)
- Signs and symptoms of access problems (clotted fistula or graft, infection)

These signs and symptoms of decreasing renal function, in addition to increasing BUN and serum creatinine levels, may indicate a need to alter the dialysis prescription. The dialysis nurses also provide ongoing education and support at each treatment visit.

Continuing and Transitional Care

The importance of follow-up examinations and treatment is stressed with the patient and family because of changing physical status, renal function, and dialysis requirements. Referral for home care provides the home care nurse with the opportunity to assess the patient's environment, emotional status, and the coping strategies used by the patient and family to deal with the changes in family roles often associated with chronic illness.

The home care nurse also assesses the patient for further deterioration of renal function and signs and symptoms of complications resulting from the primary kidney disorder, the resulting kidney disease, and effects of treatment strategies (e.g., dialysis, medications, dietary restrictions) (Hain, 2015). Patients need education and reinforcement of the dietary restrictions required, including fluid, sodium, potassium, and protein restriction. Reminders about the need for health promotion activities and health screening are an important part of nursing care for the patient with kidney disease.

Gerontologic Considerations

Diabetes, hypertension, chronic glomerulonephritis, interstitial nephritis, and urinary tract obstruction are among the causes for ESKD in older adults. The signs and symptoms of kidney disease in older adults are often nonspecific. The occurrence of symptoms of other disorders (heart failure, dementia) can mask the symptoms of kidney disease and delay or prevent diagnosis and treatment.

Hemodialysis and PD are used effectively in treating older patients with ESKD. Initiation of dialysis among older patients has dramatically increased in the past decade. Implementation of palliative care has also increased among patients who choose not to start dialysis or who decide to stop dialysis. Although

Chart 44-7 PLAN OF NURSING CARE

The Patient with End-Stage Kidney Disease

NURSING DIAGNOSIS: Excess fluid volume related to decreased urine output, dietary excesses, and retention of sodium and water
GOAL: Maintenance of ideal body weight without excess fluid

Nursing Interventions	Rationale	Expected Outcomes
1. Assess fluid status: a. Daily weight b. Intake and output balance c. Skin turgor and presence of edema d. Distention of neck veins e. Blood pressure, pulse rate, and rhythm f. Respiratory rate and effort	1. Assessment provides baseline and ongoing database for monitoring changes and evaluating interventions.	• Demonstrates no rapid weight changes • Maintains dietary and fluid restrictions • Exhibits normal skin turgor without edema • Exhibits normal vital signs • Exhibits no neck vein distention
2. Limit fluid intake to prescribed volume.	2. Fluid restriction will be determined on basis of weight, urine output, and response to therapy.	• Reports no difficulty breathing or shortness of breath • Performs oral hygiene frequently
3. Identify potential sources of fluid: a. Medications and fluids used to take or administer medications: oral and IV b. Foods	3. Unrecognized sources of excess fluids may be identified.	• Reports decreased thirst • Reports decreased dryness of oral mucous membranes
4. Explain to patient and family the rationale for fluid restriction.	4. Understanding promotes patient and family cooperation with fluid restriction.	
5. Assist patient to cope with the discomforts resulting from fluid restriction.	5. Increasing patient comfort promotes compliance with dietary restrictions.	
6. Provide or encourage frequent oral hygiene.	6. Oral hygiene minimizes dryness of oral mucous membranes.	

NURSING DIAGNOSIS: Imbalanced nutrition: less than body requirements related to anorexia, nausea, vomiting, dietary restrictions, and altered oral mucous membranes
GOAL: Maintenance of adequate nutritional intake

Nursing Interventions	Rationale	Expected Outcomes
1. Assess nutritional status: a. Weight changes b. Laboratory values (serum electrolyte, blood urea nitrogen [BUN], creatinine, protein, transferrin, and iron levels) (see Appendix A)	1. Baseline data allow for monitoring of changes and evaluating effectiveness of interventions.	• Consumes protein of high biologic value • Chooses foods within dietary restrictions that are appealing • Consumes high-calorie foods within dietary restrictions
2. Assess patient's nutritional dietary patterns: a. Diet history b. Food preferences c. Calorie counts	2. Past and present dietary patterns are considered in planning meals.	• Explains in own words rationale for dietary restrictions and relationship to urea and creatinine levels
3. Assess for factors contributing to altered nutritional intake: a. Anorexia, nausea, or vomiting b. Diet unpalatable to patient c. Depression d. Lack of understanding of dietary restrictions e. Stomatitis	3. Information about other factors that may be altered or eliminated to promote adequate dietary intake is provided.	• Takes medications on schedule that does not produce anorexia or feeling of fullness • Consults written lists of acceptable foods • Reports increased appetite at meals • Exhibits no rapid increases or decreases in weight
4. Provide patient's food preferences within dietary restrictions.	4. Increased dietary intake is encouraged.	• Demonstrates normal skin turgor without edema; wound healing and acceptable plasma albumin levels
5. Promote intake of high–biologic-value protein foods: eggs, dairy products, meats.	5. Complete proteins are provided for positive nitrogen balance needed for growth and healing.	
6. Encourage high-calorie, low-protein, low-sodium, and low-potassium snacks between meals.	6. Reduces source of restricted foods and proteins and provides calories for energy, sparing protein for tissue growth and healing.	
7. Alter schedule of medications so that they are not given immediately before meals.	7. Ingestion of medications just before meals may produce anorexia and feeling of fullness.	
8. Explain rationale for dietary restrictions and relationship to kidney disease and increased urea and serum creatinine levels.	8. Promotes patient understanding of relationships between diet and urea and creatinine levels to kidney disease.	

(Continued)

(Continued)

9. Provide written lists of foods allowed and suggestions for improving their taste without the use of sodium or potassium.	9. Lists provide a positive approach to dietary restrictions and a reference for patient and family to use when at home.	
10. Provide pleasant surroundings at mealtimes.	10. Unpleasant factors that contribute to patient's anorexia are eliminated.	
11. Weigh patient daily.	11. Allows monitoring of fluid and nutritional status.	
12. Assess for evidence of inadequate protein intake: a. Edema formation b. Delayed wound healing c. Decreased serum albumin levels	12. Inadequate protein intake can lead to decreased albumin and other proteins, edema formation, and delay in wound healing.	

NURSING DIAGNOSIS: Deficient knowledge regarding condition and treatment
GOAL: Increased knowledge about condition and related treatment

Nursing Interventions	Rationale	Expected Outcomes
1. Assess understanding of cause of kidney disease, consequences of kidney disease, and its treatment: a. Cause of patient's kidney disease b. Meaning of kidney disease c. Understanding of renal function d. Relationship of fluid and dietary restrictions to kidney disease e. Rationale for treatment (hemodialysis, peritoneal dialysis, transplantation)	1. Provides baseline for further explanations and education.	• Verbalizes relationship of cause of kidney disease to consequences • Explains fluid and dietary restrictions as they relate to failure of kidney's regulatory functions • States in own words relationship of kidney disease and need for treatment • Asks questions about treatment options, indicating readiness to learn • Verbalizes plans to continue as normal a life as possible • Uses written information and instructions to clarify questions and seek additional information
2. Provide explanation of renal function and consequences of kidney disease at patient's level of understanding and guided by patient's readiness to learn.	2. Patient can learn about kidney disease and treatment as they become ready to understand and accept the diagnosis and consequences.	
3. Assist patient to identify ways to incorporate changes related to illness and its treatment into lifestyle.	3. Patient can see that their life does not have to revolve around the disease.	
4. Provide oral and written information as appropriate about: a. Renal function and failure b. Fluid and dietary restrictions c. Medications d. Reportable problems, signs, and symptoms e. Follow-up schedule f. Community resources g. Treatment options	4. Provides patient with information that can be used for further clarification at home.	

NURSING DIAGNOSIS: Activity intolerance related to fatigue, anemia, retention of waste products, and dialysis procedure
GOAL: Participation in activity within tolerance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess factors contributing to activity intolerance: a. Fatigue b. Anemia c. Fluid and electrolyte imbalances d. Retention of waste products e. Depression	1. Indicates factors contributing to severity of fatigue.	• Participates in increasing levels of activity and exercise • Reports increased sense of well-being • Alternates rest and activity • Participates in selected self-care activities
2. Promote independence in self-care activities as tolerated; assist if fatigued.	2. Promotes improved self-esteem.	
3. Encourage alternating activity with rest.	3. Promotes activity and exercise within limits and adequate rest.	
4. Encourage patient to rest after dialysis treatments.	4. Adequate rest is encouraged after dialysis treatments, which are exhausting to many patients.	

(Continued)

(Continued)

NURSING DIAGNOSIS: Risk for situational low self-esteem related to dependency, role changes, change in body image, and change in sexual function
GOAL: Improved self-esteem

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's and family's responses and reactions to illness and treatment.	1. Provides data about problems encountered by patient and family in coping with changes in life.	• Identifies previously used coping styles that have been effective and those no longer possible due to disease and treatment (alcohol or drug use; extreme physical exertion)
2. Assess relationship of patient and significant family members.	2. Identifies strengths and supports of patient and family.	
3. Assess usual coping patterns of patient and family members.	3. Coping patterns that may have been effective in past may be harmful in view of restrictions imposed by disease and treatment.	• Patient and family identify and verbalize feelings and reactions to disease and necessary changes in their lives
4. Encourage open discussion of concerns about changes produced by disease and treatment: a. Assess factors contributing to activity intolerance: Role changes b. Assess factors contributing to activity intolerance: Changes in lifestyle c. Assess factors contributing to activity intolerance: Changes in occupation d. Assess factors contributing to activity intolerance: Sexual changes e. Assess factors contributing to activity intolerance: Dependence on health care team	4. Encourages patient to identify concerns and steps necessary to deal with them.	• Seeks professional counseling, if necessary, to cope with changes resulting from kidney disease • Reports satisfaction with method of sexual expression
5. Explore alternate ways of sexual expression other than sexual intercourse.	5. Alternative forms of sexual expression may be acceptable.	
6. Discuss role of giving and receiving love, warmth, and affection.	6. Sexuality means different things to different people, depending on stage of maturity.	

COLLABORATIVE PROBLEMS: Hyperkalemia; pericarditis, pericardial effusion, and pericardial tamponade; hypertension; anemia; bone disease and metastatic calcifications
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Hyperkalemia		
1. Monitor serum potassium levels. Notify primary provider if level is at or approaching >5.5 mEq/L, and prepare to treat hyperkalemia.	1. Hyperkalemia causes potentially life-threatening changes in the body.	• Has normal potassium level • Experiences no muscle weakness or diarrhea
2. Assess patient for muscle weakness, diarrhea, electrocardiographic (ECG) changes (tall-tented T waves and widened QRS).	2. Cardiovascular signs and symptoms are characteristic of hyperkalemia.	• Exhibits normal ECG pattern • Vital signs are within normal limits
Pericarditis, Pericardial Effusion, and Pericardial Tamponade		
1. Assess patient for fever, chest pain, and a pericardial friction rub (signs of pericarditis); if present, notify primary provider.	1. About 30–50% of patients with chronic kidney disease develop pericarditis due to uremia; fever, chest pain, and a pericardial friction rub are classic signs.	• Has strong and equal peripheral pulses • Absence of a paradoxical pulse • Absence of pericardial effusion or tamponade on cardiac ultrasound
2. If patient has pericarditis, assess for the following every 4 hours: a. Paradoxical pulse, >10 mm Hg b. Extreme hypotension c. Weak or absent peripheral pulses d. Altered level of consciousness e. Jugular venous distention	2. Pericardial effusion is a common fatal sequela of pericarditis. Signs of an effusion include a paradoxical pulse (>10 mm Hg drop in blood pressure during inspiration) and signs of shock due to compression of the heart by a large effusion. Cardiac tamponade exists when the patient is severely compromised hemodynamically.	• Has normal heart sounds
3. Prepare patient for echocardiogram to aid in diagnosis of pericardial effusion and cardiac tamponade.	3. Echocardiogram is useful in visualizing pericardial effusions and cardiac tamponade.	

(Continued)

(Continued)

4. If cardiac tamponade develops, prepare patient for emergency pericardiocentesis.	4. Cardiac tamponade is a life-threatening condition, with a high mortality rate. Immediate aspiration of fluid from the pericardial space is essential.	
Hypertension		
1. Monitor and record blood pressure as indicated.	1. Provides objective data for monitoring. Elevated levels may indicate nonadherence to the treatment regimen.	• Blood pressure within normal limits • Reports no headaches, visual problems, or seizures • Edema is absent
2. Administer antihypertensive medications as prescribed.	2. Antihypertensive medications play a key role in treatment of hypertension associated with chronic kidney disease.	• Demonstrates adherence to dietary and fluid restrictions
3. Encourage adherence to dietary and fluid restriction therapy.	3. Adherence to diet and fluid restrictions and dialysis schedule prevents excess fluid and sodium accumulation.	
4. Instruct patient to report signs of fluid overload, vision changes, headaches, edema, or seizures.	4. These are indications of inadequate control of hypertension and the need to alter therapy.	
Anemia		
1. Monitor red blood cell (RBC) count and hemoglobin and hematocrit levels as indicated.	1. Provides assessment of degree of anemia.	• Patient has a normal skin color without pallor
2. Administer medications as prescribed, including iron and folic acid supplements, an erythrocyte stimulating agent, and multivitamins.	2. RBCs need iron, folic acid, and vitamins to be produced. An erythrocyte-stimulating agent stimulates the bone marrow to produce RBCs.	• Exhibits hemoglobin levels within acceptable limits • Experiences no bleeding from any site
3. Avoid drawing unnecessary blood specimens.	3. Anemia is worsened by drawing numerous specimens.	
4. Educate patient to prevent bleeding: Avoid vigorous nose blowing and contact sports, and use a soft toothbrush.	4. Bleeding from anywhere in the body worsens anemia.	
5. Administer blood component therapy as indicated.	5. Blood component therapy may be needed if the patient has symptoms.	
Bone Disease and Metastatic Calcifications		
1. Administer the following medications as prescribed: phosphate binders, calcium supplements, vitamin D supplements.	1. Chronic kidney disease causes numerous physiologic changes affecting calcium, phosphorus, and vitamin D metabolism.	• Exhibits serum calcium, phosphorus, and aluminum levels within acceptable ranges • Exhibits no symptoms of hypocalcemia
2. Monitor serum laboratory values as indicated (calcium, phosphorus, aluminum levels), and report abnormal findings to primary provider.	2. Hyperphosphatemia, hypocalcemia, and excess aluminum accumulation are common in chronic kidney disease.	• Has no bone demineralization on bone scan
3. Assist patient with an exercise program.	3. Bone demineralization increases with immobility.	• Discusses importance of maintaining activity level and exercise program

there is no specific age limitation for kidney transplantation, concomitant disorders (e.g., coronary artery disease, peripheral vascular disease) have made it a less common treatment for older adults. However, the outcome is comparable to that in younger patients. Some older patients elect not to undergo dialysis or transplantation. Conservative management and palliative care, including nutritional therapy, fluid control, and medications such as phosphate binders, may be considered in patients who are not suitable for or elect not to have dialysis or transplantation (Prentice, 2013). Palliative care for the patient with ESKD focuses on relieving suffering, promoting health-related quality of life, and facilitating dignity at the end of life (see Chapter 59).

RENAL REPLACEMENT THERAPIES

The use of renal replacement therapies becomes necessary when the kidneys can no longer remove wastes, maintain electrolytes, and regulate fluid balance. This can occur rapidly or over a long period of time, and the need for replacement therapy can be acute (short term) or chronic (long term). The main renal replacement therapies include the various types of dialysis and kidney transplantation.

Dialysis

Types of dialysis include hemodialysis, CRRT, and PD. Acute or urgent dialysis is indicated when there is a high

and increasing level of serum potassium, fluid overload, or impending pulmonary edema; increasing acidosis; pericarditis; and advanced uremia (Grossman & Porth, 2014). It may also be used to remove medications or toxins (poisoning or medication overdose) from the blood or for edema that does not respond to other treatment, hepatic coma, hyperkalemia, hypercalcemia, hypertension, and uremia.

Chronic or maintenance dialysis is indicated in advanced CKD and ESKD in the following instances: the presence of uremic signs and symptoms affecting all body systems (nausea and vomiting, severe anorexia, increasing lethargy, mental confusion), hyperkalemia, fluid overload not responsive to diuretics and fluid restriction, and a general lack of well-being. An urgent indication for dialysis in patients with kidney disease is pericardial friction rub, which is indicative of uremic pericarditis.

The decision to initiate dialysis should be reached only after thoughtful discussion among the patient, family, primary provider, and other health care team members. The nurse can assist the patient and family by answering their questions, clarifying the information provided, and supporting their decision.

Successful kidney transplantation eliminates the need for dialysis. Not only is the quality of life much improved in patients with ESKD who undergo transplantation, but physiologic function is improved as well. Patients who undergo kidney transplantation from living donors before dialysis is initiated generally have longer survival of the transplanted kidney than patients who receive transplantation after dialysis treatment is initiated (Trevitt, Dunsmore, Murphy, et al., 2012).

Hemodialysis

Hemodialysis is used for patients who are acutely ill and require short-term dialysis for days to weeks until kidney function resumes and for patients with advanced CKD and ESKD who require long-term or permanent renal replacement therapy. Hemodialysis prevents death but does not cure kidney disease and does not compensate for the loss of endocrine or metabolic activities of the kidneys. More than 90% of patients requiring long-term renal replacement therapy are on chronic hemodialysis (USRDS, 2015). Most patients receive intermittent hemodialysis that involves treatments three times a week with an average treatment duration of 3 to 5 hours in an outpatient setting. Hemodialysis can also be performed at home by the patient and a caregiver. With home dialysis, treatment time and frequency can be adjusted to meet optimal patient needs.

The objectives of hemodialysis are to extract toxic nitrogenous substances from the blood and to remove excess fluid. A dialyzer (also referred to as an artificial kidney) is a synthetic semipermeable membrane through which blood is filtered to remove uremic toxins and a desired amount of fluid. In hemodialysis, the blood, laden with toxins and nitrogenous wastes, is diverted from the patient to a machine via the use of a blood pump to the dialyzer, where toxins are filtered from the blood and the blood is returned to the patient.

Diffusion, osmosis, and ultrafiltration are the principles on which hemodialysis is based (see Chapter 7). The toxins and wastes in the blood are removed by diffusion—that is, they move from an area of higher concentration in the blood to an area of lower concentration in the dialysate. The dialysate is a solution that circulates through the dialyzer, made up of all the electrolytes in their ideal extracellular concentrations. The electrolyte level in the patient's blood can be brought under control by properly adjusting the electrolytes in the dialysate solution. The semipermeable membrane impedes the diffusion of large molecules, such as RBCs and proteins.

Excess fluid is removed from the blood by osmosis, in which water moves from an area of low concentration potential (the blood) to an area of high concentration potential (the dialysate bath). In **ultrafiltration**, fluid moves under high pressure to an area of lower pressure. This process is much more efficient than osmosis for fluid removal and is accomplished by applying negative pressure or a suctioning force to the dialysis membrane. Because patients with disease requiring dialysis usually cannot excrete water, this force is necessary to remove fluid to achieve fluid balance.

The body's buffer system is maintained using a dialysate bath made up of bicarbonate (most common) or acetate, which is metabolized to form bicarbonate. The anticoagulant heparin is given to keep blood from clotting in the extracorporeal dialysis circuit. Cleansed blood is returned to the body with the goal of removing fluid, balancing electrolytes, and managing acidosis.

Dialyzers

Dialyzers are hollow-fiber devices containing thousands of tiny capillary tubes that carry the blood through the artificial kidney. The tubes are porous and act as a semipermeable membrane, allowing toxins, fluid, and electrolytes to pass across the membrane. The constant flow of the solution maintains the concentration gradient to facilitate the exchange of wastes from the blood across the semipermeable membrane into the dialysate solution, where they are removed and discarded (see Fig. 44-5).

Dialyzers have undergone many technologic changes in performance and biocompatibility. High-flux dialysis uses highly permeable membranes to increase the clearance of low- and mid–molecular-weight molecules. These special membranes are used with higher than traditional rates of flow for the blood entering and exiting the dialyzer (500 to 550 mL/min). High-flux dialysis increases the efficiency of treatments while shortening their duration and reducing the need for heparin.

Vascular Access

Access to the patient's vascular system must be established to allow blood to be removed, cleansed, and returned to the patient's vascular system at the rapid rates of 300 and 800 mL/min. Several types of access can be surgically created or placed during procedures performed in interventional radiology suites or at the bedside.

Vascular Access Devices

Immediate access to the patient's circulation for acute hemodialysis is achieved by inserting a double-lumen, noncuffed, large-bore catheter into the subclavian, internal jugular, or femoral vein by the physician (see Fig. 44-6). This method of vascular access involves some risk (e.g., hematoma, pneumothorax, infection, thrombosis of the subclavian vein, inadequate flow). The catheter is removed when no longer needed (e.g., because the patient's condition has improved or another type of permanent access has been established). Double-lumen, cuffed catheters may also be inserted, usually by either a surgeon or interventional radiologist, into the internal jugular vein of the patient. Because these catheters have cuffs under the skin, the insertion site heals, sealing the wound and reducing the risk for ascending infection. This feature makes these catheters safe for longer-term use. However, infection rates remain high, and sepsis continues to be a common cause for hospital admission (Figueiredo, 2014).

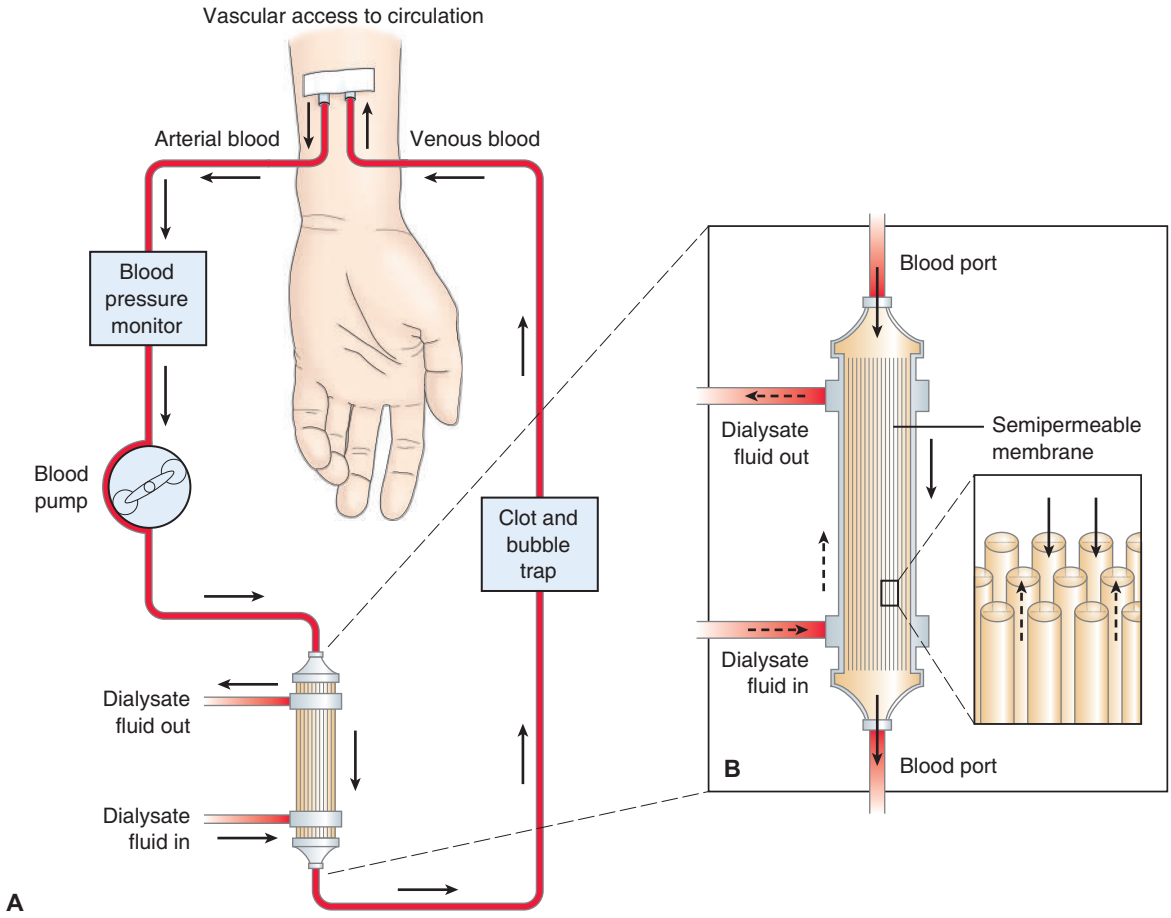

Figure 44-5 • Hemodialysis system. Blood from an artery is pumped (**A**) into a dialyzer, where it flows through the synthetic capillary tubes (**B**), which act as the semipermeable membrane (*inset*). The dialysate, which has a particular chemical composition, flows into the dialyzer around the capillary tubes that the blood flows through. The waste products in the blood diffuse across the semipermeable membrane into the dialysate solution.

Arteriovenous Fistula

The preferred method of permanent vascular access for dialysis is an arteriovenous fistula (AVF) that is created surgically (usually in the forearm) by joining (anastomosing) an artery to a vein, either side to side or end to side (see Fig. 44-7A). Needles are inserted into the vessel to obtain blood flow adequate to pass through the dialyzer. The arterial segment of the fistula is used for arterial flow to the dialyzer and the venous segment for reinfusion of the dialyzed blood. This access will need time (2 to 3 months) to "mature" before it can be used. As the AVF matures, the venous segment dilates due to the increased blood flow coming directly from the artery. Once sufficiently dilated, it will then accommodate two large-bore (14-, 15-, or 16-gauge) needles that are inserted for each dialysis treatment. The patient is encouraged to perform hand exercises to increase the size of these vessels (i.e., squeezing a rubber ball for forearm fistulas) to accommodate the large-bore needles. Once established, this access has the longest useful life and thus is the best option for vascular access for the patient requiring ongoing hemodialysis (MacRae, Ahmed, & Hemmelgam, 2014).

Arteriovenous Graft

An arteriovenous graft can be created by subcutaneously interposing a biologic, semibiologic, or synthetic graft material between an artery and vein (see Fig. 44-7B). Usually, a graft is created when the patient's vessels are not suitable for creation of an AVF. Patients with compromised vascular systems (e.g., from diabetes) often require a graft because their native vessels may not be suitable for creation of an AVF. Grafts are usually placed in the arm but may be placed in the thigh or chest wall. Stenosis, infection, and thrombosis are the most common complications of this access. It is not at all uncommon to see a dialysis patient with numerous "old" or "nonfunctioning" accesses present on their arms. The patient is asked to identify the current access in use, and it is checked carefully for the presence of a bruit and thrill.

See the Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized section later in this chapter for nursing interventions and care of the patient with an arteriovenous graft or fistula.

Nursing Alert: Failure of the permanent dialysis access (fistula or graft) accounts for most hospital admissions of patients undergoing chronic hemodialysis. Thus, protection of the access is of high priority.

Complications

Although hemodialysis can prolong life, it does not alter the natural course of the underlying CKD, nor does it completely replace kidney function. The CKD complications previously

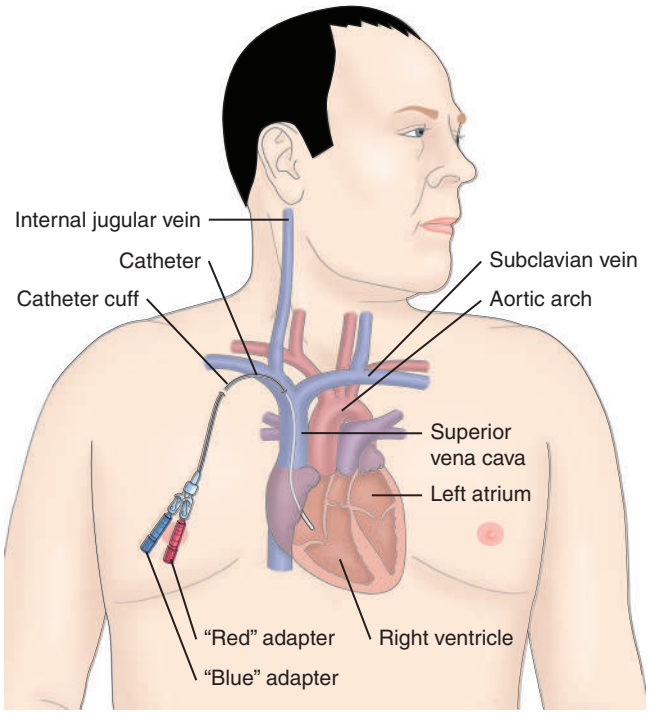

Figure 44-6 • Double-lumen, cuffed hemodialysis catheter used in acute hemodialysis. The red lumen is attached to a blood line through which blood is pumped from the patient to the dialyzer. After the blood passes through the dialyzer (artificial kidney), it returns to the patient through the blue lumen of the catheter.

discussed will continue to worsen and require treatment. With the initiation of dialysis, disturbances of lipid metabolism (hypertriglyceridemia) are accentuated and contribute to cardiovascular complications. Heart failure, coronary artery disease, angina, stroke, and peripheral vascular disease may occur and can incapacitate the patient. Cardiovascular disease remains the leading cause of death in patients receiving dialysis (Deng & Forbes, 2015); (Ludvigsen, Hermansen, & Lindberg, 2014).

Anemia is compounded by blood lost during hemodialysis. Gastric ulcers may result from the physiologic stress of chronic illness, medication, and pre-existing medical conditions (e.g., diabetes). Patients with uremia report a metallic taste and nausea when they require dialysis. Vomiting may occur during the hemodialysis treatment when rapid fluid shifts and hypotension occur. These contribute to the malnutrition seen in patients on dialysis. Poor calcium metabolism and renal osteodystrophy can result in bone pain and fractures, interfering with mobility. As time on dialysis continues, calcification of major blood vessels has been reported and linked to hypertension and other vascular complications. Phosphorus deposits in the skin can occur and cause itching.

Many people undergoing hemodialysis experience major sleep problems that further complicate their overall health status. Early-morning or late-afternoon dialysis may be a risk factor for developing sleep disturbances.

Other complications of dialysis treatment may include the following:

- Episodes of shortness of breath often occur as fluid accumulates between dialysis treatments.
- Hypotension may occur during the treatment as fluid is removed. Nausea and vomiting, diaphoresis, tachycardia, and dizziness are common signs of hypotension.

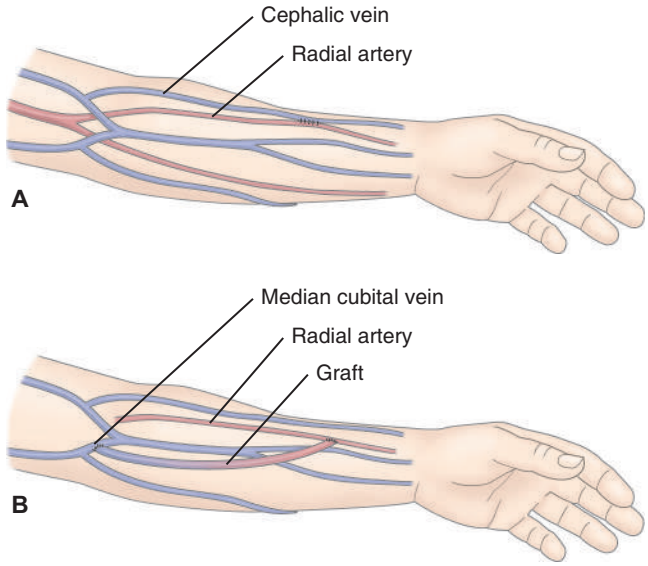

Figure 44-7 • **A.** Arteriovenous fistulas are created by anastomosing a patient's vein to an artery. This illustrates a side-to-side anastomosis. **B.** Arteriovenous grafts are established by connecting the artery and vein using synthetic tubing.

- Painful muscle cramping may occur, usually late in dialysis as fluid and electrolytes rapidly leave the extracellular space.
- Exsanguination may occur if blood lines separate or dialysis needles become dislodged.
- Dysrhythmias may result from electrolyte and pH changes or from removal of antiarrhythmic medications during dialysis.
- Air embolism is rare but can occur if air enters the vascular system.
- Chest pain may occur in patients with anemia or arteriosclerotic heart disease.
- Dialysis disequilibrium results from cerebral fluid shifts. Signs and symptoms include headache, nausea and vomiting, restlessness, decreased level of consciousness, and seizures. It is rare and more likely to occur in AKI or when BUN levels are very high (exceeding 150 mg/dL).

Nursing Management

The nurse in the dialysis unit has an important role in monitoring, supporting, assessing, and educating the patient. During dialysis, the patient, the dialyzer, and the dialysate bath require constant monitoring because numerous complications are possible, including clotting of the dialysis tubing or dialyzer, air embolism, inadequate or excessive fluid removal, hypotension, cramping, vomiting, blood leaks, contamination, and access complications. Nursing care of the patient and maintenance of the vascular access device are especially important and are discussed in the Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized section.

Promoting Pharmacologic Therapy

Many medications are removed from the blood during hemodialysis; therefore, dosage or timing of the medication administration may require adjustment. Medications that are water soluble are readily removed during hemodialysis treatment, and those that are fat soluble or adhere to other substances (like albumin) are not dialyzed out very well. This is the reason some drug overdoses are treated with emergency hemodialysis and others are not.

Patients undergoing hemodialysis who require medications (e.g., cardiac glycosides, antibiotic agents, antiarrhythmic medications, antihypertensive agents) are monitored closely to ensure that blood and tissue levels of these medications are maintained without toxic accumulation. Antihypertensive therapy, often part of the regimen of patients on dialysis, is one example when communication, education, and evaluation can make a difference in patient outcomes. The patient must know when—and when not—to take the medication. For example, if an antihypertensive agent is taken on a dialysis day, hypotension may occur during dialysis, causing dangerously low blood pressure. Many medications that are taken once daily can be held until after the dialysis treatment.

Promoting Nutritional and Fluid Therapy

Diet is important for patients on hemodialysis because of the effects of uremia. Goals of nutritional therapy are to minimize uremic symptoms and fluid and electrolyte imbalances; to maintain good nutritional status through adequate protein, calorie, vitamin, and mineral intake; and to enable the patient to eat a palatable and enjoyable diet. Restricting dietary protein decreases the accumulation of nitrogenous wastes, reduces uremic symptoms, and may even postpone the initiation of dialysis for a few months. Restriction of fluid is also part of the dietary prescription because fluid accumulation may occur, leading to weight gain, heart failure, and pulmonary edema.

With the initiation of hemodialysis, the patient usually requires some restriction of dietary protein, sodium, potassium, phosphorus, and fluid intake. Protein intake is restricted to about 1.2 to 1.3 g/kg ideal body weight per day; therefore, protein must be of high biologic quality. Sodium is usually restricted to 2 to 3 g/day; fluids are restricted to an amount equal to the daily urine output plus 500 mL/day. The goal for patients on hemodialysis is to keep their interdialytic (between dialysis treatments) weight gain under 1.5 kg. Potassium restriction depends on the amount of residual renal function and the frequency of dialysis. Dietary restriction is an unwelcome change in lifestyle for many patients with ESKD. Patients can feel stigmatized in social situations because there may be few food choices available for their diet. If the restrictions are ignored, life-threatening complications, such as hyperkalemia and pulmonary edema, may result. Thus, the patient may feel punished for responding to basic human drives to eat and drink. The nurse who cares for a patient with symptoms or complications resulting from dietary indiscretion must avoid harsh, judgmental, or punitive tones when communicating with him or her. Regular education with reinforcement is needed to achieve these difficult changes in lifestyle.

Meeting Psychosocial Needs

Patients requiring long-term hemodialysis are often concerned about the unpredictability of the illness and the quality of their lives (Wright & Wilson, 2015). They often have financial problems, difficulty holding a job, waning sexual desire and impotence, clinical depression, and fear of dying. Younger patients worry about marriage, having children, and the burden that they bring to their families. The regimented lifestyle that frequent dialysis treatments and restrictions in food and fluid intake impose can be demoralizing to the patient and family. Researchers have studied the quality of life and self-efficacy in patient undergoing dialysis (see Chart 44-8).

Dialysis alters the lifestyle of the patient and family. The amount of time required for dialysis and primary provider visits and being chronically ill can create conflict, frustration, guilt, and depression. It may be difficult for the patient, spouse, and family to express anger and negative feelings.

The nurse needs to give the patient and family the opportunity to express feelings of anger and concern about the limitations that the disease and treatment impose, possible financial problems, and job insecurity. If anger is not expressed, it may be directed inward and lead to depression, despair, and attempts at suicide (suicide is more prevalent in patients on dialysis); however, if anger is projected outward to other people, it may damage family relationships.

Although these feelings are normal in this situation, they are often profound. Counseling and psychotherapy may be useful. Depression may require treatment with antidepressant agents. Referring the patient and family to a mental health provider with expertise in the care of patients receiving dialysis may also be helpful. Clinical nurse specialists, psychologists, and social workers

Chart 44-8 NURSING RESEARCH PROFILE

Quality of Life in Patients Receiving Dialysis

Wright, L. S. & Wilson, L. (2015). Quality of life and self-efficacy in three dialysis modalities: Incenter hemodialysis, home hemodialysis, and home peritoneal dialysis. Nephrology Nursing Journal, 42(5), 463–476.

Purpose

Previous research has focused almost exclusively on the quality of life among patients receiving incenter hemodialysis (HD). The purpose of this study was to describe the quality of life and self-efficacy of patients receiving incenter HD compared to those receiving a home HD (HD or peritoneal dialysis [PD]).

Design

This study utilized a correlational cross-sectional design and quota sampling to achieve equal group size. Patients were recruited from outpatient dialysis facilities and included 77 community dwelling adult patients who had been on dialysis for at least 6 months. Quality of life was measured using the Kidney Disease Quality of Life (QOL) Instrument, and self-efficacy was measured using the Strategies Used by People to Promote Health instrument.

Findings

The sample included 29 participants receiving incenter HD treatments, 22 on home HD, and 26 on home PD. There were no significant differences in demographic characteristics. Participants on PD scored the highest in 6 of the 11 CKD-specific to QOL measures. Patients on PD also scored highest in 8 of the 9 generic QOL measures. The results of this study suggest a possible benefit for patients on PD with regard to QOL and self-efficacy.

Nursing Implications

This information helps nurses to understand patient needs, both medical and social, and to recognize their key role in educating patients about treatment options and other care-related issues. By knowing the differences in reported self-efficacy and QOL across dialysis modalities, nurses can help empower patients to make decisions about which mode of dialysis treatment will meet their individual needs.

may be helpful in assisting the patient and family to cope with the changes brought about by kidney disease and its treatment.

The sense of loss that the patient experiences cannot be underestimated because every aspect of a "normal life" is disrupted. Some patients use denial to deal with the array of medical problems (e.g., infections, hypertension, anemia, neuropathy). Staff who are tempted to label the patient as noncompliant must consider the impact of kidney disease and its treatment on the patient and family and the coping strategies that they may use.

Palliative care principles that focus on symptom control are becoming increasingly important as greater attention is focused on quality-of-life issues (Hain, 2015). Patients and their families are encouraged to discuss end-of-life options and to develop advanced directives or living wills.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Preparing a patient for hemodialysis is essential. Assessment helps identify the learning needs of the patient and family members. In many cases, the patient is discharged home before learning needs and readiness to learn can be thoroughly evaluated; therefore, hospital-based nurses, dialysis staff, and home care nurses must work together to provide appropriate education that meets the patient's and family's changing needs and readiness to learn (see Chart 44-9).

The diagnosis of ESKD and the need for dialysis can be devastating for the patient and family. In addition, many patients with ESKD have clinical depression, a shortened attention span, a decreased level of concentration, and altered perception. Therefore, education must occur in brief, 10- to 15-minute sessions, with time added for clarification, repetition, reinforcement, and questions from the patient and family. The nurse needs to convey a nonjudgmental attitude to enable the patient and family to discuss options and their feelings about those options. Team conferences are helpful for sharing information and providing every team member the opportunity to discuss the needs of the patient and family.

Home Hemodialysis

Most patients who undergo hemodialysis do so in an outpatient setting, but home hemodialysis is an option for some. Home hemodialysis requires a highly motivated patient who is willing to take responsibility for the procedure and is able to adjust each treatment to meet the body's changing needs. It also requires the commitment and cooperation of a caregiver to assist the patient. However, many patients are not comfortable imposing on others this way and do not wish to subject family members to the feeling that their home is being turned into a clinic. The health care team never forces a patient to use home hemodialysis, because this treatment requires changes in the home and family. Home hemodialysis must be the patient's and family's decision (Wright & Wilson, 2015).

The patient undergoing home hemodialysis and the caregiver assisting that patient must be trained to prepare, operate, and disassemble the dialysis machine; maintain and clean the equipment; administer medications (e.g., heparin) into the machine lines; and handle emergency problems (hemodialysis dialyzer rupture, electrical or mechanical problems, hypotension, shock, and seizures) (Tennankore, d'Gama, Faratro, et al., 2015). Because home hemodialysis places primary responsibility for the treatment on the patient and the family member, they must understand and be capable of performing all aspects of the hemodialysis procedure.

Before home hemodialysis is initiated, the home environment, household and community resources, and ability and willingness of the patient and family to carry out this treatment are assessed. The home is surveyed to see if electrical outlets, plumbing facilities, and storage space are adequate. Modifications may be needed to enable the patient and assistant to perform dialysis safely and to deal with emergencies.

Once home hemodialysis is initiated, the home care nurse must visit periodically to evaluate compliance with the recommended techniques, to assess the patient for complications, to reinforce previous instruction, and to provide reassurance.

Continuing and Transitional Care

The health care team's goal in treating patients with CKD is to maximize their vocational potential, functional status, and quality of life (Wright & Wilson, 2015). To facilitate renal rehabilitation, appropriate follow-up and monitoring by members of the health care team (physicians, dialysis nurses,

Chart 44-9 HOME CARE CHECKLIST

The Patient Undergoing Hemodialysis

At the completion of education, the patient and/or caregiver will be able to:

- Discuss kidney disease and its effects on the body.
- State the goal and purpose of hemodialysis and its impact on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Discuss common problems that may occur during hemodialysis and their prevention and management.
- State the name, dose, side effects, frequency, and schedule for all medications on dialysis and nondialysis days.
- Describe commonly measured laboratory values, results, and implications.
- State changes in lifestyle (e.g., diet, activity) necessary to maintain health.
  - Acknowledge dietary and fluid restrictions, rationale, and consequences of nonadherence.
  - State dietary restrictions and changes required to provide adequate protein, calorie, vitamin, and mineral intake.
- List guidelines for prevention and detection of fluid overload, meaning of "dry" weight, and how to weigh self.
- Demonstrate vascular access care, how to check patency, signs and symptoms of infection, and prevention of complications.
- Develop strategies to manage or reduce anxiety and maintain independence.
- Discuss strategies for detection, management, and relief of pruritus, neuropathy, and other potential complications of kidney disease.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Coordinate financial arrangements for hemodialysis and strategies to identify and obtain resources.
- Identify sources of support (e.g., friends, relatives, faith community, support groups, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

social worker, psychologist, home care nurses, and others as appropriate) are essential to identify and resolve problems early on. Many patients with chronic kidney disease can resume relatively normal lives, doing the things that are important to them: traveling, exercising, working, or actively participating in family activities. If appropriate interventions are available early in the course of dialysis, the potential for better health improves, and the patient can remain active in family and community life. Outcome goals for renal rehabilitation include employment for those able to work, improved physical functioning of all patients, improved understanding about adaptation and options for living well, increased control over the effects of kidney disease and dialysis, and resumption of activities enjoyed before dialysis.

Continuous Renal Replacement Therapies

Continuous renal replacement therapies (CRRTs) may be indicated for patients with acute or chronic kidney disease who are too clinically unstable for traditional hemodialysis, for patients with fluid overload secondary to oliguric (low urine output) kidney disease, and for patients whose kidneys cannot handle their acutely high metabolic or nutritional needs. Some forms of CRRT may not require dialysis machines or dialysis personnel to carry out the procedures and can be initiated quickly. Several types of CRRT are available and widely used in critical care units (see Fig. 44-8). The methods are similar, as they require access to the circulation and blood to pass through an artificial filter. A hemofilter (an extremely porous blood filter containing a semipermeable membrane) is used in all types.

Continuous Venovenous Hemofiltration

Continuous venovenous hemofiltration (CVVH) is often used to manage AKI. Blood from a double-lumen venous catheter is pumped (using a small blood pump) through a hemofilter and then returned to the patient through the same catheter (Richardson & Whatmore, 2015). CVVH provides continuous slow fluid removal (**ultrafiltration**); therefore, hemodynamic effects are mild and better tolerated by patients with unstable conditions. CVVH requires a dual-lumen venous catheter and critical care nurses trained in management of the therapy who can set up, initiate, maintain, and terminate the system. Many hospitals have developed a collaborative approach to managing the CVVH therapy between the critical care and nephrology nursing staff.

Continuous Venovenous Hemodialysis

Continuous venovenous hemodialysis (CVVHD) is similar to CVVH. Blood is pumped from a double-lumen venous catheter through a hemofilter and returned to the patient through the same catheter. In addition to the benefits of **ultrafiltration**, CVVHD uses a concentration gradient to facilitate the removal of uremic toxins and fluid by adding a dialysate solution into the circuit. A dual-lumen venous catheter is required; hemodynamic effects are usually mild; and critical care nurses can set up, initiate, maintain, and terminate the system with the support of the nephrology nursing staff.

Peritoneal Dialysis

The goals of PD are to remove toxic substances and metabolic wastes and to reestablish normal fluid and electrolyte balance. PD may be the treatment of choice for patients with kidney disease who are unable or unwilling to undergo hemodialysis or kidney transplantation. Patients who are susceptible to the rapid fluid, electrolyte, and metabolic changes that occur during hemodialysis experience fewer of these problems with the slower rate of PD. Therefore, patients with diabetes or cardiovascular disease, many older patients, and those who may be at risk for

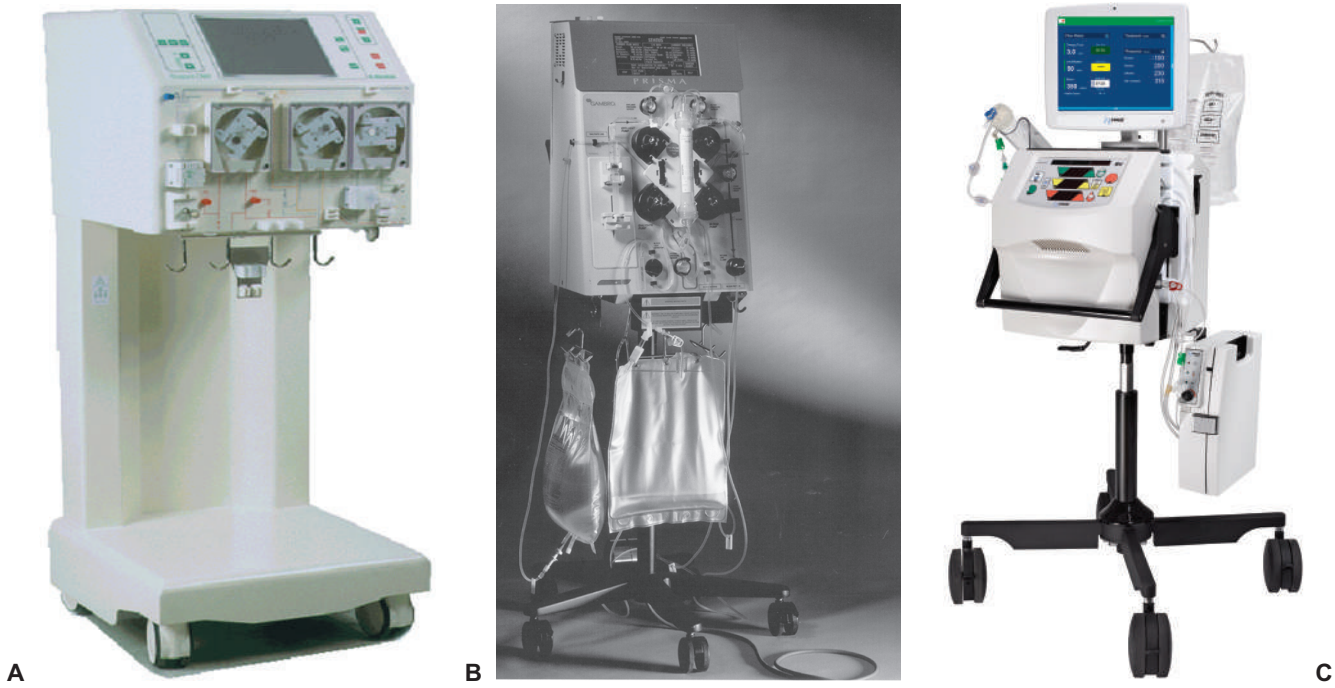

Figure 44-8 • Devices for administering continuous renal replacement therapy (CRRT) offer an integrated fluid warmer for the heating of infusion and dialysate fluids, a weighing system to reduce the possibility of error in assessing fluid balance, and a battery backup that allows treatments to continue when the patient is moved. **A.** Diapact CRRT System, B-Braun Medical, Inc., Bethlehem, PA. **B.** PRISMA, Gambro Corporation, Lakewood, CO. **C.** System One, NxStage Medical Inc., Lawrence, MA.

adverse effects of systemic heparin are likely candidates for PD. In addition, severe hypertension, heart failure, and pulmonary edema not responsive to usual treatment regimens have been successfully treated with PD. Fewer than 8% of patients with ESKD receive PD as their treatment modality (USRDS, 2015).

In PD, the peritoneal membrane that covers the abdominal organs and lines the abdominal wall serves as the semipermeable membrane. A sterile dextrose dialysate fluid is introduced into the peritoneal cavity through an abdominal catheter at established intervals (see Fig. 44-9). Once the sterile solution is in the peritoneal cavity, uremic toxins such as urea and creatinine begin to be cleared from the blood. Diffusion and osmosis occur as waste products move from an area of higher concentration (the bloodstream) to an area of lesser concentration (the dialysate fluid) through a semipermeable membrane (the peritoneum). This movement of solute from the blood into the dialysate fluid is called clearance. Because substances cross the peritoneal membrane at different rates, adjustments in solution dwell time in the peritoneal cavity and amount of fluid used are made to facilitate the process. **Ultrafiltration** (water removal) occurs in PD through an osmotic gradient created by using a dialysate fluid with a higher glucose concentration than the blood.

Procedure

As with other forms of treatment, the decision to begin PD is made by the patient and family in consultation with the primary provider. The patient may be acutely ill, thus requiring short-term treatment to correct severe disturbances in fluid and electrolyte status, or may have ESKD and need to receive ongoing treatments.

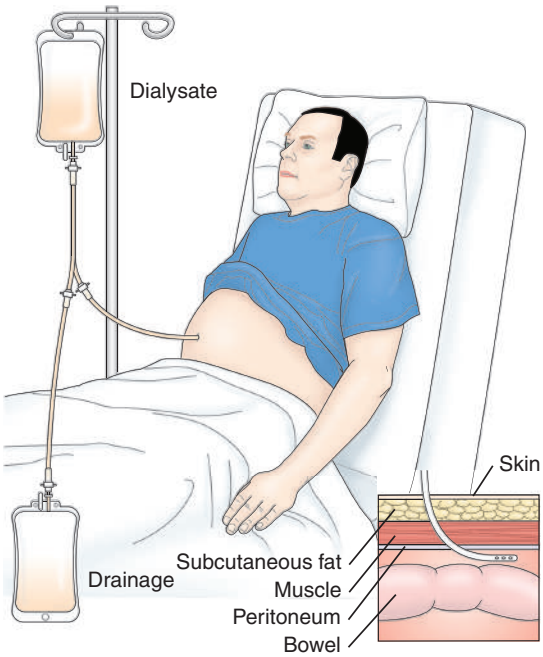

Figure 44-9 • In peritoneal dialysis and in acute intermittent peritoneal dialysis, dialysate is infused into the peritoneal cavity by gravity, after which the clamp on the infusion line is closed. After a dwell time (when the dialysate is in the peritoneal cavity), the drainage tube is unclamped and the fluid drains from the peritoneal cavity, again by gravity. A new container of dialysate is infused as soon as drainage is complete. The duration of the dwell time depends on the type of peritoneal dialysis.

Preparing the Patient

The nurse's preparation of the patient and family for PD depends on the patient's physical and psychological status, level of alertness, previous experience with dialysis, and understanding of and familiarity with the procedure.

The nurse explains the procedure to the patient and assists in obtaining signed consent for insertion of the catheter. Baseline vital signs, weight, and serum electrolyte levels are recorded. Evaluation of the abdomen for placement of the catheter is done to facilitate self-care. Typically, the catheter is placed on the nondominant side to allow the patient easier access to the catheter connection site when exchanges are done. The patient is encouraged to empty the bladder and bowel to reduce the risk of puncture of internal organs during the insertion procedure. Broad-spectrum antibiotic agents may be given to prevent infection. The peritoneal catheter can be inserted in interventional radiology, in the operating room, or at the bedside. Depending on the situation, this will need to be explained to the patient and family.

Preparing the Equipment

In addition to assembling the equipment for PD, the nurse consults with the physician to determine the concentration of dialysate to be used and the medications to be added. Heparin may be added to prevent fibrin formation and resultant occlusion of the peritoneal catheter. Potassium chloride may be prescribed to prevent hypokalemia. Antibiotic agents may be added to treat peritonitis (inflammation of the peritoneal membrane) caused by infection. Regular insulin may be added for patients with diabetes due to the high dextrose concentration of the PD solution. Aseptic technique is imperative whenever medications are added to the PD solution.

Before medications are added, the dialysate is warmed to body temperature to prevent patient discomfort and abdominal pain and to dilate the vessels of the peritoneum to increase urea clearance. Solutions that are too cold cause pain, cramping, and vasoconstriction and reduce clearance. Dry heating (heating cabinet, incubator, or heating pad) is recommended. Methods not recommended include soaking the bags of solution in warm water (can introduce bacteria to the exterior of the bags of solution and increase the chance of peritonitis) and the use of a microwave oven to heat the fluid (increases the danger of burning the peritoneum).

Immediately before initiating dialysis, using aseptic technique, the nurse assembles the administration set and tubing. The tubing is filled with the prepared dialysate to reduce the amount of air entering the catheter and peritoneal cavity, which could increase abdominal discomfort and interfere with instillation and drainage of the fluid.

Inserting the Catheter

Ideally, the peritoneal catheter is inserted in the operating room or radiology suite to maintain surgical asepsis and minimize the risk of contamination. Catheters for long-term use are usually soft and flexible and made of silicone with a radiopaque strip to permit visualization on x-ray. These catheters have three sections: (1) an intraperitoneal section, with numerous openings and an open tip to allow dialysate to flow freely; (2) a subcutaneous section that passes from the peritoneal membrane and tunnels through muscle and subcutaneous fat to the skin; and (3) an external section for connection to the dialysate and tubing system. Most of these catheters have 2 cuffs made of Dacron polyester. The cuffs stabilize the catheter, limit movement,

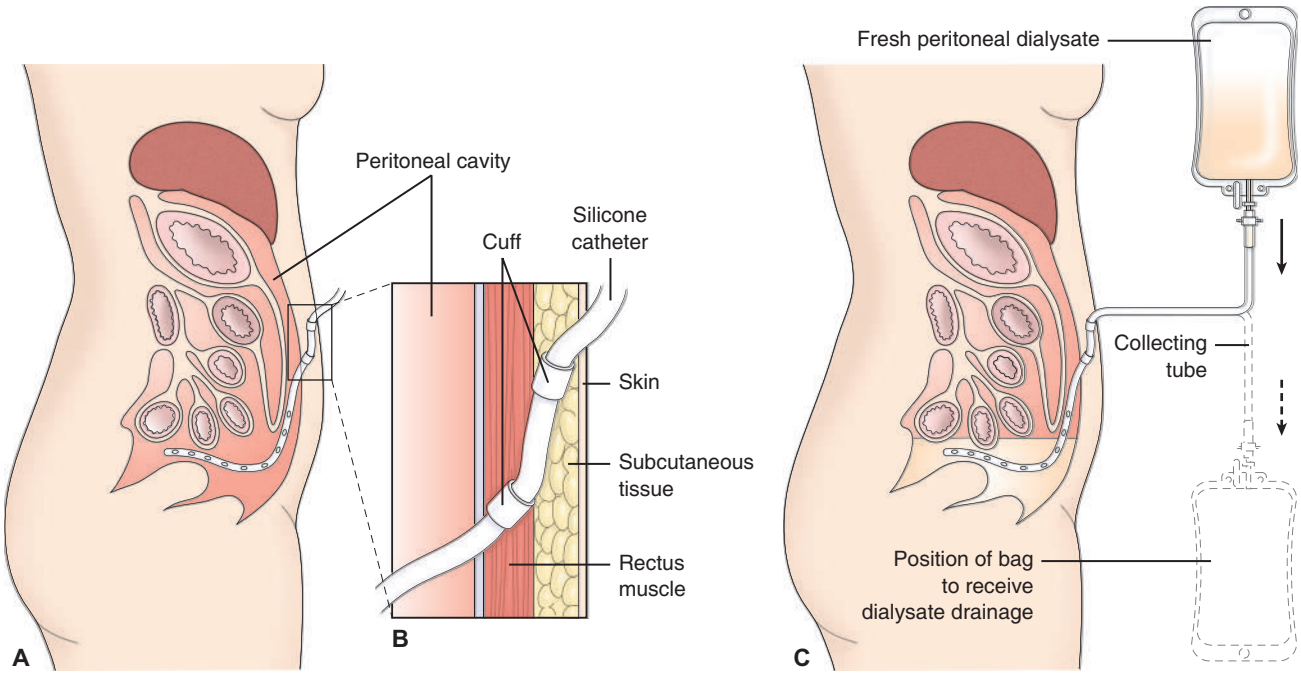

Figure 44-10 • Continuous ambulatory peritoneal dialysis. **A.** The peritoneal catheter is implanted through the abdominal wall. **B.** Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. **C.** Dialysate flows by gravity through the peritoneal catheter into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. New solution is then infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis, during which the patient is free to move around and engage in their usual activities.

prevent leaks, and provide a barrier against microorganisms. One cuff is placed just distal to the peritoneum, and the other cuff is placed subcutaneously. The subcutaneous tunnel (5 to 10 cm long) further protects against bacterial infection (see Fig. 44-10).

Performing the Exchange

PD involves a series of exchanges or cycles. An exchange is the entire cycle including the infusion (fill), dwell, and drainage of the dialysate. This cycle is repeated throughout the course of the dialysis. The dialysate is infused by gravity into the peritoneal cavity. A period of about 5 to 10 minutes is usually required to infuse 2 to 3 L of fluid. The prescribed dwell, or equilibration, time allows diffusion and osmosis to occur. At the end of the dwell time, the drainage portion of the exchange begins. The tube is unclamped, and the solution drains from the peritoneal cavity by gravity through a closed system. Drainage is usually completed in 10 to 20 minutes. The drainage fluid is normally colorless or straw colored and should not be cloudy. Bloody drainage may be seen in the first few exchanges after insertion of a new catheter but should not occur after that time. The number of cycles or exchanges and their frequency are prescribed based on monthly laboratory values and the presence of uremic symptoms. The exchanges can be performed manually during the waking hours by the patient (continuous ambulatory peritoneal dialysis [CAPD]) or via the use of a PD machine (cycler) that automatically performs exchanges, usually while the patient is sleeping at night (continuous cycling peritoneal dialysis [CCPD]).

The removal of excess water during PD occurs because dialysate has a high dextrose concentration, making it hypertonic. An osmotic gradient is created between the blood and the dialysate solution. Dextrose solutions of 1.5%, 2.5%, and 4.25% are available in several volumes, from 1000 to 3000 mL. The higher the dextrose concentration, the greater the osmotic gradient and the more water will be removed. Selection of the appropriate solution is based on the patient's fluid status.

Complications

Most complications of PD are often minor; however, several, if unattended, can have serious consequences.

Acute Complications

Peritonitis

Peritonitis is the most common and serious complication of PD. The first sign of peritonitis is cloudy dialysate drainage fluid. Diffuse abdominal pain and rebound tenderness occur much later. Hypotension and other signs of shock may also occur with advancing infection. The patient with peritonitis may be treated as an inpatient or outpatient (most common), depending on the severity of the infection and the patient's clinical status. Drainage fluid is examined for cell count; Gram stain and culture are used to identify the organism and guide treatment. Antibiotic agents (aminoglycosides or cephalosporins) are usually added to subsequent exchanges until Gram stain or culture results are available for appropriate antibiotic determination. Intraperitoneal administration of antibiotic agents is as effective as IV administration and therefore most often used. Antibiotic therapy continues for 10 to 14 days (Figueiredo, 2014). Careful selection and calculation of the antibiotic dosage are needed to prevent nephrotoxicity and further compromise of residual renal function.

Regardless of the organism causing peritonitis, the patient loses large amounts of protein through the peritoneum. Acute malnutrition and delayed healing may result. Therefore, attention must be given to detecting and promptly treating peritonitis.

Leakage

Leakage of dialysate through the catheter site may occur immediately after the catheter is inserted. Usually, the leak stops spontaneously if dialysis is withheld for several days, giving the

tissue surrounding the cuffs located on the abdominal catheter a chance to infiltrate the Dacron and seal the insertion tunnel. It also allows the exit site time to heal. During this time, it is important to reduce factors that might delay healing, such as undue abdominal muscle activity and straining during bowel movement. In many cases, leakage can be avoided by using small volumes (500 mL) of dialysate, gradually increasing the volume up to 2000 to 3000 mL.

Bleeding

A bloody effluent (drainage) may be observed occasionally, especially in young, menstruating women. (The hypertonic fluid pulls blood from the uterus, through the opening in the fallopian tubes, and into the peritoneal cavity.) Bleeding is also common during the first few exchanges after a new catheter insertion because some blood enters the abdominal cavity following insertion. In many cases, no cause can be found for the bleeding, although catheter displacement from the pelvis has occasionally been associated with bleeding. Some patients have had bloody effluent after an enema or from minor trauma. Most often, bleeding stops in 1 to 2 days and requires no specific intervention. More frequent exchanges and the addition of heparin to the dialysate during this time may be necessary to prevent blood clots from obstructing the catheter.

Long-Term Complications

Hypertriglyceridemia is common in patients undergoing long-term PD, suggesting that the therapy may accelerate atherogenesis. Cardiovascular disease is the leading cause of morbidity and mortality in patients with kidney failure, and many patients have suboptimal blood pressure control. Beta-blockers and ACE inhibitors should be used to control hypertension or protect the heart, and the use of aspirin and statins should be considered (James, Oparil, Carter, et al., 2014).

Other complications that may occur with long-term PD include abdominal hernias (incisional, inguinal, diaphragmatic, and umbilical), probably resulting from continuously increased intra-abdominal pressure. The persistently elevated intra-abdominal pressure also aggravates symptoms of hiatal hernia and hemorrhoids. Low back pain and anorexia from fluid in the abdomen and a constant sweet taste related to glucose absorption may also occur.

Mechanical problems occasionally occur and may interfere with instillation or drainage of the dialysate. Formation of clots in the peritoneal catheter and constipation are factors that may contribute to these problems.

Approaches

PD can be performed using several different approaches: acute intermittent peritoneal dialysis, CAPD, and CCPD.

Acute Intermittent Peritoneal Dialysis

Indications for acute intermittent PD, a variation of PD, include uremic signs and symptoms (nausea, vomiting, fatigue, altered mental status), fluid overload, acidosis, and hyperkalemia. Although PD is not as efficient as hemodialysis in removing solute and fluid, it permits a more gradual change in the patient's fluid volume status and in waste product removal. Therefore, it may be the treatment of choice for the hemodynamically unstable patient. It can be carried out manually (the nurse warms, spikes, and hangs each container of dialysate) or by a cycler machine. Exchange times range from 30 minutes to 2 hours. One routine is hourly exchanges consisting of a 10-minute infusion, a 30-minute dwell time, and a 20-minute drain time (Figueiredo, 2014).

Maintaining the PD cycle is a nursing responsibility. Aseptic technique is maintained when changing solution containers and emptying drainage containers. Vital signs, weight, I&O, laboratory values, and patient status are frequently monitored. The nurse uses a flow sheet or the electronic medical record to document each exchange and records vital signs, dialysate concentration, medications added, exchange volume, dwell time, dialysate fluid balance for each exchange (fluid lost or gained), and cumulative fluid balance. The nurse also carefully assesses skin turgor and mucous membranes to evaluate fluid status and monitor the patient for edema.

Nursing Alert: If the peritoneal fluid does not drain properly, the nurse can facilitate drainage by turning the patient from side to side or raising the head of the bed. The catheter should never be pushed further into the peritoneal cavity.

Other measures to promote drainage include checking the patency of the catheter by inspecting for kinks, closed clamps, or an air lock. The nurse monitors for complications, including peritonitis, bleeding, respiratory difficulty, and leakage of peritoneal fluid. Abdominal girth may be measured periodically to determine if the patient is retaining large amounts of dialysis solution. In addition, the nurse must ensure that the PD catheter remains secure and that the dressing remains dry. Physical comfort measures, frequent turning, and skin care are provided. The patient and family are educated about the procedure and are kept informed about progress (fluid loss, weight loss, laboratory values). Emotional support and encouragement are given to the patient and family during this stressful and uncertain time.

Continuous Ambulatory Peritoneal Dialysis

Continuous Ambulatory Peritoneal Dialysis (CAPD) is the second most common form of dialysis for patients with ESKD (USRDS, 2015). CAPD is performed at home by the patient or a trained caregiver who is usually a family member. The procedure allows the patient reasonable freedom and control of daily activities but requires a serious commitment to be successful. Chart 44-10 discusses suitability for CAPD.

CAPD works on the same principles as other forms of PD: diffusion and osmosis. Less extreme fluctuations in the patient's laboratory values occur with CAPD than with intermittent PD or hemodialysis because the dialysis is constantly in progress. The serum electrolyte levels usually remain in the normal range.

Procedure

The patient performs exchanges 4 or 5 times a day, 24 hours a day, 7 days a week, at intervals scheduled throughout the day. Different manufacturers supply different equipment. A Y-shaped system is most commonly used, in which a bag containing dialysate solution comes connected to one branch of the "Y" and a sterile empty bag is connected to the second branch. This leaves the third part of the "Y" open and available for connection to the transfer set on the PD catheter. To perform an exchange, the patient (or person doing the exchange) washes their hands, dons a mask, and then removes the cap from the transfer set while maintaining sterility. The open end of the "Y" set is connected to the end of the transfer set and the dialysate infused where it will dwell. After the dialysate is infused, the patient clamps off the transfer set and the tubing set, disconnects the tubing set, and applies a new cap to the transfer set, making

Chart 44-10

Considerations in Continuous Ambulatory Peritoneal Dialysis

Although continuous ambulatory peritoneal dialysis (CAPD) is not suitable for all patients with end-stage kidney disease (ESKD), it is a viable therapy for those who can perform self-care and fluid exchanges and fit therapy into their own routines. Often, patients report having more energy and feeling healthier once they begin CAPD. Nurses can be instrumental in helping patients with ESKD find the dialysis therapy that best suits their lifestyle. Those considering CAPD need to understand the advantages and disadvantages along with the indications and contraindications for this form of therapy.

Advantages

- Freedom from a hemodialysis machine
- Control over daily activities
- Opportunities to eat a more liberal diet than allowed with hemodialysis, increase fluid intake, raise serum hematocrit values, improve blood pressure control, avoid venipuncture, and gain a sense of well-being

Disadvantages

- Continuous dialysis 24 hours a day, 7 days a week
- Dietary alterations related to protein and potassium losses. Patients may be encouraged to increase the intake of protein and potassium in the diet due to these losses with peritoneal dialysis fluid exchanges

Indications

- Patient's willingness, motivation, and ability to perform dialysis at home
- Strong family or community support system (essential for success), particularly if the patient is an older adult
- Special problems with long-term hemodialysis, such as dysfunctional or failing vascular access devices, excessive thirst, severe hypertension, postdialysis headaches, and severe anemia requiring frequent transfusion
- Interim therapy while awaiting kidney transplantation
- ESKD secondary to diabetes because hypertension, uremia, and hyperglycemia are easier to manage with CAPD than with hemodialysis

Contraindications

- Adhesions from previous surgery (adhesions reduce clearance of solutes) or systemic inflammatory disease
- Chronic backache and pre-existing disc disease, which could be aggravated by the continuous pressure of dialysis fluid in the abdomen
- Severe arthritis or poor hand strength necessitating assistance in performing the exchange. However, patients who are blind or partially blind and those with other physical limitations can learn to perform CAPD

it a closed system. The patient drains the fluid (effluent) from the peritoneal cavity through the catheter (over about 20 to 30 minutes) into an empty bag. Once the effluent has been fully drained, fresh fluid is instilled into the peritoneal cavity.

The longer the dwell time, the better the clearance of uremic toxins. If dwell time is excessive, the patient will absorb some of the effluent back into the body simply because the osmotic gradient is lost. Once equilibrium is reached, the movement of fluid and toxins stops.

Complications

To reduce the risk of peritonitis, the patient (and all caregivers) must use meticulous care to avoid contaminating the catheter, fluid, or tubing and to avoid accidentally disconnecting the catheter from the tubing. Whenever a connection or disconnection is made, hand hygiene must be used and a mask worn by anyone within 6 ft of the area to avoid contamination with airborne bacteria. Excess manipulation should be avoided, and meticulous care of the catheter entry site is provided using a standardized protocol.

Continuous Cyclic Peritoneal Dialysis

Continuous cyclic peritoneal dialysis (CCPD) uses a machine called a cycler to provide the fluid exchanges. It is programmed to deliver an established amount of PD solution that will dwell in the peritoneal cavity for a programmed period of time before it drains from the peritoneal cavity via gravity. The cycler is also set to deliver a specific number of fluid changes in a designated period of time. Because it is programmed, it also keeps track of the total amounts removed and will sound an alarm if limits are not met. It requires that a person set up and break down the system for use, which typically takes about 15 minutes.

CCPD combines overnight intermittent PD with a prolonged dwell time during the day. The peritoneal catheter is connected to a cycler machine every evening, usually just before the patient goes to sleep for the night. Because the machine is very quiet, the patient can sleep, and the extra-long tubing allows the patient to move and turn normally during sleep.

In the morning, the patient disconnects from the cycler. Sometimes, dialysate is left in the abdominal cavity for a longer day dwell cycle. This day exchange is drained during the day either by using a "Y" set or reattaching to the cycler. This process is done every day to achieve the effects of dialysis required.

CCPD has a lower infection rate than other forms of PD because there are fewer opportunities for contamination with bag changes and tubing disconnections (Hain & Chan, 2013). It also allows the patient to be free from exchanges throughout the day, making it possible to engage in work and activities of daily living more freely.

Nursing Management

Meeting Psychosocial Needs

In addition to the complications of PD described previously, patients who elect to do PD may experience altered body image because of the presence of the abdominal catheter, bag, tubing, and cycler. Waist size increases from 1 to 2 inches (or more) with fluid in the abdomen. This affects clothing selection and may make the patient feel "fat." Body image may be threatened if patients do not want to look at or care for the catheter. The nurse may arrange for the patient to talk with other patients who have adapted well to PD. Although some patients have no psychological problems with the catheter—they think of it as their lifeline and as a life-sustaining device—other patients feel they are doing exchanges all day long and have no free time, particularly in the beginning. They may experience depression because they feel crushed with the responsibility of self-care.

Patients undergoing PD may also experience altered sexuality patterns and sexual dysfunction. The patient and partner may be reluctant to engage in sexual activities, partly

because of the catheter being psychologically "in the way" of sexual performance. The peritoneal catheter, drainage bag, and about 2 L of dialysate may interfere with the patient's sexual function and body image as well. In patients on CCPD, the presence of the dialysis cycler in the bedroom and the continual connection during the sleeping hours can also cause interference with intimacy. Although these problems may resolve with time, some problems may warrant special counseling. Questions by the nurse about concerns related to sexuality and sexual function often provide the patient with a welcome opportunity to discuss these issues and a first step toward their resolution.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patients are educated as inpatients or outpatients to perform PD once their condition is medically stable. Education usually takes 5 days to 2 weeks. Patients are taught according to their own learning ability and knowledge level and only as much at one time as they can handle without feeling uncomfortable or becoming saturated. Education topics for the patient and family who will be performing PD at home are described in Chart 44-11. The use of an adult learning theory–based curriculum may decrease peritonitis and exit site infection rates (Hain & Chan, 2013).

Because of protein loss with continuous PD, the patient is instructed to eat a high-protein, nutritious diet. The patient is also encouraged to increase their daily fiber intake to help prevent constipation, which can impede the flow of dialysate into or out of the peritoneal cavity. Many patients gain 1 to 2 Kg within a month of initiating PD, so they may be asked to limit their carbohydrate intake to avoid excessive weight gain. Potassium, sodium, and fluid restrictions are not usually needed. Patients commonly lose about 2 to 3 L of fluid over and above the volume of dialysate infused into the abdomen during a 24-hour period, permitting a normal fluid intake even in a patient who is without functional kidneys.

Continuing and Transitional Care

Follow-up care through phone calls, visits to the dialysis clinic, outpatient department, and continuing home care assists patients in the transition to home and promotes their active participation in their own health care. Patients often check with the nurse to see if they are making the correct choices about dialysate or control of blood pressure, or simply to discuss a problem.

Patients may be seen by the PD team as outpatients once a month or more often if needed. The exchange procedure is evaluated at that time to see that strict aseptic technique is being used. Blood chemistry values are followed closely to make certain the therapy is adequate for the patient.

If a referral is made for home care, the home care nurse assesses the home environment and suggests modifications to accommodate the equipment and facilities needed to carry out PD. In addition, the nurse assesses the patient's and family's understanding of PD and evaluates their technique in performing PD. Assessments include checking for changes related to kidney disease; complications such as peritonitis; and treatment-related problems such as heart failure, inadequate drainage, and weight gain or loss. The nurse continues to reinforce and clarify education about PD and ESKD and assesses the patient's and family's progress in coping with the procedure. This is also an opportunity to remind patients about the need to participate in appropriate health promotion activities and health screening (e.g., gynecologic examinations, colonoscopy).

Chart 44-11 HOME CARE CHECKLIST

Peritoneal Dialysis, Continuous Ambulatory Peritoneal Dialysis, or Continuous Cycling Peritoneal Dialysis

At the completion of education, the patient and/or caregiver will be able to:

- Discuss kidney disease and its effects on the body.
- State the goal and purpose of dialysis and its impact on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- Describe the basic principles of peritoneal dialysis (PD) and exchange options such as continuous ambulatory peritoneal dialysis (CAPD), or continuous cycling peritoneal dialysis (CCPD).
- State what types of changes are needed (if any) to support home PD therapy and maintain a clean home environment and prevent infection.
- State how to contact the primary provider, the team of home care professionals overseeing care, and supply vendor.
  - Discuss ordering, storage, and inventory of dialysis supplies.
  - List emergency phone numbers.
- State the name, dose, side effects, frequency, and schedule for all medications.
  - Demonstrate procedure for adding medications to the dialysis solution.
- Demonstrate catheter and exit site care.
- Demonstrate measurement of vital signs and weight measurement.
- Discuss monitoring and management of fluid balance.
- Discuss basic principles of aseptic technique.
- Demonstrate the CAPD or CCPD exchange procedure using aseptic technique (patients receiving CCPD should also demonstrate exchange procedure in case of failure or unavailability of cycling machine) and discuss cycling machine warning signals and how to address these signals.
- Demonstrate maintenance of home dialysis records.
- Demonstrate procedure for obtaining sterile peritoneal dialysis fluid samples.
- Discuss routine laboratory tests needed and implications of results.
- Discuss high protein diet and diet to avoid constipation, any other dietary restrictions as indicated.
- Discuss complications of peritoneal dialysis; prevention, recognition, and management of complications.
- Describe actions in case of emergency.
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Coordinate financial arrangements for peritoneal dialysis and strategies to identify and obtain resources.
- Identify sources of support (e.g., friends, relatives, faith community, support groups, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

Special Considerations: Nursing Management of the Patient on Dialysis Who Is Hospitalized

Whether undergoing hemodialysis or PD, the patient may be hospitalized for treatment of complications related to the dialysis treatment, the underlying kidney disorder, or health problems not related to renal dysfunction or its treatment.

Protecting Vascular Access

When the patient undergoing hemodialysis is hospitalized for any reason, care must be taken to protect the vascular access. The nurse assesses the vascular access for patency and takes precautions to ensure that the extremity with the vascular access is not used for measuring blood pressure or for obtaining blood specimens; tight dressings, restraints, or jewelry over the vascular access must be avoided as well (Arslanian, 2015).

The bruit, or "thrill," over the venous access site must be evaluated at least every shift. Absence of a palpable thrill or audible bruit may indicate blockage or clotting in the vascular access. Clotting can occur if the patient has an infection anywhere in the body (serum viscosity increases) or if the blood pressure has dropped. When blood flow is reduced through the access for any reason (hypotension, application of blood pressure cuff or tourniquet), the access can clot. If a patient has a hemodialysis catheter or implanted hemodialysis access device, the nurse must observe for signs and symptoms of infection such as redness, swelling, drainage from the exit site, fever, and chills. The nurse must assess the integrity of the dressing and change it as needed. Patients with kidney disease are more prone to infection; therefore, appropriate infection control measures must be used for all procedures. The patient's vascular access device should not be used for any purpose other than dialysis, unless it is an emergency situation and no other access is available. In this situation, a dialysis nurse or physician should cannulate the vascular access.

Taking Precautions During Intravenous Therapy

When the patient needs IV therapy, the rate of administration must be as slow as possible. Accurate I&O records are essential.

Nursing Alert: Because patients on dialysis cannot excrete water, rapid administration of IV fluid can result in pulmonary edema.

Monitoring Symptoms of Uremia

As metabolic end products accumulate, symptoms of uremia worsen. Patients whose metabolic rate accelerates (those receiving corticosteroid medications or parenteral nutrition, those with infections or bleeding disorders, those undergoing surgery) accumulate waste products more quickly and may require daily dialysis. These same patients are more likely than other patients receiving dialysis to experience complications.

Detecting Cardiac and Respiratory Complications

Cardiac and respiratory assessment must be conducted frequently. As fluid builds up, fluid overload, heart failure, and pulmonary edema develop. Crackles in the bases of the lungs may indicate pulmonary edema.

Pericarditis may result from the accumulation of uremic toxins. If not detected and treated promptly, this serious complication may progress to pericardial effusion and cardiac tamponade. Pericarditis is detected by the patient's report of substernal chest pain (if the patient can communicate), low-grade fever, and pericardial friction rub. A pulsus paradoxus (a decrease in blood pressure of more than 10 mm Hg during inspiration) is often present. When pericarditis progresses to effusion, the friction rub disappears, heart sounds become distant and muffled, ECG waves show very low voltage, and the pulsus paradoxus worsens (Yamamoto, Shoji, Yamakawa, et al., 2015).

The effusion may progress to life-threatening cardiac tamponade, noted by narrowing of the pulse pressure in addition to muffled or inaudible heart sounds, crushing chest pain, dyspnea, and hypotension.

Nursing Alert: Although pericarditis, pericardial effusion, and cardiac tamponade can be detected by chest x-ray, they should also be detected through astute nursing assessment. Because of their clinical significance, assessment of the patient for these complications is a priority.

Controlling Electrolyte Levels and Diet

Electrolyte alterations are common, and potassium changes can be life threatening. All IV solutions and medications to be given are evaluated for their electrolyte content. Serum laboratory values are assessed daily. If blood transfusions are required, they may be given during hemodialysis, if possible, so that excess potassium can be removed and hypervolemia is avoided. Dietary intake must also be monitored. The patient's frustrations related to dietary restrictions typically increase if the food is unappetizing. The nurse needs to recognize that this may lead to dietary indiscretion and hyperkalemia.

Hypoalbuminemia is an indicator of malnutrition in patients undergoing long-term or maintenance dialysis. Although some patients can be treated with adequate nutrition alone, some patients remain hypoalbuminemic for reasons that are poorly understood.

Managing Discomfort and Pain

Complications such as pruritus and pain secondary to neuropathy must be managed. Antihistamine agents, such as diphenhydramine (Benadryl), are commonly used, and analgesic medications may be prescribed. However, because elimination of the metabolites of medications occurs through dialysis rather than through renal excretion, medication dosages may need to be adjusted. Keeping the skin clean and well moisturized using bath oils, superfatted soap, and creams or lotions helps promote comfort and reduce itching. Instructing the patient to keep the nails trimmed to avoid scratching and excoriation also promotes comfort.

Monitoring Blood Pressure

Hypertension in kidney disease is common. It is usually the result of fluid overload and, in part, oversecretion of renin. Many patients undergoing dialysis receive some form of antihypertensive therapy. Patients require detailed education and reinforcement of information regarding their antihypertensive regimen, because it is not uncommon for patients to need more than one antihypertensive agent. Rapid fluid fluctuations in patients receiving dialysis also create challenges to maintaining blood pressure control. Antihypertensive agents must be withheld before dialysis to avoid hypotension due to the combined effect of fluid removal with the dialysis treatment and the medication (Doss-McQuitty, 2014).

Typically, these patients require single or multiple antihypertensive agents to achieve normal blood pressure, thus adding to the total number of medications needed on an ongoing basis (James et al., 2014).

Preventing Infection

Patients with ESKD commonly have low WBC counts (and decreased phagocytic ability), low RBC counts (anemia), and impaired platelet function. Together, these pose a high risk of infection and potential for bleeding after even minor trauma. Preventing and controlling infection are essential because the incidence of infection is high. Infection of the vascular access site and pneumonia are common.

Caring for the Catheter Site

Patients receiving CAPD usually know how to care for the catheter site; however, the hospital stay is an opportunity to assess catheter care technique and correct misperceptions or deviations from recommended technique. Recommended daily or 3 or 4 times-weekly routine catheter site care is typically performed during showering or bathing (Hain & Chan, 2013). The exit site should not be submerged in bathwater. The most common cleaning method is soap and water; liquid soap is recommended. During care, the nurse and patient need to make sure that the catheter remains secure to avoid tension and trauma. The patient may wear a gauze or semitransparent dressing over the exit site.

Administering Medications

All medications and the dosage prescribed for any patient on dialysis must be closely monitored to avoid those that are toxic to the kidneys and may threaten remaining renal function. Medications are also scrutinized for potassium and magnesium content; those medications that contain them are avoided. Care must be taken to evaluate all problems and symptoms that the patient reports without automatically attributing them to kidney disease or to dialysis therapy.

Providing Psychological Support

Patients undergoing dialysis for a while may begin to reevaluate their status, the treatment modality, their satisfaction with life, and the impact of these factors on their families and support systems. Nurses must provide opportunities for these patients to express their feelings and reactions and to explore options. The decision to begin dialysis does not require that dialysis be continued indefinitely, and it is not uncommon for patients to consider discontinuing treatment. These feelings and reactions must be taken seriously, and the patient should have the opportunity to discuss them with the dialysis team as well as with a psychologist, psychiatrist, psychiatric nurse, trusted friend, or spiritual advisor. The patient's informed decision about discontinuing treatment, after thoughtful deliberation, should be respected.

KIDNEY SURGERY

A patient may undergo surgery to remove obstructions that affect the kidney (tumors or calculi), to insert a tube for draining the kidney (nephrostomy, ureterostomy), or to remove the kidney involved in unilateral kidney disease, renal carcinoma, or kidney transplantation.

Management of Patients Undergoing Kidney Surgery

Preoperative Considerations

Surgery is performed only after a thorough evaluation of renal function. Patient preparation to ensure that optimal renal function is maintained is essential. Fluids are encouraged to promote increased excretion of waste products before surgery unless contraindicated because of pre-existing renal or cardiac dysfunction. If kidney infection is present preoperatively, broad-spectrum antimicrobial agents may be prescribed to prevent bacteremia. Antibiotic agents must be given with extreme care because many are toxic to the kidneys. Coagulation studies (prothrombin time, partial thromboplastin time, platelet count) may be indicated if the patient has a history of bruising and bleeding. The preoperative preparation is similar to that described in Chapter 4.

Because many patients facing kidney surgery are apprehensive, the nurse encourages the patient to recognize and verbalize concerns. Confidence is reinforced by establishing a relationship of trust and by providing expert care. Patients faced with the prospect of losing a kidney may think that they will have to depend on dialysis for the rest of their lives. The nurse reassures the patient and family that normal function may be maintained by a single healthy kidney.

Perioperative Concerns

Kidney surgery requires various patient positions to expose the surgical site adequately. Three surgical approaches are common: flank, lumbar, and thoracoabdominal (see Fig. 44-11). During surgery, plans are carried out for managing altered urinary drainage. These may include inserting a nephrostomy or other drainage tube.

Postoperative Management

Because the kidney is a highly vascular organ, hemorrhage and shock are the chief potential complications of kidney surgery. Fluid and blood component replacement is frequently necessary in the immediate postoperative period to treat intraoperative blood loss.

Abdominal distention and paralytic ileus are fairly common after renal and ureteral surgery and are thought to be due to a reflex paralysis of intestinal peristalsis and manipulation of the colon or duodenum during surgery. Abdominal distention is relieved by decompression through a nasogastric tube. See Chapter 18 for treatment of paralytic ileus. Oral fluids are permitted when the passage of flatus is noted.

If infection occurs, antibiotics are prescribed after a culture reveals the causative organism. The toxic effects that antibiotic agents have on the kidneys (nephrotoxicity) must be kept in mind when assessing the patient. Low-dose heparin therapy may be initiated postoperatively to prevent thromboembolism in patients who have had any type of urologic surgery.

Nursing Management

In addition to those interventions listed in this section, Chart 44-12 provides a plan of nursing care for the patient undergoing kidney surgery.

Providing Immediate Postoperative Care

Immediate postoperative care of the patient who has undergone surgery of the kidney includes assessment of all body systems.

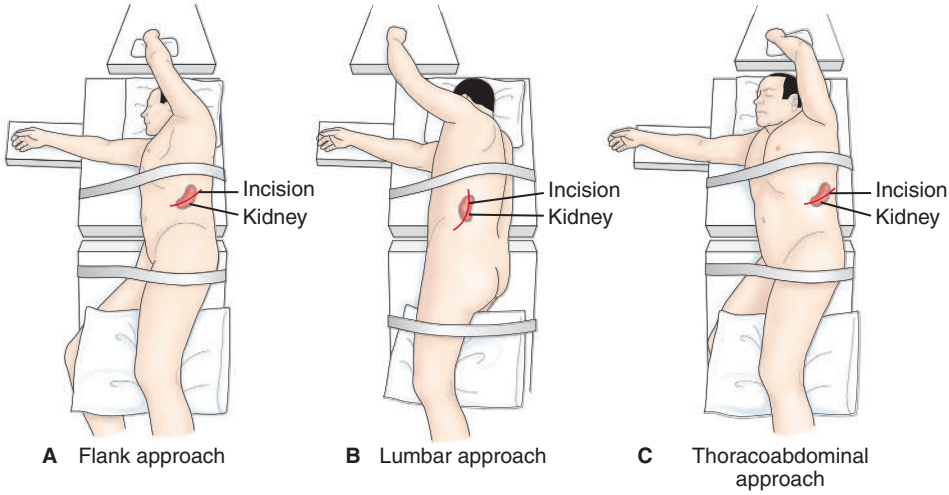

Figure 44-11 • Patient positioning and incisional approaches—flank (**A**), lumbar (**B**), thoracoabdominal (**C**)—for kidney surgery are associated with significant postoperative discomfort.

Chart 44-12 PLAN OF NURSING CARE

Care of the Patient Undergoing Kidney Surgery

NURSING DIAGNOSIS: Ineffective airway clearance related to pain of high abdominal or flank incision, abdominal discomfort, and immobility; risk for ineffective breathing pattern related to high abdominal incision
GOAL: Improved airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Assess respiratory status: a. Rate b. Breath sounds	1. Baseline data allow for monitoring of changes and evaluating effectiveness of interventions.	• Exhibits respiratory rate of 12–18 breaths/min and normal breath sounds without adventitious sounds
2. Administer analgesic agent as prescribed.	2. Adequate pain relief enables patient to take deep breaths and cough.	• Takes deep breaths and coughs adequately when encouraged and assisted sounds
3. Splint incision with hands or pillow to assist patient in coughing.	3. Splinting the incision promotes adequate cough thereby prevents atelectasis.	• Exhibits full thoracic excursion without shallow respirations
4. Assist patient to change positions frequently.	4. Promotes drainage and inflation of all lobes of the lungs.	• Uses incentive spirometer with encouragement
5. Encourage the use of incentive spirometer if indicated or prescribed.	5. Encourages adequate deep breaths.	• Splints incision while taking deep breaths and coughing
6. Assist with and encourage early ambulation.	6. Mobilizes pulmonary secretions.	• Reports progressively less pain and discomfort with coughing and deep breaths

NURSING DIAGNOSIS: Acute pain and discomfort related to surgical incision, positioning, and stretching of muscles during kidney surgery
GOAL: Relief of pain and discomfort

Nursing Interventions	Rationale	Expected Outcomes
1. Assess level of pain.	1. Provides baseline for later evaluation of pain relief strategies.	• Reports relief of severe pain and discomfort • Takes analgesia as prescribed
2. Administer analgesic agents as prescribed.	2. Promotes pain relief.	• Exercises aching muscles within recommendations
3. Splint incision with hands or pillow during movement or deep breathing and coughing exercises.	3. Minimizes sensation of pulling or tension on incision and provides sense of support to the patient.	• Uses distraction, relaxation exercises, and imagery to relieve pain
4. Assist and encourage early ambulation.	4. Promotes resumption of muscle activity exercise.	• Exhibits no behavioral manifestations of pain and discomfort (e.g., restlessness, perspiration, verbal expressions of pain)
5. Offer and educate patient how to use appropriate nonpharmacologic interventions.	5. Many nonpharmacologic interventions, such as distraction, relaxation exercises, and imagery assist patients to decrease their pain.	• Participates in deep-breathing and coughing exercises • Gradually increases physical activity and exercise

(Continued)

(Continued)

NURSING DIAGNOSIS: Fear and anxiety related to diagnosis, outcome of surgery, and alteration in urinary function
GOAL: Reduction of fear and anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's anxiety and fear before surgery if possible.	1. Provides a baseline for postoperative assessment.	• Verbalizes reactions and feelings to staff • Shares reactions and feelings with family or partner • Grieves appropriately for self and for changes in role and function • Identifies information needed to promote own adaptation and coping • Participates in activities and events in immediate environment • Accepts visit from support group if indicated • Identifies support person or support group
2. Assess patient's knowledge about procedure and expected surgical outcome preoperatively.	2. Provides a basis for further education.	
3. Evaluate the meaning of alterations resulting from surgical procedure for the patient and family or partner.	3. Enables understanding of patient's reactions and responses to expected and unexpected results of surgery.	
4. Encourage patient to verbalize reactions, feelings, and fears.	4. Affirms patient's understanding of and ultimate resolution of feelings and fears.	
5. Encourage patient to share feelings with spouse or partner.	5. Enables patient and partner to receive mutual support and reduces sense of isolation from each other.	
6. Offer and arrange for visit from member of support group (e.g., ostomy group, transplant group, if indicated).	6. Provides support from another person who has encountered the same or a similar surgical procedure and an example of how others have coped with the alteration.	

NURSING DIAGNOSIS: Impaired urinary elimination related to urinary drainage; risk for infection related to altered urinary drainage
GOAL: Maintenance of urinary elimination; infection-free urinary tract

Nursing Interventions	Rationale	Expected Outcomes
1. Assess urinary drainage system immediately.	1. Provides basis for further assessment and action.	• Exhibits adequate urinary output and patent drainage system • Exhibits urinary output consistent with fluid intake • Demonstrates normal laboratory values: blood urea nitrogen, serum creatinine levels, urine specific gravity, and osmolality • Exhibits sterile urine on urine culture • Exhibits clear, dilute urine without debris or encrustation in the drainage system • States rationale for avoiding manipulation of catheter, drainage, or irrigation system • Exhibits normal placement of urinary stent or ureteral catheters until removed by physician • Maintains closed urinary drainage system • Exhibits normal body temperature without signs or symptoms of urinary tract infection • Cleans catheter with soap and water • Consumes adequate fluid intake (6–8 glasses of water or more per day, unless contraindicated) • Urinary drainage system remains in place until physician removes or discontinues it • Maintains urinary drainage system without infection or obstruction • Maintains urinary diversion as instructed • Maintains self-care so that environment is odor free
2. Assess adequacy of urinary output and patency of drainage system.	2. Provides baseline.	
3. Assess pertinent laboratory values (see Table 43-5).	3. Provides basis for further assessment and action.	
4. Use asepsis and hand hygiene when providing care and manipulating drainage system.	4. Prevents or reduces risk of contamination of urinary drainage system.	
5. Maintain closed urinary drainage system.	5. Reduces risk of bacterial contamination and infection.	
6. If irrigation of the drainage system is necessary, use sterile gloves and sterile irrigating solution and a closed drainage and irrigation system.	6. Permits irrigation when necessary while maintaining closed drainage system, minimizing risk of infection.	
7. If irrigation is necessary and prescribed, perform it gently with sterile saline and the prescribed amount of irrigating fluid.	7. Maintains patency of the catheter or drainage system and prevents sudden increases in pressure in the urinary tract that may cause trauma, pressure on sutures or urinary tract structures, and pain.	
8. Assist patient in turning and moving in bed and when ambulating to prevent displacement or inadvertent removal of urinary stent or ureteral catheters if in place.	8. Prevents trauma from accidental displacement of urinary stent or ureteral catheter necessitating repeated instrumentation of the urinary tract (e.g., cystoscopy) to replace them.	
9. Observe urine color, volume, odor, and components.	9. Provides information about adequacy of urine output, condition and patency of drainage system, and debris in urine.	
10. Minimize trauma and manipulation of catheter, drainage system, and urethra.	10. Reduces risk of contamination of drainage system and eliminates site of bacterial invasion.	
11. Clean catheter gently with soap during bathing, avoiding any to-and-fro movement of catheter.	11. Removes debris and encrustations without causing trauma to or contamination of urethra.	

(Continued)

(Continued)

12. Anchor drainage tube.	12. Prevents movement or slipping of drainage tube, minimizing trauma to and contamination of urethra or catheter.
13. Maintain adequate fluid intake.	13. Promotes adequate urine output and prevents urinary stasis.
14. Assist with and encourage early ambulation while ensuring placement of urinary drainage system.	14. Minimizes cardiovascular and pulmonary complications while preventing loss, dislodging, or disruption of drainage system.
15. If patient is to be discharged with urinary drainage system (catheter) in place or a urinary diversion, instruct patient and family member in care.	15. Knowledge and understanding of the drainage system or urinary diversion are essential to prevent infection and other complications.

NURSING DIAGNOSIS: Risk for imbalanced fluid volume related to surgical fluid loss, altered urinary output, parenteral fluid administration
GOAL: Normal fluid balance will be maintained

Nursing Interventions	Rationale	Expected Outcomes
1. Weigh patient daily.	1. Daily weight is the most sensitive indicator of fluid loss or gain.	• Patient's weight will be within 1–1.25 Kg of patient's baseline.
2. Take accurate intake and output measurements.	2. Detects fluid retention due to poor cardiac or renal output.	• Intake that exceeds output will be detected early.
3. Place all parenteral therapy on an infusion pump.	3. Ensures that the patient does not receive excess or insufficient IV fluids.	
4. Monitor amount and characteristics of urine.	4. Assists in early detection of possible complications of surgery or tube insertion.	• The exact amount of solution is infused with no adverse effects resulting from over- or underinfusion.
5. Monitor vital signs: temperature, pulse, respirations, and blood pressure.	5. When fluid volume or cardiac output is altered, vital signs are affected.	• Urine is clear and absent of blood, pus, or any foreign substances.
6. Auscultate heart and lungs every shift.	6. When fluid volume is increased because of poor cardiac or renal output, fluid accumulates in the lungs. In addition, heart sounds change as heart failure develops; frequent auscultation ensures early detection.	• Temperature, pulse, respiration, and blood pressure are normal. • Normal heart and lung sounds are present.

Respiratory and circulatory status, pain level, fluid and electrolyte status, and patency and adequacy of urinary drainage systems are assessed.

Respiratory Status

As with any surgery, the use of anesthesia increases the risk of respiratory complications. Noting the location of the surgical incision assists the nurse in anticipating respiratory problems and pain. Respiratory status is assessed by monitoring the rate, depth, and pattern of respirations. The location of the incision frequently causes pain on inspiration and coughing; therefore, the patient tends to splint the chest wall and take shallow respirations. Auscultation is performed to assess normal and adventitious breath sounds.

Circulatory Status and Blood Loss

The patient's vital signs and arterial or central venous pressure are monitored. Skin color and temperature and urine output provide information about circulatory status. The surgical incision and drainage tubes are observed frequently to help detect unexpected blood loss and hemorrhage.

Pain

Postoperative pain is a major problem for the patient because of the location of the surgical incision and patient's position on the operating table to permit access to the kidney. The location and severity of pain are assessed before and after analgesic medications are given. Abdominal distention, which increases discomfort, is also noted.

Urinary Drainage

Urine output and drainage from tubes inserted during surgery are monitored for amount, color, and type or characteristics. Decreased or absent drainage is promptly reported to the primary provider because it may indicate obstruction that could cause pain, infection, and disruption of the suture lines.

Monitoring and Managing Potential Complications

Bleeding is a major complication of kidney surgery. If undetected and untreated, it can result in hypovolemia and hemorrhagic shock. The nurse's role is to observe for these complications, to report their signs and symptoms, and to administer prescribed parenteral fluids and blood and blood components. Monitoring of vital signs, skin condition, the urinary drainage system, the surgical incision, and the level of consciousness is necessary to detect evidence of bleeding, decreased circulating blood, and fluid volume and cardiac output. Frequent monitoring of vital signs (initially monitored at least at hourly intervals) and urinary output is necessary for early detection of these complications.

If bleeding goes undetected or is not detected promptly, the patient may lose significant amounts of blood and may experience hypoxemia. In addition to hypovolemic shock due to hemorrhage, this type of blood loss may precipitate a myocardial infarction or transient ischemic attack. Bleeding may be suspected when the patient experiences fatigue and when urine output is less than 0.5 mL/kg/hr. As bleeding persists, late signs of hypovolemia occur, such as cool skin, flat neck veins, and change in level of consciousness or responsiveness. Transfusions of blood components are indicated, along with surgical repair of the bleeding vessel.

Pneumonia may be prevented through the use of an incentive spirometer, adequate pain control, and early ambulation. Early signs of pneumonia include fever, increased heart and respiratory rates, and adventitious breath sounds.

Preventing infection involves using asepsis when changing dressings and handling and preparing catheters, other drainage tubes, central venous catheters, and IV catheters for administration of fluids. Insertion sites are monitored closely for signs and symptoms of inflammation: redness, drainage, heat, and pain. Special care must be taken to prevent UTI, which is associated with the use of indwelling urinary catheters. Catheters and other invasive tubes are removed as soon as they are no longer needed.

Antibiotics are commonly given postoperatively to prevent infection. If antibiotic agents are prescribed, serum creatinine and BUN values must be monitored closely because many antibiotic agents are toxic to the kidney or can accumulate to toxic levels if renal function is decreased.

Preventing fluid imbalance is critical when caring for a patient undergoing kidney surgery, because both fluid loss and fluid excess are possible adverse effects of the surgery. Fluid loss may occur during surgery as a result of excessive urinary drainage when the obstruction is removed, or it may occur if diuretic agents are used. Such loss may also occur with GI losses, in the form of diarrhea resulting from antibiotic use, or excessive nasogastric drainage. When postoperative IV therapy is inadequate to match the output or fluids lost, a fluid deficit results. Fluid excess, or overload, may result from cardiac effects of anesthesia, administration of excessive amounts of fluids, or the patient's inability to excrete fluid because of changes in renal function. Decreased urine output may be an indication of fluid excess.

Astute assessment skills are needed to detect early signs of fluid excess (such as weight gain, pedal edema, urine output below 0.5 mL/kg/hr, and slightly elevated pulmonary artery wedge pressure if available) before they become severe (appearance of adventitious breath sounds, shortness of breath).

Fluid excess may be treated with fluid restriction and administration of furosemide (Lasix) or other diuretic agents. If renal insufficiency is present, these medications may prove ineffective; therefore, dialysis may be necessary to prevent heart failure and pulmonary edema.

Deep vein thrombosis (DVT) may occur postoperatively because of surgical manipulation of the iliac vessels during surgery or prolonged immobility. Antiembolism stockings are applied, and the patient is monitored closely for signs and symptoms of thrombosis and encouraged to exercise the legs. Heparin may be given postoperatively to reduce the risk of thrombosis.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

If the patient has a drainage system in place, measures are taken to ensure that both the patient and family understand the importance of maintaining the system correctly at home and preventing infection. Verbal and written instructions and guidelines are provided to the patient and family at the time of hospital discharge. The patient may be asked to demonstrate management of the drainage system to ensure understanding. The importance of strategies to prevent postoperative complications (urinary tract obstruction and infection, DVT, atelectasis, and pneumonia) is stressed to the patient and family. The nurse reviews the signs, symptoms, problems, and questions that should be referred to the physician or other primary provider with the patient and family.

Continuing and Transitional Care

The need for postoperative assessment and care after kidney surgery continues regardless of the setting: the home, subacute care unit, outpatient clinic or office, or rehabilitation facility. Referral for home care is indicated for the patient going home with a urinary drainage system in place. During the home visit, the home care nurse reviews the instructions and guidelines given to the patient at hospital discharge. The nurse assesses the patient's ability to carry out the instructions in the home and answers questions that the patient or family has about management of the drainage system and the surgical incision.

In addition, the home care nurse obtains vital signs and assesses the patient for signs and symptoms of urinary tract obstruction and infection. The nurse also ensures that pain is adequately controlled and that the patient is complying with recommendations. The home care nurse encourages adequate fluid intake and increased levels of activity. Together, the nurse, patient, and family review the signs, symptoms, problems, and questions that should be referred to the primary provider. If the patient has a drainage tube in place, the nurse assesses the site and the patency of the system and monitors the patient for complications, such as DVT, bleeding, or pneumonia.

Because it is easy for the patient, family, and health care team to focus on the patient's immediate disorder to the exclusion of other health issues, the nurse reminds the patient and family about the importance of participating in health promotion activities, including appropriate health screenings.

Kidney Transplantation

Kidney transplantation has become the treatment of choice for most patients with ESKD. In the United States and globally, there are many more patients on the waiting list for kidney transplantation than there are organ donors. More than 99,000 Americans are on the waiting list to receive a kidney (Organ Procurement and Transplantation Network [OPTN], 2016). In India, the number of people requiring transplantation is estimated to be around 220,000. Against this huge demand, meager 7500 kidney transplantations are performed at the 250 kidney transplant centers across India. Most of the transplants done are live related donors and only 10% are from deceased donors (Shroff, 2016).

Patients choose kidney transplantation for various reasons, such as the desire to avoid dialysis or to improve their sense of well-being and the wish to lead a more normal life. In addition, the cost of maintaining a successful transplantation is one third the cost of dialysis treatment (Trevitt et al., 2012). Kidney transplantation is an elective procedure, not an emergency lifesaving procedure. Therefore, patients should be in the best possible condition prior to transplantation.

Chart 44-13

Kidney Donation

An inadequate number of available kidneys remain the greatest limitation to treating patients with end-stage kidney disease successfully. For those interested in donating a kidney, the Organ India or Organ Donation India provides written information describing the organ donation program and a card specifying the organs to be donated in the event of death.

The organ donation card is signed by the donor and two witnesses and should be carried by the donor at all times. Inform about the intention for organ donation to the family members as soon as organ donation registration process is over. Before harvesting the organs, family members' consent is mandatory. Hence, make them understand the process and insist that organ donation will not cause any disfigurement. Procurement of an adequate number of kidneys for potential recipients is still a major problem in India, despite national legislation that requires relatives of deceased patients or patients declared brain dead to be asked if they would consider organ donation.

Kidney transplantation involves transplanting a kidney from a living or deceased donor to a recipient who no longer has renal function (see Chart 44-13). A living donor is a person who is alive at the time of donation and may or may not be related to the recipient. A deceased or cadaveric transplant comes from someone who has died and donated their organs. Transplantation from well-matched living donors who are related to the patient (those with compatible ABO and human leukocyte antigens) is slightly more successful than from cadaver donors (Gaber, Knight, & Patel, 2013). A contemporary development in kidney transplantation is paired donor exchange. In paired donor exchange, recipients essentially swap willing donors (Gaber et al., 2013). Although medically eligible to donate a kidney, a willing donor may be incompatible with the intended recipient due to blood type or antigens. The donor then agrees to donate the kidney to a compatible and unknown recipient, with the intention that the donor's originally intended organ recipient will be part of the donation chain and be the recipient of a donated kidney through organized donor and recipient matches.

Prior to either receiving or donating an organ, an extensive medical evaluation is performed. Not everyone is suitable for kidney transplantation. Contraindications include recent malignancy, active or chronic infection, severe irreversible extrarenal disease (e.g., inoperable cardiac disease, chronic lung disease, severe peripheral vascular disease), active infection (e.g., HIV, hepatitis B and C), Class II obesity (body mass index greater than 35 kg/m^2), current substance abuse, inability to give informed consent, and history of nonadherence to treatment regimens (Dring & Hipkiss 2015). Donors may be rejected for the same reasons or any condition that is determined to have an impact on the remaining kidney. Examples include hypertension and diabetes because both are known causes of kidney disease. It is imperative when donors are evaluated that serious consideration be given to the overall long-term health of the donor. Every precaution must be taken to ensure that the remaining kidney in the donor will remain healthy. If these conditions are met, the donor should remain healthy after donation and have a normal lifespan. Because one kidney can easily handle the body's needs, no long-term adjustments will need to be made.

The recipient's native kidneys are not usually removed. The transplanted kidney is placed in the patient's iliac fossa anterior to the iliac crest because it allows for easier access to the blood supply needed to perfuse the kidney. The ureter of the newly transplanted kidney is transplanted into the bladder or anastomosed to the ureter of the recipient (see Fig. 44-12). Once the blood supply has been reestablished to the transplanted kidney in the operating room, urine should begin to flow. The production of urine at this stage is an important indicator of the overall success of the procedure and ultimate long-term outcome.

Preoperative Management

Preoperative management goals include bringing the patient's metabolic state to a level as close to normal as possible through

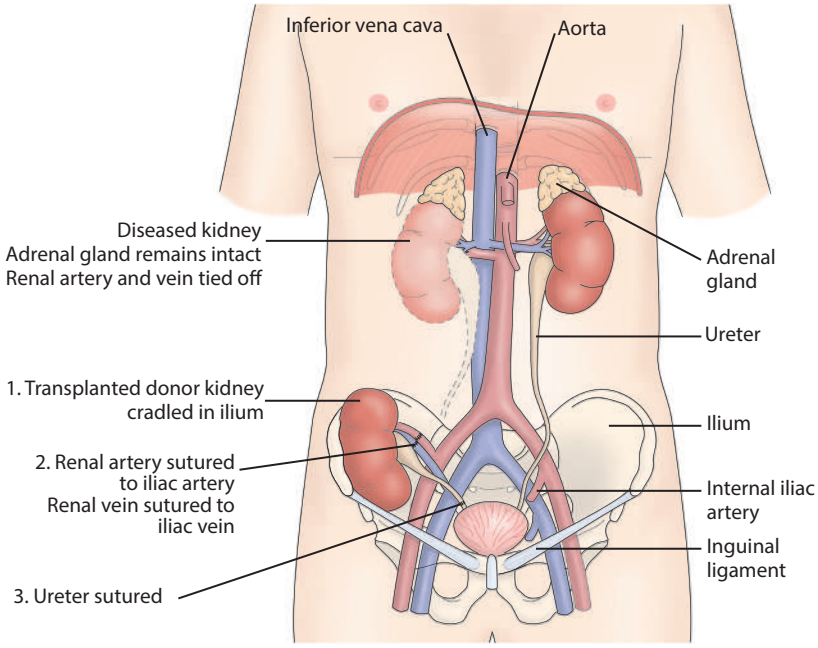

Figure 44-12 • Kidney transplantation. **1.** The transplanted kidney is placed in the iliac fossa. **2.** The renal artery of the donated kidney is sutured to the iliac artery, and the renal vein is sutured to the iliac vein. **3.** The ureter of the donated kidney is sutured to the bladder or to the patient's ureter.

diet, possibly dialysis and medical management, making sure that the patient is free of infection, and preparing the patient for surgery and the postoperative course.

Medical Management

A complete physical examination is performed on the donor and the recipient to detect and treat any conditions that could cause complications after the donor and transplantation procedure. Tissue typing, blood typing, and antibody screening are performed to determine compatibility of the tissues and cells of the donor and recipient. Other diagnostic tests must be completed to identify conditions requiring treatment before transplantation for either individual. The lower urinary tract is studied to assess bladder neck function and to detect ureteral reflux.

Both patients must be free of infection at the time of kidney transplantation. After surgery, medications to prevent transplant rejection will be prescribed to the transplant recipient. These medications suppress the immune response, leaving the patient immunosuppressed and at risk for infection. Therefore, both the donor and recipient are evaluated and treated for any infections, including gingival (gum) disease and dental caries.

A psychosocial evaluation is conducted to assess the organ recipient's ability to adjust to the transplant, coping styles, social history, social support available, and financial resources. A history of psychiatric illness is important to obtain because psychiatric conditions are often aggravated by the corticosteroids needed for immunosuppression after transplantation (Colaneri, 2014). A psychosocial evaluation is also conducted to assess the organ donor's motive for giving the organ. The donor should not be coerced to donate this organ; it should be an altruistic act (Choudhury, Jotterand, Casenave, et al., 2014); (Robbins, 2014) (see Chart 44-14). If a dialysis routine has been established, hemodialysis is often performed the day before the scheduled transplantation procedure to optimize the physical status of the patient receiving the transplant.

Nursing Management

The nursing aspects of preoperative care for the patient undergoing kidney transplant and donation are similar to those for patients undergoing other types of kidney or elective abdominal surgery. Preoperative education can be conducted in a variety of settings, including the outpatient preadmission area, the hospital, or the transplantation clinic during the preliminary workup phase. Patient education directed at the kidney transplant donor and recipient addresses postoperative pulmonary hygiene, pain management options, dietary restrictions, IV and arterial lines, tubes (indwelling catheter and possibly a nasogastric tube), and early ambulation. Most patients have been on dialysis for months or years before transplantation. Many have waited months to years for a kidney transplant and are anxious about the surgery, possible rejection, and the need to return to or begin dialysis. Helping the patient to deal with these concerns is part of the nurse's role in preoperative management, as is educating the patient about what to expect after surgery.

Chart 44-14 ETHICAL DILEMMA

The Gift of Life for Whom? Whose Life is It?

Case Scenario

You are a nurse working in a solid organ transplant clinic that is affiliated with a university health science center. A 52-year-old man with a history of type 2 diabetes and end-stage kidney disease and each of his three biologic siblings, none of whom have diabetes, have been worked up to see if one may be a match for a living transplant. The youngest sibling, who is the only sister in the family, is a perfect donor match. The patient assumes that his sister will donate a kidney, which will improve his quality of life. However, the sister confides in you when other family members are not present, "You know, his need for a kidney is because he never managed his diabetes and everyone is pressuring me into donating. I'm not really certain I want to do this. What if I need this kidney one day?"

Discussion

Living donor transplants offer the best possibility for successful organ engraftment. Biologic siblings are the best candidates for finding good organ matches; there is a greater likelihood that siblings will share all human leukocyte antigens. Patient advocacy and informed consent are imperative as a potential living donor contemplates donating an organ. The Transplantation of Human Organs (THO) Act in 1994 enacted by the Government of India mandates that all transplant centers provide any potential donor with an unbiased advocate. The goal is to ensure that the donor is mentally competent, adequately educated about the risks of the procedure, and capable of autonomous decision making. The THO Act mandates that the donor appears before the authorization Committee which counter checks the mental soundness of the donor to make the decision of organ donation voluntarily and not by any coercion.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have preeminence as you proceed to work with the potential living donor?
- There are two patients in this case—one is the brother with end-stage kidney disease who is hoping to receive a donated kidney from a sibling, and the other is the sister with healthy kidneys who is reluctant to donate one to her brother. Should the autonomous right of one patient have preeminence over the autonomous right of the other? How would you respond to the sister when she confides in you?
- For whom is there an obligation to advocate for in this situation—the brother, the sister, or the extended family? What resources might you mobilize to help them reconcile their differences?
- Is it morally ethical to donate an organ to a patient whose noncompliance in the management of their disease may have directly caused the organ to fail?

See Chapter 2, Chart 2-6 for ethics resources.

The patient who receives a kidney from a living related donor is often concerned about the donor and how the donor will tolerate the surgical procedure. If the patient is receiving a cadaveric donor transplant, the recipient may express sadness and grief over the loss of the donor's life. The nurse must maintain open communication with the recipient of the organ and allow the patient to express these concerns.

The nurse working in an intensive care setting may provide care to the organ donor who is brain dead prior to organ removal. The overall goal is to preserve the function of the organs through maintaining hemodynamic stability, decreasing the risk for infection, and monitoring laboratory values while providing dignified care to the donor and family members (Derkowski, 2014). Continuing care for the donor can be complex and last several hours. Care is often provided in collaboration with the organ procurement coordinator and transplant coordinator.

Postoperative Management

The goal of postoperative care is to maintain homeostasis until the transplanted kidney is functioning well. The patient whose kidney functions immediately has a more favorable prognosis than the patient whose kidney does not.

Often, the organ donor will be on the same unit as the transplant recipient. The donor will require the same level of care provided to the recipient, including follow-up after the procedure and lifelong. The organ donor may experience more pain than the recipient, possibly requiring more analgesia for pain control. Fluid, electrolyte, and hemodynamic status will also be closely monitored in the organ donor.

Medical Management

After a kidney transplantation, rejection and failure can occur within 24 hours (hyperacute), within 3 to 14 days (acute), or after many years. A hyperacute rejection is caused by an immediate antibody-mediated reaction that leads to generalized glomerular capillary thrombosis and necrosis. An acute rejection typically occurs within a few days to weeks of the transplant surgery, and the patient experiences tenderness at the transplant site, a decrease in serum creatinine values, fever, malaise, and oliguria (Colaneri, 2014). An acute rejection requires early recognition and treatment with immunosuppressant therapy, whereas a hyperacute reaction requires immediate removal of the transplanted organ (Colaneri, 2014). The long-term survival of a transplanted kidney depends on how well it matches the recipient and how well the body's immune response is controlled. The body's immune system views the transplanted kidney as "foreign"; therefore, it continually works to reject it. To overcome or minimize the body's defense mechanisms, immunosuppressive agents are given. Optimally, medications modify the immune system enough to prevent rejection, although not enough to allow infections or malignancies to occur (see Table 44-4).

Combinations of corticosteroids and medications specifically developed to affect the action of lymphocytes are used to minimize the body's reaction to the transplanted organ. Treatment with combinations of new agents has dramatically improved survival rates, and now 90% to 95% of transplanted kidneys still function after 1 year (Colaneri, 2014). Doses of immunosuppressive agents are often adjusted depending on the patient's immunologic response to the transplant. However, the patient will be required to take some form of immunosuppressive therapy for the entire time that they have the transplanted kidney.

The risks associated with taking these medications include nephrotoxicity, hypertension, hyperlipidemia, hirsutism, tremors, blood dyscrasias, cataracts, gingival hyperplasia, and several types of cancer (Colaneri, 2014).

Nursing Management

Assessing the Patient for Transplant Rejection

After kidney transplantation, the nurse assesses the patient for signs and symptoms of transplant rejection: oliguria, edema, fever, increasing blood pressure, weight gain, and swelling or tenderness over the transplanted kidney or graft. Patients receiving cyclosporine (Neoral) may not exhibit the usual signs and symptoms of acute rejection. In these patients, the only sign may be an asymptomatic rise in the serum creatinine level (more than a 20% rise is considered acute rejection) (Colaneri, 2014).

Preventing Infection

The results of blood chemistry tests and leukocyte and platelet counts are monitored closely because immunosuppression depresses the formation of leukocytes and platelets. The patient is closely monitored for infection because of susceptibility to impaired healing and infection related to immunosuppressive therapy and complications of kidney disease. Clinical manifestations of infection include shaking chills, fever, rapid heartbeat (tachycardia), and respirations (tachypnea), as well as either an increase or a decrease in WBCs (leukocytosis or leukopenia).

Infection may be introduced through many sources. Urine cultures are performed frequently because of the high incidence of bacteriuria during early and late stages of transplantation. Any type of wound drainage should be viewed as a potential source of infection because drainage is an excellent culture medium for bacteria. Catheter and drain tips may be cultured when removed by cutting off the tip of the catheter or drain (using aseptic technique) and placing the tip in a sterile container to be taken to the laboratory for culture (see Chart 44-15).

The nurse ensures that the patient is protected from exposure to infection by hospital staff, visitors, and other patients with active infections. Attention to hand hygiene by all who come in contact with the patient is imperative.

Monitoring Urinary Function

A kidney from a living donor who is related to the patient usually begins to function immediately after surgery and may produce large quantities of dilute urine. A kidney from a cadaver donor may undergo ATN and therefore may not function for 2 or 3 weeks, during which time anuria, oliguria, or polyuria may be present. During this stage, the patient may experience significant changes in fluid and electrolyte status. Therefore, careful monitoring is indicated. The output from the urinary catheter (connected to a closed drainage system) is measured every hour. IV fluids are given on the basis of urine volume and serum electrolyte levels and as prescribed by the primary provider. Hemodialysis may be necessary postoperatively to maintain homeostasis until the transplanted kidney is functioning well. It also may be required if fluid overload and hyperkalemia occur. After successful kidney transplantation, the vascular access device may clot, possibly from improved coagulation with the return of renal function. The vascular access for hemodialysis is monitored to ensure patency and to evaluate for evidence of infection.

Addressing Psychological Concerns

The rejection of a transplanted kidney is of great concern to the patient, the family, and the health care team for many

TABLE 44-4 Immunosuppressant Agents Used Following Organ Transplant

Agent	Action	Nursing Implications
Azathioprine (Azasan, Imuran)	Antagonizes purine metabolism and appears to inhibit DNA, RNA, and normal protein synthesis in rapidly growing cells; suppresses T-cell effects	Give oral drug in divided doses with food. Monitor leukocyte and platelet counts and bleeding.
Belatacept (Nulojix)	Inhibition of T-lymphocyte proliferation and cytokine production	Contraindicated in patients with EBV seronegativity or unknown EBV serostatus, liver transplantation, breast-feeding. Monitor for symptoms of infection, hypertension, progressive multifocal leukoencephalopathy. Administer IV.
Cyclosporine (Gengraf, Neoral, Sandimmune)	Selective and reversible inhibition of first phase of T-cell activation with T lymphocytes	Do not dilute oral solution with grapefruit juice (use orange juice, regular or chocolate milk, or apple juice and administer immediately after mixing). Observe for adverse reactions for 30 minutes after initiation of the IV infusion. Be aware that nephrotoxicity is reported in up to 1/3 of transplant recipients. Give medication with food to reduce gastrointestinal upset. Administer medication at the same time each day.
Everolimus (Afinitor, Zortess)	Protein–tyrosine kinase inhibitor	Monitor for hypersensitivity reaction. Watch for changes in pulmonary status and cough. Avoid administration of live vaccines. Administer at the same time each day with food; do not crush or allow patient to chew tablet.
Mycophenolate mofetil (CellCept) Mycophenolic acid (Myfortic)	Inhibition of T- and B-lymphocyte responses, thus inhibiting antibody formation and generation of cytotoxic T cells	Administer on an empty stomach. Do not crush or open capsules. Avoid contact with powder in capsules; wash thoroughly with soap and water if contact occurs. Obtain baseline complete blood count with differential prior to initiating therapy. Instruct the patient to avoid over-the-counter antacids.
Prednisone (Apo-Prednisone, Deltasone, Orasone, Panasol, Winpred)	Immediate-acting synthetic analog of hydrocortisone that has anti-inflammatory and immunosuppressant properties	Give with meals or a snack. Crush tablet and give with fluid if patient is unable to swallow it whole. Note that the drug should not be stopped abruptly; the dosage is reduced gradually. Monitor weight, blood pressure, blood glucose levels, and sleep patterns. Monitor for hypocalcemia. Instruct patient to avoid or minimize alcohol intake.
Sirolimus (Rapamune)	Inhibits the response of helper T and B lymphocytes	Administer 4 hours after oral cyclosporine. Instruct patient to swallow tablets whole and to avoid chewing or crushing tablets. Refrigerate drug and protect from light. Instruct patient to avoid grapefruit juice within 2 hours of taking drug and to mix the drug only with orange juice or water. Instruct the patient to limit exposure to sunlight.
Tacrolimus (Prograf)	Inhibits helper T lymphocytes	Monitor for neurotoxicity (tremors and changes in mental status). Assess for hypertension. Monitor tacrolimus levels.

months. The fear of kidney rejection and the complications of immunosuppressive therapy (Cushing syndrome, diabetes, capillary fragility, osteoporosis, glaucoma, cataracts, acne, nephrotoxicity) place tremendous psychological stress on the patient. If the organ donor was a family member there may be added feelings of guilt and anger that need to be addressed. Anxiety and uncertainty about the future and difficult adjustment are often sources of stress for the patient and family.

An important nursing function is the assessment of the patient's stress and coping. The nurse uses each visit with the patient to determine if the patient and family are coping effectively and the patient is adhering to the prescribed medication regimen. If indicated or requested, the nurse refers the patient for counseling.

Monitoring and Managing Potential Complications

The patient undergoing kidney transplantation is at risk for the postoperative complications that are associated with any surgical procedure. In addition, the patient's physical condition may be compromised because of the effects of long-standing kidney disease and its treatment. Therefore, careful assessment of the complications related to kidney disease and those associated with a major surgery are important aspects of nursing care.

Chart 44-15

Kidney Transplant Rejection and Infection

Renal graft rejection and failure may occur within 24 hours (hyperacute), within 3–14 days (most commonly acute), or after many years (most commonly chronic). It is not uncommon for rejection to occur during the first year after transplantation.

Detecting Rejection

Ultrasonography may be used to detect enlargement of the kidney; percutaneous renal biopsy (most reliable) and x-ray techniques are used to evaluate transplant rejection. If the body rejects the transplanted kidney, the patient needs to commence dialysis. The rejected kidney may or may not be removed, depending on when the rejection occurs (acute vs. chronic) and the risk for infection if the kidney is left in place.

Potential Infection

About 75% of kidney transplant recipients have at least one episode of infection in the first year after transplantation because of immunosuppressant therapy. Immunosuppressants of the past made the transplant recipient more vulnerable to opportunistic infections (candidiasis, cytomegalovirus, Pneumocystis pneumonia) and infection with other relatively nonpathogenic viruses, fungi, and protozoa, which can be a major hazard. Immunosuppressive therapy, such as cyclosporine (Neoral) has reduced the incidence of opportunistic infections because it selectively exerts its effect, sparing T cells that protect the patient from life-threatening infections. In addition, combination immunosuppressant therapy and improved clinical care have produced 1-year patient survival rates approaching 100% and graft survival exceeding 90%. Infections, however, remain a major cause of death at all points in time for kidney transplant recipients.

Adapted from Colaneri, J. (2014). An overview of transplant immunosuppression—History, principles, and current practices in kidney transplantation. Nephrology Nursing Journal, 41(6), 549–560.

Breathing exercises, early ambulation, and care of the surgical incision are important aspects of postoperative care.

GI ulceration and corticosteroid-induced bleeding may occur. Fungal colonization of the GI tract (especially the mouth) and urinary bladder may occur secondary to corticosteroid and antibiotic therapy. Closely monitoring the patient and notifying the primary provider about the occurrence of these complications are important nursing interventions. In addition, the patient is monitored closely for signs and symptoms of adrenal insufficiency if the treatment has included the use of corticosteroids.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

The nurse works closely with the patient and family to be sure that they understand the need for continuing immunosuppressive therapy as prescribed. In addition, the patient and family are instructed to assess for and report signs and symptoms of transplant rejection, infection, or significant adverse effects of the immunosuppressive regimen. These include decreased urine output; weight gain; malaise; fever; respiratory distress; tenderness over the transplanted kidney; anxiety; depression; changes in eating, drinking, or other habits; and changes in blood pressure. The patient is instructed to inform other health care providers (e.g., dentist) about the kidney transplant and the use of immunosuppressive agents.

Continuing and Transitional Care

The patient needs to know that follow-up care after transplantation is a lifelong necessity. Individual verbal and written instructions are provided concerning diet, medication, fluids, daily weight, daily measurement of urine, management of I&O, prevention of infection and chronic rejection, resumption of activity, and avoidance of contact sports in which the transplanted kidney may be injured. Because of the risk of other potential complications, the patient is followed closely by a health care team that includes the nephrologist, transplant surgeon, transplant coordinator or nurse, social worker, and dietician. Medications are often obtained at one pharmacy or through the pharmacy at the hospital where the transplant surgery was performed for the purpose of quality control. Follow-up with providers from the transplant team will initially occur once a week upon discharge from the hospital and taper with time. Laboratory studies will also be obtained and followed on an ongoing basis to monitor the function of the kidney.

Cardiovascular disease is the major cause of morbidity and mortality after transplantation, due in part to the increasing age of patients with transplants. An additional problem is possible malignancy; patients receiving long-term immunosuppressive therapy are at higher risk for cancers than the general population. The nurse reminds the patient of the importance of health promotion and health screening and provides information on local transplantation support groups at the transplant hospital or through the procurement organization.

RENAL TRAUMA

The kidneys are protected by the rib cage and musculature of the back posteriorly and by a cushion of abdominal wall and viscera anteriorly. They are highly mobile and are fixed only at the renal pedicle (stem of renal blood vessels and the ureter). With traumatic injury, the kidneys can be thrust against the lower ribs, resulting in contusion and rupture. Rib fractures or fractures of the transverse process of the upper lumbar vertebrae may be associated with renal contusion or laceration. Failure to wear seat belts contributes to the incidence of renal trauma in motor vehicle crashes. Up to 80% of patients with renal trauma have associated injuries of other internal organs.

Injuries may be blunt (automobile and motorcycle crashes, falls, athletic injuries, assaults) or penetrating (gunshot wounds, stabbings). Blunt renal trauma accounts for 80% to 90% of all renal injuries; penetrating renal trauma accounts for the remaining 10% to 20% (Counts, 2015); (USRDS, 2015).

Blunt renal trauma is classified into one of four groups, as follows:

- Contusion: Bruises or hemorrhages under the renal capsule; capsule and collecting system intact
- Minor laceration: Superficial disruption of the cortex; renal medulla and collecting system are not involved
- Major laceration: Parenchymal disruption extending into cortex and medulla, possibly involving the collecting system
- Vascular injury: Tears of renal artery or vein

The most common renal injuries are contusions, lacerations, ruptures, and renal pedicle injuries or small internal lacerations of the kidney (see Fig. 44-13). The kidneys receive half of the blood flow from the abdominal aorta; therefore, even a fairly small renal laceration can produce massive bleeding. The majority of patients are in shock when admitted to the hospitals. In some cases, there is an isolated renal artery thrombosis.

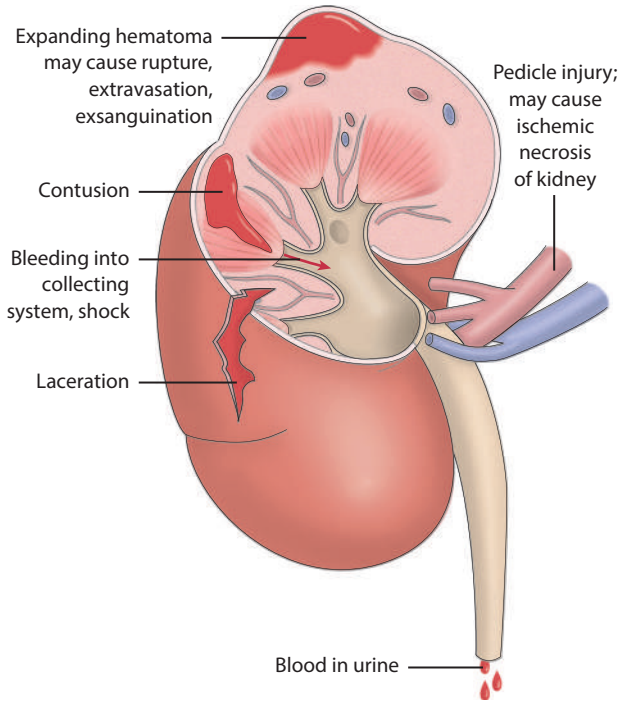

Figure 44-13 • Types and pathophysiologic effects of kidney injuries: contusions, lacerations, rupture, and pedicle injury.

Clinical manifestations include pain, renal colic (due to blood clots or fragments obstructing the collecting system), hematuria, mass or swelling in the flank, ecchymoses, and lacerations or wounds of the lateral abdomen and flank. Hematuria is the most common manifestation of renal trauma; its presence after trauma suggests kidney injury. There is no relationship between the degree of hematuria and the degree of injury. Hematuria may not occur, or it may be detectable only on microscopic examination. Signs and symptoms of hypovolemia and shock (see Chapter 8) are likely with significant hemorrhage.

Medical Management

The goals of management in patients with renal trauma are to control hemorrhage, pain, and infection as well as to preserve and restore renal function. All urine is saved and sent to the laboratory for analysis to detect RBCs and to evaluate the course of bleeding. Hematocrit and hemoglobin levels are monitored closely; decreasing values indicate hemorrhage.

The patient is monitored for oliguria and signs of hemorrhagic shock, because a pedicle injury or shattered kidney can lead to rapid exsanguination (lethal blood loss). An expanding hematoma may cause rupture of the kidney capsule. To detect hematoma, the area around the lower ribs, upper lumbar vertebrae, flank, and abdomen is palpated for tenderness. A palpable flank or abdominal mass with local tenderness, swelling, and ecchymosis suggests renal hemorrhage. The area of the original mass can be outlined with a marking pen so that the examiner can evaluate the area for change.

Renal trauma is often associated with other injuries to the abdominal organs (liver, colon, small intestines); therefore, the patient is assessed for skin abrasions, lacerations, and entry and exit wounds of the upper abdomen and lower thorax, because these may be associated with kidney injury.

With a contusion of the kidney, healing may take place with conservative measures. If the patient has microscopic hematuria and a normal IV urogram, outpatient management is possible. If gross hematuria or a minor laceration is present, the patient is hospitalized and kept on bed rest until the hematuria clears. Antimicrobial medications may be prescribed to prevent infection from perirenal hematoma or urinoma (a cyst containing urine). Patients with retroperitoneal hematomas may develop low-grade fever as absorption of the clot takes place.

Surgical Management

In renal trauma, any sudden change in the patient's condition suggests hemorrhage and requires rapid surgical intervention. Depending on the patient's condition and the nature of the injury, major lacerations may be treated through surgical intervention or conservatively (bed rest, no surgery). Vascular injuries require immediate exploratory surgery because of the high incidence of involvement of other organ systems and the serious complications that may result if these injuries are untreated. The patient is often in shock and requires aggressive fluid resuscitation. The damaged kidney may have to be removed (nephrectomy).

Early postoperative complications (within 6 months) include rebleeding, perinephric abscess formation, sepsis, urine extravasation, and fistula formation. Other complications include stone formation, infection, cysts, vascular aneurysms, and loss of renal function. Hypertension can be a complication of any surgery but usually is a late complication of kidney injury.

Nursing Management

The patient with renal trauma must be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank. During this time, the patient who has undergone surgery is educated about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the physician, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided. Guidelines for gradually increasing activity, lifting, and driving are also provided in accordance with the physician's prescription.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding. The patient should be advised to schedule periodic follow-up assessments of renal function (creatinine clearance, BUN, and serum creatinine analyses). If a nephrectomy was necessary, the patient is advised to wear medical identification.

CRITICAL THINKING EXERCISES

1. You are a staff nurse in an outpatient dialysis facility. A 40-year-old man with ESKD is seen in the clinic for the first time and states that he wants to begin home hemodialysis. The patient lives alone and is employed full-time. What should be the priorities for educating this patient about the options for dialysis? How should the priorities change if the patient decides on PD?
2. You are caring for a 75-year-old patient who has been recently diagnosed with renal cancer. What is the evidence base for her treatment options? Identify the criteria used to evaluate the strength of the evidence.

3. A 23-year-old man is admitted to the surgical intensive care unit after a motor vehicle crash. The patient sustained multiple abdominal injuries that resulted in intra-abdominal hemorrhage requiring emergent surgery. The patient's blood pressure was 58/42 upon arrival to the emergency department, and the patient was not responsive. Due to broken ribs and a pneumothorax, the patient is also being mechanically ventilated. The nurse notes that the patient's urine output is less than 0.5 mL/kg/hr and that the patient remains hypotensive. Based on the assessment information, what type of AKI is this patient most likely experiencing? Describe the nursing plan of care for this patient.

CHAPTER 45

Management of Patients with Urinary Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the factors contributing to upper and lower urinary tract infections (UTIs).
2. Use the nursing process as a framework for care of the patient with a lower UTI.
3. Differentiate between the various adult dysfunctional voiding patterns.
4. Develop an education plan for a patient who has mixed (stress and urge) urinary incontinence.
5. Identify potential causes of an obstruction of the urinary tract along with the medical and surgical management of the patient with this condition.
6. Apply the nursing process as a framework for care of the patient with kidney stones.
7. Describe the pathophysiology, clinical manifestations, medical management, and nursing management for patients with genitourinary trauma and urinary tract cancers.
8. Use the nursing process as a framework for care of the patient undergoing urinary diversion surgery.

GLOSSARY

bacteriuria: bacteria in the urine
cystectomy: surgical removal of the urinary bladder
cystitis: inflammation of the urinary bladder
ileal conduit: transplantation of the ureters to an isolated section of the terminal ileum, with one end of the ureters brought to the abdominal wall
interstitial cystitis: inflammation of the bladder wall that eventually causes disintegration of the lining and loss of bladder elasticity
micturition: voiding or urination
neurogenic bladder: bladder dysfunction that results from a disorder or dysfunction of the nervous system and leads to urinary incontinence
nocturia: awakening at night to urinate
overflow incontinence: involuntary urine loss associated with overdistention of the bladder
prostatitis: inflammation of the prostate gland
pyelonephritis: inflammation of the renal pelvis
pyuria: white blood cells in the urine
residual urine: urine that remains in the bladder after voiding
suprapubic catheter: a urinary catheter that is inserted through a suprapubic incision into the bladder
ureterosigmoidostomy: transplantation of the ureters into the sigmoid colon, allowing urine to flow through the colon and out the rectum
ureterovesical or vesicoureteral reflux: backward flow of urine from the bladder into one or both ureters
urethritis: inflammation of the urethra
urethrovesical reflux: An obstruction to free-flowing urine leading to the reflux of urine from the urethra into the bladder
urinary frequency: voiding more often than every 3 hours
urinary incontinence: involuntary or uncontrolled loss of urine from the bladder
urosepsis: spread of infection from the urinary tract to the bloodstream that results in a systemic infection

Introduction

The urinary system is responsible for providing the route for drainage of urine formed by the kidneys. Care of the patient with disorders of the urinary tract requires an understanding of the anatomy, physiology, diagnostic testing, medical, and nursing care, as well as rehabilitation of patients with the multiple processes that affect the urinary system. Nurses care for patients with urologic disorders in all settings. This chapter focuses on the nursing management of patients with common urinary dysfunctions, including infections, dysfunctional voiding patterns, urolithiasis, genitourinary trauma, cancer of the urinary tract, and urinary diversions.

INFECTIONS OF THE URINARY TRACT

Urinary tract infections (UTIs) are caused by pathogenic microorganisms in the urinary tract (the normal urinary tract is sterile above the urethra). UTIs are generally classified as infections involving the upper or lower urinary tract and further classified as uncomplicated or complicated, depending on other patient-related conditions (see Chart 45-1).

Lower UTIs include bacterial cystitis (inflammation of the urinary bladder), bacterial prostatitis (inflammation of the prostate gland), and bacterial urethritis (inflammation of the urethra). Acute or chronic nonbacterial causes of inflammation in any of these areas can be misdiagnosed as bacterial infections. Upper UTIs are much less common and include acute or chronic pyelonephritis (inflammation of the renal pelvis), interstitial nephritis (inflammation of the kidney), and kidney abscesses. Upper and lower UTIs are further classified as uncomplicated or complicated, depending on whether the UTI is recurrent and the duration of the infection. Most uncomplicated UTIs are community acquired (Hopkins, McCroskey, Reeves, et al., 2014). Complicated UTIs usually occur in people with urologic abnormalities or recent catheterization and are often acquired during hospitalization.

A UTI is the second most common infection in the body followed by respiratory infections. Most cases occur in women;

Chart 45-1

Classifying Urinary Tract Infections

Urinary tract infections (UTIs) are classified by location: the lower urinary tract (which includes the bladder and structures below the bladder) or the upper urinary tract (which includes the kidneys and ureters). They can also be classified as uncomplicated or complicated UTIs.

Lower UTIs

Cystitis, prostatitis, urethritis

Upper UTIs

Acute pyelonephritis, chronic pyelonephritis, renal abscess, interstitial nephritis, perirenal abscess

Uncomplicated Lower or Upper UTIs

Community-acquired infection; common in young women and not usually recurrent

Complicated Lower or Upper UTIs

Often acquired in the hospital and related to catheterization; occur in patients with urologic abnormalities, pregnancy, immunosuppression, diabetes, and obstructions and are often recurrent

Chart 45-2 RISK FACTORS

Urinary Tract Infection

- Contributing conditions such as:
  - Female gender
  - Diabetes
  - Pregnancy
  - Neurologic disorders
  - Gout
  - Altered states caused by incomplete emptying of the bladder and urinary stasis
- Decreased natural host defenses or immunosuppression
- Inability or failure to empty the bladder completely
- Inflammation or abrasion of the urethral mucosa
- Instrumentation of the urinary tract (e.g., catheterization, cystoscopic procedures)
- Obstructed urinary flow caused by:
  - Congenital abnormalities
  - Urethral strictures
  - Contracture of the bladder neck
  - Bladder tumors
  - Calculi (stones) in the ureters or kidneys
  - Compression of the ureters

Adapted from Hagerty, T., Kertesz, L., Schmidt, J. M., et al. (2015). Risk factors for catheter associated urinary tract infections in critically ill patients with subarachnoid hemorrhage. Journal of Neuroscience Nursing, 47(1), 51–54; Hopkins, L., McCroskey, D., Reeves, G., et al. (2014). Implementing a urinary tract infection clinical practice guideline in an ambulatory urgent care practice. The Nurse Practitioner, 39(4), 50–54.

approximately 50% of women develop at least one episode of UTI during their lifetime. The urinary tract infection is the cause for seeking medical consultation in 5% of general practitioner visits (Singh, Katiyar, Tilak, et al., 2018). Urinary tract is the most common site of nosocomial infection, accounting for 71% of the total number reported by a tertiary care hospital in South India (Narendrnath.et al., 2017). In most of these hospital-acquired UTIs, instrumentation of the urinary tract or catheterization is the precipitating cause.

Lower Urinary Tract Infections

Several mechanisms maintain the sterility of the bladder: the physical barrier of the urethra, urine flow, ureterovesical junction competence, various antibacterial enzymes and antibodies, and antiadherent effects mediated by the mucosal cells of the bladder. Abnormalities or dysfunctions of these mechanisms are contributing risk factors for lower UTIs (see Chart 45-2).

Pathophysiology

For infection to occur, bacteria must gain access to the bladder, attach to and colonize the epithelium of the urinary tract to avoid being washed out with voiding, evade host defense mechanisms, and initiate inflammation. Many UTIs result from fecal organisms ascending from the perineum to the urethra and the bladder and then adhering to the mucosal surfaces.

Bacterial Invasion of the Urinary Tract

By increasing the normal slow shedding of bladder epithelial cells (resulting in bacteria removal), the bladder can clear large numbers of bacteria. Glycosaminoglycan (GAG), a hydrophilic protein, normally exerts a nonadherent protective effect against various bacteria. The GAG molecule attracts water molecules, forming a water barrier that serves as a defensive layer between the bladder and the urine. GAG may be impaired by certain agents (cyclamate, saccharin, aspartame, and tryptophan metabolites). The normal bacterial flora of the vagina and urethral area also interfere with adherence of *Escherichia coli.* Urinary immunoglobulin A (IgA) in the urethra may also provide a barrier to bacteria.

Reflux

An obstruction to free-flowing urine is a condition known as urethrovesical reflux, which is the reflux (backward flow) of urine from the urethra into the bladder (see Fig. 45-1). With coughing, sneezing, or straining, the bladder pressure increases, which may force urine from the bladder into the urethra. When the pressure returns to normal, the urine flows back into the bladder, bringing into the bladder bacteria from the anterior portions of the urethra. Urethrovesical reflux is also caused by dysfunction of the bladder neck or urethra. The urethrovesical angle and urethral closure pressure may be altered with menopause, increasing the incidence of infection in postmenopausal women. Reflux is most often noted in young children, and treatment is based on its severity.

Ureterovesical or vesicoureteral reflux refers to the backward flow of urine from the bladder into one or both ureters (see Fig. 45-1). Normally, the ureterovesical junction prevents urine from traveling back into the ureter. The ureters tunnel into the bladder wall so that the bladder musculature compresses a small portion of the ureter during normal voiding. When the ureterovesical valve is impaired by congenital causes or ureteral abnormalities, the bacteria may reach the kidneys and eventually destroy them.

Uropathogenic Bacteria

Bacteriuria is the term used to describe the presence of bacteria in the urine. Because urine samples (especially in women) can be easily contaminated by the bacteria normally present in the urethral area, a clean-catch midstream urine specimen is the

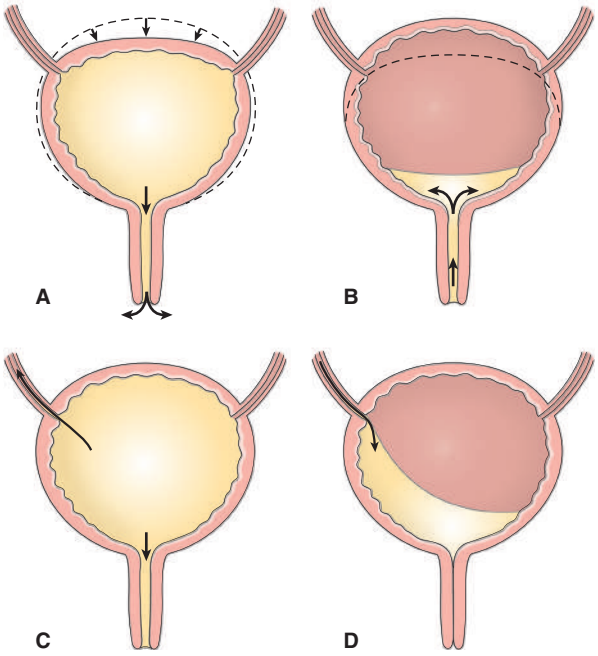

Figure 45-1 • Mechanisms of urethrovesical and ureterovesical reflux may cause urinary tract infection. *Urethrovesical reflux*: With coughing and straining, bladder pressure rises, which may force urine from the bladder into the urethra. **A**. When bladder pressure returns to normal, the urine flows back to the bladder (**B**), which introduces bacteria from the urethra to the bladder. *Ureterovesical reflux*: With failure of the ureterovesical valve, urine moves up the ureters during voiding (**C**) and flows into the bladder when voiding stops (**D**). This prevents complete emptying of the bladder. It also leads to urinary stasis and contamination of the ureters with bacteria-laden urine.

measure used to establish bacteriuria. In men, contamination of the collected urine sample occurs less frequently. Bacteriuria is defined as 100,000 colony-forming units (CFU)/mL urine (Fischbach & Dunning, 2015); (Grossman & Porth, 2014). Community-acquired UTIs are among the most common bacterial infections in women (Hopkins, et al., 2014).The organisms most frequently responsible for UTIs are those normally found in the lower gastrointestinal (GI) tract, usually *Escherichia coli* (Grossman & Porth, 2014).

Routes of Infection

Bacteria enter the urinary tract in three ways: by the transurethral route (ascending infection), through the bloodstream (hematogenous spread), or by means of a fistula from the intestine (direct extension).

The most common route of infection is transurethral, in which bacteria (often from fecal contamination) colonize the periurethral area and subsequently enter the bladder by means of the urethra (Grossman & Porth, 2014). In women, the short urethra offers little resistance to the movement of uropathogenic bacteria. Sexual intercourse forces the bacteria from the urethra into the bladder. This accounts for the increased incidence of UTIs in sexually active women. Bacteria may also enter the urinary tract by means of the blood from a distant site of infection or through direct extension by way of a fistula from the intestinal tract.

Clinical Manifestations

Signs and symptoms of UTI depend on whether the infection involves the lower (bladder) or upper (kidney) urinary tract and whether the infection is acute or chronic. Signs and symptoms of an uncomplicated lower UTI include burning on urination, urinary frequency (voiding more than every 3 hours), urgency, nocturia (awakening at night to urinate), incontinence, and suprapubic or pelvic pain. Hematuria and back pain may also be present. In older adults, these symptoms are less common (see Gerontologic Considerations section).

In patients with complicated UTIs, manifestations can range from asymptomatic bacteriuria to gram-negative sepsis with shock. Complicated UTIs often are caused by a broader spectrum of organisms, have a lower response rate to treatment, and tend to recur. Many patients with catheter-associated UTIs are asymptomatic; however, any patient with a catheter who suddenly develops signs and symptoms of septic shock should be evaluated for urosepsis (the spread of infection from the urinary tract to the bloodstream that results in a systemic infection).

Gerontologic Considerations

The incidence of bacteriuria in older adults differs from that in younger adults. Bacteriuria increases with age and disability, and women are affected more frequently than men. UTI is the most common infection of older adults and increases in prevalence with age. UTIs occur more frequently in women than in men at younger ages but the gap between the sexes narrows in later life, which is due to reduced sexual intercourse in women and a higher incidence of bladder outlet obstruction secondary to benign prostatic hyperplasia in men (Eliopoulos, 2018).

In older adults, structural abnormalities secondary to decreased bladder tone, neurogenic bladder (dysfunctional bladder) secondary to stroke, or autonomic neuropathy of diabetes may prevent complete emptying of the bladder and increase the risk of UTI (Eliopoulos, 2018). When indwelling catheters are used, the risk of UTI increases dramatically (Hagerty, Kertesz, Schmidt, et al., 2015). Older women often have incomplete emptying of the bladder and urinary stasis. In the absence of estrogen, postmenopausal women are susceptible to colonization and increased adherence of bacteria to the vagina and urethra. Oral or topical estrogen has been used to restore the glycogen content of vaginal epithelial cells and an acidic pH for some postmenopausal women with recurrent cystitis.

The antibacterial activity of prostatic secretions that protect men from bacterial colonization of the urethra and bladder decreases with aging. The use of catheterization or cystoscopy in evaluation or treatment for prostatic hyperplasia or carcinoma, strictures of the urethra, and neuropathic bladder may contribute to the higher incidence of UTIs in men. The incidence of bacteriuria also increases in men with confusion, dementia, or bowel or bladder incontinence. The most common cause of recurrent UTIs in older males is chronic bacterial prostatitis. Resection of the prostate gland may help reduce its incidence (see Chapter 46).

Chart 45-3 lists other factors that may contribute to UTI in older patients. Diligent hand hygiene, careful perineal care, and frequent toileting may decrease the incidence of UTIs.

The organisms responsible for UTIs in the institutionalized older adult may differ from those found in patients residing in the community; this is thought to result in part from the frequent use of antibiotic agents by patients in long-term care facilities. *E. coli* is the most common organism seen in older patients in the community or hospital. However, patients with indwelling catheters are more likely to be infected with organisms such as *Proteus, Klebsiella, Pseudomonas,* or *Staphylococcus.* Patients who have been previously treated with antibiotics may be

Chart 45-3

Factors That Contribute to Urinary Tract Infection in Older Adults

- Cognitive impairment
- Frequent use of antimicrobial agents
- High incidence of multiple chronic medical conditions
- Immunocompromise
- Immobility and incomplete emptying of bladder
- Obstructed flow of urine (e.g., urethral strictures, neoplasms, or a clogged indwelling catheter)

Adapted from Eliopoulos, C. (2018). Gerontological nursing (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

infected with *Enterococcus* species. Frequent reinfections are common in older adults.

Early symptoms of UTI in older adults include burning, urgency, and fever (Eliopoulos, 2018). Some patients develop incontinence and delirium with the onset of a UTI.

Antibiotics are prescribed when bacteriuria is present (Eliopoulos, 2018). Treatment regimens are generally the same as those for younger adults, although age-related changes in the intestinal absorption of medications and decreased kidney function and hepatic flow may necessitate alterations in the antimicrobial regimen. Kidney function must be monitored, and medication dosages should be altered accordingly. The nurse carefully monitors fluid intake and output. Increasing fluid intake is advisable, provided that the patient's cardiac status does not contraindicate this action (Eliopoulos, 2018).

Assessment and Diagnostic Findings

Results of various tests, such as bacterial colony counts, cellular studies, and urine cultures, help confirm the diagnosis of UTI. In an uncomplicated UTI, the strain of bacteria determines the antibiotic of choice (Grossman & Porth, 2014).

Urine Cultures

Urine cultures are useful for documenting a UTI and identifying the specific organism present. UTI is diagnosed by bacteria in the urine culture. A colony count greater than 100,000 CFU/mL of urine on a clean-catch midstream or catheterized specimen indicates infection (Fischbach & Dunning, 2015). However, UTI and subsequent sepsis have occurred with lower bacterial colony counts. The presence of any bacteria in specimens obtained by suprapubic needle aspiration of the urinary bladder, straight catheterization (insertion of a tube into the urinary bladder), or during surgery or cystoscopy is considered clinically significant (Fischbach & Dunning, 2015).

The following groups of patients should have urine cultures obtained when bacteriuria is present:

- All children
- All men (because of the likelihood of structural or functional abnormalities)
- Patients who have been recently hospitalized or who live in long-term care facilities
- Patients who have undergone recent instrumentation (including catheterization) of the urinary tract
- Patients with diabetes
- Patients with prolonged or persistent symptoms
- Patients with three or more UTIs in the previous year
- Women who are postmenopausal
- Women who are pregnant
- Women who are sexually active
- Women who have new sexual partners
- Women with a history of compromised immune function or renal problems

Cellular Studies

Microscopic hematuria is present in about half of patients with an acute UTI (see Chapter 43). Pyuria (white blood cells [WBCs] in the urine) occurs in all patients with UTI; however, it is not specific for bacterial infection. Pyuria can also be seen with kidney stones, interstitial nephritis, and renal tuberculosis.

Other Studies

A multiple-test dipstick often includes testing for WBCs, known as the leukocyte esterase test, and nitrite testing (Grossman & Porth, 2014). Tests for sexually transmitted infections may be performed because acute urethritis caused by sexually transmitted organisms (i.e., *Chlamydia trachomatis, Neisseria gonorrhoeae,* herpes simplex) or acute vaginitis infections (caused by *Trichomonas* or *Candida* species) may be responsible for symptoms similar to those of UTIs.

X-ray images, computed tomography (CT) scan, ultrasonography, and kidney scans are useful diagnostic tools. A CT scan may detect pyelonephritis or abscesses. Ultrasonography and kidney scans are extremely sensitive for detecting obstruction, abscesses, tumors, and cysts (Grossman & Porth, 2014).

Medical Management

Management of UTIs typically involves pharmacologic therapy and patient education. Various prescribed medication regimens are used to treat UTI.

Acute Pharmacologic Therapy

The ideal medication for treatment of UTI is an antibacterial agent that eradicates bacteria from the urinary tract with minimal effects on fecal and vaginal flora, thereby minimizing the incidence of vaginal yeast infections. The antibacterial agent should be affordable and should have few adverse effects and low resistance. Because the organism in initial, uncomplicated UTIs in women is most likely *E. coli* or other fecal flora, the agent should be effective against these organisms. Various treatment regimens have been successful in treating uncomplicated lower UTIs in women: single-dose administration, short-course (3-day) regimens, or 7-day regimens (Hopkins et al., 2014). The trend is toward a shortened course of antibiotic therapy for uncomplicated UTIs, because most cases are cured after 3 days of treatment. Medications commonly used to treat UTIs are listed in Table 45-1. Regardless of the regimen prescribed, the patient is instructed to take all doses prescribed, even if relief of symptoms occurs promptly. Longer medication courses are indicated for men, pregnant women, and women with pyelonephritis and other types of complicated UTIs. Hospitalization and intravenous (IV) antibiotics are occasionally necessary (Hopkins et al., 2014).

Long-Term Pharmacologic Therapy

Although brief pharmacologic treatment of UTIs for 3 days is usually adequate in women, infection recurs in about 20% of women treated for uncomplicated UTIs. Infections that recur within 2 weeks of therapy do so because organisms of the original offending strain remain. Relapses suggest that the source of bacteriuria may be the upper urinary tract or

TABLE 45-1 Examples of Medications Used to Treat Urinary Tract Infections and Pyelonephritis

Drug Classes	Generic (Brand) Name	Major Indications
Anti-infective, urinary tract Bactericidal	Nitrofurantoin (Macrodantin, Furadantin) Cephalexin (Keflex)	UTI Genitourinary infection
Cephalosporin	Cefadroxil (Duricef, Ultracef)	UTI
Fluoroquinolone	Ciprofloxacin (Cipro) Ofloxacin (Floxin) Norfloxacin (Noroxin) Gatifloxacin (Zymar)	UTI Pyelonephritis
Fluoroquinolone	Levofloxacin (Levaquin)	Uncomplicated UTI
Penicillin	Ampicillin (Principen, Omnipen) Amoxicillin (Amoxil)	UTI—not commonly used alone due to *Escherichia coli* resistance Pyelonephritis UTI—not commonly used alone due to *E. coli* resistance
Trimethoprim–sulfamethoxazole combination	Co-trimoxazole (Bactrim, Septra)	UTI Pyelonephritis
Urinary analgesic agent	Phenazopyridine (Pyridium)	For relief of burning, pain, and other symptoms associated with UTI

UTI, urinary tract infection.

Adapted from Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer; Hopkins, L., McCroskey, D., Reeves, G., et al. (2014). Implementing a urinary tract infection clinical practice guideline in an ambulatory urgent care practice. The Nurse Practitioner, 39(4), 50–54.

that initial treatment was inadequate or given for too short a time. Recurrent infections in men are usually caused by persistence of the same organism; further evaluation and treatment are indicated (Hopkins et al., 2014).

If infection recurs after completing antimicrobial therapy, another short course (3 to 4 days) of full-dose antimicrobial therapy followed by a regular bedtime dose of an antimicrobial agent may be prescribed. If there is no recurrence, medication is taken every other night for 6 to 7 months. Long-term use of antimicrobial agents decreases the risk of reinfection and may be indicated in patients with recurrent infections.

If recurrence is caused by persistent bacteria from preceding infections, the cause (i.e., kidney stone, abscess), if known, must be treated. After treatment and sterilization of the urine, low-dose prophylactic therapy (trimethoprim with or without sulfamethoxazole) each night at bedtime may be prescribed (Hopkins et al., 2014).

Daily intake of cranberry juice can help prevent and control symptoms of UTI (Bass-Ware, Weed, Johnson, et al., 2014); (Hopkins et al., 2014). One group of researchers reported that daily consumption of cranberry juice over an 8-week period decreased symptoms (i.e., urgency, frequency, nocturia, dysuria, and pain) in women diagnosed with a UTI in an ambulatory setting (Bass-Ware, et al., 2014).

NURSING PROCESS

The Patient With a Lower Urinary Tract Infection

Nursing care of the patient with a lower UTI focuses on treating the underlying infection and preventing its recurrence.

Assessment

A history of pertinent signs and symptoms is obtained from the patient with a suspected UTI. The presence of pain, frequency, urgency, hesitancy, and changes in urine are assessed, documented, and reported. The patient's usual pattern of voiding is assessed to detect factors that may predispose him or her to UTI. Infrequent emptying of the bladder, the association of symptoms of UTI with sexual intercourse, contraceptive practices, and personal hygiene are assessed. The patient's knowledge about prescribed antimicrobial medications and preventive health care measures is also assessed. In addition, the urine is assessed for volume, color, concentration, cloudiness, and odor—all of which are altered by bacteria in the urinary tract. Patients need to be asked specifically about the use of complementary and alternative therapies. Researchers in one study reported that women with interstitial cystitis (inflammation of the bladder wall) used both complementary and conventional therapies. The most common complementary therapies reported included diet, biofeedback, dietary supplements, meditation, yoga, and massage (Anderson & Zinkgraf, 2013).

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain related to infection within the urinary tract
- Deficient knowledge about factors predisposing the patient to infection and recurrence, detection and prevention of recurrence, and pharmacologic therapy

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Sepsis (urosepsis)
- Acute kidney injury and/or chronic kidney disease may occur as the long-term result of either an extensive infective or inflammatory process

Planning and Goals

Major goals for the patient may include relief of pain and discomfort, increased knowledge of preventive measures and treatment modalities, and absence of complications.

Nursing Interventions

Relieving Pain

The pain associated with a UTI is quickly relieved once effective antimicrobial therapy is initiated. Antispasmodic agents may also be useful in relieving bladder irritability and pain. Analgesic agents and the application of heat to the perineum help relieve pain and spasm. The patient is encouraged to drink liberal amounts of fluids (water is the best choice) to promote renal blood flow and to flush the bacteria from the urinary tract. Urinary tract irritants (e.g., coffee, tea, citrus, spices, colas, alcohol) should be avoided. Frequent voiding (every 2 to 3 hours) is encouraged to empty the bladder completely, because doing so can lower urine bacterial counts, reduce urinary stasis, and prevent reinfection (Bass-Ware, et al., 2014); (Hopkins et al., 2014).

Monitoring and Managing Potential Complications

Early recognition of UTI and prompt treatment are essential to prevent recurrent infection and the possibility of complications, such as kidney disease, sepsis (urosepsis), strictures, and obstructions. The goal of treatment is to prevent infection from progressing and causing permanent kidney damage and injury. Thus, the patient must be educated to recognize early signs and symptoms, to test for bacteriuria, and to initiate treatment as prescribed. Appropriate antimicrobial therapy, liberal fluid intake, frequent voiding, and hygienic measures are commonly prescribed for managing UTIs. The patient is instructed to notify the primary provider if fatigue, nausea, vomiting, fever, or pruritus occurs. Periodic monitoring of renal function and evaluation for strictures, obstructions, or stones may be indicated for patients with recurrent UTIs.

Patients with UTIs are at increased risk for gram-negative sepsis. For each day a urinary catheter is in place, the risk of developing catheter-associated urinary tract infection (CAUTI) increases. The risk of sepsis in patients with a urinary catheter is about 15% (Booker, 2015). CAUTIs should be avoided as they result in unpleasant symptoms, additional pharmacologic therapy, serious complications, and delayed discharge (Booker, 2015); (Carter, Reitmeier, & Goodloe, 2014).

If an indwelling catheter is necessary, the following specific nursing interventions are initiated to prevent infection and urosepsis:

- Using strict aseptic technique during insertion of the smallest catheter possible
- Securing the catheter to prevent movement
- Frequently inspecting urine color, odor, and consistency
- Performing meticulous daily perineal care with soap and water
- Maintaining a closed system
- Following the manufacturer's instructions when using the catheter port to obtain urine specimens

Careful assessment of vital signs and level of consciousness may alert the nurse to kidney involvement or impending sepsis. Positive blood cultures and elevated WBC counts must be reported immediately. At the same time, appropriate antibiotic therapy and increased fluid intake are prescribed (IV antibiotic therapy and fluids may be required). Aggressive early treatment is the key to reducing the mortality rate associated with CAUTI especially in older patients, those with anemia, and those with elevated blood sugar levels (Hagerty et al., 2015). See Chart 45-4 for more information on risk factors for CAUTIs.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. In helping patients learn about and prevent or manage a recurrent UTI, the nurse implements education that meets the patient's needs. Health-related behaviors that help prevent recurrent UTIs include practicing careful personal hygiene, increasing fluid intake to promote voiding and dilution of urine, urinating regularly and more frequently, and adhering to the therapeutic regimen. For a detailed discussion of patient education, see Chart 45-5.

Evaluation

Expected patient outcomes may include:

1. Experiences relief of pain
   a. Reports absence of pain, urgency, frequency, nocturia, or hesitancy on voiding

Chart 45-4 NURSING RESEARCH PROFILE

Risk Factors for Catheter-Associated Urinary Tract Infections

Hagerty, T., Kertesz, L., Schmidt, J. M., et al. (2015). Risk factors for catheter associated urinary tract infections in critically ill patients with subarachnoid hemorrhage. Journal of Neuroscience Nursing, 47(1), 51–54.

Purpose

The use of indwelling urinary catheters can lead to complications, most importantly catheter-associated urinary tract infections (CAUTI). These infections are the most common health care–associated infection in the United States. The purpose of this study was to assess the prevalence of and risk factors for CAUTIs among patients with subarachnoid hemorrhage (SAH) in one neurologic intensive care unit.

Design

This quantitative study used a retrospective design and included 242 patients with SAH admitted between 2005 and 2012 for whom data had been included in an existing data set. Logistic regression was used to identify predictors of CAUTI.

Findings

Catheterized adult patients (n = 242) with SAH over the 8-year period were included in the analysis. The rate of CAUTIs was 21%, or 6 times higher than the reported national average. Variables statistically significantly associated with CAUTI were older age (odds ratio [OR] = 1.06, 95% confidence interval [CI] [1.01, 1.11]), increased blood sugar levels (OR = 13.0, 95% CI [1.28, 107.4]), and anemia requiring transfusion (OR = 3.78, 95% CI [0.977, 14.67]).

Nursing Implications

Nurses should know that the high rates of CAUTI in this study were likely associated with prolonged catheterization. These findings indicate that nurses should carefully assess the need for catheterization and have increased vigilance regarding urinary catheter care in patients admitted with an SAH. Particular attention should be paid to patients who are older, those with anemia requiring transfusion, and those with elevated blood glucose levels due to their increased risk of CAUTI.

Chart 45-5 PATIENT EDUCATION

Preventing Recurrent Urinary Tract Infections

The nurse instructs the patient on the following basic information:

Hygiene

- Shower rather than bathe in the tub because bacteria in the bathwater may enter the urethra.
- Clean the perineum and urethral meatus from front to back after each bowel movement. This will help reduce concentrations of pathogens at the urethral opening and, in women, the vaginal opening.

Fluid Intake

- Drink liberal amounts of fluids daily to flush out bacteria. It may be helpful to include at least one glass of cranberry juice per day.
- Avoid coffee, tea, colas, alcohol, and other fluids that are urinary tract irritants.

Voiding Habits

Void every 2–3 hours during the day, and completely empty the bladder. This prevents overdistention of the bladder and compromised blood supply to the bladder wall. Both predispose the patient to urinary tract infection. Precautions expressly for women include voiding immediately after sexual intercourse.

Interventions

- Take medication *exactly* as prescribed. Special timing of administration may be required.
- Keep in mind that if bacteria continue to appear in the urine, long-term antimicrobial therapy may be required to prevent colonization of the periurethral area and recurrence of infection.
- For recurrent infection, consider acidification of the urine through ascorbic acid (vitamin C), 1000 mg daily, or daily consumption of cranberry juice.
- To decrease recurrences, consider *Lactobacillus* probiotics use in oral or vaginal form.
- If prescribed, test urine for presence of bacteria following manufacturer's and health care provider's instructions.
- Notify the primary provider if fever occurs or if signs and symptoms persist.
- Consult the primary provider regularly for follow-up.

Adapted from Bass-Ware, A., Weed, D., Johnson. T., et al. (2014). Evaluation of the effect of cranberry juice on symptoms associated with a urinary tract infection. Urologic Nursing, 34(3), 121–127; Chisholm, A. H. (2015). Probiotics in preventing recurrent urinary tract infections in women: A literature review. Urologic Nursing, 35(1), 18–21, 29.

   b. Takes analgesic, antispasmodic, and antibiotic agents as prescribed
2. Explains UTIs and their treatment
   a. Demonstrates knowledge of preventive measures and prescribed treatments
   b. Drinks 8 to 10 glasses of fluids daily
   c. Voids every 2 to 3 hours
   d. Produces urine that is clear and odorless
3. Experiences no complications
   a. Reports no symptoms of infection (fever, frequency)
   b. Has normal kidney function, negative urine and blood cultures
   c. Exhibits normal vital signs and temperature; no signs or symptoms of sepsis (urosepsis)
   d. Maintains adequate urine output more than 0.5 mL/kg/hr

Upper Urinary Tract Infections

Pyelonephritis is a bacterial infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Causes involve either the upward spread of bacteria from the bladder or spread from systemic sources reaching the kidney via the bloodstream. Pathogenic bacteria from a bladder infection can ascend into the kidney, resulting in pyelonephritis. An incompetent ureterovesical valve or obstruction occurring in the urinary tract increases the susceptibility of the kidneys to infection (see Fig. 45-1), because static urine provides a good medium for bacterial growth. Bladder or prostate tumors, strictures, benign prostatic hyperplasia, and urinary stones are some potential causes of obstruction that can lead to infections. Systemic infections (such as tuberculosis) can spread to the kidneys and result in abscesses.

Pyelonephritis may be acute or chronic. Acute pyelonephritis usually leads to enlargement of the kidneys with interstitial infiltrations of inflammatory cells (Grossman & Porth, 2014). Abscesses may be noted on or within the renal capsule and at the corticomedullary junction. Eventually, atrophy and destruction of tubules and the glomeruli may result. When pyelonephritis becomes chronic, the kidneys become scarred, contracted, and nonfunctioning. Chronic pyelonephritis is a cause of chronic kidney disease that can result in the need for renal replacement therapies such as transplantation or dialysis.

Acute Pyelonephritis

Clinical Manifestations

The patient with acute pyelonephritis has chills, fever, leukocytosis, bacteriuria, and pyuria. Low back pain, flank pain, nausea and vomiting, headache, malaise, and painful urination are common findings. Physical examination reveals pain and tenderness in the area of the costovertebral angle (see Fig. 43-6 in Chapter 43). In addition, symptoms of lower urinary tract involvement, such as urgency and frequency, are common.

Assessment and Diagnostic Findings

An ultrasound study or a CT scan may be performed to locate an obstruction in the urinary tract. Relief of obstruction is essential to prevent complications and eventual kidney damage. An IV pyelogram may be indicated with pyelonephritis if functional and structural renal abnormalities are suspected (Fischbach & Dunning, 2015). Radionuclide imaging with gallium citrate and indium-111 (^{111}In)–labeled WBCs may be useful to identify sites of infection that may not be visualized on CT scan or ultrasound. Urine culture and sensitivity tests are performed to determine the causative organism so that appropriate antimicrobial agents can be prescribed (Fischbach & Dunning, 2015).

Medical Management

Patients with acute uncomplicated pyelonephritis are most often treated on an outpatient basis if they are not exhibiting

acute symptoms of sepsis, dehydration, nausea, or vomiting. In addition, they must be responsible and reliable to ensure that all medications will be taken as prescribed. For outpatients, a 2-week course of antibiotic agents is recommended because renal parenchymal disease is more difficult to eradicate than mucosal bladder infections. Commonly prescribed agents include many of the same medications prescribed for the treatment of UTIs (see Table 45-1).

Following acute pyelonephritis treatment, the patient may develop a chronic or recurring symptomless infection persisting for months or years. After the initial antibiotic regimen, the patient may need antibiotic therapy for up to 6 weeks if a relapse occurs. A follow-up urine culture is obtained 2 weeks after completion of antibiotic therapy to document clearing of the infection.

Hydration with oral or parenteral fluids is essential in all patients with UTIs when there is adequate kidney function. Hydration helps facilitate "flushing" of the urinary tract and reduces pain and discomfort.

Chronic Pyelonephritis

Repeated bouts of acute pyelonephritis may lead to chronic pyelonephritis.

Clinical Manifestations

The patient with chronic pyelonephritis usually has no symptoms of infection unless an acute exacerbation occurs. Noticeable signs and symptoms may include fatigue, headache, poor appetite, polyuria, excessive thirst, and weight loss. Persistent and recurring infection may produce progressive scarring of the kidney, resulting in chronic kidney disease (see Chapter 44).

Assessment and Diagnostic Findings

The extent of the disease is assessed by an IV urogram and measurements of creatinine clearance, blood urea nitrogen, and creatinine levels (Fischbach & Dunning, 2015).

Complications

Complications of chronic pyelonephritis include end-stage kidney disease (from progressive loss of nephrons secondary to chronic inflammation and scarring), hypertension, and formation of kidney stones (from chronic infection with urea-splitting organisms).

Medical Management

Bacteria, if detected in the urine, are eradicated if possible. Long-term use of prophylactic antimicrobial therapy may help limit recurrence of infections and kidney scarring. Impaired kidney function alters the excretion of antimicrobial agents and necessitates careful monitoring of kidney function, especially if the medications are potentially toxic to the kidneys.

Nursing Management

The patient may require hospitalization or may be treated as an outpatient. When the patient requires hospitalization, fluid intake and output are carefully measured and recorded. Unless contraindicated, 3 to 4 L of fluids per day is encouraged to dilute the urine, decrease burning on urination, and prevent dehydration. The nurse assesses the patient's temperature every 4 hours and administers antipyretic and antibiotic agents as prescribed.

Patient education focuses on prevention of further infection by consuming adequate fluids, emptying the bladder regularly, and performing recommended perineal hygiene. The importance of taking antimicrobial medications exactly as prescribed is stressed, as is the need for keeping follow-up appointments.

ADULT VOIDING DYSFUNCTION

Both neurogenic and nonneurogenic disorders can cause adult voiding dysfunction (see Table 45-2). The micturition (voiding or urination) process involves several highly coordinated neurologic responses that mediate bladder function. A functional urinary system allows for appropriate bladder filling and complete bladder emptying (see Chapter 43). If voiding dysfunction goes undetected and untreated, the upper urinary system may be compromised. Chronic incomplete bladder emptying from poor detrusor pressure results in recurrent bladder infection. Incomplete bladder emptying due to bladder outlet obstruction (such as benign prostatic hyperplasia), causing high-pressure detrusor contractions, can result in hydronephrosis from the high detrusor pressure that radiates up the ureters to the renal pelvis.

Urinary Incontinence

Approximately 22% of women are estimated to have urinary incontinence (involuntary or uncontrolled loss of urine from the bladder), with most of them experiencing stress incontinence (Singh, Agarwal & Shankwhar, 2013). Despite widespread media coverage, urinary incontinence remains underdiagnosed and underreported. Patients may be too embarrassed to seek help, causing them to ignore or conceal symptoms. Many patients use absorbent pads or other devices without having their condition properly diagnosed and treated (Day, Leahy-Warren, Loughran, et al., 2014). Health care providers must be alert to subtle cues of urinary incontinence and stay informed about current management strategies.

The costs of care for patients with urinary incontinence include the expenses of absorbent products, medications, and surgical or nonsurgical treatment modalities, as well as psychosocial costs (i.e., embarrassment, loss of self-esteem, and social isolation) (Day et al., 2014); (McCooty & Latthe, 2014).

Although urinary incontinence is commonly regarded as a condition that occurs in older multiparous women, it can occur in young nulliparous women, especially during vigorous high-impact activity. Age, gender, and number of vaginal deliveries are established risk factors that explain, in part, the increased incidence in women (see Chart 45-6). Men can have urinary incontinence, especially those with certain comorbid conditions. One group of researchers, for example, reported that 40% of men with Parkinson disease reported urinary incontinence (Robinson, Bradway, Bunting-Perry, et al., 2013). Urinary incontinence is a symptom of many possible disorders.

Types

There are many types of urinary incontinence, including the following:

Stress incontinence is the involuntary loss of urine through an intact urethra as a result of sneezing, coughing, or changing position (Miller, 2015); (Weber & Kelley, 2014). It predominantly affects women who have had vaginal deliveries and is thought to be the result of decreasing ligament and pelvic floor support of the urethra and decreasing or absent estrogen levels within the urethral walls and bladder base. In men, stress incontinence

TABLE 45-2 Conditions Causing Adult Voiding Dysfunction

Condition	Voiding Dysfunction	Treatment
Neurogenic Disorders		
Cerebellar ataxia	Incontinence or dyssynergia	Timed voiding; anticholinergic agents
Stroke	Retention or incontinence	Anticholinergic agents; bladder retraining
Dementia	Incontinence	Prompted voiding; anticholinergic agents
Diabetes	Incontinence and/or incomplete bladder emptying	Timed voiding; EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic/antispasmodic agents; well-controlled blood glucose levels
Multiple sclerosis	Incontinence or incomplete bladder emptying	Timed voiding; EMG/biofeedback to learn pelvic muscle exercises and urge inhibition; pelvic floor nerve stimulation; antispasmodic agents
Parkinson disease	Incontinence	Anticholinergic/antispasmodic agents
Spinal Cord Dysfunction		
Acute injury	Urinary retention	Indwelling catheter
Degenerative disease	Incontinence and/or incomplete bladder emptying	EMG/biofeedback; pelvic floor nerve stimulation; anticholinergic agents
Nonneurogenic Disorder		
"Bashful bladder"	Inability to initiate voiding in public bathrooms	Relaxation therapy; EMG/biofeedback
Overactive bladder	Urgency, frequency, and/or urge incontinence	EMG/biofeedback; pelvic floor nerve stimulation; bladder drill (see Chart 45-8); anticholinergic agents
Post general surgery	Acute urine retention	Catheterization
Post prostatectomy	Incontinence	*Mild*: Biofeedback; bladder drill (see Chart 45-8); pelvic floor nerve stimulation *Moderate/severe*: *Surgery*—artificial sphincter
Stress incontinence	Incontinence with cough, laugh, sneeze, position change	*Mild*: Biofeedback; bladder drill (see Chart 45-8); periurethral bulking with collagen *Moderate/severe*: Surgery

EMG, electromyogram.

Chart 45-6 RISK FACTORS

Urinary Incontinence

- Age-related changes in the urinary tract
- Caregiver or toilet unavailable
- Cognitive disturbances—dementia, Parkinson disease
- Diabetes
- Genitourinary surgery
- High-impact exercise
- Immobility
- Incompetent urethra due to trauma or sphincter relaxation
- Medications—diuretic, sedative, hypnotic, and opioid agents
- Menopause
- Morbid obesity
- Pelvic muscle weakness
- Pregnancy—vaginal delivery, episiotomy
- Stroke

Adapted from Robinson, J. P., Bradway. C. W., Bunting-Perry, L., et al. (2013). Lower urinary tract symptoms in men with Parkinson's disease. Journal of Neuroscience Nursing, 45(6). 382–392.

is often experienced after a radical prostatectomy for prostate cancer because of the loss of urethral compression that the prostate had supplied before the surgery, and possibly bladder wall irritability.

Urge incontinence is the involuntary loss of urine associated with a strong urge to void that cannot be suppressed (Miller, 2015); (Weber & Kelley, 2014). The patient is aware of the need to void but is unable to reach a toilet in time. An uninhibited detrusor contraction is the precipitating factor. This can occur in a patient with neurologic dysfunction that impairs inhibition of bladder contraction or in a patient without overt neurologic dysfunction.

Functional incontinence refers to those instances in which lower urinary tract function is intact but other factors, such as severe cognitive impairment (e.g., Alzheimer dementia), make it difficult for the patient to identify the need to void or physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding (Miller, 2015).

Iatrogenic incontinence refers to the involuntary loss of urine due to extrinsic medical factors, predominantly medications. One such example is the use of alpha-adrenergic agents to decrease blood pressure. In some people with an intact urinary system, these agents adversely affect the alpha receptors responsible for bladder neck closing pressure; the bladder neck relaxes to the point of incontinence with a minimal increase in intra-abdominal pressure, thus mimicking stress incontinence. As soon as the medication is discontinued, the apparent incontinence resolves.

Mixed urinary incontinence, which encompasses several types of urinary incontinence, is involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing (Miller, 2015).

Only with appropriate recognition of the problem, assessment, and referral for diagnostic evaluation and treatment can the outcome of incontinence be determined. All people with incontinence should be considered for evaluation and treatment.

Gerontologic Considerations

Although urinary incontinence is not a normal consequence of aging, age-related changes in the urinary tract do predispose the older person to incontinence. However, if nurses and other health care providers accept incontinence as an inevitable part of illness or aging or consider it irreversible and untreatable, it cannot be treated successfully. Collaborative, interdisciplinary efforts are essential in assessing and effectively treating urinary incontinence.

Urinary incontinence can decrease an older person's ability to maintain an independent lifestyle, which increases dependence on caregivers and may lead to institutionalization. Between 25% and 45% of older women have urinary incontinence (Day et al., 2014).

Many older adults experience transient episodes of incontinence that tend to be abrupt in onset. When this occurs, the nurse should question the patient, as well as the family if possible, about the onset of symptoms and any signs or symptoms of a change in other organ systems. Acute UTI, infection elsewhere in the body, constipation, decreased fluid intake, and a change in a chronic disease pattern, such as elevated blood glucose levels in patients with diabetes or decreased estrogen levels in menopausal women, can provoke the onset of urinary incontinence. If the cause is identified and modified or eliminated early at the onset of incontinence, the incontinence itself may be eliminated. Although the bladder of the older person is more vulnerable to altered detrusor activity, age alone is not a risk factor for urinary incontinence (Miller, 2015).

Decreased bladder muscle tone is a normal age-related change found in older adults. This leads to decreased bladder capacity, increased residual urine (urine remaining in the bladder after voiding), and an increase in urgency.

Many medications affect urinary continence in addition to causing other unwanted or unexpected effects (Miller, 2015). All medications need to be assessed for potential interactions.

Assessment and Diagnostic Findings

Once incontinence is recognized, a thorough history is necessary. This includes a detailed description of the problem and a history of medication use. The patient's voiding history, a diary of fluid intake and output, and bedside tests (e.g., residual urine, stress maneuvers) may be used to help determine the type of urinary incontinence involved. Extensive urodynamic tests may be performed (see Chapter 43). Urinalysis and urine culture are performed to identify infection.

Urinary incontinence may be transient or reversible if the underlying cause is successfully treated and the voiding pattern reverts to normal. Chart 45-7 provides causes of transient incontinence.

Medical Management

Management depends on the type of urinary incontinence and its causes. Management of urinary incontinence may be behavioral, pharmacologic, or surgical.

Behavioral Therapy

Behavioral therapies are the first choice to decrease or eliminate urinary incontinence (see Chart 45-8). In using these techniques, health care professionals help patients avoid potential adverse effects of pharmacologic or surgical interventions. Pelvic floor muscle exercises (sometimes referred to as Kegel exercises) represent the cornerstone of behavioral intervention for addressing symptoms of stress, urge, and mixed incontinence (Miller, 2015); (Weber & Kelley, 2014). Other behavioral treatments include the use of a voiding diary, biofeedback, verbal instruction (prompted voiding), and physical therapy (Day et al., 2014); (McCooty & Latthe, 2014).

Chart 45-7

Causes of Transient Incontinence

- Atrophic vaginitis, urethritis, prostatitis
- Delirium or confusion
- Excessive urine production (increased intake, diabetes, diabetic ketoacidosis)
- Limited or restricted activity
- Pharmacologic agents (anticholinergic agents, sedatives, alcohol, analgesic agents, diuretics, muscle relaxants, adrenergic agents)
- Psychological factors (depression, regression)
- Stool impaction or constipation
- Urinary tract infections (UTI)

Pharmacologic Therapy

Pharmacologic therapy works best when used as an adjunct to behavioral interventions. Anticholinergic agents inhibit bladder contraction and are considered first-line medications for urge incontinence. A tricyclic antidepressant medication (e.g., amitriptyline [Elavil]) can also decrease bladder contractions as well as increase bladder neck resistance (Comerford, 2015). Pseudoephedrine sulfate (Sudafed), which acts on alpha-adrenergic receptors, causing urinary retention, may be used to treat stress incontinence; it needs to be used with caution in men with prostatic hyperplasia and patients with hypertension.

Surgical Management

Surgical correction may be indicated in patients who have not achieved continence using behavioral and pharmacologic therapy. Surgical options vary according to the underlying anatomy and the physiologic problem. Most procedures involve lifting and stabilizing the bladder or urethra to restore the normal urethrovesical angle or to lengthen the urethra.

Women with stress incontinence may undergo an anterior vaginal repair, retropubic suspension, or needle suspension to reposition the urethra. Procedures to compress the urethra and increase resistance to urine flow include sling procedures and placement of periurethral bulking agents such as artificial collagen.

Periurethral bulking is a semipermanent procedure in which small amounts of artificial collagen are placed within the walls of the urethra to enhance the closing pressure of the urethra (Matsuoka, Locali, Pacetta, et al., 2016). This procedure takes only 10 to 20 minutes and may be performed under local anesthesia or moderate sedation. A cystoscope is inserted into the urethra. An instrument is inserted through the cystoscope to deliver a small amount of collagen into the urethral wall at locations selected by the urologist. The patient is usually discharged home after voiding. There are no restrictions following the procedure, although occasionally more than one collagen bulking session may be necessary if the initial procedure did not halt stress incontinence. Collagen placement anywhere in the body is considered semipermanent because its durability averages between 12 and 24 months, until the body absorbs the material. Periurethral bulking with collagen is a relatively safe alternative to surgery (Matsuoka et al., 2016). It is also an option for people who are seeking help with stress incontinence who prefer to avoid surgery and who do not have access to behavioral therapies.

An artificial urinary sphincter can be used to close the urethra and promote continence. Two types of artificial sphincters are a periurethral cuff and a cuff inflation pump.

Men with overflow and stress incontinence may undergo a transurethral resection to relieve symptoms of prostatic enlargement. An artificial sphincter can be used after prostatic surgery for sphincter incompetence (see Fig. 45-2). After surgery, periurethral bulking agents can be injected into the periurethral area to increase compression of the urethra (Matsuoka et al., 2016).

Chart 45-8 HEALTH PROMOTION

Interventions for Urinary Incontinence

Behavioral strategies are largely carried out, coordinated, and monitored by the nurse. These interventions may or may not be augmented by the use of medications.

Fluid Management

An adequate daily fluid intake of approximately 50–60 oz (1500–1600 mL), taken as small increments between breakfast and the evening meal, helps to reduce urinary urgency related to concentrated urine production, decreases the risk of urinary tract infection, and maintains bowel functioning. (Constipation, resulting from inadequate daily fluid intake, can increase urinary urgency and urine retention.) The best fluid is water, although some suggest it may be helpful to include at least one glass of cranberry juice per day. Fluids containing caffeine, carbonation, alcohol, or artificial sweetener should be avoided because they irritate the bladder wall, thus resulting in urinary urgency. Some patients who have heart failure or end-stage kidney disease need to discuss their daily fluid limit with their primary provider.

Standardized Voiding Frequency

After establishing a patient's natural voiding and urinary incontinence tendencies, voiding on a schedule can be very effective in those with and without cognitive impairment, although patients with cognitive impairment may require assistance with this technique from nursing personnel or family members. The object is to purposely empty the bladder before the bladder reaches the critical volume that would cause an urge or stress incontinence episode. This approach involves the following:

- **Timed voiding** involves establishing a set voiding frequency (such as every 2 hours if incontinent episodes tend to occur 2 or more hours after voiding). The individual chooses to "void by the clock" at the given interval while awake rather than wait until a voiding urge occurs.
- **Prompted voiding** is timed voiding that is carried out by staff or family members when the individual has cognitive difficulties that make it difficult to remember to void at set intervals. The caregiver checks the patient to assess if he or she has remained dry and, if so, assists the patient to use the bathroom while providing positive reinforcement for remaining dry.
- **Habit retraining** is timed voiding at an interval that is more frequent than the individual would usually choose. This technique helps to restore the sensation of the need to void in individuals who are experiencing diminished sensation of bladder filling due to various medical conditions such as a stroke.
- **Bladder retraining**, also known as "bladder drill," incorporates a timed voiding schedule and urinary urge inhibition exercises to inhibit voiding, or leaking urine, in an attempt to remain dry for a set time. When the first timing interval is easily reached on a consistent basis without urinary urgency or incontinence, a new voiding interval, usually 10–15 minutes beyond the last, is established. Again, the individual practices urge inhibition exercises to delay voiding or avoid incontinence until the next preset interval arrives. When an acceptable voiding interval is reached, the patient continues that timed voiding sequence throughout the day.

Pelvic Muscle Exercise

Also known as Kegel exercises, pelvic muscle exercise (PME) aims to strengthen the voluntary muscles that assist in bladder and bowel continence in both men and women. Research shows that written or verbal instruction alone is usually inadequate to educate an individual about how to identify and strengthen the pelvic floor for sufficient bladder and bowel control. Biofeedback-assisted PME uses either electromyography or manometry to help the individual identify the pelvic muscles as they attempt to learn which muscle group is involved when performing PME. The biofeedback method also allows assessment of the strength of this muscle area.

PME involves gently tightening the same muscles used to stop flatus or the stream of urine for 5–10-second increments, followed by 10-second resting phases. To be effective, these exercises need to be performed 2 or 3 times a day for at least 6 weeks. Depending on the strength of the pelvic musculature when initially evaluated, anywhere from 10–30 repetitions of PME are prescribed at each session. Older patients may need to exercise for an even longer time to strengthen the pelvic floor muscles. Pelvic muscle exercises are helpful for women with stress, urge, or mixed incontinence and for men who have undergone prostate surgery.

Vaginal Cone Retention Exercises

Vaginal cone retention exercises are an adjunct to the Kegel exercises. Vaginal cones of varying weight are inserted intravaginally twice a day. The patient tries to retain the cone for 15 minutes by contracting the pelvic muscles.

Transvaginal or Transrectal Electrical Stimulation

Commonly used to treat urinary incontinence, electrical stimulation is known to elicit a passive contraction of the pelvic floor musculature, thus re-educating these muscles to provide enhanced levels of continence. This modality is often used with biofeedback-assisted pelvic muscle exercise training and voiding schedules. At high frequencies, it is effective for stress incontinence. At low frequencies, electrical stimulation can also relieve symptoms of urinary urgency, frequency, and urge incontinence. Intermediate ranges are used for mixed incontinence.

Neuromodulation

Neuromodulation via transvaginal or transrectal nerve stimulation of the pelvic floor inhibits detrusor overactivity and hypersensory bladder signals and strengthens weak sphincter muscles.

Probiotics in preventing recurrent urinary tract infections in women: A literature review. Urologic Nursing, 35(1), 18–21, 29.

Nursing Management

Nursing management is based on the premise that incontinence is not inevitable with illness or aging and that it is often reversible and treatable. The nursing interventions are determined in part by the type of treatment that is undertaken. For behavioral therapy to be effective, the nurse must provide support and encouragement, because it is easy for the patient to become discouraged if therapy does not quickly improve the level of continence. Patient education is important and should be provided verbally and in writing (see Chart 45-9). The patient should be educated to develop and use a log or diary to record timing of pelvic floor muscle exercises, frequency of voiding, any changes in bladder function, and any episodes of incontinence (Miller, 2015).

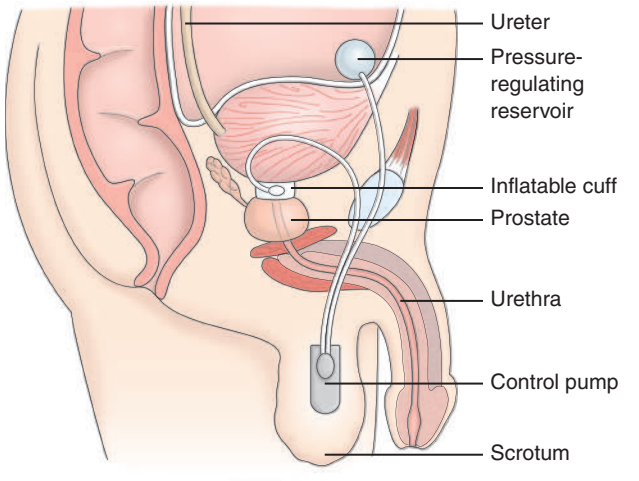

Figure 45-2 • Male artificial urinary sphincter. An inflatable cuff is inserted surgically around the urethra or neck of the bladder. To empty the bladder, the cuff is deflated by squeezing the control pump located in the scrotum.

Chart 45-9 PATIENT EDUCATION

Strategies for Promoting Urinary Continence

The nurse instructs the patient to:

- Avoid bladder irritants, such as caffeine, alcohol, and aspartame (NutraSweet).
- Avoid taking diuretic agents after 4 PM.
- Increase awareness of the amount and timing of all fluid intake.
- Perform all pelvic floor muscle exercises as prescribed, every day.
- Stop smoking (smokers usually cough frequently, which increases incontinence).
- Take steps to avoid constipation: Drink adequate fluids, eat a well-balanced diet high in fiber, exercise regularly, and take stool softeners if recommended.
- Void regularly, 5–8 times a day (about every 2–3 hours):
  - First thing in the morning
  - Before each meal
  - Before retiring to bed
  - Once during the night if necessary

If pharmacologic treatment is used, the patient and family are educated about its purpose. Patients with mixed incontinence must be informed that anticholinergic and antispasmodic agents can help decrease urinary urgency and frequency and urge incontinence but do not decrease the urinary incontinence related to stress incontinence. If surgical correction is undertaken, the procedure and its desired outcomes are described to the patient and family. Follow-up contact with the patient enables the nurse to answer the patient's questions and to provide reinforcement and encouragement.

Urinary Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Chronic urine retention often leads to overflow incontinence (involuntary urine loss associated with overdistention of the bladder). Residual urine is urine that remains in the bladder after voiding. In a healthy adult younger than 60 years, complete bladder emptying should occur with each voiding. In adults older than 60 years, 50 to 100 mL of residual urine may remain after each voiding because of the decreased contractility of the detrusor muscle.

Urinary retention can occur postoperatively in any patient, particularly if the surgery affected the perineal or anal regions and resulted in reflex spasm of the sphincters. General anesthesia reduces bladder muscle innervation and suppresses the urge to void, impeding bladder emptying.

Pathophysiology

Urinary retention may result from diabetes, prostatic enlargement, urethral pathology (infection, tumor, calculus), trauma (pelvic injuries), pregnancy, or neurologic disorders (e.g., stroke, spinal cord injury, multiple sclerosis, or Parkinson disease). Some medications cause urinary retention either by inhibiting bladder contractility or by increasing bladder outlet resistance (Comerford, 2015).

Assessment and Diagnostic Findings

The assessment of a patient for urinary retention is multifaceted because the signs and symptoms are challenging to detect. The following questions serve as a guide in assessment:

- What was the time of the last voiding, and how much urine was voided?
- Is the patient voiding small amounts of urine frequently?
- Is the patient dribbling urine?
- Does the patient complain of pain or discomfort in the lower abdomen? (Discomfort may be relatively mild if the bladder distends slowly.)
- Is the pelvic area rounded and swollen (could indicate urine retention and a distended bladder)?
- Does percussion of the suprapubic region elicit dullness (possibly indicating urine retention and a distended bladder)?
- Are other indicators of urinary retention present, such as restlessness and agitation?
- Does a postvoid bladder ultrasound test reveal residual urine?

The patient may verbalize an awareness of bladder fullness and a sensation of incomplete bladder emptying. Signs and symptoms of UTI (hematuria, urgency, frequency, and nocturia) may be present. A series of urodynamic studies (described in Chapter 43) may be performed to identify the type of bladder dysfunction and to aid in determining appropriate treatment. A voiding diary can be used to provide a written record of the amount of urine voided and the frequency of voiding. Postvoid residual urine may be assessed by using either straight catheterization or an ultrasound bladder scanner and is considered diagnostic of urinary retention. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2014).

Complications

The retention of urine can lead to chronic infections that if unresolved predispose the patient to renal calculi (urolithiasis or nephrolithiasis), pyelonephritis, sepsis, or hydronephrosis. In addition, urine leakage can lead to perineal skin breakdown, especially if regular hygiene measures are neglected.

Nursing Management

Strategies are instituted to prevent overdistention of the bladder and to treat infection or correct obstruction. However, many complications can be prevented with careful assessment and

appropriate nursing interventions. The nurse explains to the patient why normal voiding is not occurring and monitors urine output closely. The nurse also provides reassurance about the temporary nature of retention and successful management strategies.

Promoting Urinary Elimination

Nursing measures to encourage normal voiding patterns include providing privacy, ensuring an environment and body position conducive to voiding, and assisting the patient with the use of the bathroom or bedside commode, rather than a bedpan, to provide a more natural setting for voiding. If his condition allows, the male patient may stand beside the bed to use the urinal; most men find this position more comfortable and natural.

Additional measures include applying warmth to relax the sphincters (i.e., sitz baths, warm compresses to the perineum, showers), giving the patient hot caffeine free beverage and offering encouragement and reassurance. Simple trigger techniques, such as turning on the water faucet while the patient is trying to void, may also be used. Other examples of trigger techniques are stroking the abdomen or inner thighs, tapping above the pubic area, and dipping the patient's hands in warm water. After surgery or childbirth, prescribed analgesic agents should be given because pain in the perineal area can make voiding difficult. A combination of techniques may be necessary to initiate voiding.

When the patient cannot void, bladder scanning is used to assess for distension, then straight catheterization (as prescribed) is used to prevent overdistention of the bladder (see later discussion of neurogenic bladder and catheterization). In the case of prostatic obstruction, attempts at catheterization (by the urologist) may not be successful, requiring insertion of a suprapubic catheter (catheter inserted through a small abdominal incision into the bladder). After urinary drainage is restored, bladder retraining is initiated for the patient who cannot void spontaneously.

Promoting Home, Community-Based, and Transitional Care

In addition to the strategies listed for promoting urinary continence found in Chart 45-9, modifications to the home environment can provide simple and effective ways to assist in treating urinary incontinence and retention. For example, the patient may need to remove obstacles, such as throw rugs or other objects, to provide easy, safe access to the bathroom. Other modifications that the nurse may recommend include installing support bars in the bathroom; placing a bedside commode, bedpan, or urinal within easy reach; leaving lights on in the bedroom and bathroom; and wearing clothing that is easy to remove quickly.

Neurogenic Bladder

Neurogenic bladder is a dysfunction that results from a disorder or dysfunction of the nervous system and leads to urinary incontinence. It may be caused by spinal cord injury, spinal tumor, herniated vertebral disc, multiple sclerosis, congenital disorders (spina bifida or myelomeningocele), infection, or complications of diabetes (Bader, Littlejohns, & Olson, 2016) (see Chapter 51).

Pathophysiology

The two types of neurogenic bladder are spastic (or reflex) bladder and flaccid bladder. Spastic bladder is the more common type and is caused by any spinal cord lesion above the voiding reflex arc (upper motor neuron lesion) (Bader et al., 2016). The result is a loss of conscious sensation and cerebral motor control. A spastic bladder empties on reflex, with minimal or no controlling influence to regulate its activity.

Flaccid bladder is caused by a lower motor neuron lesion, commonly resulting from trauma. This form of neurogenic bladder is also increasingly being recognized in patients with diabetes. The bladder continues to fill and becomes greatly distended, and overflow incontinence occurs. The bladder muscle does not contract forcefully at any time. Because sensory loss may accompany a flaccid bladder, the patient feels no discomfort.

Assessment and Diagnostic Findings

Evaluation for neurogenic bladder involves measurement of fluid intake, urine output, and residual urine volume; urinalysis; and assessment of sensory awareness of bladder fullness and degree of motor control. Comprehensive urodynamic studies are also performed.

Complications

The most common complication of neurogenic bladder is infection resulting from urinary stasis and catheterization. Other complications include renal calculi, impaired skin integrity, and urinary incontinence or retention (Bader et al., 2016).

Medical Management

The problems resulting from neurogenic bladder disorders vary considerably from patient to patient and are a major challenge to the health care team. Several long-term objectives appropriate for all types of neurogenic bladders include preventing overdistention of the bladder, emptying the bladder regularly and completely, maintaining urine sterility with no stone formation, and maintaining adequate bladder capacity with no reflux.

Specific interventions include continuous, intermittent, or self-catheterization (discussed later in this chapter); the use of an external condom-type catheter; a diet low in calcium (to prevent calculi); and encouragement of mobility and ambulation. A liberal fluid intake is encouraged to reduce the urinary bacterial count, reduce stasis, decrease the concentration of calcium in the urine, and minimize the precipitation of urinary crystals and subsequent stone formation.

A bladder retraining program may be effective in treating a spastic bladder or urine retention. The use of a timed, or habit, voiding schedule may be established. To further enhance emptying of a flaccid bladder, the patient may be taught to "double void." After each voiding, the patient is instructed to remain on the toilet, relax for 1 to 2 minutes, and then attempt to void again in an effort to further empty the bladder.

Pharmacologic Therapy

Parasympathomimetic medications, such as bethanechol (Urecholine), may help to increase the contraction of the detrusor muscle.

Surgical Management

Surgery may be carried out to correct bladder neck contractures or vesicoureteral reflux, or to perform a urinary diversion procedure.

Catheterization

In patients with a urologic disorder or with marginal kidney function, care must be taken to ensure that urinary drainage

is adequate and that kidney function is preserved. When urine cannot be eliminated naturally and must be drained artificially, catheters may be inserted directly into the bladder, the ureter, or the renal pelvis. Catheters vary in size, shape, length, material, and configuration (Carter et al., 2014). The type of catheter used depends on its purpose.

Catheterization is performed to achieve the following:

- Relieve urinary tract obstruction
- Assist with postoperative drainage in urologic and other surgeries
- Provide a means to monitor accurate urine output in patients who are critically ill
- Promote urinary drainage in patients with neurogenic bladder dysfunction or urine retention
- Prevent urinary leakage in patients with stage III to IV pressure ulcers (see Chapter 51)

A patient should be catheterized only if necessary, because catheterization commonly leads to UTI. Catheters impede most of the natural defenses of the lower urinary tract by obstructing the periurethral ducts, irritating the bladder mucosa, and providing an artificial route for organisms to enter the bladder (Hagerty et al., 2015). Organisms may be introduced from the urethra into the bladder during catheterization, or they may migrate along the epithelial surface of the urethra or external surface of the catheter. In addition, urinary catheters have been associated with other complications, such as bladder spasms, urethral strictures, and pressure necrosis (Bader et al., 2016).

Indwelling Catheters

When an indwelling catheter cannot be avoided, a closed drainage system is essential. This drainage system is designed to prevent any disconnections, thereby reducing the risk of contamination. Triple-lumen catheters are commonly used after transurethral prostate surgery (see Chapter 46). This system has a triple-lumen indwelling urethral catheter attached to a closed sterile drainage system. With the triple-lumen catheter, urinary drainage occurs through one channel. The retention balloon of the catheter is inflated with water or air through the second channel, and the bladder is continuously irrigated with sterile irrigating solution through the third channel.

The spout (or drainage port) of any urinary drainage bag can become contaminated when opened to drain the bag. Bacteria enter the urinary drainage bag, multiply rapidly, and then migrate to the drainage tubing, catheter, and bladder. By keeping the drainage bag lower than the patient's bladder and not allowing urine to flow back into the bladder, this risk is reduced.

Suprapubic Catheters

Suprapubic catheterization allows bladder drainage by inserting a catheter or tube into the bladder through a suprapubic (above the pubis) incision or puncture (see Fig. 45-3). The catheter or suprapubic drainage tube is then threaded into the bladder and secured with sutures or tape, and the area around the catheter is covered with a sterile dressing. The catheter is connected to a sterile closed drainage system, and the tubing is secured to prevent tension on the catheter. This may be a temporary measure to divert the flow of urine from the urethra when the urethral route is impassable (because of injuries, strictures, prostatic obstruction), after gynecologic or other abdominal surgery when bladder dysfunction is likely to occur, and occasionally after pelvic fractures.

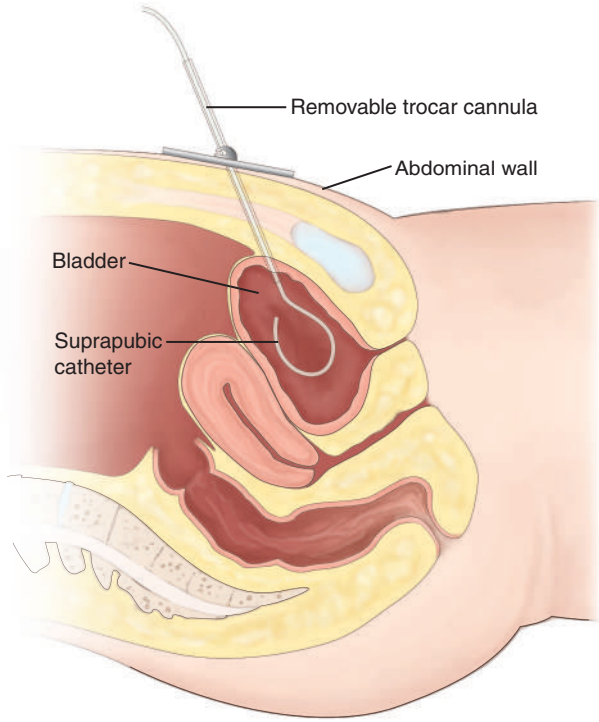

Figure 45-3 • Suprapubic bladder drainage. A trocar cannula is used to puncture the abdominal and bladder walls. The catheter is threaded through the trocar cannula, which is then removed, leaving the catheter in place. The catheter is secured by tape or sutures to prevent unintentional removal.

Suprapubic bladder drainage may be maintained continuously for several weeks. When the patient's ability to void is to be tested, the catheter is clamped for 4 hours, during which time the patient attempts to void. After the patient voids, the catheter is unclamped, and the residual urine is measured. If the amount of residual urine is less than 100 mL on two separate occasions (morning and evening), the catheter is usually removed. However, if the patient complains of pain or discomfort, the suprapubic catheter is usually left in place until the patient can void successfully.

Suprapubic drainage offers certain advantages. Patients can usually void sooner after surgery than those with urethral catheters, and they may be more comfortable. The catheter allows greater mobility, permits measurement of residual urine without urethral instrumentation, and presents less risk of bladder infection. The suprapubic catheter is removed when it is no longer required, and a sterile dressing is placed over the site.

The patient requires liberal amounts of fluid to prevent encrustation around the catheter. Other potential problems include the formation of bladder stones, acute and chronic infections, and problems collecting urine. A enterostomal therapy (ET) nurse may be consulted to assist the patient and family in selecting the most suitable urine collection system and to educate them about its use and care.

Nursing Management

Assessing the Patient and the System

For patients with indwelling catheters, the nurse assesses the drainage system to ensure that it provides adequate urinary drainage. The color, odor, and volume of urine are also monitored. An accurate record of fluid intake and urine output

provides essential information about the adequacy of kidney function and urinary drainage.

Patients at high risk for UTI from catheterization need to be identified and monitored carefully. These include women; older adults; and patients who are debilitated, malnourished, chronically ill, immunosuppressed, or have diabetes (Carter et al., 2014); (Hagerty et al., 2015). They are observed for signs and symptoms of UTI: cloudy malodorous urine, hematuria, fever, chills, anorexia, and malaise. Any drainage and excoriation in the area around the urethral orifice is noted. Urine cultures provide the most accurate means of assessing a patient for infection.

Gerontologic Considerations

The older patient with an indwelling catheter may not exhibit the typical signs and symptoms of infection (Eliopoulos, 2018). Therefore, any subtle change in physical condition or mental status must be considered a possible indication of infection and promptly investigated because sepsis may occur before the infection is diagnosed. Figure 45-4 summarizes the sequence of events leading to infection and leakage of urine that often follow long-term use of an indwelling catheter in an older patient (Miller, 2015).

Preventing Infection

Certain principles of care are essential to prevent infection in patients with a closed urinary drainage system (see Chart 45-10). The catheter is an object foreign to the body and produces a reaction in the urethral mucosa with some urethral discharge. Vigorous cleansing of the meatus while the catheter is in place is discouraged because the cleansing action can move the catheter back and forth, increasing the risk of infection. To clean the external catheter surface, gentle washing with soap and water or wipes during the daily bath is used by some (Strouse, 2015). Others report that using 2% chlorhexidine gluconate no-rinse wipes during the daily bath helps decrease CAUTI rates (Carter et al., 2014). The catheter is anchored as securely as possible to prevent it from moving in the urethra (Carter et al., 2014); (Mori, 2014).

A liberal fluid intake, within the limits of the patient's cardiac and renal reserve, and an increased urine output must be ensured to flush the catheter and to dilute urinary substances that might form encrustations (Carter et al., 2014); (Hagerty et al., 2015).

Urine cultures are obtained as prescribed or indicated when monitoring the patient for infection; many catheters have an aspiration (puncture) port from which a specimen can be obtained.

Bacteriuria is considered inevitable in patients with indwelling catheters; therefore, controversy remains about the usefulness of taking cultures and treating asymptomatic bacteriuria, because overtreatment may lead to resistant strains of bacteria. Continual observation for fever, chills, and other signs and symptoms of systemic infection is necessary. Infections are treated aggressively.

Minimizing Trauma

Trauma to the urethra can be minimized by:

- Using an appropriately sized catheter
- Lubricating the catheter adequately with a water-soluble lubricant during insertion
- Inserting the catheter far enough into the bladder to prevent trauma to the urethral tissues when the retention balloon of the catheter is inflated

Manipulation of the catheter is the most common cause of trauma to the bladder mucosa in the catheterized patient. Infection can occur when urine invades the damaged mucosa.

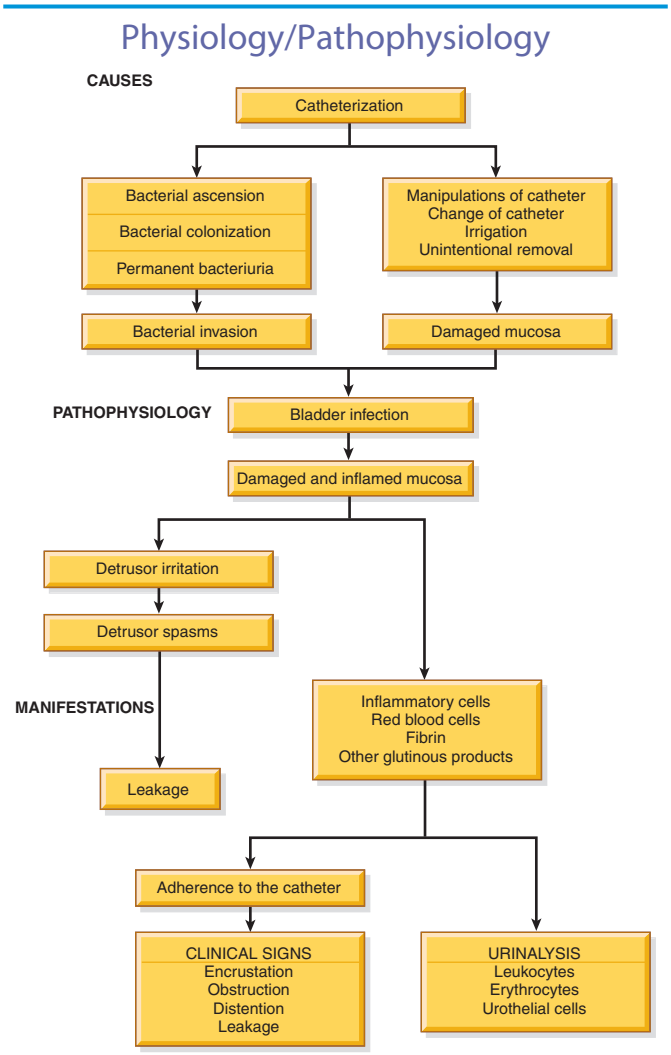

Figure 45-4 • Pathophysiology and manifestations of bladder infection with long-term catheterization in older patients.

The catheter is secured properly to prevent it from moving, causing traction on the urethra, or being unintentionally removed, and care is taken to ensure that the catheter position permits leg movement. In male patients, the drainage tube (not the catheter) is taped laterally to the thigh to prevent pressure on the urethra at the penoscrotal junction, which can eventually lead to formation of a urethrocutaneous fistula. In female patients, the drainage tubing attached to the catheter is taped to the thigh to prevent tension and traction on the bladder.

Special care should be taken to ensure that any patient who is confused does not remove the catheter with the retention balloon still inflated, because this could cause bleeding and considerable injury to the urethra.

Retraining the Bladder

When an indwelling urinary catheter is in place, the detrusor muscle does not actively contract the bladder wall to stimulate emptying because urine is continuously draining from the bladder. As a result, the detrusor may not immediately respond to bladder filling when the catheter is removed, resulting in either urine retention or urinary incontinence. This condition, known as postcatheterization detrusor instability, can be managed with bladder retraining (see Chart 45-11).

Chart 45-10

Preventing Infection in the Patient with an Indwelling Urinary Catheter

- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Ensure a free flow of urine to prevent infection. Improper drainage occurs when the tubing is kinked or twisted, allowing pools of urine to collect in the tubing loops.
- Evaluate the benefit of placing an indwelling urinary catheter versus the risk the patient developing a catheter-associated urinary tract infection.
- If the collection bag *must* be raised above the level of the patient's bladder, clamp the drainage tube. This prevents backflow of contaminated urine into the patient's bladder from the bag.
- Monitor the patient's voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never leave the catheter in place longer than is necessary to decrease the risk of CAUTI.
- Obtain a urine specimen for culture at the first sign of infection.
- To prevent contamination of the closed system, *never* disconnect the tubing. The drainage bag must *never* touch the floor. The bag and collecting tubing are changed if contamination occurs, if urine flow becomes obstructed, or if tubing junctions start to leak at the connections.
- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Use scrupulous aseptic technique during insertion of the catheter. Use a preassembled, sterile, closed urinary drainage system of the smallest catheter size possible to minimize trauma.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Dry the area well, but avoid applying powder because it may irritate the perineum.

Adapted from Carter, N. M., Reitmeier, L., & Goodloe, L. R. (2014). An evidence-based approach to the prevention of catheter-associated urinary tract infections. Urologic Nursing, 34(5), 238–245.

Chart 45-11

Bladder Retraining After Indwelling Catheterization

- Instruct the patient to drink a measured amount of fluid from 8 AM to 10 PM to avoid bladder overdistention. Offer no fluids (except sips) after 10 PM.
- At specific times, ask the patient to void by applying pressure over the bladder, tapping the abdomen, or running water to trigger the bladder.
- Immediately after the voiding attempt, perform a bladder scan to determine the amount of residual urine.
- Measure the volumes of urine voided.
- Palpate the bladder at repeated intervals to assess for distention.
- Instruct the patient who has no voiding sensation to be alert to any signs that indicate a full bladder, such as perspiration, cold hands or feet, or feelings of anxiety.
- Perform straight catheterization, as prescribed, usually for residual urine of >300 mL.
- Lengthen the intervals between catheterizations as the volume of residual urine decreases. Catheterization is usually discontinued when the volume of residual urine is <100 mL.

Adapted from Carter, N. M., Reitmeier, L., & Goodloe, L. R. (2014). An evidence-based approach to the prevention of catheter-associated urinary tract infections. Urologic Nursing, 34(5), 238–245.

Immediately after the indwelling catheter is removed, the patient is placed on a timed voiding schedule, usually every 2 to 3 hours. At the given time interval, the patient is instructed to void. The bladder is then scanned using a portable ultrasonic bladder scanner, and if the bladder has not emptied completely, straight catheterization may be performed (Carter et al., 2014); (Mori, 2014). After a few days, as the nerve endings in the bladder wall become resensitized to the bladder filling and emptying, bladder function usually returns to normal. If the patient has had an indwelling catheter in place for an extended period (e.g., greater than 1 month), bladder retraining will take longer; in some cases, function may never return to normal, and long-term intermittent catheterization may become necessary.

Assisting With Intermittent Self-Catheterization

Intermittent self-catheterization provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of UTIs, and improves continence. It is the treatment of choice in some patients with spinal cord injury and other neurologic disorders, such as multiple sclerosis, when the ability to empty the bladder is impaired. Self-catheterization promotes independence, results in few complications, and enhances self-esteem and quality of life.

When educating the patient about how to perform self-catheterization, the nurse must use aseptic technique to minimize the risk of cross-contamination. However, the patient may use a "clean" (nonsterile) technique at home, where the risk of cross-contamination is reduced. Either antibacterial liquid soap or povidone-iodine (Betadine) solution is recommended for cleaning urinary catheters at home. The catheter is thoroughly rinsed with warm tap water after soaking in the cleaning solution. It must dry before reuse. It should be kept in its own container, such as a plastic food storage bag.

In educating the patient, the nurse emphasizes the importance of frequent catheterization and emptying the bladder at the prescribed time. The average daytime clean intermittent catheterization schedule is every 4 to 6 hours and just before bedtime. If the patient is awakened at night with an urge to void, catheterization may be performed after an attempt is made to void normally.

The female patient assumes a Fowler position and uses a mirror to help locate the urinary meatus. She lubricates the catheter and inserts it 7.5 cm (3 inches) into the urethra, in a downward and backward direction. The male patient assumes a

Fowler or sitting position, lubricates the catheter, and retracts the foreskin of the penis with one hand while grasping the penis and holding it at a right angle to the body. (This maneuver straightens the urethra and makes it easier to insert the catheter.) He inserts the catheter 15 to 25 cm (6 to 10 inches) until urine begins to flow. After removal, the catheter is cleaned, rinsed, dried, and placed in a plastic bag or case. Patients who follow an intermittent catheterization routine should consult a primary provider at regular intervals to assess urinary function and to detect complications. If the patient cannot perform intermittent self-catheterization, a family member or caregiver may be taught to carry out the procedure at regular intervals during the day.

An alternative to self-catheterization is creation of the Mitrofanoff umbilical appendicovesicostomy, which provides easy access to the bladder but requires an extensive surgical procedure (Wille, Zagaja, Shalhav, et al., 2011). In this procedure, the bladder neck is closed and the appendix is used to create access to the bladder from the skin surface through a submucosal tunnel created with the appendix. One end of the appendix is brought to the skin surface and used as a stoma, and the other end is tunneled into the bladder. The appendix serves as an artificial urinary sphincter when an alternative is necessary to empty the bladder. A surgically prepared continent urine reservoir with a sphincter mechanism is required in cases of bladder cancer and severe interstitial cystitis. Various types of urinary diversions may be used when a radical cystectomy (surgical removal of the bladder) is necessary (see discussion later in chapter).

UROLITHIASIS AND NEPHROLITHIASIS

Urolithiasis and nephrolithiasis refer to stones (calculi) in the urinary tract and kidney, respectively. Urinary stones predominantly occur in the third to fifth decades of life and affect men twice as often as women (Cunningham, Noble, Al-Modhefer, et al., 2016). Stones may develop in one or both kidneys and yearly episodes are increasing (Cunningham et al., 2016). Incidence of renal stones is more in countries that fall in tropical region. These countries are called *stone belt*. Saudi Arabia, Sudan, Egypt, UAE, Iran, Pakistan, India, Myanmar, Thailand, Indonesia, and Philippines are part of the stone belt. The prevalence of renal calculi is high in North India compared to South India. Maharashtra has the highest prevalence of renal calculi (7.6%) and Rajasthan has prevalence rate of 3–5% (Kumari, Dokwal, Mittal, et al., 2016).

Pathophysiology

When total urine volume decreases (<2 L/day), the concentration of urinary calcium oxalates, calcium phosphates, and uric acid increases. With increased urinary concentrations of these substances, stones are formed in the urinary tract. Referred to as supersaturation, this depends on the amount of the substance, ionic strength, and pH of the urine. Stones may be found anywhere from the kidney to the bladder and may vary in size from minute granular deposits, called *sand* or *gravel,* to bladder stones as large as an orange. The different sites of calculi formation in the urinary tract are shown in Figure 45-5.

Certain factors favor the formation of stones, including infection, urinary stasis, and periods of immobility, all of which slow kidney drainage and alter calcium metabolism (Grossman & Porth, 2014). In addition, increased calcium concentrations in the blood and urine promote precipitation of calcium and formation of stones (about 80% of all kidney stones are calcium

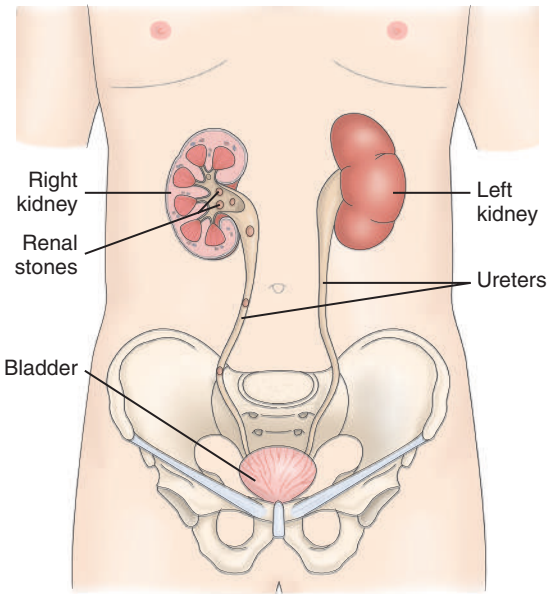

Figure 45-5 • Examples of potential sites of calculi formation (urolithiasis) in the urinary tract.

based) (Cunningham et al., 2016). Causes of hypercalcemia (high serum calcium) and hypercalciuria (high urine calcium) may include the following:

- Hyperparathyroidism
- Renal tubular acidosis
- Cancers (e.g., leukemia, multiple myeloma)
- Dehydration
- Granulomatous diseases (e.g., sarcoidosis, tuberculosis), which may cause increased vitamin D production by the granulomatous tissue
- Excessive intake of vitamin D
- Excessive intake of milk and alkali
- Myeloproliferative diseases such as polycythemia vera, which produce an unusual proliferation of blood cells from the bone marrow

For patients with stones containing uric acid, struvite, or cystine, a thorough physical examination and metabolic workup are indicated because of associated disturbances contributing to the stone formation. Uric acid stones (5% to 10% of all stones) may be seen in patients with gout or myeloproliferative disorders. Struvite stones account for 15% of urinary calculi and form in persistently alkaline, ammonia-rich urine caused by the presence of urease-splitting bacteria such as *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* or *Mycoplasma* species. Predisposing factors for struvite stones include neurogenic bladder, foreign bodies, and recurrent UTIs.

Several conditions, as well as certain metabolic risk factors, predispose patients to stone formation. These include anatomic derangements such as polycystic kidney disease, horseshoe kidneys, chronic strictures, and medullary sponge disease. Urinary stone formation can occur in patients with inflammatory bowel disease and in those with an ileostomy or bowel resection because these patients absorb more oxalate. Medications known to cause stones in some patients include antacids, acetazolamide (Diamox), vitamin D, laxatives, and high doses of aspirin (Comerford, 2015). However, in many patients, no cause may be found.

Pathophysiology of urolithiasis/nephrolithiasis is presented in Figure 45-6.

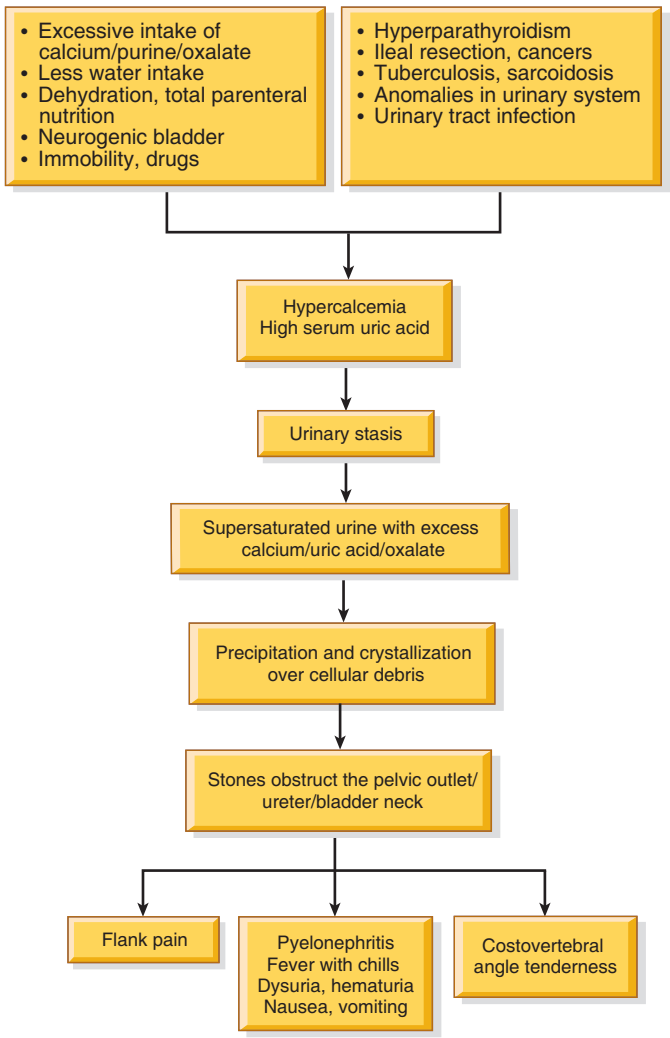

Figure 45-6 • Pathophysiology of urolithiasis/nephrolithiasis.

Clinical Manifestations

Signs and symptoms of stones in the urinary system depend on the presence of obstruction, infection, and edema. When stones block the flow of urine, obstruction develops, producing an increase in hydrostatic pressure and distending the renal pelvis and proximal ureter (Cunningham et al., 2016). Infection (pyelonephritis and UTI with chills, fever, and frequency) can be a contributing factor with struvite stones. Some stones cause few, if any, symptoms while slowly destroying the functional units (nephrons) of the kidney; others cause excruciating pain and discomfort.

Stones in the renal pelvis may be associated with an intense, deep ache in the costovertebral region. Hematuria is often present. On the contrary, an Indian study conducted in Imphal, Manipur, reported that majority of the patients (57.8%) diagnosed with urolithiasis were asymptomatic at the time of presentation (Faridi & Singh, 2020).

Pyuria may also be noted. Pain originating in the renal area radiates anteriorly and downward toward the bladder in the female and toward the testes in the male. If the pain suddenly becomes acute, with tenderness over the costovertebral area, and nausea and vomiting occur, the patient is having an episode of renal colic. Diarrhea and abdominal discomfort are due to renointestinal reflexes and the anatomic proximity of the kidneys to the stomach, pancreas, and large intestine.

Stones lodged in the ureter (ureteral obstruction) cause acute, excruciating, colicky, wavelike pain that radiates down the thigh and to the genitalia. Often, the patient has a desire to void, but little urine is passed, and it usually contains blood because of the abrasive action of the stone. This group of symptoms is called *ureteral colic*. Colic is mediated by prostaglandin E, a substance that increases ureteral contractility and renal blood flow and that leads to increased intraureteral pressure and pain. In general, the patient is able to pass stones 0.5 to 1 cm in diameter. Stones larger than 1 cm in diameter usually must be removed or fragmented (broken up by lithotripsy) so that they can be removed or passed spontaneously.

Stones lodged in the bladder usually produce symptoms of irritation and may be associated with UTI and hematuria. If the stone obstructs the bladder neck, urinary retention occurs. If infection is associated with a stone, the condition is far more serious, with the potential for developing urosepsis.

Assessment and Diagnostic Findings

The diagnosis is confirmed by a noncontrast CT scan (Cunningham et al., 2016). Blood chemistries and a 24-hour urine test for measurement of calcium, uric acid, creatinine, sodium, pH, and total volume may be part of the diagnostic workup. Dietary and medication histories and family history of kidney stones are obtained to identify factors predisposing the patient to the formation of stones.

When stones are recovered (whether freely passed by the patient or removed through special procedures), chemical analysis is carried out to determine their composition. Stone analysis can provide a clear indication of the underlying disorder. For example, calcium oxalate or calcium phosphate stones usually indicate disorders of oxalate or calcium metabolism, whereas urate stones suggest a disturbance in uric acid metabolism (Cunningham et al., 2016).

Medical Management

The goals of management are to eradicate the stone, determine the stone type, prevent nephron destruction, control infection, and relieve any obstruction that may be present. The immediate objective of treatment of renal or ureteral colic is to relieve the pain until its cause can be eliminated. Opioid analgesic agents are given to prevent shock and syncope that may result from the excruciating pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in treating kidney stone pain because they provide specific pain relief (Cunningham et al., 2016). They also inhibit the synthesis of prostaglandin E, reducing swelling and facilitating passage of the stone. Generally, once the stone has passed, the pain is relieved. Hot baths or moist heat to the flank area may also be helpful. Unless the patient is vomiting or has heart failure or any other condition requiring fluid restriction, fluids are encouraged. This increases the hydrostatic pressure behind the stone, assisting it in its downward passage. A high, around-the-clock fluid intake reduces the concentration of urinary crystalloids, dilutes the urine, and ensures a high urine output.

Nutritional Therapy

Nutritional therapy plays an important role in preventing kidney stones (Cunningham et al., 2016) (see Chart 45-12). Fluid intake is the mainstay of most medical therapy for kidney stones. Unless fluids are contraindicated, patients with kidney stones should

Chart 45-12 PATIENT EDUCATION

Preventing Kidney Stones

The nurse instructs the patient to:

- Avoid protein intake to decrease urinary excretion of calcium and uric acid. Nonvegetarian food items such as chicken, mutton, beef, pork, milk, and egg to be reduced.
- Limit sodium intake to 3–4 g/day. Table salt and high-sodium foods should be reduced, because sodium competes with calcium for reabsorption in the kidneys.
- Be aware that low-calcium diets are not generally recommended, except for true absorptive hypercalciuria. Evidence shows that limiting calcium, especially in women, can lead to osteoporosis and does not prevent stones.
- Avoid intake of oxalate-containing foods (e.g., spinach, strawberries, tomato, rhubarb, tea, peanuts, wheat bran).
- Drink fluids to a minimum of 3 to 4 liters per day (ideally water and one glass of cranberry juice per day) every 1–2 hours during the day. In Indian setting Tender coconut water will be helpful.
- Drink two glasses of water at bedtime and an additional glass at each nighttime awakening to prevent urine from becoming too concentrated during the night.
- Avoid activities leading to sudden increases in environmental temperatures that may cause excessive sweating and dehydration.
- Contact the primary provider at the first sign of a urinary tract infection.

drink at least 3 L of water daily or have IV fluids prescribed to keep the urine dilute. A urine output exceeding 2 L/day is advisable.

Calcium Stones

Historically, patients with calcium-based kidney stones were recommended to restrict calcium in their diet. However, evidence has questioned this practice, except for patients with type II absorptive hypercalciuria (half of all patients with calcium stones), in whom stones are clearly the result of excess dietary calcium. Liberal fluid intake is encouraged. Medications such as ammonium chloride may be used, and if increased parathormone production (resulting in increased serum calcium levels in blood and urine) is a factor in the formation of stones, therapy with thiazide diuretics may be beneficial in reducing the calcium loss in the urine and lowering the elevated parathormone levels (Cunningham et al., 2016).

Uric Acid Stones

For uric acid stones, the patient is placed on a low-purine diet to reduce the excretion of uric acid in the urine. Foods high in purine (shellfish, anchovies, asparagus, mushrooms, and organ meats) are avoided, and other proteins may be limited. Allopurinol (Zyloprim) may be prescribed to reduce serum uric acid levels and urinary uric acid excretion (Comerford, 2015).

Cystine Stones

A low-protein diet is prescribed, the urine is alkalinized, and fluid intake is increased.

Oxalate Stones

A dilute urine is maintained, and the intake of oxalate is limited. Many foods contain oxalate; however, only certain foods increase the urinary excretion of oxalate. These include spinach, strawberries, rhubarb, chocolate, tea, peanuts, and wheat bran.

Interventional Procedures

If the stone does not pass spontaneously or if complications occur, common interventions include endoscopic or other procedures. For example, ureteroscopy, extracorporeal shock wave lithotripsy (ESWL), or endourologic (percutaneous) stone removal may be necessary.

Ureteroscopy (see Fig. 45-7A) involves first visualizing the stone and then destroying it. Access to the stone is accomplished by inserting a ureteroscope into the ureter and then inserting a laser, electrohydraulic lithotriptor, or ultrasound device through the ureteroscope to fragment and remove the stones. A stent may be inserted and left in place for 48 hours or more after the procedure to keep the ureter patent. Length of hospital stay is generally brief, and some patients can be treated as outpatients.

ESWL is a noninvasive procedure used to break up stones in the calyx of the kidney (see Fig. 45-7B). After the stones are fragmented to the size of grains of sand, the remnants of the stones are spontaneously voided. In ESWL, a high-energy amplitude of pressure, or shock wave, is generated by the abrupt release of energy and transmitted through water and soft tissues. When the shock wave encounters a substance of different intensity (a kidney stone), a compression wave causes the surface of the stone to fragment. Repeated shock waves focused on the stone eventually reduce it to many small pieces that are excreted in the urine.

Discomfort from the multiple shocks may occur, although the shock waves usually do not cause damage to other tissue. The patient is observed for obstruction and infection resulting from blockage of the urinary tract by stone fragments. All urine is strained after the procedure; voided gravel or sand is sent to the laboratory for chemical analysis. Several treatments may be necessary to ensure disintegration of stones (Cunningham et al., 2016).

Endourologic methods of stone removal (see Fig. 45-7C) may be used to extract kidney calculi that cannot be removed by other procedures. A percutaneous nephrostomy or a percutaneous nephrolithotomy (which are similar procedures) may be performed. A nephroscope is introduced through a percutaneous route into the renal parenchyma. Depending on its size, the stone may be extracted with forceps or by a stone retrieval basket. If the stone is too large to initially be removed, an ultrasound probe inserted through a nephrostomy tube is used to pulverize the stone. Small stone fragments and stone dust are then removed.

Electrohydraulic lithotripsy is a similar method in which an electrical discharge is used to create a hydraulic shock wave to break up the stone. A probe is passed through the cystoscope, and the tip of the lithotriptor is placed near the stone. The strength of the discharge and pulse frequency can be varied. This procedure is performed under topical anesthesia. After the stone is extracted, the percutaneous nephrostomy tube is left in place for a time to ensure that the ureter is not obstructed by edema or blood clots. The most common complications are hemorrhage, infection, and urinary extravasation. After the tube is removed, the nephrostomy tract usually closes spontaneously.

Chemolysis, stone dissolution using infusions of chemical solutions (e.g., alkylating agents, acidifying agents) for the purpose of dissolving the stone, is an alternative treatment sometimes used in patients who are at risk for complications with other types of therapy, who refuse to undergo other methods, or who have stones (struvite) that dissolve easily. A percutaneous nephrostomy is performed, and the warm chemical solution is allowed to flow continuously onto the stone. The solution exits the renal collecting system by means of the ureter or the nephrostomy tube. The pressure inside the renal pelvis is monitored during the procedure.

Several of these treatment modalities may be used in combination to ensure removal of the stones.

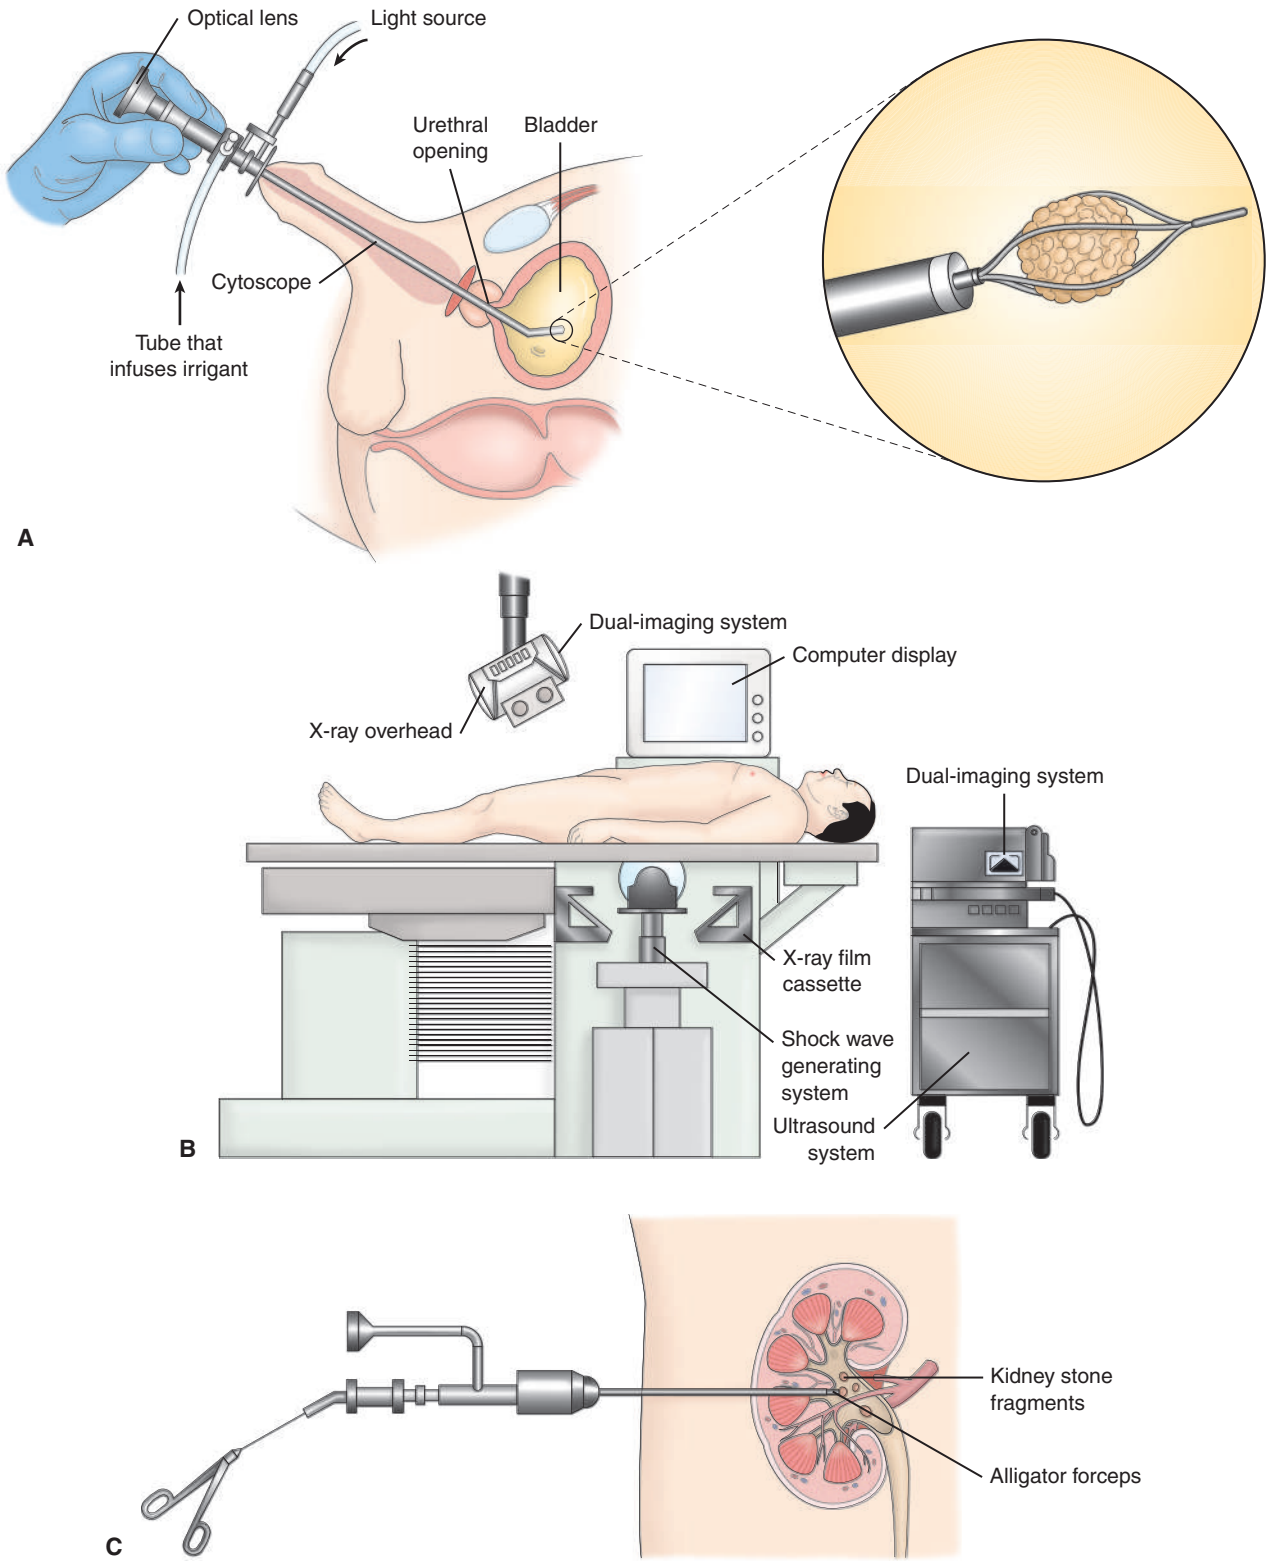

Figure 45-7 • Methods of treating kidney stones. **A**. During ureteroscopy, which is used for removing small stones located in the ureter close to the bladder, a ureteroscope is inserted into the ureter to visualize the stone. The stone is then fragmented or captured and removed. **B**. Extracorporeal shock water lithotripsy is used for most symptomatic, nonpassable upper urinary stones. Electromagnetically generated shock waves are focused over the area of the kidney stone. The high-energy dry shock waves pass through the skin and fragment the stone. **C**. Percutaneous nephrolithotomy is used to treat larger stones. A percutaneous tract is formed, and a nephroscope is inserted through it. Then, the stone is extracted or pulverized.

Surgical Management

Surgical removal was the major mode of therapy before the advent of lithotripsy. However, today, surgery is performed in only 1% to 2% of patients (Cunningham et al., 2016). Surgical intervention is indicated if the stone does not respond to other forms of treatment. It may also be performed to correct anatomic abnormalities within the kidney to improve urinary drainage. If the stone is in the kidney, the surgery performed may be a nephrolithotomy (incision into the kidney with removal of the stone) or a nephrectomy, if the kidney is nonfunctional secondary to infection or hydronephrosis. Stones in the kidney pelvis are removed by a pyelolithotomy, those in the ureter by ureterolithotomy, and those in the bladder by cystotomy. If the stone is in the bladder, an instrument may be inserted through the urethra into the bladder, and the stone crushed. Such a procedure is called a *cystolitholapaxy.* Nursing management following kidney surgery is discussed in Chapter 44.

NURSING PROCESS

The Patient With Kidney Stones

Assessment

The patient with suspected kidney stones is assessed for pain and discomfort as well as associated symptoms, such as nausea, vomiting, diarrhea, and abdominal distention. The severity and location of pain are determined, along with any radiation of the pain. Nursing assessment also includes observing for signs and symptoms of UTI (chills, fever, frequency, and hesitancy) and obstruction (frequent urination of small amounts, oliguria, or anuria). The urine is inspected for blood and is strained for stones or gravel.

The history focuses on factors that predispose the patient to urinary tract stones or that may have precipitated the current episode of renal or ureteral colic. The patient's knowledge about kidney stones and measures to prevent their occurrence or recurrence is also assessed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Acute pain related to inflammation, obstruction, and abrasion of the urinary tract
- Deficient knowledge regarding prevention of recurrence of kidney stones

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Infection and urosepsis (from UTI and pyelonephritis)
- Obstruction of the urinary tract by a stone or edema with subsequent acute kidney injury

Planning and Goals

The major goals for the patient may include relief of pain and discomfort, prevention of recurrence of kidney stones, and absence of complications.

Nursing Interventions

Relieving Pain

Severe acute pain is often the presenting symptom of a patient with kidney and urinary calculi and requires immediate attention. Opioid analgesic agents (IV or intramuscular) may be prescribed and given to provide rapid relief along with an IV NSAID. The patient is encouraged and assisted to assume a position of comfort. If activity brings pain relief, the patient is assisted to ambulate. The pain level is monitored closely, and an increase in severity is reported promptly to the primary provider so that relief can be provided and additional treatment initiated.

Monitoring and Managing Potential Complications

Increased fluid intake is encouraged to prevent dehydration and increase hydrostatic pressure within the urinary tract to promote passage of the stone. If the patient cannot take adequate fluids orally, IV fluids are prescribed. The total urine output and patterns of voiding are monitored. Ambulation is encouraged as a means of moving the stone through the urinary tract.

All urine is strained because uric acid stones may crumble. Any blood clots passed in the urine should be crushed and the sides of the urinal and bedpan inspected for clinging stones. Because kidney stones increase the risk of infection, sepsis, and obstruction of the urinary tract, the patient is instructed to report decreased urine volume, bloody or cloudy urine, fever, and pain.

Patients with calculi require frequent nursing observation to detect the spontaneous passage of a stone. The patient is instructed to immediately report any sudden increases in pain intensity because of the possibility of a stone fragment obstructing a ureter. Vital signs, including temperature, are monitored closely to detect early signs of infection. UTIs may be associated with kidney stones due to an obstruction from the stone or from the stone itself. All infections should be treated with the appropriate antibiotic agent before efforts are made to dissolve the stone.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. Because the risk of recurring kidney stones is high, the nurse provides education about the causes of kidney stones and recommendations to prevent their recurrence (see Chart 45-12). The patient is encouraged to follow a regimen to avoid further stone formation, including maintaining a high fluid intake because stones form more readily in concentrated urine. A patient who has shown a tendency to form stones should drink enough fluid to excrete greater than 2000 mL (preferably 3000 to 4000 mL) of urine every 24 hours (Cunningham et al., 2016).

Urine cultures may be performed every 1 to 2 months in the first year and periodically thereafter. Recurrent UTI is treated vigorously. Because prolonged immobilization slows renal drainage and alters calcium metabolism, increased mobility is encouraged whenever possible. In addition, excessive ingestion of vitamins (especially vitamin D) and minerals is discouraged.

If lithotripsy, percutaneous stone removal, ureteroscopy, or other surgical procedures for stone removal have been performed, the nurse instructs the patient about the signs and symptoms of complications (e.g., urinary retention, infection) that need to be reported to the primary provider. The importance of follow-up to assess kidney function and to ensure the eradication or removal of all kidney stones is emphasized to the patient and family.

If ESWL has been performed, the nurse must provide instructions for home care and necessary follow-up. The patient is encouraged to increase fluid intake to assist in the passage of stone fragments, which may occur for 6 weeks to several months after the procedure. The patient and family are instructed about signs and symptoms of complications. It is also important to inform the patient to expect hematuria (it is anticipated in all patients), but it should disappear within 4 to 5 days. If the patient

has a stent in the ureter, hematuria may be expected until the stent is removed. The patient is instructed to check their temperature daily and notify the primary provider if the temperature is greater than 38°C (about 101°F) or the pain is unrelieved by the prescribed medication. The patient is also informed that a bruise may be observed on the treated side of the back.

Continuing and Transitional Care. Close monitoring of the patient in follow-up care is essential to ensure that treatment has been effective and that no complications develop. The nurse has the opportunity to assess the patient's understanding of ESWL and possible complications. In addition, the nurse has the opportunity to assess the patient's understanding of factors that increase the risk of recurrence of renal calculi and strategies to reduce those risks.

The nurse must assess the patient's ability to monitor urinary pH and interpret the results during follow-up visits. Because of the high risk of recurrence, the patient with kidney stones needs to understand the signs and symptoms of stone formation, obstruction, and infection and the importance of reporting these signs promptly. If medications are prescribed for the prevention of stone formation, the nurse explains their actions, importance, and side effects to the patient.

Evaluation

Expected patient outcomes may include:

1. Reports relief of pain
2. States increased knowledge of health-seeking behaviors to prevent recurrence
   a. Consumes increased fluid intake (at least 3L of water per day)
   b. Participates in appropriate activity
   c. Consumes diet prescribed to reduce dietary factors predisposing to stone formation
   d. Recognizes symptoms (fever, chills, flank pain, hematuria) to be reported to primary provider
   e. Monitors urinary pH as directed
   f. Takes prescribed medication as directed to reduce stone formation
3. Experiences no complications
   a. Reports no signs or symptoms of infection or urosepsis
   b. Voids 200 to 400 mL per voiding of clear urine without evidence of bleeding
   c. Experiences absence of urgency, frequency, and hesitancy
   d. Maintains normal body temperature

GENITOURINARY TRAUMA

Various types of injuries to the flank, back, or upper abdomen may result in trauma to the ureters, bladder, or urethra. Abdominal trauma is responsible for approximately 90% of all genitourinary trauma (Hallis, Amasyali, Yucak, et al., 2015). Kidney trauma is discussed in Chapter 44.

Specific Injuries

Ureteral Trauma

The main causes are motor vehicle crashes, sports injuries, falls, and assaults (Hallis et al., 2015). Injuries range from contusions to complete transection. Unintentional injury to the ureter may occur during gynecologic or urologic surgery. There are no specific signs or symptoms of ureteral injury; many traumatic injuries are discovered during exploratory surgery. Surgical repair with placement of stents (to divert urine away from an anastomosis) is usually necessary. If the ureteral trauma is not detected and urine leakage continues, fistulas can develop.

Bladder Trauma

Injury to the bladder may occur with pelvic fractures, multiple trauma, or from a blow to the lower abdomen when the bladder is full. Blunt trauma may result in contusion evident as an ecchymosis—a large bruise resulting from escape of blood into the tissues and involving a segment of the bladder wall—or in rupture of the bladder extraperitoneally, intraperitoneally, or both. Complications from these injuries include hemorrhage, shock, sepsis, and extravasation of blood into the tissues, which must be treated promptly.

Urethral Trauma

Urethral injuries usually occur with blunt trauma to the lower abdomen or pelvic region. Many patients also have associated pelvic fractures. The classic triad of symptoms comprises blood at the urinary meatus, inability to void, and a distended bladder.

Medical Management

The goals of management in patients with genitourinary trauma are to control hemorrhage, pain, and infection and to maintain urinary drainage. Genitourinary trauma is frequently associated with kidney trauma (see Chapter 44). Hematocrit and hemoglobin levels are monitored closely; decreasing values can indicate hemorrhage within the genitourinary system. The patient is also monitored for oliguria, signs of hemorrhagic shock, and signs and symptoms of acute peritonitis.

Surgical Management

In urethral trauma, a patient whose condition is unstable and who needs monitoring of urine output may need a suprapubic catheter inserted. The patient is catheterized after urethrography has been performed to minimize the risk of urethral disruption and extensive, long-term complications, such as stricture, incontinence, and impotence. Surgical repair may be performed using either open or laparoscopic approaches (Hallis et al., 2015). After surgery, an indwelling urinary catheter may remain in place for up to 1 month.

Nursing Management

The patient with genitourinary trauma should be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank.

During this time, patients are instructed about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the primary provider, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided (Hallis et al., 2015). The patient with a ruptured bladder may have gross bleeding for several days after repair. Guidelines for increasing activity gradually, lifting, and driving are also provided.

Follow-up nursing care includes monitoring the blood pressure to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding.

URINARY TRACT CANCERS

Urinary tract cancers include those of the urinary bladder; kidney and renal pelvis; ureters; and other urinary structures, such as the prostate. Kidney cancer is discussed in Chapter 44, and prostate cancer is discussed in Chapter 46.

Cancer of the Bladder

Cancer of the urinary bladder is more common in people older than 55years. As per the ICMR data, the incidence of bladder cancer among Indians was 26,886 in 2015 and it is predicted that by the year 2020 it may go up to 33,608 (ICMR, 2016). Cancers arising from the prostate, colon, and rectum in males and from the lower gynecologic tract in females may metastasize to the bladder.

Tobacco use continues to be a leading risk factor for all urinary tract cancers. People who smoke develop bladder cancer twice as often as those who do not smoke (NCI, 2016) (see Chart 45-13).

Clinical Manifestations

Bladder tumors usually arise at the base of the bladder and involve the ureteral orifices and bladder neck. Visible, painless hematuria is the most common symptom of bladder cancer. Infection of the urinary tract is a common complication, producing frequency and urgency. However, any alteration in voiding or change in the urine may indicate cancer of the bladder. Pelvic or back pain may occur with metastasis.

Assessment and Diagnostic Findings

The diagnostic evaluation includes ureteroscopy (the mainstay of diagnosis), excretory urography, CT and MRI scans, ultrasonography, and bimanual examination with the patient anesthetized. Biopsies of the tumor and adjacent mucosa are the definitive diagnostic procedures (NCI, 2016). Transitional cell carcinomas and carcinomas in situ shed recognizable cancer cells. Cytologic examination of fresh urine and saline bladder washings provide information about the prognosis and staging, especially for patients at high risk for recurrence of primary bladder tumors. See Chapter 58 for more information on cancer grading and staging.

Chart 45-13 SELECTED RISK FACTORS

Bladder Cancer

- Certain genetic mutations including:
  - *HRAS* mutation (Costello syndrome, Facio-cutaneous-skeletal syndrome).
  - *Rb1* mutation.
  - *PTEN/MMAC1* mutation (Cowden syndrome).
  - *NAT2* slow acetylator phenotype.
  - *GSTM1* null phenotype.
- Exposure to arsenic
- Occupational exposure to chemicals in processed paint, dye, metal, and petroleum products
- Positive family history of bladder cancer
- Pelvic radiation therapy or treatment for other cancers
- Tobacco use, cigarette smoking in particular

Adapted from National Cancer Institute (NCI). (2016). Bladder cancer treatment (PDQ®)–Health professional version. Retrieved 12/13/2016 at: www.cancer.gov/types/bladder/hp/bladder-treatment-pdq#section/all

Medical Management

Treatment of bladder cancer depends on the grade of the tumor (the degree of cellular differentiation), the stage of tumor growth (the degree of local invasion and the presence or absence of metastasis) (NCI, 2016). The patient's age and physical, mental, and emotional status are considered when determining treatment modalities.

Surgical Management

Transurethral resection or fulguration (cauterization) may be performed for simple papillomas (benign epithelial tumors). These procedures (described in more detail in Chapter 46) eradicate the tumors through surgical incision or electrical current with the use of instruments inserted through the urethra. After this bladder-sparing surgery, intravesical administration of bacille Calmette–Guérin (BCG) is the treatment of choice. BCG Live (TheraCys) is an attenuated live strain of *Mycobacterium bovis,* the causative agent in tuberculosis; treatment is recommended for a minimum of 1 year (NCI, 2016). The exact action of BCG is unknown, but it is thought to produce a local inflammatory and a systemic immunologic response.

Management of superficial bladder cancers presents a challenge because there are usually widespread abnormalities in the bladder mucosa. The entire lining of the urinary tract, or urothelium, is at risk because carcinomatous changes can occur in the mucosa of the bladder, kidney pelvis, ureter, and urethra.

A simple cystectomy or a radical cystectomy is performed for invasive or multifocal bladder cancer. Radical cystectomy in men involves removal of the bladder, prostate, and seminal vesicles and immediate adjacent perivesical tissues. In women, radical cystectomy involves removal of the bladder, lower ureter, uterus, fallopian tubes, ovaries, anterior vagina, and urethra. It may include removal of pelvic lymph nodes. Removal of the bladder requires a urinary diversion procedure, which is described later in this chapter.

Although radical cystectomy remains the standard of care for invasive bladder cancer, clinical trials are exploring trimodality therapy—transurethral resection of the bladder tumor, radiation, and chemotherapy—in an effort to spare patients the need for cystectomy (NCI, 2016). This approach to transitional cell bladder cancer mandates lifelong surveillance with periodic cystoscopy. Although most patients respond completely and their bladders remain free from invasive relapse, one fourth develop a relapse of noninvasive disease. This may be managed with transurethral resection of the bladder tumor and intravesical therapies but carries an additional risk that a late cystectomy may be required.

Pharmacologic Therapy

Chemotherapy with a combination of methotrexate, 5-fluorouracil, vinblastine (Velban), doxorubicin (Adriamycin), and cisplatin (Platinol) has been effective in producing partial remission of transitional cell carcinoma of the bladder in some patients. IV chemotherapy may be accompanied by radiation therapy (NCI, (2016). Topical chemotherapy (intravesical

chemotherapy or instillation of antineoplastic agents into the bladder, resulting in contact of the agent with the bladder wall) is considered when there is a high risk of recurrence, when cancer in situ is present, or when tumor resection has been incomplete. Topical chemotherapy delivers a high concentration of medication (thiotepa [Thioplex], doxorubicin, mitomycin [Mutamycin], and BCG Live) to the tumor to promote tumor destruction. Bladder cancer may also be treated by direct infusion of the cytotoxic agent through the bladder's arterial blood supply to achieve a higher concentration of the chemotherapeutic agent with fewer systemic toxic effects (NCI, 2016).

BCG Live is now considered the most predominant and conservative intravesical agent for recurrent bladder cancer, especially superficial transitional cell carcinoma, because it is an immunotherapeutic agent that enhances the body's immune response to cancer. BCG Live has a 43% advantage in preventing tumor recurrence, a significantly better rate than the 16% to 21% advantage of intravesical chemotherapy. In addition, BCG Live is particularly effective in the treatment of carcinoma in situ, eradicating it in more than 80% of cases. In contrast to intravesical chemotherapy, BCG Live has also been shown to decrease the risk of tumor progression. Although BCG Live treatment is the current standard of care, this treatment fails or is not tolerated in a significant proportion of patients (Askeland, Newton, O'Donnell, et al., 2012).

The optimal course of BCG Live appears to be a 6-week course of weekly instillations, followed by a 3-week course at 3 months for tumors that do not respond. In high-risk cancers, maintenance BCG Live given in a 3-week course at 6, 12, 18, and 24 months may limit recurrence and prevent progression. However, the adverse effects associated with this prolonged therapy may limit its widespread applicability.

The patient is allowed to eat and drink before the instillation procedure. Once the bladder is full, the patient must retain the intravesical solution for 2 hours before voiding. At the end of the procedure, the patient is encouraged to void and to drink liberal amounts of fluid to flush the medication from the bladder.

Radiation Therapy

Radiation of the tumor may be performed preoperatively to reduce microextension of the neoplasm and viability of tumor cells, thus decreasing the chances that the cancer may recur in the immediate area or spread through the circulatory or lymphatic systems. Radiation therapy is also used in combination with surgery or to control the disease in patients with inoperable tumors.

For more advanced bladder cancer or for patients with intractable hematuria (especially after radiation therapy), a large, water-filled balloon placed in the bladder produces tumor necrosis by reducing the blood supply of the bladder wall (hydrostatic therapy). The instillation of formalin, phenol, or silver nitrate relieves hematuria and strangury (slow and painful discharge of urine) in some patients.

URINARY DIVERSIONS

Urinary diversion procedures are performed to divert urine from the bladder to a new exit site, usually through a surgically created opening (stoma) in the skin. These procedures are primarily performed when a bladder tumor necessitates cystectomy (NCI, 2016). Urinary diversion has also been used in managing pelvic malignancy, birth defects, strictures, trauma to the ureters and urethra, neurogenic bladder, chronic infection causing severe ureteral and kidney damage, and intractable interstitial cystitis. It may also be used as a last resort in managing incontinence.

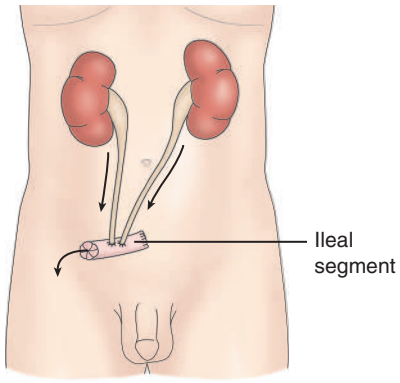
Controversy exists about the best method of establishing permanent diversion of the urinary tract. New techniques are frequently introduced in an effort to improve patient outcomes and quality of life. The age of the patient, condition of the bladder, body build, degree of obesity, degree of ureteral dilation, status of kidney function, and the patient's learning ability and willingness to participate in postoperative care are all taken into consideration when determining the appropriate surgical procedure.

The outcome for a patient with a urinary diversion depends to a large degree on the location or position of the stoma, whether the drainage device (pouch or bag) establishes a watertight seal to the skin, and the patient's ability to manage the pouch and drainage apparatus (Rubenwolf, Hampel, Roos, et al., 2016).

There are two types of urinary diversion. In a cutaneous urinary diversion, urine drains through an opening created in the abdominal wall and skin (see Fig. 45-8). In a **continent urinary diversion**, a portion of the intestine is used to create a new reservoir for urine (see Fig. 45-9A).

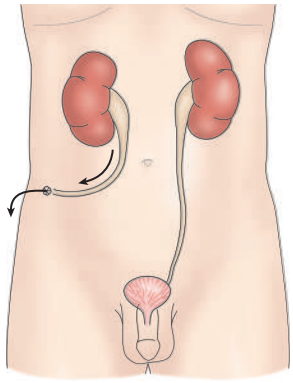
Cutaneous Urinary Diversions

Ileal Conduit



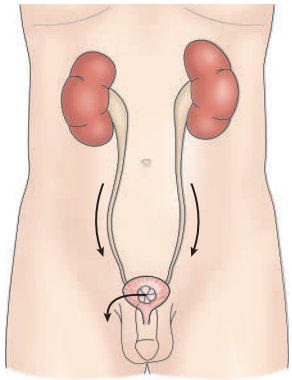
The ileal conduit (ileal loop) is the oldest and most common of the urinary diversion procedures in use because of the low number of complications and surgeons' familiarity with the procedure. In an ileal conduit, the urine is diverted by implanting the ureter into a 12-cm loop of ileum that is led out through the abdominal wall. This loop of ileum is a simple conduit (passageway) for urine from the ureters to the surface. A loop of the sigmoid colon may also be used (Rubenwolf et al., 2016). An ileostomy bag is used to collect the urine. The resected (cut) ends of the remaining intestine are anastomosed (connected) to provide an intact bowel.

Stents, usually made of thin, pliable tubing, are placed in the ureters to prevent occlusion secondary to postsurgical edema. The bilateral ureteral stents allow urine to drain from the kidney to the stoma and provide a method for accurate measurement of urine output. They may be left in place 10 to 21 days postoperatively. Jackson–Pratt drains or other types of drains are inserted to prevent the accumulation of fluid in the space created by removal of the bladder.

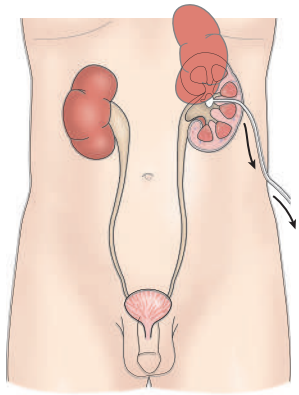


After surgery, a skin barrier and a transparent, disposable urinary drainage bag are applied around the conduit and connected to drainage. A custom-cut appliance is used until the edema subsides and the stoma shrinks to normal size. The clear bag allows the stoma to be inspected and the patency of the stent and the urine output to be monitored. The ileal bag drains urine (not feces) continuously. The appliance (bag) usually remains in place as long as it is watertight; it is changed when necessary to prevent leakage of urine.

Complications

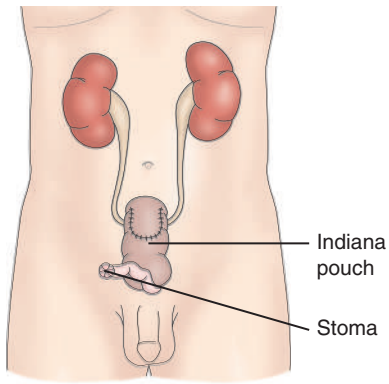


Complications that may follow placement of an ileal conduit include wound infection or wound dehiscence, urinary leakage, ureteral obstruction, hyperchloremic acidosis, small bowel obstruction, ileus, and gangrene of the stoma. Delayed complications include ureteral obstruction, contraction or narrowing of the stoma (stenosis), kidney deterioration due

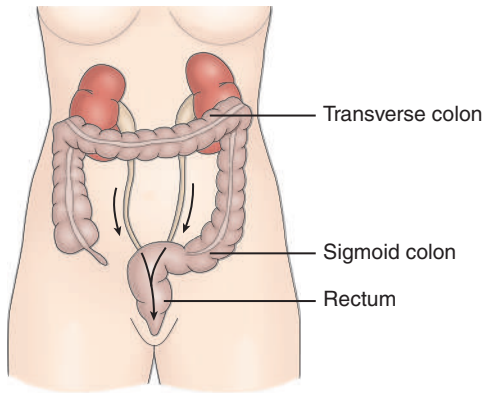


A Conventional ileal conduit.
The surgeon transplants the ureters to an isolated section of the terminal ileum (ileal conduit), bringing one end to the abdominal wall. The ureter may also be transplanted into the transverse sigmoid colon (colon conduit) or proximal jejunum (jejunal conduit).

B Cutaneous ureterostomy.
The surgeon brings the detached ureter through the abdominal wall and attaches it to an opening in the skin.



C Vesicostomy.
The surgeon sutures the bladder to the abdominal wall and creates an opening (stoma) through the abdominal and bladder walls for urinary drainage.



D Nephrostomy.
The surgeon inserts a catheter into the renal pelvis via an incision in the flank or by percutaneous catheter placement into the kidney.

Figure 45-8 • Types of cutaneous diversions include the conventional ileal conduit (**A**), cutaneous ureterostomy (**B**), vesicostomy (**C**), and nephrostomy (**D**).

A Indiana pouch.
The surgeon introduces the ureters into a segment of ileum and cecum. Urine is drained periodically by inserting a catheter into the stoma.

B Ureterosigmoidostomy.
The surgeon introduces the ureters into the sigmoid colon, thereby allowing urine to flow through the colon and out of the rectum.

Figure 45-9 • Types of continent urinary diversions include the Indiana pouch (**A**) and ureterosigmoidostomy (**B**).

to chronic reflux, pyelonephritis, renal calculi, and cancer recurrence (Rubenwolf et al., 2016); (Smolar, Salemi, Horst, et al., 2016).

Nursing Management

In the immediate postoperative period, urine volumes are monitored hourly. Throughout the patient's hospitalization, the nurse monitors closely for complications, reports signs and symptoms of them promptly, and intervenes quickly to prevent their progression.

A urine output below 0.5 mL/kg/hr may indicate dehydration or an obstruction in the ileal conduit, with possible backflow or leakage from the ureteroileal anastomosis. A catheter may be inserted through the urinary conduit to monitor the patient for possible stasis or residual urine from a constricted stoma. Urine may drain through the bilateral ureteral stents as well as around the stents. If the ureteral stents are not draining, the nurse may be instructed to carefully irrigate with 5 to 10 mL sterile normal saline solution, being careful not to exert tension that could dislodge the stent. Hematuria may be noted in the first 48 hours after surgery but usually resolves spontaneously.

Providing Stoma and Skin Care

Because the patient requires specialized care, a consultation is initiated with a ET nurse. The stoma is inspected frequently for color and viability. A healthy stoma is pink or red. A change from this normal color to purple, brown, or black suggests that the vascular supply may be compromised. If cyanosis and a compromised blood supply persist, surgical intervention may be necessary. The stoma is not sensitive to touch, but the skin around the stoma becomes sensitive if urine or the appliance causes irritation. The skin is inspected for (1) signs of irritation and bleeding of the stoma mucosa, (2) encrustation and skin irritation around the stoma (from alkaline urine coming in contact with exposed skin), and (3) wound infections (Dukes, Lowther, Martin, et al., 2013).

Testing Urine and Caring for the Ostomy

Moisture in bed linens or clothing or the odor of urine around the patient should alert the nurse to the possibility of leakage from the appliance, potential infection, or a problem in hygienic management. Because severe alkaline encrustation can accumulate rapidly around the stoma, the urine pH is kept below 6.5 by administration of ascorbic acid by mouth. Urine pH is determined by testing the urine draining from the stoma, not from the collecting appliance. A properly fitted appliance is essential to prevent exposure of the skin around the stoma to urine. If the urine is foul smelling, the stoma is catheterized, if prescribed, to obtain a urine specimen for culture and sensitivity testing.

Encouraging Fluids and Relieving Anxiety

Because mucous membrane is used in forming the conduit, the patient may excrete a large amount of mucus mixed with urine. This causes anxiety in many patients. To help relieve this anxiety, the nurse reassures the patient that this is a normal occurrence after an ileal conduit procedure. The nurse encourages adequate fluid intake to flush the ileal conduit and decrease the accumulation of mucus.

Selecting the Ostomy Appliance

Various urine collection appliances are available, and the nurse is instrumental (often with consultation with an ET nurse) in selecting an appropriate one. The urinary appliance may consist of one or two pieces and may be disposable (usually used once and discarded) or reusable. The choice of appliance is determined by the location of the stoma and by the patient's normal activity, manual dexterity, visual function, body build, economic resources, and preference.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Patient education begins in the hospital but continues in the home setting because patients are usually discharged within days of surgery. The nurse instructs the patient how to assess and manage the urinary diversion as well as how to deal with changes in body image. An ET nurse is invaluable in consulting with the nurse on various aspects of care and patient education.

Changing the Appliance

The patient and family are educated about how to apply and change the appliance so that they are comfortable carrying out the procedure and can do so proficiently. Ideally, the appliance system is changed before the system leaks and at a time that is convenient for the patient. Many patients find that early morning is most convenient because the urine output is reduced. A variety of appliances are available; an average collecting appliance lasts 3 to 7 days before leakage occurs.

Regardless of the type of appliance used, a skin barrier is essential to protect the skin from irritation and excoriation. To maintain skin integrity, a skin barrier or leaking pouch is never patched with tape to prevent accumulation of urine under the skin barrier or faceplate. The patient is instructed to avoid moisturizing soaps and body washes when cleaning the area because they interfere with the adhesion of the pouch. The degree to which the stoma protrudes is not the same in all patients; thus, there are various accessories and custom-made appliances to solve individual problems. Patient guidelines for applying reusable and disposable systems are presented in Chart 45-14.

Controlling Odor

The patient is instructed to avoid foods that give the urine a strong odor (e.g., asparagus, cheese, eggs). Most appliances contain odor barriers, but, if needed, a few drops of liquid deodorizer or diluted white vinegar may be introduced through the drain spout into the bottom of the pouch with a syringe or eyedropper to reduce odors. Ascorbic acid by mouth helps acidify the urine and suppress urine odor. Patients should be cautioned not to put aspirin tablets in the pouch to control odor, because they may ulcerate the stoma. In addition, the patient is reminded that odor will develop if the pouch is worn longer than recommended and not cared for properly.

Managing the Ostomy Appliance

The patient is instructed to empty the pouch by means of a drain valve when it is one third full because the weight of more urine will cause the pouch to separate from the skin. Some patients prefer wearing a leg bag attached with an adapter to the drainage apparatus. To promote uninterrupted sleep, a collecting bottle and tubing (one unit) are snapped onto an adapter that connects to the ileal appliance. A small amount of urine is left in the bag when the adapter is attached to prevent the bag from collapsing against itself. The tubing may be threaded down the pajama or pants leg to prevent kinking. The collecting bottle and tubing are rinsed daily with cool water and once a week with a 3:1 solution of water and white vinegar.

Chart 45-14 PATIENT EDUCATION

Using Urinary Diversion Collection Appliances

Applying a Reusable Pouch System

The nurse instructs the patient to:

1. Gather all necessary supplies.
2. Prepare new appliance according to the manufacturer's directions:
   - Apply double-faced adhesive disc that has been properly sized to fit the reusable pouch faceplate.
   - Remove paper backing and set pouch aside, or apply thin layer of contact cement to one side of the reusable pouch faceplate.
   - Set pouch aside.
3. Remove soiled pouch gently. Lay aside to clean later.
4. Clean peristomal skin (skin around stoma) with small amount of soap and water. Rinse thoroughly and dry. If a film of soap remains on the skin and the site does not dry, the appliance will not adhere adequately.
5. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry throughout the appliance change.
6. Inspect peristomal skin for irritation.
7. Note that a skin protector wipe or barrier ring may be applied before centering the faceplate opening directly over the stoma.
8. Position appliance over stoma, and press gently into place.
9. If desired, use a pouch cover or apply cornstarch under the pouch to prevent perspiration and skin irritation.
10. Clean soiled pouch, and prepare for reuse.

Applying a Disposable Pouch System

The nurse instructs the patient to:

1. Gather all necessary supplies.
2. Measure stoma, and prepare an opening in the skin barrier about 1/8-inch larger than the stoma and the same shape as the stoma.
3. Remove paper backing from skin barrier, and set aside.
4. Gently remove old appliance, and set aside.
5. Clean peristomal skin with warm water, and dry thoroughly.
6. Inspect peristomal skin (skin around stoma) for irritation.
7. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine, and keep the skin dry during the appliance change.
8. Center opening of skin barrier over stoma, and apply with firm, gentle pressure to attain a watertight seal.
9. If using a two-piece system, snap pouch onto the flanged wafer that adheres to skin.
10. Close drainage tap or spout at bottom of pouch.
11. Note that a pouch cover can be used or cornstarch applied under pouch to prevent perspiration and skin irritation.
12. Apply hypoallergenic tape around the skin barrier in a picture-frame manner.
13. Dispose of soiled appliance.

Adapted from Dukes, S., Lowther, C., Martin, T., et al. (2013). Guidelines for standardizing the treatment of stoma granulomas at the mucocutaneous junction. World Council of Enterostomal Therapists Journal, 33(1), 12–15.

Cleaning and Deodorizing the Appliance

Usually, the reusable appliance is rinsed in warm water and soaked in a 3:1 solution of water and white vinegar or a commercial deodorizing solution for 30 minutes. It is rinsed with tepid water and air-dried away from direct sunlight. (Hot water and exposure to direct sunlight dry the pouch and increase the incidence of cracking.) After drying, the appliance may be powdered with cornstarch and stored. Two appliances are necessary—one to be worn while the other is air-drying.

Continuing and Transitional Care

Follow-up care is essential to determine how the patient has adapted to the altered body image and lifestyle changes. Referral for home care is indicated to determine how well the patient and family are coping with the urinary drainage diversion. The nurse assesses the patient's physical status and emotional response. In addition, the nurse assesses the ability of the patient and family to manage the urinary diversion and appliance, reinforces previous education, and provides additional information (e.g., community resources, sources of ostomy supplies, insurance coverage for supplies).

As the postoperative edema subsides, the nurse assists in determining the appropriate changes needed in the ostomy appliance. The size of the stoma is measured every 3 to 6 weeks for the first few months postoperatively. The correct appliance size is determined by measuring the widest part of the stoma with a ruler. The permanent appliance should be no more than 1.6 mm (1/8 inch) larger than the diameter of the stoma and the same shape as the stoma to prevent contact of the skin with drainage.

Cutaneous Ureterostomy

A cutaneous ureterostomy (see Fig. 45-8), in which the ureters are directed through the abdominal wall and attached to an opening in the skin, is used for selected patients with ureteral obstruction (i.e., advanced pelvic cancer) because it requires less extensive surgery than other urinary diversion procedures. It is also an appropriate procedure for patients who have had previous abdominal irradiation.

A urinary appliance is fitted immediately after surgery. The management of the patient with a cutaneous ureterostomy is similar to the care of the patient with an ileal conduit, although the stomas are usually flush with the skin or retracted.

Continent Urinary Diversions

Continent Ileal Urinary Reservoir (Indiana Pouch)

The most common continent urinary diversion is the Indiana pouch, created for the patient whose bladder is removed or no longer functions. The Indiana pouch uses a segment of the ileum and cecum to form the reservoir for urine (see Fig. 45-9A). The ureters are tunneled through the muscular bands of the intestinal pouch and anastomosed. The reservoir is made continent by narrowing the efferent portion of the ileum and sewing the terminal ileum to the subcutaneous tissue, forming a continent stoma flush with the skin. The pouch is sewn to the anterior abdominal wall around a cecostomy tube. Urine collects in the pouch until a catheter is inserted and the urine is drained.

The pouch must be drained at regular intervals by a catheter to prevent absorption of metabolic waste products from the urine, reflux of urine to the ureters, and UTI. Postoperative nursing care of the patient with a continent ileal urinary pouch is similar to nursing care of the patient with an ileal conduit. However, these patients usually have additional drainage tubes (cecostomy catheter from the pouch, stoma catheter exiting from the stoma, ureteral stents, and Penrose drain, as well

as a urethral catheter). All drainage tubes must be carefully monitored for patency and amount and type of drainage. In the immediate postoperative period, the cecostomy tube is irrigated two or three times daily to remove mucus and prevent blockage.

Other variations of continent urinary reservoirs are used occasionally (Crawshaw, Williams, & Woodhouse, 2014). With these methods, the pouch must be drained at regular intervals by inserting a catheter.

The procedural guidelines for draining a continent ileostomy are discussed in Procedure Guideline 45-1.

Ureterosigmoidostomy

Ureterosigmoidostomy, another form of continent urinary diversion, is a transplantation of the ureters into the sigmoid colon, allowing urine to flow through the colon and out the rectum (see Fig. 45-9B). It is usually performed in patients who have had extensive pelvic irradiation, previous small bowel resection, or coexisting small bowel disease.

After surgery, voiding occurs from the rectum (for life), and an adjustment in lifestyle will be necessary because of urinary frequency. Drainage has a consistency equivalent to watery diarrhea, and the patient has some degree of nocturia. Patients usually need to plan activities around the frequent need to urinate, which in turn may affect the patient's social life. However, patients have the advantage of urinary control without having to wear an external appliance.

Nursing Management

In addition to the usual preoperative regimen, the patient may be placed on a liquid diet for several days preoperatively to reduce residue in the colon. Antibiotic agents (neomycin, kanamycin) are given to disinfect the bowel. Ureterosigmoidostomy requires a competent anal sphincter, adequate kidney function, and

Procedural Guidelines 45-1

Draining a Continent Ileostomy (Kock Pouch)

A continent ileostomy is the surgical creation of a pouch of small intestine that can serve as an internal receptacle for fecal and urinary discharge; a nipple valve is constructed at the outlet. Postoperatively, a catheter extends from the stoma and is attached to a closed drainage suction system. To ensure patency of the catheter, 10–20 mL of normal saline is instilled gently into the pouch usually every 3 hours; return flow is not aspirated but is allowed to drain by gravity.

After approximately 2 weeks, when the healing process has progressed to the point at which the catheter is removed from the stoma, the patient is taught to drain the pouch. A catheter is inserted into the reservoir to drain the fluid. The length of time between drainage periods is gradually increased until the reservoir needs to be drained only every 4–6 hours and irrigated once each day. A pouch is not necessary; instead, most patients wear a small dressing over the opening.

When the fecal discharge is thick, water can be injected through the catheter to loosen and soften it. The consistency of the effluent is affected by food intake. At first, drainage is only 60–80 mL, but as time goes on, the amount increases significantly. The internal Kock pouch stretches, eventually accommodating 500–1000 mL. The patient learns to use the sensation of pressure in the pouch as a gauge to determine how often the pouch should be drained.

The following procedure is used to drain the pouch; the patient is helped to participate in this procedure to learn to perform it unassisted.

Equipment

- Catheter
- Tissues
- Water-soluble lubricant
- Gauze squares
- Syringe
- Irrigating solution in a bowl
- Emesis or receiving basin

Implementation

Nursing Actions	Rationale
1. Perform hand hygiene	1. Hand hygiene is necessary before any intervention to decrease the likelihood of transmitting a hospital associated infection.
2. Lubricate the catheter and gently insert it about 5 cm (2 inches), at which point some resistance may be felt at the valve or nipple.	2. When gentle pressure is used, the catheter usually enters the pouch.
3. If there is much resistance, fill a syringe with 20 mL of air or water and inject it through the catheter, while still exerting some pressure on the catheter.	3. This permits the catheter to enter the pouch.
4. Place the other end of the catheter in a drainage basin held below the level of the stoma. Later, this process can be carried out at the toilet with drainage delivered into the toilet bowl.	4. Gravity facilitates drainage. Drainage may include flatus as well as effluent.
5. After drainage, the catheter is removed and the area around the stoma is gently washed with warm water. Pat dry and apply an absorbent pad over the stoma. Fasten the pad with hypoallergenic tape.	5. The entire procedure requires about 5–10 minutes; at first, it is performed every 3 hours. The time between procedures is gradually lengthened until irrigation is only required once daily.

Adapted from Chapman, G. M., Sinclair, L., & Langevin, J. M. (2009).Ileoanal reservoir guide. United Ostomy Associations of America: Author.

active renal peristalsis. The degree of anal sphincter control may be determined by assessing the patient's ability to retain enemas.

The postoperative regimen initially includes placing a catheter in the rectum to drain the urine and prevent reflux of urine into the ureters and kidneys. The tube is taped to the buttocks, and special skin care is given around the anus to prevent excoriation. Irrigations of the rectal tube may be prescribed, but force is never used because of the danger of introducing bacteria into the newly implanted ureters.

Monitoring Fluid and Electrolytes

In ureterosigmoidostomy, larger areas of the bowel mucosa are exposed to urine and electrolyte reabsorption. As a result, electrolyte imbalance and acidosis may occur. Potassium and magnesium in the urine may cause diarrhea. Fluid and electrolyte balance is maintained in the immediate postoperative period by closely monitoring the serum electrolyte levels and administering appropriate IV fluids. Acidosis may be prevented by placing the patient on a low-chloride diet supplemented with sodium potassium citrate.

The patient should be instructed never to wait longer than 2 to 3 hours before emptying urine from the intestine. This keeps rectal pressure low and minimizes the absorption of urinary constituents from the colon. It is essential to educate the patient about the symptoms of UTI: fever, flank pain, urgency, and frequency.

Retraining the Anal Sphincter

After the rectal catheter is removed, the patient learns to control the anal sphincter through special sphincter exercises. At first, urination is frequent. With reassurance and encouragement and the passage of time, the patient gains greater control and learns to differentiate between the need to void and the need to defecate.

Promoting Dietary Measures

Specific dietary instructions include avoidance of gas-forming foods (flatus can cause stress incontinence and offensive odors). Other ways to avoid gas are to avoid chewing gum, smoking, and any other activity that involves swallowing air. Salt intake may be restricted to prevent hyperchloremic acidosis. Potassium intake is increased through foods and medication because potassium may be lost in acidosis.

Monitoring and Managing Potential Complications

Pyelonephritis (upper UTI) due to reflux of bacteria from the colon is fairly common. Long-term antibiotic therapy may be prescribed to prevent infection. A late complication is adenocarcinoma of the sigmoid colon, possibly from cellular changes due to exposure of the colonic mucosa to urine. Urinary carcinogens promote late malignant transformation of the colon after a ureterosigmoidostomy, warranting lifelong medical follow-up.

Other Urinary Diversion Procedures

Variations in urinary diversion surgical procedures are devised frequently in an effort to identify and perfect procedures that will improve patient outcomes and reduce the incidence of postoperative problems (Rubenwolf et al., 2016). These include cecal, patched cecal, and Mainz reservoirs. These techniques involve isolating a part of the large intestine to form a reservoir for urine and creating an abdominal stoma. Another surgical procedure, the Camey procedure, uses a portion of the ileum as a bladder substitute. In this procedure, the isolated ileum serves as the reservoir for urine; it is anastomosed directly to the portion of the remaining urethra after cystectomy. This procedure permits emptying of the bladder through the urethra. However, the Camey procedure applies only to men because the entire urethra is removed when a cystectomy is performed in women.

NURSING PROCESS

The Patient Undergoing Urinary Diversion Surgery

Preoperative Assessment

The following are key preoperative nursing assessment concerns:

- Cardiopulmonary function assessments are performed because patients undergoing cystectomy are often older adults who may be at greater risk for cardiac and respiratory complications.
- A nutritional status assessment is important because of possible poor nutritional intake related to underlying health problems.
- Learning needs are assessed in consultation with an ET nurse to evaluate the patient's and the family's understanding of the procedure as well as the changes in physical structure and function that result from the surgery. The patient's self-concept and self-esteem are assessed in addition to methods for coping with stress and loss. The patient's mental status, manual dexterity and coordination, vision, and preferred method of learning are noted because they affect postoperative self-care.

Preoperative Diagnosis

Nursing Diagnoses

Based on the assessment data, preoperative nursing diagnoses may include the following:

- Anxiety related to anticipated losses associated with the surgical procedure
- Imbalanced nutrition: less than body requirements related to inadequate nutritional intake
- Deficient knowledge about the surgical procedure and postoperative care

Preoperative Planning and Goals

The major goals for the patient may include relief of anxiety; improved preoperative nutritional status; and increased knowledge about the surgical procedure, expected outcomes, and postoperative care.

Preoperative Nursing Interventions

Relieving Anxiety

The threat of cancer and removal of the bladder create anxiety related to changes in body image. Patients may face problems adapting to an external appliance, a stoma, a surgical incision, and altered toileting habits. Men must also adapt to sexual impotency; a penile implant is considered if the patient is a candidate for the procedure. Women also have anxiety related to altered appearance, body image, and self-esteem. A supportive approach, both physical and psychosocial, is needed and includes assessing the patient's self-concept and manner of coping with stress and loss; helping the patient to identify ways to maintain their lifestyle and independence with as few

changes as possible; and encouraging the patient to express fears and anxieties about the ramifications of the upcoming surgery.

Ensuring Adequate Nutrition

A low-residue diet is prescribed to cleanse the bowel to minimize fecal stasis, decompress the bowel, and minimize postoperative ileus. In addition, antibiotic medications are given to reduce pathogenic flora in the bowel and to reduce the risk of infection. Because the patient undergoing a urinary diversion procedure for cancer may be severely malnourished due to the tumor, previous treatments, and anorexia, enteral or parenteral nutrition may be prescribed to promote healing. Adequate preoperative hydration is imperative to ensure urine flow during surgery and to prevent hypovolemia during the prolonged surgical procedure.

Explaining Surgery and Its Effects

Participation of an ET nurse in patient education and care, is invaluable for informed preoperative education and postoperative planning. Explanations of the surgical procedure, the appearance of the stoma, the rationale for preoperative bowel preparation, the reasons for wearing a collection device, and the anticipated effects of the surgery on sexual functioning are part of patient education. The placement of the stoma site is planned preoperatively with the patient standing, sitting, and lying down to locate the stoma away from bony prominences, skin creases, and folds. The stoma should also be placed away from old scars, the umbilicus, and the belt line.

For ease of self-care, the patient must be able to see and reach the site comfortably. The site is marked with indelible ink so that it can be located easily during surgery. The patient is assessed for allergies or sensitivity to tape or adhesives. Patch testing of certain appliances may be necessary before the ostomy equipment is selected. This is particularly important if the patient is or may be allergic to latex (see Chapter 4; Figure 4-1).

Preoperative Evaluation

To measure the effectiveness of care, the nurse evaluates the patient's preoperative anxiety level and nutritional status as well as pre-existing knowledge and expectations of surgery.
Expected patient outcomes may include:

1. Exhibits reduced anxiety about surgery and expected losses
   a. Verbalizes fears with health care team and family
   b. Expresses positive attitude about outcome of surgery
2. Exhibits adequate nutritional status
   a. Maintains adequate intake before surgery
   b. Maintains body weight
   c. States rationale for enteral or parenteral nutrition if needed
   d. Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst
3. Demonstrates knowledge about the surgical procedure and postoperative course
   a. Identifies limitations expected after surgery
   b. Discusses expected immediate postoperative environment (tubes, equipment, nursing surveillance)
   c. Practices deep-breathing, coughing, and foot exercises

Postoperative Assessment

The role of the nurse in the immediate postoperative period is to prevent complications and to assess the patient carefully for any signs and symptoms of complications. The catheters and any drainage devices are monitored closely. Urine volume, patency of the drainage system, and color of the drainage are assessed. A sudden decrease in urine volume or increase in drainage is reported promptly to the primary provider, because these may indicate obstruction of the urinary tract, inadequate blood volume, or bleeding. In addition, the patient's need for pain control is assessed regularly, as with all postoperative patients.

Postoperative Diagnosis

Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Risk for impaired skin integrity related to problems in managing the urine collection appliance
- Acute pain related to surgical incision
- Disturbed body image related to urinary diversion
- Ineffective sexuality pattern related to structural and physiologic alterations
- Deficient knowledge about management of urinary function

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Peritonitis due to disruption of anastomosis
- Stoma ischemia and necrosis due to compromised blood supply to stoma
- Stoma retraction and separation of mucocutaneous border due to tension or trauma

Postoperative Planning and Goals

The major goals for the patient may include maintaining skin integrity, relieving pain, increasing self-esteem, developing appropriate coping mechanisms to accept and deal with altered urinary function and sexuality, increasing knowledge about management of urinary function, and preventing potential complications.

Postoperative Nursing Interventions

Postoperative management focuses on monitoring urinary function, preventing postoperative complications (infection and sepsis, respiratory complications, fluid and electrolyte imbalances, fistula formation, and urine leakage), and promoting patient comfort. Catheters or drainage systems are monitored, and urine output is monitored carefully. A nasogastric tube is inserted during surgery to decompress the GI tract and to relieve pressure on the intestinal anastomosis. It is usually kept in place for several days after surgery. As soon as bowel function resumes—as indicated by bowel sounds, the passage of flatus, and a soft abdomen—oral fluids are permitted. Until that time, IV fluids and electrolytes are given. The patient is assisted to ambulate as soon as possible to prevent complications of immobility.

Maintaining Skin Integrity

Strategies to promote skin integrity begin with reducing and controlling those factors that increase the patient's risk of poor nutrition and poor healing. Meticulous skin care and management of the drainage system are provided by the nurse until the patient can manage them and is comfortable doing so. Care is taken to keep the system intact to protect the skin from exposure to drainage. Supplies must be readily available to manage the drainage in the immediate postoperative period. Consistency in implementing the skin care program throughout the postoperative period results in maintenance of skin integrity and patient comfort. In addition, maintenance of skin integrity

around the stoma enables the patient and family to adjust more easily to the alterations in urinary function and helps them learn skin care techniques.

Relieving Pain

Analgesic medications are given liberally postoperatively to relieve pain and promote comfort, thereby allowing the patient to turn, cough, and perform deep-breathing exercises. Patient-controlled analgesia and regular administration of analgesic agents around the clock are two options that may be used to ensure adequate pain relief. A pain intensity scale is used to evaluate the adequacy of the medication and the approach to pain management. See Chapter 9 for further discussion of pain management.

Improving Body Image

The patient's ability to cope with the changes associated with the surgery depends to some degree on their body image and self-esteem before the surgery and the support and reaction of others. Allowing the patient to express concerns and anxious feelings can help, especially in adjusting to the changes in toileting habits. The nurse can also help improve the patient's self-concept by educating about skills needed to be independent in managing the urinary drainage devices. Education about ostomy care is conducted in a private setting to encourage the patient to ask questions without fear of embarrassment. Explaining why the nurse must wear gloves when performing ostomy care can prevent the patient from misinterpreting the use of gloves as a sign of aversion to the stoma.

Exploring Sexuality Issues

Patients who experience altered sexual function as a result of the surgical procedure may mourn this loss. One study of 82 patients reported that sexual function in all domains was negatively affected in both genders (Rubenwolf et al., 2016). Encouraging the patient and partner to share their feelings about this loss with each other and acknowledging the importance of sexual function and expression may encourage the patient and partner to seek sexual counseling and to explore alternative ways of expressing sexuality. A visit from another patient with an ostomy who is functioning fully in society and family life may also assist the patient and family in recognizing that full recovery is possible.

Monitoring and Managing Potential Complications

Complications are not unusual because of the complexity of the surgery, the underlying reason (cancer, trauma) for the urinary diversion procedure, and the patient's frequently less-than-optimal nutritional status. Complications may include respiratory disorders (e.g., atelectasis, pneumonia), fluid and electrolyte imbalances, breakdown of any anastomosis, sepsis, fistula formation, fecal or urine leakage, and skin irritation. If these occur, the patient will remain hospitalized for an extended length of time and will probably require parenteral nutrition, GI decompression by means of nasogastric suction, and further surgery. The goals of management are to establish drainage, provide adequate nutrition for healing to occur, and prevent sepsis.

Peritonitis. Peritonitis can occur postoperatively if urine leaks at the anastomosis. Signs and symptoms include abdominal pain and distention, muscle rigidity with guarding, nausea and vomiting, paralytic ileus (absence of bowel sounds), fever, and leukocytosis.

Urine output must be monitored closely, because a sudden decrease in output with a corresponding increase in drainage from the incision or drains may indicate urine leakage. In addition, the urine drainage device is observed for leakage. The pouch is changed if a leak is observed. Small leaks in the anastomosis may seal themselves, but surgery may be needed for larger leaks.

Vital signs (blood pressure, pulse and respiratory rates, temperature) are monitored. Changes in vital signs, as well as increasing pain, nausea and vomiting, and abdominal distention, are reported and may indicate peritonitis.

Stoma Ischemia and Necrosis. The stoma is monitored because ischemia and necrosis of the stoma can result from tension on the mesentery blood vessels, twisting of the bowel segment (conduit) during surgery, or arterial insufficiency. The new stoma must be inspected at least every 4 hours to assess the adequacy of its blood supply. The stoma should be red or pink. If the blood supply to the stoma is compromised, the color changes to purple, brown, or black. These changes are reported immediately. The surgeon or ET nurse may insert a small, lubricated tube into the stoma and shine a flashlight into the lumen of the tube to assess for superficial ischemia or necrosis. A necrotic stoma requires surgical intervention. If the ischemia is superficial, the dusky stoma is observed and may slough its outer layer in several days.

Stoma Retraction and Separation. Stoma retraction and separation of the mucocutaneous border can occur as a result of trauma or tension on the internal bowel segment used for creation of the stoma. In addition, mucocutaneous separation can occur if the stoma does not heal as a result of accumulation of urine on the stoma and mucocutaneous border. Using a collection drainage pouch with an antireflux valve is helpful because the valve prevents urine from pooling on the stoma and mucocutaneous border. Meticulous skin care to keep the area around the stoma clean and dry promotes healing. If a separation of the mucocutaneous border occurs, surgery is not usually needed. The separated area is protected by applying karaya powder, stoma adhesive paste, and a properly fitted skin barrier and pouch. By protecting the separation, healing is promoted. If the stoma retracts into the peritoneum, surgical intervention is mandatory.

If surgery is needed to manage these complications, the nurse provides explanations to the patient and family. The need for additional surgery is usually perceived as a setback by the patient and family. Emotional support of the patient and family is provided along with physical preparation of the patient for surgery.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. A major postoperative objective is to assist the patient to achieve the highest level of independence and self-care possible. The nurse and ET nurse work closely with the patient and family to instruct and assist them in all phases of managing the ostomy. Adequate supplies and complete instruction are necessary to enable the patient and a family member to develop competence and confidence in their skills. Written and verbal instructions are provided, and the patient is encouraged to contact the nurse or primary provider with follow-up questions. Follow-up telephone calls from the nurse to the patient and family after discharge may provide added support and provide another opportunity to answer their questions. Follow-up visits and reinforcement of correct skin care and appliance management techniques also promote skin integrity. Specific techniques for managing the appliance are described in Chart 45-14.

The patient is encouraged to participate in decisions regarding the type of collecting appliance and the time of day to change the appliance. The patient is assisted and encouraged to look at and

touch the stoma early to overcome any fears. The patient and family need to know the characteristics of a normal stoma:

- Pink or red and moist, like the inside of the mouth
- Insensitive to pain because it has no nerve endings
- Vascular, which means it may bleed when cleaned

In addition, if a segment of the GI tract was used to create the urinary diversion, mucus may be visible in the urine. By learning what is normal, the patient and family become familiar with what signs and symptoms they should report and what problems they can handle themselves.

Information provided to the patient and the extent of involvement in self-care are determined by the patient's physical recovery and ability to accept and acquire the knowledge and skill needed for independence. Verbal and written instructions are provided, and the patient is given the opportunity to practice and demonstrate the knowledge and skills needed to manage urinary drainage.

Continuing and Transitional Care. Follow-up care is essential to determine how the patient has adapted to the changes in body image and lifestyle adjustments. Visits from a nurse are important to assess the patient's adaptation to the home setting and management of the ostomy. Education and reinforcement may assist the patient and family to cope with altered urinary function. It is important to assess for long-term complications that may occur, such as pouch leakage or rupture, stone formation, stenosis of the stoma, deterioration in kidney function, or incontinence.

Long-term monitoring for anemia is performed to identify vitamin B_{12} deficiency, which may occur when a significant portion of the terminal ileum is removed. This may take several years to develop and can be treated with vitamin B_{12} injections. The patient and family are informed about the Ostomy Associations of India (OAI) and any local ostomy support groups to provide ongoing support, assistance, and education.

Postoperative Evaluation

Expected patient outcomes may include:

1. Maintains skin integrity
   a. Maintains intact skin and demonstrates skill in managing drainage system and appliance
   b. States actions to take if skin excoriation occurs
2. Reports relief of pain
3. Exhibits improved body image as evidenced by the following:
   a. Voices acceptance of urinary diversion, stoma, and appliance
   b. Demonstrates increasingly independent self-care, including hygiene and grooming
   c. States acceptance of support and assistance from family members, health care providers, and another patient with an ostomy
4. Copes with sexuality issues
   a. Verbalizes concern about possible alterations in sexuality and sexual function
   b. Reports discussion of sexual concerns with partner and appropriate counselor
5. Demonstrates knowledge needed for self-care
   a. Performs self-care and proficient management of urinary diversion and appliance
   b. Asks questions relevant to self-management and prevention of complications
   c. Identifies signs and symptoms needing care from primary provider, nurse, or other health care providers
6. Absence of complications as evidenced by the following:
   a. Reports absence of pain or tenderness in abdomen
   b. Has temperature within normal range
   c. Reports no urine leakage from incision or drains
   d. Has urine output within desired volume limits
   e. Maintains stoma that is red or pink, moist, and appropriate in size without edema
   f. Has intact and healed border of the stoma

CRITICAL THINKING EXERCISES

1. You are caring for a patient in the intensive care unit who has had an indwelling urinary catheter inserted. What strategies should be used to avoid a CAUTI in the patient? Identify the factors that would put this patient at risk for CAUTI.
2. You are a nurse in a busy urology practice who often cares for patients with incontinence. Describe the major types of incontinence, and compare and contrast each. What are the evidence-based management techniques used in treating the different types of incontinence? How do practices differ for men and women? Identify the criteria used to evaluate the strength of the evidence for these practices.
3. A 55-year-old woman is admitted to a medical-surgical nursing unit with bladder cancer. She is scheduled for a radical cystectomy and urinary diversion. Identify the priorities, approach, and techniques you would use to provide care for this patient in the pre-operative phase of care. How will your priorities, approach, and techniques differ in the post-operative phase of care?

Male Reproductive Function

Chapter 46 Assessment and Management of Patients with Male Reproductive Disorders 1469

CHAPTER 46

Assessment and Management of Patients with Male Reproductive Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe structures and function of the male reproductive system.
2. Discuss nursing assessment of the male reproductive system including climacteric changes; identify diagnostic tests used and their related nursing implications.
3. Explain the causes and management of male sexual dysfunction.
4. Compare the types of prostatectomy with regard to advantages and disadvantages.
5. Use the nursing process as a framework for care of the patient with prostate cancer or undergoing prostatectomy.
6. Identify the nursing management of patients with testicular cancer.
7. Compare and contrast the various disorders of the penis, including pathophysiology, clinical manifestations, and management.
8. Explain the features and causes of gynecomastia.

GLOSSARY

androgen deprivation therapy (ADT): surgical (orchiectomy) or medical castration (e.g., with luteinizing hormone–releasing hormone agonists)
benign prostatic hyperplasia (BPH): noncancerous enlargement or hypertrophy of the prostate; the most common pathologic condition in older men
brachytherapy: delivery of internal radiation therapy to a localized area of tissue
circumcision: excision of the foreskin, or prepuce, of the glans penis
cystostomy: surgical creation of an opening into the urinary bladder
epididymitis: infection of the epididymis that usually descends from an infected prostate or urinary tract; also may develop as a complication of gonorrhea, chlamydia, or *Escherichia coli*
erectile dysfunction: the inability to either achieve or maintain an erection sufficient to accomplish sexual intercourse; also called *impotence*
gynecomastia: abnormal tender breast mass development that occurs in males
hydrocele: a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord
orchiectomy: surgical removal of one or both of the testes
orchitis: acute inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors
phimosis: condition in which the foreskin is constricted so that it cannot be retracted over the glans; can occur congenitally or from inflammation and edema
priapism: an uncontrolled, persistent erection of the penis from either neural or vascular causes, including medications, sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors, and tumor invasion of the penis or its vessels
prostatectomy: surgical removal of the entire prostate, the prostate urethra, and the attached seminal vesicles plus the ampulla of the vas deferens
prostate-specific antigen (PSA): substance that is produced by the prostate gland; is used in combination with digital rectal examination to screen for prostate cancer
prostatitis: inflammation of the prostate gland caused by infectious agents (bacteria, fungi, mycoplasma) or various other problems (e.g., urethral stricture, prostatic hyperplasia)
retrograde ejaculation: during ejaculation, semen travels to the urinary bladder instead of exiting through the penis
spermatogenesis: production of sperm in the testes
testosterone: male sex hormone secreted by the testes; induces and preserves the male sex characteristics
transurethral resection of the prostate (TURP): resection of the prostate through endoscopy; the surgical and optical instrument is introduced directly through the urethra to the prostate, and the gland is then removed in small chips with an electrical cutting loop
varicocele: an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord)
vasectomy: ligation and transection of part of the vas deferens, with or without removal of a segment of the vas, to prevent the passage of the sperm from the testes; also called *male sterilization*

Introduction

Disorders of the male reproductive system include a wide variety of conditions that usually affect both urinary and reproductive systems. Because these disorders involve the genitalia and often affect sexuality, the patient may experience anxiety and embarrassment. The nurse must be aware of the patient's need for privacy as well as his need for education and support. This requires an openness to discuss critical and sensitive issues with the patient, including his partner when appropriate, as well as effective assessment, management, and communication. Nurses must be comfortable when examining male genitalia and must recognize their own attitudes and perceptions about male reproductive disorders. Education of the patient and partner about treatment and self-care strategies is essential (Tabloski, 2014).

ASSESSMENT OF THE MALE REPRODUCTIVE SYSTEM

Anatomic and Physiologic Overview

In the male, several organs serve as parts of both the urinary tract and the reproductive system. Disorders in the male reproductive

organs may interfere with the functions of one or both of these systems. As a result, diseases of the male reproductive system are usually treated by a urologist. The structures in the male reproductive system include the (1) external male genitalia, consisting of the testes, epididymis, scrotum, and penis, and the (2) internal male genitalia, consisting of the vas deferens (ductus deferens), ejaculatory duct, and prostatic and membranous sections of the urethra, seminal vesicles, and certain accessory glands, such as the prostate gland and Cowper glands (bulbourethral glands) (see Fig. 46-1).

The testes have a dual function: spermatogenesis (production of sperm) and secretion of the male sex hormone testosterone, which induces and preserves the male sex characteristics. The testes are formed in the embryo, within the abdominal cavity near the kidney. During the last month of fetal life, they descend posterior to the peritoneum and pierce the abdominal wall in the groin. Later, they progress along the inguinal canal into the scrotal sac. In this descent, they are accompanied by blood vessels, lymphatics, nerves, and ducts, which support the tissue and make up the spermatic cord. This cord extends from the internal inguinal ring through the abdominal wall and the inguinal canal to the scrotum. As the testes descend into the scrotum in the final 2 to 3 months of gestation, a tubular extension of peritoneum accompanies them (Hall, 2015). Normally, this tissue is obliterated during fetal development; only the tunica vaginalis, which covers the testes, remains. If the peritoneal process remains open into the abdominal cavity, a potential sac remains into which abdominal contents may enter to form an indirect inguinal hernia.

The testes, or ovoid sex glands, are encased in the scrotum, which keeps them at a slightly lower temperature than the rest of the body to facilitate spermatogenesis (Hall, 2015). The testes consist of numerous seminiferous tubules in which the spermatozoa form. Collecting tubules transmit the spermatozoa into the epididymis, a hoodlike structure lying on the testes and containing winding ducts that lead into the vas deferens. This firm, tubular structure passes upward through the inguinal canal to enter the abdominal cavity behind the peritoneum. It then extends downward toward the base of the bladder. An out-pouching from this structure is the seminal vesicle, which acts as a reservoir for testicular secretions. The tract is continued as the ejaculatory duct, which passes through the prostate gland to enter the urethra. Testicular secretions take this pathway when they exit the penis during ejaculation.

The penis is the organ for both copulation and urination. It consists of the glans penis, the body, and the root. The glans penis is the soft, rounded portion at the distal end of the penis. The urethra (the tube that carries urine) opens at the tip of the glans. The glans is naturally covered by elongated penile skin—the foreskin—which may be retracted to expose the glans. However, many men as newborns have undergone circumcision, which is a procedure to remove the foreskin. The body of the penis is composed of erectile tissues containing numerous blood vessels that become dilated, leading to an erection during sexual excitement. The urethra, which passes through the penis, extends from the bladder through the prostate to the distal end of the penis.

The prostate gland, lying just below the neck of the bladder, is composed of four zones and four lobes. It surrounds the urethra and is traversed by the ejaculatory duct, a continuation of the vas deferens. This gland produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes. Cowper glands lie below the prostate, within the posterior aspect of the urethra. This gland empties its secretions into the urethra during ejaculation, providing lubrication.

Gerontologic Considerations

As men age, the prostate gland enlarges; prostate secretion decreases; the scrotum hangs lower; the testes decrease in weight, atrophy, and become softer; and pubic hair becomes sparser and stiffer. Changes in gonadal function include a decline in plasma testosterone levels and reduced production of progesterone (see Table 46-1). Libido and potency often decrease in as many as two thirds of men older than 70 years (Tabloski, 2014). Vascular problems cause about half of the cases of impotence in men older than 50 years.

However, male reproductive capability is maintained with advancing age. Although degenerative changes occur in the seminiferous tubules and sperm production decreases,

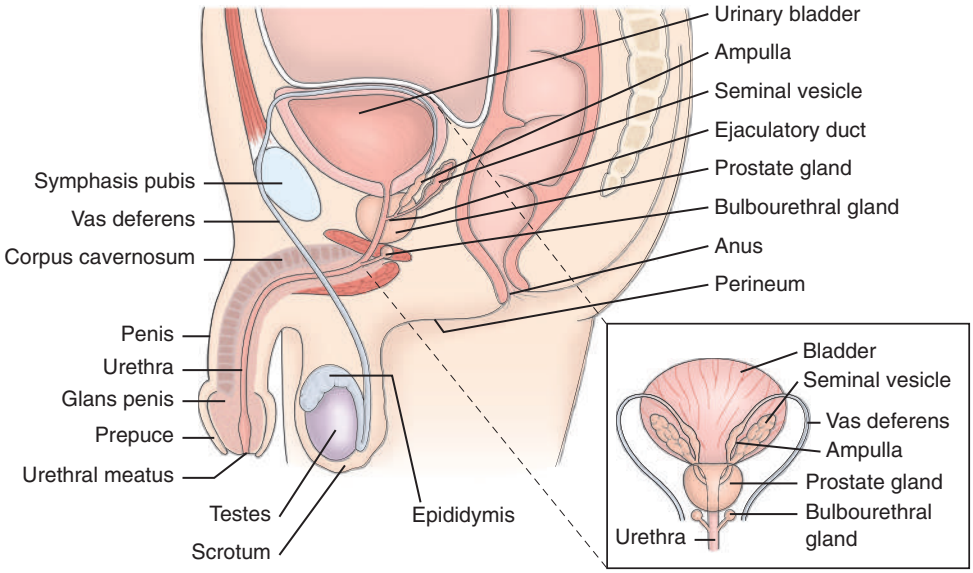

Figure 46-1 • Structures of the male reproductive system.

TABLE 46-1 Age-Related Changes in the Male Reproductive System

Age-Related Changes	Physiologic Changes	Manifestations
Decrease in sex hormone secretion, especially testosterone	Decreased muscle strength and sexual energy	Changes in sexual response—prolonged time to reach full erection, rapid penile detumescence, and prolonged refractory period
		Decrease in number of viable sperm
	Shrinkage and loss of firmness of testes; thickening of seminiferous tubules	Smaller testes
	Fibrotic changes of corpora cavernosa	Erectile dysfunction
	Enlargement of prostate gland	Weakening of prostatic contractions
		Hyperplasia of prostate gland
		Signs and symptoms of obstruction of lower urinary tract (urgency, frequency, nocturia)

Adapted from Tabloski, P. A. (2014). Gerontological nursing: The essential guide to clinical practice (3rd ed.). New York: Pearson.

spermatogenesis continues, allowing men to produce viable sperm throughout their lives (McCance, Huether, Braskers, et al., 2013).

Male hypogonadism (decreased function of the testes) starts gradually at approximately 50 years of age, resulting in decreased testosterone production. The older man notices that the sexual response slows, erection takes longer, full erections may not be attained, and ejaculation takes longer to occur and control or resolution may occur without orgasm. Sexual function can be affected by psychological problems, illnesses, and medications (Mulhall & Hsiao, 2014). In general, the entire sexual act takes longer. Sexual activity is closely correlated with the man's sexual activity in his earlier years; if he was more active than average as a young man, he will most likely continue to be more active than average in his later years.

Men older than 50 years are at increased risk for genitourinary tract cancers, including those of the kidney, bladder, prostate, and penis. The digital rectal examination (DRE), prostate-specific antigen (PSA) test, and urinalysis, which screens for hematuria, may uncover a higher percentage of malignancies at earlier stages and lead to lower treatment-associated morbidity as well as a lower mortality.

Urinary incontinence occurs in one fifth of elderly man residing in families and rises to nearly 50% in men in old-age homes. Older adults admitted to hospitals should be screened for this problem. Urinary incontinence may have many causes, including medications, neurologic disease, or benign prostatic hyperplasia (BPH). Incontinence may also be linked to erectile dysfunction when there is damage to the neural pathways that initiate an erection (Lim, 2013). Diagnostic tests are performed to exclude reversible causes. New-onset urinary incontinence is a nursing priority that requires evaluation.

Assessment

Health History

Male sexuality is a complex phenomenon that is strongly influenced by personal, cultural, religious, and social factors. Sexuality and male reproductive function become concerns in the presence of illness and disability (Norton & Tremayne, 2015). Throughout the assessment process, the nurse must recognize the importance of sexuality to the patient. Assessment of male reproductive function begins with an evaluation of urinary function and symptoms. The patient is asked about his usual state of health and any recent change in general physical and sexual activity. Any symptoms or changes in function are explored fully and described in detail. Symptoms related to bladder function and urination, collectively referred to as prostatism, are explored further. They may occur with an obstruction caused by an enlarged prostate gland: increased urinary frequency, decreased force of urine stream, and "double" or "triple" voiding (the patient needs to urinate two or three times over a period of several minutes to completely empty his bladder). The patient is also assessed for dysuria (painful urination), hematuria (blood in the urine), nocturia (urination during the night), and hematospermia (blood in the ejaculate).

Assessment also involves addressing sexual function, including manifestations of sexual dysfunction. The extent of the history depends on the patient's presenting symptoms and the presence of factors that may affect sexual function such as chronic illnesses or disability (e.g., diabetes, multiple sclerosis, stroke, cardiac disease), the use of medications that affect sexual function (e.g., antihypertensive and anticholesterolemic medications, psychotropic agents), stress, the use of alcohol, and the patient's willingness to discuss sexual issues.

By initiating an assessment about sexual concerns, the nurse conveys the message that changes in sexual functioning are valid topics and provides a safe environment for discussing these sensitive topics. A number of models are available to assist in assessing patient's problems and concerns. The PLISSIT (*p*ermission, *l*imited *i*nformation, *s*pecific *s*uggestions, *i*ntensive *t*herapy) model of sexual assessment and intervention may be used to provide a framework for nursing interventions (Norton & Tremayne, 2015). It provides a graded counseling approach that allows health care professionals to deal with sexual issues with a level of comfort and expertise. The model begins by asking the patient's permission (P) to discuss sexual functioning. Limited information (LI) about sexual function may then be provided to the patient. As the discussion progresses, the nurse may offer specific suggestions (SS) for interventions. A professional who specializes in sex therapy may provide more intensive therapy (IT) as needed. The BETTER (*b*ringing up the topic, *e*xplaining, *t*elling, *t*iming, *e*ducate about treatment-related sexual side effects, *r*ecording) model was developed more recently to assist health care professionals to include sexuality in the assessment of patients with cancer (Tannenbaum, 2015).

Patients may find it difficult to express their feelings and concerns regarding their sexuality, especially after a body image change (e.g., after major surgery such as amputation). Discussing sexuality with patients who have an illness or disability can be uncomfortable for nurses and other health care providers; this, in turn, makes discussion of these issues more difficult and uncomfortable for patients. Health care professionals may unconsciously have stereotypes about the sexuality of people

who are ill or have a disability (e.g., the belief that people with disabilities are asexual or should be sexually inactive). In addition, patients are often embarrassed to initiate a discussion about sexual issues with their health care providers (Gledhill & Schweitzer, 2013); (Mitchell, Mercer, Ploubidis, et al., 2013).

Physical Assessment

In addition to the usual aspects of the physical examination, two essential components address disorders of the male genital or reproductive system: the DRE and the testicular examination.

Digital Rectal Examination

The DRE is used to screen for prostate cancer and is recommended annually for every man older than 50 years (45 years for men at high risk). The DRE enables the skilled examiner, using a lubricated, gloved finger placed in the rectum, to assess the size, symmetry, shape, and consistency of the posterior surface of the prostate gland (see Fig. 46-2). The clinician assesses for tenderness of the prostate gland on palpation and for the presence and consistency of any nodules. The DRE may be performed with the patient leaning over an examination table or positioning the man in a side-lying position with legs flexed toward the abdomen or supine with legs resting in stirrups. To minimize discomfort and relax the anal sphincter during the rectal examination, the patient is instructed to take a deep breath and exhale slowly as the practitioner inserts a finger. If possible, he should turn his feet inward so his toes are touching. Although this examination may be uncomfortable and embarrassing for the patient, it is an important screening tool.

Testicular Examination

The male genitalia are inspected for abnormalities and palpated for masses. The scrotum is palpated carefully for nodules, masses, or inflammation. Examination of the scrotum can reveal such disorders as hydrocele, inguinal hernia, testicular torsion, orchitis, epididymitis, or a tumor of the testis. The penis is inspected and palpated for ulcerations, nodules, inflammation, discharge, and curvature. If the patient is uncircumcised, the foreskin should be retracted for visualization of the glans penis. The testicular examination provides an excellent opportunity to instruct the patient on how to perform a testicular self-examination (TSE) and its importance in early detection of testicular cancer. TSE should begin during adolescence. For more details on TSE, see later discussion in the chapter and Chart 46-6.

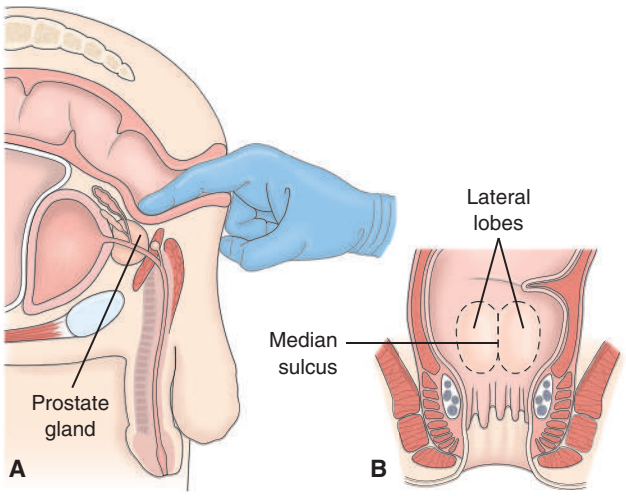

Figure 46-2 • A. Palpation of the prostate gland during digital rectal examination enables the examiner to assess the size, shape, and texture of the gland. **B.** The prostate is round, with a palpable median sulcus or groove separating the lateral lobes. It should feel rubbery and free of nodules and masses.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in men with reproductive disorders. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these tests and examinations prior to testing. The nurse should note trends in results because they provide information about disease progression as well as the patient's response to therapy.

Prostate-Specific Antigen Test

The cells within the prostate gland produce a protein that can be measured in the blood called the prostate-specific antigen (PSA). It is a sensitive but not specific test for prostate cancer. In the absence of prostate cancer, serum PSA levels vary with age, race, and prostate volume. Increased levels may indicate prostate cancer. However, a number of other conditions such as BPH, acute urinary retention, and acute prostatitis may cause high PSA levels. Values of PSA may also increase after ejaculation. PSA levels are measured in nanograms per milliliter (ng/mL). In most laboratories, values less than 4 ng/mL are generally considered normal, and values greater than 4 ng/mL are considered elevated (Barry & Hayes, 2015); (Pagana & Pagana, 2013). The use of age-specific reference ranges is encouraged to help minimize unnecessary biopsies.

A serum PSA level and a DRE, which are recommended by the ACS (2015), are used to screen for prostate cancer for men with at least a 10-year life expectancy and for men at high risk, including those with a strong family history of prostate cancer. The PSA test is also used to monitor patients for recurrence after treatment for cancer of the prostate, based on evidence-based guidelines (National Comprehensive Cancer Network [NCCN], 2016b). Neither the DRE nor PSA is 100% accurate, but when used together, their accuracy increases.

Ultrasonography

Transrectal ultrasound (TRUS) may be performed in patients with abnormalities detected by DRE and in those with elevated PSA levels. After DRE has been completed, a lubricated, condom-covered, rectal probe transducer is inserted into the rectum (Itano, Brant, Conde, et al., 2016). Water may be introduced into the condom to help transmit sound waves to the prostate. TRUS may be used in detecting nonpalpable prostate cancers and in staging localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS.

Prostate Fluid or Tissue Analysis

Specimens of prostate fluid or tissue may be obtained for culture if disease or inflammation of the prostate gland is suspected. A biopsy of the prostate gland may be necessary to obtain tissue for histologic examination. This may be performed at the time of prostatectomy or by means of a perineal or transrectal needle biopsy. Six to 12 biopsies from all four prostate zones may be obtained during a TRUS-guided biopsy.

Tests of Male Sexual Function

If the patient cannot engage in sexual intercourse to his satisfaction, a detailed history is obtained. Nocturnal erections occur in healthy males of all ages. Nocturnal penile tumescence tests may be conducted in a sleep laboratory to monitor changes in penile circumference during sleep using various methods to determine number, duration, rigidity, and circumference of penile erections; the results help identify whether the erectile dysfunction is caused by physiologic or psychological factors. Additional tests, including psychological evaluations, are also part of the diagnostic workup and are usually conducted by a specialized team of health care providers.

DISORDERS OF MALE SEXUAL FUNCTION

Erectile Dysfunction

Erectile dysfunction, also called *impotence,* is the inability to achieve or maintain an erect penis (Grossman & Porth, 2014). The man may report decreased frequency of erections, inability to achieve a firm erection, or rapid detumescence (subsiding of erection). In the United States, 30 million men experience erectile dysfunction; more than half of men 40 to 70 years of age are unable to attain or maintain an erection sufficient for satisfactory sexual performance (Keane & Graham, 2016). The physiology of erection and ejaculation is complex and involves parasympathetic and sympathetic components. Erection involves the release of nitric oxide into the corpus cavernosum during sexual stimulation. Its release activates cyclic guanosine monophosphate (cGMP), causing smooth muscle relaxation. This allows flow of blood into the corpus cavernosum, resulting in erection (Grossman & Porth, 2014); (McDougal, Wein, Kavoussi, et al., 2016).

There are no sufficient statistical data to reveal the exact number of patients suffering from erectile dysfunction in India, though a study reports about 47.8% of men with erectile dysfunction. Prevalence rate of erectile dysfunction is higher (69.9%) among diabetic patients than in nondiabetic persons (Seid, Gerensea, Tarko, et al., 2017). The most common causes of this condition are diabetes mellitus, financial stress, and use of psychiatric treatment for disorders such as depression and anxiety (Thangadurai, Gopalakrishnan, Abraham, et al., 2014).

Erectile dysfunction has both psychogenic and organic causes. Psychogenic causes include anxiety, fatigue, depression, pressure to perform sexually, negative body image, absence of desire, and privacy, as well as trust and relationship issues. Organic causes include cardiovascular disease, endocrine disease (diabetes, pituitary tumors, testosterone deficiency, hyperthyroidism, and hypothyroidism), cirrhosis, chronic kidney injury, genitourinary conditions (radical pelvic surgery), hematologic conditions (Hodgkin lymphoma, leukemia), neurologic disorders (neuropathies, parkinsonism, spinal cord injury [SCI], multiple sclerosis), trauma to the pelvic or genital area, alcohol, smoking, medications (see Chart 46-1), and drug abuse.

Chart 46-1 PHARMACOLOGY

Medications Associated with Erectile Dysfunction

- *Antiadrenergics and antihypertensives:* Guanethidine (Ismelin), clonidine (Catapres), hydralazine (Apresoline)
- *Anticholinergics and phenothiazines:* Prochlorperazine (Compazine), trihexyphenidyl (Artane)
- *Antidepressants:* tricyclic antidepressants: Amitriptyline (Elavil), desipramine (Norpramin); selective serotonin reuptake inhibitors: Fluoxetine (Prozac), sertraline (Zoloft)
- *Antifungals:* Ketoconazole (Nizoral)
- *Antihistamines:* Diphenhydramine (Benadryl), dimenhydrinate (Dramamine)
- *Antihormone (prostate cancer treatment):* Flutamide (Eulexin), leuprolide (Lupron)
- *Antipsychotics:* haloperidol (Haldol), Chlorpromazine (Thorazine)
- *Anticonvulsant agents:* Carbamazepine (Tegretol)
- *Antispasmodics:* Oxybutynin (Ditropan)
- *Anxiolytics, sedative–hypnotics, tranquilizers:* Lorazepam (Ativan), triazolam (Halcion)
- *Beta-blockers:* Nadolol (Corgard), metoprolol (Lopressor)
- *Calcium channel blockers:* Nifedipine (Adalat, Procardia)
- *Carbonic anhydrase inhibitors:* Acetazolamide (Diamox)
- *Chemotherapeutic agents:* Busulfan (Myleran), cyclophosphamide (Cytoxan)
- *Diuretics:* hydrochlorothiazide (HydroDIURIL), Furosemide (Lasix), spironolactone (Aldactone), verapamil (Calan)
- *Histamine-2 antagonists:* Nizatidine (Axid), ranitidine (Zantac)
- *Nonsteroidal anti-inflammatory drugs:* Naproxen (Naprosyn), indomethacin (Indocin)
- *Other substances:* alcohol, amphetamines, barbiturates, cocaine, marijuana, methadone, nicotine, opioids
- *Parkinson disease medications:* carbidopa/levodopa (Sinemet), benztropine (Cogentin)

Assessment and Diagnostic Findings

The diagnosis of erectile dysfunction requires a sexual and medical history; an analysis of presenting symptoms; a physical examination, including a neurologic examination; a detailed assessment of all medications, alcohol, and drugs used; and various laboratory studies. Nocturnal penile tumescence tests are conducted to monitor changes in penile circumference. This test can help to determine if erectile impotence has an organic or a psychological cause. In healthy men, nocturnal penile erections closely parallel rapid eye movement (REM) sleep in occurrence and duration. Organically impotent men show inadequate sleep-related erections that correspond to their waking performance. Arterial blood flow to the penis is measured using a Doppler probe. In addition, nerve conduction tests and extensive psychological evaluations may be carried out. Figure 46-3 describes the evaluation and treatment of erectile dysfunction.

Medical Management

Treatment can be medical, surgical, or both, depending on the cause. Treatment of erectile dysfunction includes therapy for associated disorders (e.g., alcoholism, diabetes) or adjustment of medications (Mola, 2015). Endocrine therapy instituted to treat erectile dysfunction secondary to hypothalamic–pituitary–gonadal dysfunction may reverse the condition. Insufficient penile blood flow may be treated with vascular surgery. Patients with erectile dysfunction from psychogenic causes are referred to a health care provider or therapist who specializes in sexual dysfunction. Patients with erectile dysfunction secondary to organic causes may be candidates for penile implants.

Currently available therapies for the treatment of erectile dysfunction include pharmacologic therapy (including urethral

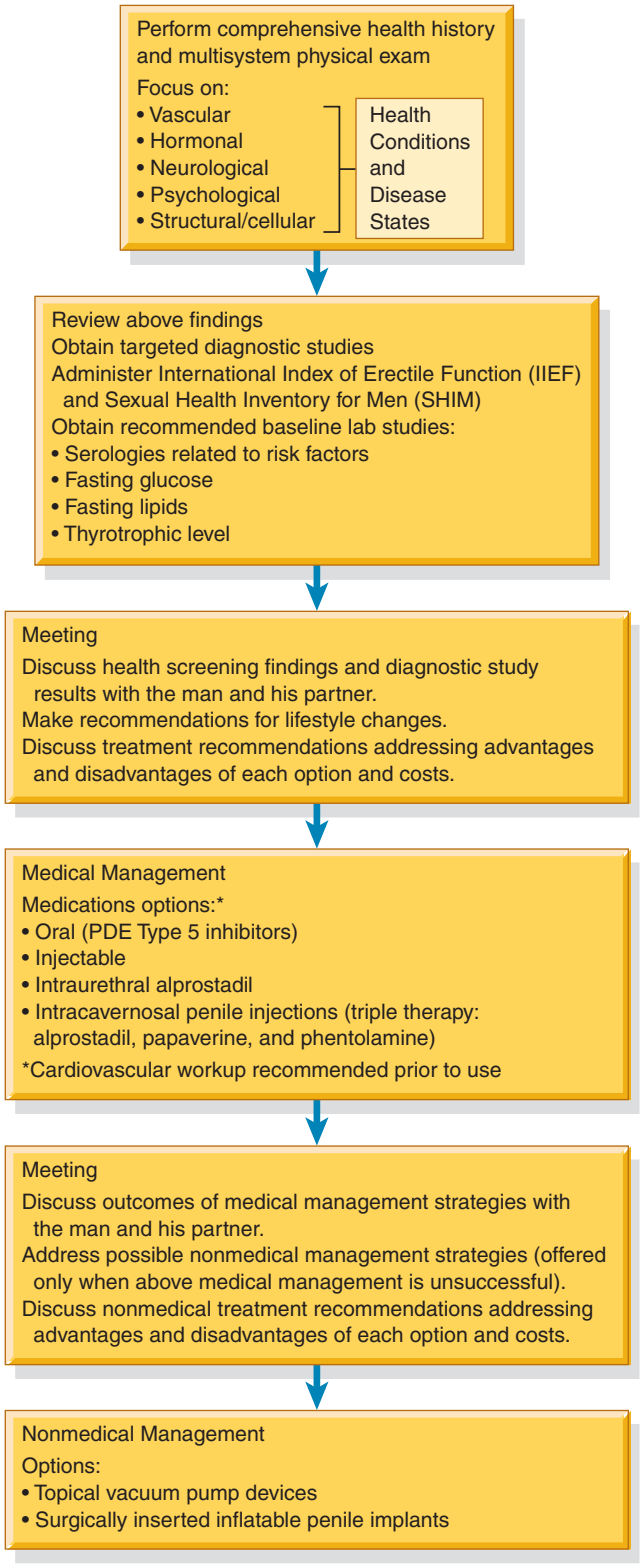

Figure 46-3 • Evaluation and treatment of erectile dysfunction.

suppositories), penile implants, and vacuum constriction devices (see Table 46-2). These options should be considered in a stepwise fashion, with increasing invasiveness and risk balanced against the likelihood of efficacy. The patient and, if possible, his partner, should be informed of the relevant treatment options and their associated risks and benefits. The choice of treatment is made jointly by the primary provider, patient, and partner, taking into consideration patient preferences and expectations.

Pharmacologic Therapy

Phosphodiesterase type 5 (PDE-5) inhibitors (oral medications that are used to treat erectile dysfunction) are first-line therapy (Hsu, Tang, & Lu, 2014). Currently available PDE-5 inhibitors include sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). Each of these agents has a similar mechanism of action but a different pharmacologic action and clinical use. Erection involves the release of nitric oxide in the vasculature of the corpus cavernosum as a result of sexual stimulation. This subsequently leads to smooth muscle relaxation in blood vessels supplying the corpus cavernosum, resulting in increased blood flow and an erection. During sexual stimulation, PDE-5 inhibitors increase blood flow to the penis (Grossman & Porth, 2014).

When PDE-5 inhibitors are taken about 1 hour before sexual activity, they are effective in producing an erection with sexual stimulation; the erection can last about 1 to 2 hours. The most common side effects of these medications include headache, flushing, dyspepsia, diarrhea, nasal congestion, and lightheadedness. These agents are contraindicated in men who take organic nitrates (e.g., isosorbide [Isordil], nitroglycerin), because taken together, these medications can cause side effects such as severe hypotension (Grossman & Porth, 2014); (McDougal et al., 2016). In addition, PDE-5 inhibitors must be used with caution in patients with retinopathy, especially in those with diabetic retinopathy. Patient education about the use of these medications and their side effects is summarized in Table 46-3.

For patients in whom PDE-5 inhibitors are contraindicated or ineffective, other pharmacologic measures to induce erections include injecting vasoactive agents, such as alprostadil, papaverine, and phentolamine, directly into the penis. Complications include priapism (a persistent abnormal erection) and development of fibrotic plaques at the injection sites. Alprostadil is also formulated in a gel pellet that can be inserted into the tip of the urethra with an applicator to create an erection.

Penile Implants

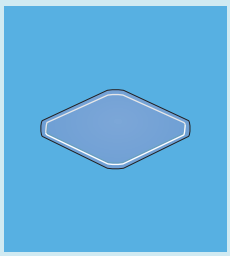
Two general types of penile implants are available: the malleable, noninflatable, nonhydraulic prosthesis (also called the *semirigid rod*) and the inflatable, hydraulic prostheses (Keane & Graham, 2016). The semirigid rod (e.g., the Small-Carrion prosthesis) results in a permanent semierection but can be bent into an unnoticeable position when appropriate. The inflatable prosthesis simulates natural erections and natural flaccidity. Complications after implantation include infection, erosion of the prosthesis through the skin (more common with the semirigid rod than with the inflatable prosthesis), and persistent pain, which may require removal of the implant. Subsequent cystoscopic surgery is more difficult with a semirigid rod than with the inflatable prosthesis.

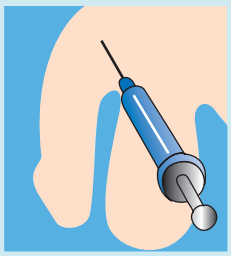
Factors to consider in choosing a penile prosthesis are the patient's activities of daily living, social activities, and the expectations of the patient and his partner. Ongoing counseling for the patient and his partner is usually necessary to help them adapt to the prosthesis.

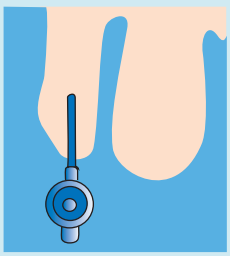
Penis Transplants

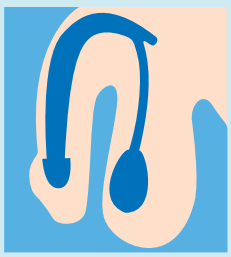
The first successful penis transplant was performed in 2014 in Cape Town, South Africa. Candidates for transplantation include military veterans and other men who have suffered

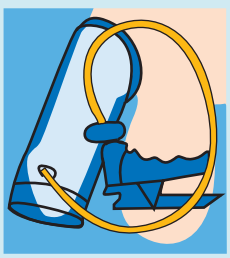
TABLE 46-2 Treatments for Erectile Dysfunction











Method	Description	Advantages and Disadvantages	Duration
Pharmacologic Therapy Oral medications (sildenafil [Viagra]; vardenafil [Levitra]; tadalafil [Cialis])  Oral medication	Smooth muscle relaxant causing blood to flow into penis	Can cause headache flushing, dyspepsia, diarrhea, nasal congestion, and lightheadedness See contraindications in Table 46-3	Taken orally before intercourse. Stimulation is required to achieve erection. Erection can last 1 hour.
Injection (alprostadil, papaverine, phentolamine)  Penile injection	Smooth muscle relaxant causing blood to flow into penis	Firm erections are achievable in >50% of cases. Pain at injection site; plaque formation, risk of priapism	Injection 20 minutes before intercourse Erection can last up to 1 hour.
Urethral suppository (alprostadil)  Penile suppository	Smooth muscle relaxant causing blood to flow into penis	May be used twice a day Urethral and genital pain; risk of hypertension and syncope Not recommended with pregnant partners	Inserted 10 minutes before intercourse Erection can last up to 1 hour.
Penile Implants • Semirigid rod • Inflatable • Soft silicone  Penile implant	Surgically implanted into corpus cavernosum	Reliable Requires surgery Healing takes up to 3 weeks. Subsequent cystoscopic surgery is difficult. Semirigid rod results in permanent semierection.	Indefinite Inflatable prosthesis—saline returns from penile receptacle to reservoir.
Negative-Pressure (Vacuum) Devices  Penile vacuum pump	Induction of erection with vacuum; maintained with constriction band around base of penis	Few side effects Cumbersome to use before intercourse Vasocongestion of penis can cause pain or numbness.	To prevent penile injury, constriction band must not be left in place >1 hour.

TABLE 46-3 Pharmacologic Treatment of Erectile Dysfunction

	Sildenafil (Viagra)	Vardenafil (Levitra)	Tadalafil (Cialis)
When to take	Take the medication 30 minutes to 4 hours before intercourse. *There must be sexual stimulation to produce an erection.*	Follow the same directions as with sildenafil; take the medication 1 hour before intercourse. The peak action occurs in 30–120 minutes. *There must be sexual stimulation to produce an erection.*	Take the medication before sexual activity. Effect peaks at 30 minutes to 6 hours; effect may last up to 36 hours. *There must be sexual stimulation to produce an erection.*
Frequency of use	If you take this medication more than once a day, it will not have an increased effect. You may take it 7 days per week if you wish, but only once in 24 hours. It does not build up in your bloodstream. Remember to take it only when you want to have intercourse.	The recommended frequency for this medication is 10 mg in 24 hours.	The effects of this medication may last up to 36 hours. This allows for increased spontaneity in the sexual experience.
Side effects	Side effects include headache, flushing, indigestion, nasal congestion, abnormal vision, diarrhea, dizziness, and rash. You may also have low blood sugar and abnormal liver function tests; your primary provider can determine this.	Side effects include headache, flushing, runny nose, indigestion, sinusitis, flulike syndrome, dizziness, nausea, back pain, and joint pain. Tell your primary provider if you experience any of these effects. You may also have abnormally elevated liver enzymes; your primary provider can determine this.	Side effects are similar to those of sildenafil and vardenafil. Tadalafil may also cause back pain and muscle aches. Tell your primary provider if you experience any of these side effects.
Contraindications	Do not take if you are taking nitrate medications such as nitroglycerin (e.g., Nitro-Bid) or isosorbide mononitrate (e.g., Imdur). Do not take if you have high uncontrolled blood pressure, coronary artery disease, or have had a heart attack within the past 6 months. Do not take if you have been diagnosed with a cardiac dysrhythmia or kidney or liver dysfunction.		
Drug interactions	This medication can react with other medications that you may be taking. Provide your primary provider and pharmacist with a complete list of all prescribed and over-the-counter medications that you are using.		
Use of PDE-5 inhibitors with penile injections or urethral suppositories	The use of PDE-5 inhibitors with other forms of therapy for erectile dysfunction has not been tested and should be avoided.		

PDE-5, phosphodiesterase type 5.

Adapted from Hsu, J. C., Tang, D. H., & Lu, C. Y. (2014). Risk-benefit assessment of oral phosphodiesterase type 5 inhibitors for treatment of erectile dysfunction: A multiple criteria decision analysis. International Journal of Clinical Practice, 69(4), 436–443.

traumatic penile injuries. It is believed that men undergoing this surgery will have their ability to urinate and their sexual functioning restored (Kuehn, 2016); (Kumnig & Jowsey-Gregoire, 2016). For more details on organ transplantation, see discussion in Chapter 44.

Negative-Pressure Devices

Negative-pressure (vacuum) devices may also be used to induce an erection. A plastic cylinder is placed over the flaccid penis, and negative pressure is applied. When an erection is attained, a constriction band is placed around the base of the penis to maintain the erection. To avoid penile injury, the patient is instructed not to leave the constricting band in place for longer than 1 hour. Only devices with a vacuum limiter are recommended for use (Mulhall & Hsiao, 2014). Although many men find this method satisfactory, others experience premature loss of penile rigidity or pain when applying suction or during intercourse.

Nursing Management

Personal satisfaction and the ability to sexually satisfy a partner are common concerns of patients. Men with illnesses and disabilities may need the assistance of a sex therapist to identify, implement, and integrate their sexual beliefs and behaviors into a healthy and satisfying lifestyle. The nurse can inform patients about support groups for men with erectile dysfunction and their partners.

Disorders of Ejaculation

Premature ejaculation (PE) is defined as the occurrence of ejaculation sooner than desired, either before or shortly after penetration, causing distress to either one or both partners. It is one of the most common complaints of men or couples, affecting 20% to 30% of men (Keane & Graham, 2016); (McDougal et al., 2016). The spectrum of responses ranges from occasional ejaculation with intercourse or self-stimulation to complete inability to ejaculate under any circumstances. Various forms of PE have been identified: (1) lifelong PE caused by neurobiologic or genetic conditions, (2) acquired PE (medical or psychological), (3) natural variable PE (normal variation), and (4) prematurelike ejaculatory dysfunction (psychological). In young men ages 18 to 25 years, factors associated with PE and erectile dysfunction include smoking, use of illegal drugs or medications without prescriptions, poor physical and mental health, lack of physical activity and lack of sexual experience (Akre, Berchtold, Gmel, et al., 2014). Other ejaculatory problems may include inhibited (delayed or

Chart 46-2 GENETICS IN NURSING PRACTICE

Male Reproductive Disorders

Various male reproductive disorders are influenced by genetic factors. Some examples are:

- 21-Hydroxylase deficiency
- Congenital absence of the vas deferens, prostate gland or seminal vesicles
- Kallmann syndrome
- Klinefelter syndrome (47, XXY)
- Prostate cancer
- Y chromosome deletions

Nursing Assessments

Refer to Chapter 3 Chart 3-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to Male Reproductive Disorders

- Collect a three-generation family history on both maternal and paternal sides of the family.
- Assess family history for other family members with similar reproductive problems/abnormalities.

Patient Assessment Specific to Male Reproductive Disorders

- In males with delayed puberty or infertility, assess for clinical features of Klinefelter syndrome (tall stature, gynecomastia, learning disabilities).
- Assess males with delayed or absent puberty for clinical features of Kallmann syndrome (cleft lip with or without cleft palate, abnormal eye movements, hearing loss, and abnormalities of tooth development).
- Assess males for history of early growth spurt, which is a symptom of 21-hydroxylase deficiency.
- Inquire about history of prostate inflammation, genital infections, medication use (steroids), or prior history of mumps.
- Assess for physical abnormalities of the genitalia

Genetics Resources

Association for X and Y Chromosome Variations, www.genetic.org
Klinefelter Syndrome Support Group, www.klinefeltersyndrome.org

retarded) ejaculation, which is the involuntary inhibition of the ejaculatory reflex (see Chart 46-2). Retrograde ejaculation occurs when semen travels toward the bladder instead of exiting through the penis, resulting in infertility. This form of PE may occur after prior prostate or urethral surgery, with diabetes, or with the use of medications such as antihypertensive agents.

Evaluation of PE involves a thorough sexual history focusing on the duration of symptoms, time to ejaculation, degree of voluntary control over ejaculation, frequency of occurrence, and course of the problem since the first sexual encounter (Keane & Graham, 2016); (McDougal et al., 2016). Treatment, which depends on the nature and severity of PE and perceived distress that it causes, includes behavioral and psychological approaches, as well as pharmacologic therapy that attempts to alter the sensory input or retard the ejaculatory response. Behavioral therapy (e.g., counseling, sex therapy, psychoeducation, and couples therapy) often involves both the man and his sexual partner. The couple is encouraged to identify their sexual needs and to communicate those needs to each other. Pharmacologic management involves selective serotonin reuptake inhibitors dapoxetine (Priligy), alpha$_1$ adrenoceptor antagonists, the tricyclic antidepressant clomipramine (Anafranil), and topical anesthetic agents. In some cases, a combination of pharmacologic and behavioral therapy may be effective.

Inhibited ejaculation is most often caused by psychological factors, neurologic disorders (e.g., SCI, multiple sclerosis, neuropathy secondary to diabetes), surgery (prostatectomy), and medications. Chemical, vibratory, and electrical methods of stimulation have been used with some success. Treatment usually addresses the physical and psychological factors involved in inhibited ejaculation (Wincze & Weisberg, 2015). Although outpatient therapy may involve numerous sessions (12 to 18), it often results in a success rate of 70% to 80%. The outcome depends on a previous satisfying sexual experience history, a short duration of the ejaculatory problem, feelings of sexual desire, feelings of attraction to one's sexual partner, motivation for treatment, and absence of serious psychological problems.

For men with retrograde ejaculation, the urine may be collected shortly after ejaculation, revealing a large amount of sperm in the urine. This urine may also be collected to obtain adequate viable sperm for use in artificial insemination. In men with SCI, techniques that may be used to obtain sperm for artificial insemination include self-stimulation, vibratory stimulation, or electroejaculation. Electroejaculation involves the use of a specially designed probe that is inserted into the rectum next to the prostate. The probe delivers a current that stimulates the nerves and produces contraction of the pelvic muscles and ejaculation. However, spontaneous or stimulated ejaculation may cause autonomic dysreflexia (overstimulation of the autonomic nervous system) in patients with SCI at T6 or higher, creating a life-threatening situation (see Chapter 51). If this disorder is not treated promptly, it may lead to seizures, stroke, and even death.

Infertility

Infertility is defined as a couple's inability to achieve pregnancy after 1 year of unprotected intercourse (Tarin, Garcia-Perez, Hamatani, et al., 2015). Approximately 12% of women aged 15 to 44 have reported ever having received any infertility services (Kessler et al., 2013). Primary infertility refers to a couple who has never had a child. Secondary infertility means that at least one conception has occurred, but currently the couple cannot achieve a pregnancy. It is often a complex physical problem and causes are related to endometriosis, uterine factors, anovulation, tubal obstruction, and male factors.

The overall prevalence rate of infertility in India ranges from 3.9% to 16.8%. In India, the infertility rate differs from state to state. The lowest rate is in Uttar Pradesh (3.7%) and the highest in Kashmir (15%); also, it varies based on region, tribe, and caste (Kumar & Singh, 2015).

Causes

Female Factors

- Ovarian and ovulation factors: Production of unhealthy ovum or no ovum at all
- Tubal and uterine factors: Endometriosis or tubal block; fibroids, polyps, and congenital malformations being the possible causative factors affecting the uterus

Male Factors

- Qualitative or quantitative deficiency in sperms: An analysis of semen provides information about the number of sperms (density), percentage of moving forms, quality of forward

movement (forward progression), and morphology (shape and form). 2–6 mL of semen with alkaline pH is considered normal. A normal count has 60 to 100 million sperms/mL. However, the incidence of impregnation is lessened only when the count decreases to fewer than 20 million sperms/mL.
- Erectile dysfunction: It may lead to infertility.
- Varicoceles (varicose veins around the testicle): These decrease the semen quality by increasing the testicular temperature.
- Retrograde ejaculation or ejaculation into the bladder: It may also lead to infertility.
- Hormonal imbalances: Blood tests for male hormones, namely, testosterone, FSH, and LH, may be reduced. These hormones are essential for optimal male sexuality.

Nursing Management

Management of male infertility is planned based on the causative factor. Nurses need to address the emotional needs of the patients as they may feel anxious and stressed. Counseling and reassurance are essential. For diagnosis and management, refer the previous sections.

INFECTIONS OF THE MALE GENITOURINARY TRACT

Acute uncomplicated cystitis in adult men is uncommon but occasionally occurs. Asymptomatic bacteriuria may also result from genitourinary manipulation, catheterization, or instrumentation. Urinary tract infections (UTIs) are discussed in Chapter 45.

According to the Centers for Disease Control and Prevention (CDC, 2015), more than 19 million people develop sexually transmitted infections (STIs) annually in the United States; almost half of all STIs occur in people 18 to 24 years of age. The incidence of STIs has declined over the past several years, except in specific populations, including men who have sex with men. Routine human papillomavirus (HPV) vaccination for all males has become the standard of preventative care since 2011, as recommended by the Advisory Committee on Immunization Practices (ACIP) (Gerend, Madkins, Phillips, et al., 2016).

As per World Health Organization (WHO) report, 498.9 million curable sexually transmitted infections (STIs) occur worldwide (WHO, 2008). In India, the population prevalence rate of STIs (e.g., syphilis, gonorrhea, and chlamydia) is 0–3.9%. The prevalence rate of HIV among adults (15–49 years) has declined in India from 0.38% (2001–2003) to 0.34% (2007). There are declining HIV prevalence trends in the traditional high-prevalent southern states such as Andhra Pradesh, Karnataka, Maharashtra, Tamil Nadu, and Telangana. However, the results have alerted the program in Gujarat, Punjab, Rajasthan, Haryana, Uttar Pradesh, Delhi, and Bihar where the epidemic is showing a rising trend. There is a target to eliminate HIV as a public health problem in India by 2030 (NACO, 2017).

STIs affect people from all walks of life—from all social, educational, economic, and racial backgrounds. The single greatest risk factor for contracting an STI is the number of sexual partners. As the number of partners increases, so does the risk of exposure to a person infected with an STI. For men who have sex with men, the CDC recommends annual testing for human immune deficiency virus (HIV), syphilis, *Chlamydia,* gonorrhea, hepatitis B viral infection, and herpes simplex virus type 2, along with counseling (CDC, 2015); (Owusu-Edusei, Gift, Patton, et al., 2015).

There are many causes of urethritis (gonococcal and nongonococcal), genital ulcers (genital herpes infections, primary syphilis, chancroid, granuloma inguinale, and lymphogranuloma venereum), genital warts (HPV), scabies, pediculosis pubis, molluscum contagiosum, hepatitis and enteric infections, proctitis, and acquired immune deficiency syndrome (AIDS). Trichomoniasis and STIs characterized by genital ulcers are thought to increase susceptibility to HIV infection. Trichomoniasis is associated with nonchlamydial, nongonococcal urethritis.

Current treatment guidelines for STIs are available from the CDC (2015); (Lanier & Sutton, 2013). Treatment must target the patient as well as his sexual partners and sometimes an unborn child. A thorough history, including a sexual history, is crucial to identify patients at risk and to direct care and education. It is essential for patient education to focus on partner safety as people can misjudge partner safety with known acquaintances, thus causing individuals to be at greater risk of STI/HIV transmission (Sparling & Cramer, 2015).

Partners of men with STIs must also be examined, treated, and counseled to prevent reinfection and complications in both partners and to limit the spread of the disease. Sexual abstinence during treatment and recovery is advised to prevent the transmission of STIs. The use of synthetic condoms for at least 6 months after completion of treatment is recommended to decrease transmission of HPV infection as well as other STIs. It is important to assess and test for other STIs because patients who have one STI may also have another. The use of spermicides with nonoxynol-9 (known as N-9) is discouraged; these agents do not protect against HIV infection and may increase the risk of transmission of the virus. See Chapter 55 for more detailed discussions of HIV infection, AIDS, and other STIs.

PROSTATIC DISORDERS

Prostatitis

Prostatitis is an inflammation of the prostate gland that is often associated with lower urinary tract symptoms and symptoms of sexual discomfort and dysfunction. The condition affects 5% to 10% of men. It is the most common urologic diagnosis in men younger than 50 years and the third most common such diagnosis in men older than 50 years (McDougal et al., 2016). Prostatitis may be caused by infectious agents (bacteria, fungi, mycoplasma) or other conditions (e.g., urethral stricture, BPH). *Escherichia coli* is the most commonly isolated organism, although *Klebsiella* and *Proteus* species are also found (Chen, Hu, Peng, et al., 2015). The microorganisms colonize the urinary tract and ascend to the prostate, ultimately causing infection. The causal pathogen is usually the same in recurrent infections.

It is reported that in North America, Europe, and Asia, about 2–10% of adult men suffer with symptoms of chronic prostatitis and approximately 15% of men suffer with symptoms of prostatitis at some point of time in their life (Krieger, Riley, Cheah, et al., 2003).

There are four types of prostatitis: acute bacterial prostatitis (type I), chronic bacterial prostatitis (type II), chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (type III), and asymptomatic inflammatory prostatitis (type IV). Type III, which occurs in more than 90% of cases, is further classified as

type IIIA or type IIIB, depending on the presence (type IIIA) or absence (type IIIB) of white blood cells in semen after prostate massage (Chen et al., 2015).

Clinical Manifestations

Acute prostatitis is characterized by the sudden onset of fever, dysuria, perineal prostatic pain, and severe lower urinary tract symptoms: dysuria, frequency, urgency, hesitancy, and nocturia. Approximately 5% of cases of type I prostatitis (acute bacterial prostatitis) progress to type II prostatitis (chronic bacterial prostatitis) (McDougal et al., 2016). Patients with type II disease are typically asymptomatic between episodes. Patients with type III prostatitis often have no bacteria in the urine in the presence of genitourinary pain. Patients with type IV prostatitis are usually diagnosed incidentally during a workup for infertility, an elevated PSA test, or other disorders.

Medical Management

The goal of treatment is to eradicate the causal organisms. Hospital admission may be necessary for patients with unstable vital signs, sepsis, or intractable pelvic pain; those who are frail or immunosuppressed; or those who have diabetes or renal insufficiency. Specific treatment is based on the type of prostatitis and on the results of culture and sensitivity testing of the urine (Wagenlehner, Weidner, Pilatz, et al., 2014). If bacteria are cultured from the urine, antibiotic agents, including trimethoprim-sulfamethoxazole (Bactrim) or a fluoroquinolone (e.g., ciprofloxacin [Cipro]), may be prescribed, and continuous therapy with low-dose antibiotic agents may be used. If the patient is afebrile and has a normal urinalysis, anti-inflammatory agents may be used. Alpha-adrenergic blocker therapy (e.g., tamsulosin [Flomax]), may be prescribed to promote bladder and prostate relaxation.

Factors contributing to prostatitis, including stress, neuromuscular factors, and myofascial pain, are also addressed. Supportive, nonpharmacologic therapies may be prescribed. These include biofeedback, pelvic floor training, physical therapy, reduction of prostatic fluid retention by ejaculation through sexual intercourse or masturbation, sitz baths, stool softeners, and evaluation of sexual partners to reduce the possibility of cross-infection.

Nursing Management

If the patient experiences symptoms of acute prostatitis (fever, severe pain and discomfort, inability to urinate, malaise), he may be hospitalized for intravenous (IV) antibiotic therapy. Nursing management includes administration of prescribed antibiotic agents and provision of comfort measures, including prescribed analgesic agents and sitz baths.

The patient with chronic prostatitis is usually treated on an outpatient basis and needs to be educated about the importance of continuing antibiotic therapy and recognizing recurrent signs and symptoms of prostatitis.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

The nurse educates the patient about the importance of completing the prescribed course of antibiotic therapy. If IV antibiotic agents are to be given at home, the nurse educates the patient and family about correct and safe administration. Arrangements for a home care nurse to oversee administration may be needed. Warm sitz baths (10 to 20 minutes) may be taken several times daily. Fluids are encouraged to satisfy thirst but are not "forced," because an effective medication level must be maintained in the urine. Foods and liquids with diuretic action or that increase prostatic secretions, such as alcohol, coffee, tea, chocolate, cola, and spices, should be avoided. A suprapubic catheter may be necessary for severe urinary retention. During periods of acute inflammation, sexual arousal and intercourse should be avoided. To minimize discomfort, the patient should avoid sitting for long periods. Medical follow-up is necessary for at least 6 months to 1 year, because prostatitis caused by the same or different organisms can recur. The patient is advised that the UTI may recur and is educated to recognize its symptoms.

Benign Prostatic Hyperplasia (Enlarged Prostate)

Benign prostatic hyperplasia (BPH), a noncancerous enlargement or hypertrophy of the prostate, is one of the most common diseases in aging men. It can cause bothersome lower urinary tract symptoms that affect quality of life by interfering with normal daily activities and sleep patterns (McDougal et al., 2016). BPH typically occurs in men older than 40 years. By the time they reach 60 years, 50% of men have BPH. It affects as many as 90% of men by 85 years of age. BPH is the second most common cause of surgical intervention in men older than 60 years.

Most of the men in Asia are vegetarian; their low-fat, high-fiber diet is weak in dietary phytoestrogens, which act as chemopreventive agents. In India, very limited studies have been conducted on BPH. The global study done across regions of the world on the incidence of BPH found that the global incidence of BPH was 280.40 per100,000 population and in the South East Asia, it was 348.05 per100,000 population (Xu, Liu, Guo, et al., 2021).

Pathophysiology

The cause of BPH is not well understood, but testicular androgens have been implicated. Dihydrotestosterone (DHT), a metabolite of testosterone, is a critical mediator of prostatic growth. Estrogens may also play a role in the cause of BPH; BPH generally occurs when men have elevated estrogen levels and when prostate tissue becomes more sensitive to estrogens and less responsive to DHT. Smoking, heavy alcohol consumption, obesity, reduced activity level, hypertension, heart disease, diabetes, and a Western diet (high in animal fat and protein and refined carbohydrates, low in fiber) are risk factors for BPH (McDougal et al., 2016); (Tantamango-Bartley, Knutsen, Knutsen, et al., 2016).

BPH develops over a prolonged period; changes in the urinary tract are slow and insidious. BPH is a result of complex interactions involving resistance in the prostatic urethra to mechanical and spastic effects, bladder pressure during voiding, detrusor muscle strength, neurologic functioning, and general physical health (McCance et al., 2013). The hypertrophied lobes of the prostate may obstruct the bladder neck or urethra, causing incomplete emptying of the bladder and urinary retention. As a result, a gradual dilation of the ureters (hydroureter) and kidneys (hydronephrosis) can occur. Urinary retention may result in UTIs because urine that remains in the urinary tract

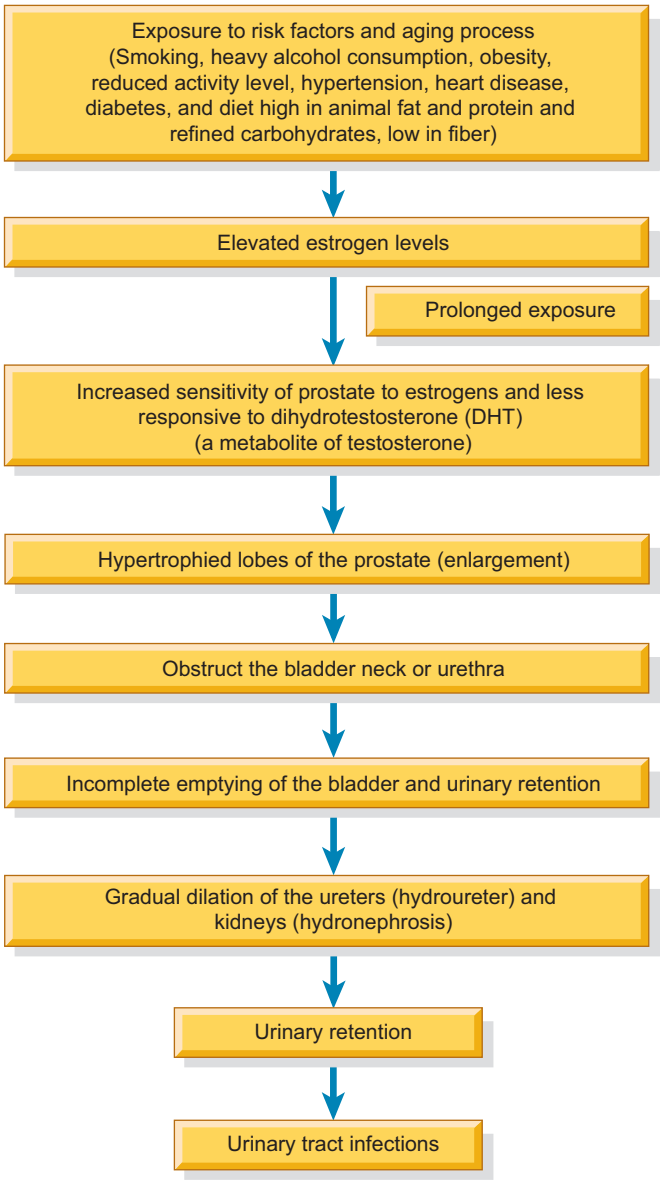


Figure 46-4 • Pathophysiology of benign prostatic hyperplasia.

serves as a medium for infective organisms. Pathophysiology of benign prostatic hyperplasia is presented in Figure 46-4.

Clinical Manifestations

BPH may or may not lead to lower urinary tract symptoms; if symptoms occur, they may range from mild to severe. Severity of symptoms increases with age, and half of men with BPH report having moderate to severe symptoms. Obstructive and irritative symptoms may include urinary frequency, urgency, nocturia, hesitancy in starting urination, decreased and intermittent force of stream and the sensation of incomplete bladder emptying, abdominal straining with urination, a decrease in the volume and force of the urinary stream, dribbling (urine dribbles out after urination), and complications of acute urinary retention and recurrent UTIs. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult (Weber & Kelley, 2014). Ultimately, chronic urinary retention and large residual volumes can lead to azotemia (accumulation of nitrogenous waste products) and kidney failure.

Generalized symptoms may also be noted, including fatigue, anorexia, nausea, vomiting, and pelvic discomfort. Other disorders that produce similar symptoms include urethral stricture, prostate cancer, neurogenic bladder, and urinary bladder stones.

Assessment and Diagnostic Findings

The health history focuses on the urinary tract, previous surgical procedures, general health issues, family history of prostate disease, and fitness for possible surgery (Pearson, 2014). A patient voiding diary is used to record voiding frequency and urine volume. A DRE often reveals a large, rubbery, and nontender prostate gland. A urinalysis to screen for hematuria and UTI is recommended. A PSA level is obtained if the patient is without a terminal disease and for whom knowledge of the presence of prostate cancer would change management. The American Urological Association (AUA) Symptom Index or International Prostate Symptom Score (IPSS) can be used to assess the severity of symptoms (Keane & Graham, 2016).

Other diagnostic tests may include recording urinary flow rate and the measurement of postvoid residual urine. If invasive therapy is considered, urodynamic studies, urethrocystoscopy, and ultrasound may be performed. Complete blood studies are performed. Cardiac status and respiratory function are assessed because a high percentage of patients with BPH have cardiac or respiratory disorders due to their age.

Medical Management

The goals of medical management of BPH are to improve quality of life, improve urine flow, relieve obstruction, prevent disease progression, and minimize complications. Treatment depends on the severity of symptoms, the cause of disease, the severity of the obstruction, and the patient's condition.

If a patient is admitted on an emergency basis because he is unable to void, he is immediately catheterized. The ordinary catheter may be too soft and pliable to advance through the urethra into the bladder. In such cases, a thin wire (stylet) is introduced (by a urologist) into the catheter to prevent the catheter from collapsing when it encounters resistance. A metal catheter with a pronounced prostatic curve may be used if obstruction is severe. A cystostomy (incision into the bladder) may be needed to provide urinary drainage.

Discussion of all treatment options by the primary provider enables the patient to make an informed decision based on symptom severity, the effect of BPH on his quality of life, and preference. Patients with mild symptoms and patients with moderate or severe symptoms who are not bothered by them and have not developed complications may be managed with "watchful waiting." With this approach, the patient is monitored and reexamined annually but receives no active intervention (Pearson, 2014). Other therapeutic choices include pharmacologic treatment, minimally invasive procedures, and surgery.

Pharmacologic Therapy

Pharmacologic treatment for BPH includes the use of alpha-adrenergic blockers and 5-alpha-reductase inhibitors (McDougal et al., 2016). Alpha-adrenergic blockers, which include alfuzosin (Uroxatral), terazosin (Hytrin), doxazosin (Cardura), and tamsulosin, relax the smooth muscle of the bladder neck and prostate. This improves urine flow and relieves symptoms of BPH. Side effects include dizziness, headache,

asthenia/fatigue, postural hypotension, rhinitis, and sexual dysfunction (Keane & Graham, 2016); (McDougal et al., 2016).

Another method of treatment involves hormonal manipulation with antiandrogen agents. The 5-alpha-reductase inhibitors finasteride (Proscar) and dutasteride (Avodart) are used to prevent the conversion of testosterone to DHT and decrease prostate size. Side effects include decreased libido, ejaculatory dysfunction, erectile dysfunction, gynecomastia (breast enlargement), and flushing. Combination therapy (doxazosin and finasteride) has decreased symptoms and reduced clinical progression of BPH (Keane & Graham, 2016); (McDougal et al., 2016).

The use of alternative and complementary phytotherapeutic agents and other dietary supplements (*Serenoa repens* [saw palmetto berry] and *Pygeum africanum* [African plum]) are not recommended by the medical community, although they are commonly used (Allkanjari & Vitalone, 2015). They may function by interfering with the conversion of testosterone to DHT. In addition, *S. repens* may directly block the ability of DHT to stimulate prostate cell growth. These agents should not be used with finasteride, dutasteride, or estrogen-containing medications (Allkanjari & Vitalone, 2015).

Surgical Management

Other treatment options include minimally invasive procedures and resection of the prostate gland.

Minimally Invasive Therapy

Several forms of minimally invasive therapy may be used to treat BPH. Transurethral microwave thermotherapy (TUMT) involves the application of heat to prostatic tissue. High-energy TUMT devices (CoreTherm, Prostatron, Targis) and low-energy devices (TherMatrx) are available (McDougal et al., 2016). A transurethral probe is inserted into the urethra, and microwaves are directed to the prostate tissue. The targeted tissue becomes necrotic and sloughs. To minimize damage to the urethra and decrease the discomfort from the procedure, some systems have a water-cooling apparatus.

Other minimally invasive treatment options include (transurethral needle ablation [TUNA]) by radiofrequency energy and the UroLume stent. TUNA uses low-level radiofrequencies delivered by thin needles placed in the prostate gland to produce localized heat that destroys prostate tissue while sparing other tissues. The body then reabsorbs the dead tissue. Prostatic stents are associated with significant complications (e.g., encrustation, infection, chronic pain); therefore, they are used only for patients with urinary retention and in patients who are poor surgical risks (McDougal et al., 2016).

Surgical Resection

Surgical resection of the prostate gland is another option for patients with moderate to severe lower urinary tract symptoms of BPH and for those with acute urinary retention or other complications. The specific surgical approach (open or endoscopic) and the energy source (electrocautery vs. laser) are based on the surgeon's experience, the size of the prostate gland, the presence of other medical disorders, and the patient's preference. If surgery is to be performed, all clotting defects must be corrected and medications for anticoagulation withheld because bleeding is a potential complication of prostate surgery.

Transurethral resection of the prostate (TURP) remains the benchmark for surgical treatment for BPH. It involves the surgical removal of the inner portion of the prostate through an endoscope inserted through the urethra; no external skin incision is made. It can be performed with ultrasound guidance. The treated tissue either vaporizes or becomes necrotic and sloughs. The procedure is performed in the outpatient setting and usually results in less postoperative bleeding than a traditional surgical prostatectomy.

Other surgical options for BPH include transurethral incision of the prostate (TUIP), transurethral electrovaporization, laser therapy, and open prostatectomy (Keane & Graham, 2016); (McDougal et al., 2016). TUIP is an outpatient procedure used to treat smaller prostates. One or two cuts are made in the prostate and prostate capsule to reduce constriction of the urethra and decrease resistance to flow of urine out of the bladder; no tissue is removed. Open prostatectomy involves the surgical removal of the inner portion of the prostate via a suprapubic, retropubic, or perineal (rare) approach for large prostate glands. Prostatectomy may also be performed laparoscopically or by robotic-assisted laparoscopy.

Nursing management of patients undergoing these procedures is described later in this chapter.

Cancer of the Prostate

Prostate cancer is the most common cancer in men other than nonmelanoma skin cancer. It is the second most common cause of cancer death in American men, exceeded only by lung cancer, and is responsible for 10% of cancer-related deaths in men. Among men diagnosed with prostate cancer, 98% survive at least 5 years, 84% survive at least 10 years, and 56% survive 15 years (ACS, 2015). There is paucity of data to precisely know the prevalence or incidence of prostate cancer in India. It was believed that the prevalence of prostate cancer is lower in India, but due to migration of rural people in cities, change in lifestyle, and increased availability of diagnostic facilities, now India is not too far from developed Western world (Jain, Saxena, S, & Kumar, 2014).

Prostate cancer is common in the United States and northwestern Europe but is rare in Africa, Central America, South America, China, and other parts of Asia. African American men have a high risk of prostate cancer; furthermore, they are more than twice as likely to die of prostate cancer as men of other racial or ethnic groups. Health care providers need to provide education about prostate cancer and appropriate screening in African American men, who are at higher risk compared to all other ethnic communities (Cremin, 2015). Health care providers should also ensure the delivery of culturally sensitive education programs and counseling about prostate cancer screening to not only the African American patient at risk for prostate cancer, but also to his friends and family (Mulheim, Fulbright, & Duncan, 2015).

The estimated age-adjusted incidence rate (AAR) of prostate cancer in India as a whole was $3.7/10^5$ persons during 2008. However, the regional variation of AAR was remarkable. It was found to be 0.8 in the state of Manipur (excluding Imphal) while in Delhi, the rate was $10.9/10^5$ person-years. The mean annual percentage change (MAPC) in the crude incidence rates ranged from 0.14 in Ahmedabad to 8.6 in Chennai (Hariharan & Padmanabha, 2016). Jain et al. (2014) also reported a wide variation in annual percentage change of prostate cancer in various population-based cancer registries of India, ranging from 3.4% in Bangalore to 11.6% in Kamrup District in Assam.

Other risk factors for prostate cancer include increasing age; the incidence of prostate cancer increases rapidly after the age of 50 years. More than 70% of cases occur in men older than 65 years. A familial predisposition may occur in men who have a father or brother previously diagnosed with prostate cancer, especially if their relatives were diagnosed at a young age. Genes that may be associated with increased risk of prostate cancer include hereditary prostate cancer 1 (*HPC1*) and *BRCA1* and *BRCA2* mutations (McDougal et al., 2016). The risk of prostate cancer is also greater in men whose diet contains excessive amounts of red meat or dairy products that are high in fat (ACS, 2015). Endogenous hormones, such as androgens and estrogens, also may be associated with the development of prostate cancer.

Clinical Manifestations

Cancer of the prostate in its early stages rarely produces symptoms. Usually, symptoms that develop from urinary obstruction occur in advanced disease. Prostate cancer tends to vary in its course. If the cancer is large enough to encroach on the bladder neck, signs and symptoms of urinary obstruction occur (difficulty and frequency of urination, urinary retention, and decreased size and force of the urinary stream). Other symptoms may include blood in the urine or semen and painful ejaculation. Hematuria may occur if the cancer invades the urethra or bladder. Sexual dysfunction is common before the diagnosis is made.

Prostate cancer can spread to lymph nodes and bone. Symptoms of metastases include backache, hip pain, perineal and rectal discomfort, anemia, weight loss, weakness, nausea, oliguria (decreased urine output), and spontaneous pathologic fractures. These symptoms may be the first indications of prostate cancer.

Assessment and Diagnostic Findings

If prostate cancer is detected early, the likelihood of cure is high (Itano et al., 2016). It can be diagnosed through an abnormal finding with the DRE, serum PSA, and ultrasound-guided TRUS with biopsy. Detection is more likely with the use of combined diagnostic procedures. Routine repeated DRE (preferably by the same examiner) is important because early cancer may be detected as a nodule within the gland or as an extensive hardening in the posterior lobe. The more advanced lesion is "stony hard" and fixed. DRE also provides useful clinical information about the rectum, anal sphincter, and quality of stool.

The diagnosis of prostate cancer is confirmed by a histologic examination of tissue removed surgically by TURP, open prostatectomy, or ultrasound-guided transrectal needle biopsy. Fine-needle aspiration is a quick, painless method of obtaining prostate cells for cytologic examination and determining the stage of disease.

Most prostate cancers are detected when a man seeks medical attention for symptoms of urinary obstruction or are found by routine DRE and PSA testing. Cancer detected incidentally when TURP is performed for clinically benign disease and lower urinary tract symptoms occurs in about 1 of 10 cases.

Nursing Alert: DRE and PSA testing are important screening procedures, because abnormal DRE and elevated levels of PSA may raise suspicion of prostate cancer. However, a diagnosis of cancer requires confirmation with a prostate biopsy.

TRUS helps detect nonpalpable prostate cancers and assists with staging of localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS. The biopsies are examined by a pathologist to both determine if cancer is present and to grade the tumor. The most commonly used tumor grading system is the Gleason score. This system assigns a grade of 1 to 5 for the most predominant architectural pattern of the glands of the prostate and a secondary grade of 1 to 5 to the second most predominant pattern. The Gleason score is then reported as, for example, 2 + 4; the combined value can range from 2 to 10. With each increase in Gleason score, there is an increase in tumor aggressiveness. Lower Gleason scores indicate well-differentiated and less aggressive tumor cells; higher Gleason scores indicate undifferentiated cells and more aggressive cancer. A total score of 8 to 10 indicates a high-grade cancer (Keane & Graham, 2016).

Categorization of low-, intermediate-, and high-risk prostate cancer is determined by the extent of cancer in the prostate gland, whether or not the cancer is localized to the prostate, the aggressiveness of the cells, and the spread to the lymph nodes and beyond. Level of risk, in turn, is used to determine treatment options.

Bone scans, skeletal x-rays, and magnetic resonance imaging (MRI) may be used to identify metastatic bone disease. Pelvic computed tomography (CT) scans may be performed to determine if the cancer has spread to the lymph nodes. The radiolabeled monoclonal antibody capromab pendetide with indium 111 (ProstaScint) is an antibody that can be used to detect either recurrent prostate cancer at low PSA levels or metastatic disease (NCCN, 2016b).

Medical Management

Treatment is based on the patient's life expectancy, symptoms, risk of recurrence after definitive treatment, size of the tumor, Gleason score, PSA level, likelihood of complications, and patient preference. Therapy is often guided by the use of a nomogram or risk stratification scheme suggested by the NCCN (2016b) clinical practice guidelines. A multidisciplinary team approach is essential for the development of appropriate treatment. Management may be nonsurgical and involve watchful waiting or be surgical and entail prostatectomy. Nursing care of the patient with cancer of the prostate is summarized in Chart 46-3.

For patients with prostate cancer who choose nonsurgical watchful waiting, this approach involves actively monitoring the course of disease and intervening only if the cancer progresses or if symptoms warrant other intervention. It is an option for patients with life expectancy of less than 5 years and low-risk cancers. Advantages include absence of side effects of more aggressive treatment, improved quality of life, avoidance of unnecessary treatment, and decreased initial costs. Disadvantages include missed chance at cure, risk of metastasis, subsequent need for more aggressive treatment, anxiety about living with untreated cancer, and need for frequent monitoring (NCCN, 2016b); (Thakur, 2016).

Therapeutic vaccines kill existing cancer cells and provide long-lasting immunity against further cancer development. In 2010, the U.S. Food and Drug Administration (FDA) approved the first therapeutic cancer vaccine, sipuleucel-T (Provenge), for use in men with metastatic prostate cancer that is no longer responding to hormone therapy. In addition, two other medications, abiraterone acetate (Zytiga) and cabazitaxel

Chart 46-3 PLAN OF NURSING CARE

The Patient with Prostate Cancer

Nursing Diagnosis: Anxiety related to concern and lack of knowledge about the diagnosis, treatment plan, and prognosis
Goal: Reduced stress and improved ability to cope

Nursing Interventions	Rationale	Expected Outcomes
1. Obtain health history to determine the following: a. Patient's concerns b. His level of understanding of his health problem c. His past experience with cancer d. Whether he knows his diagnosis of malignancy and its prognosis e. His support systems and coping methods	1. Nurse clarifies information and facilitates patient's understanding and coping.	• Appears relaxed • States that anxiety has been reduced or relieved • Demonstrates understanding of illness, diagnostic tests, and treatment when questioned • Verbalizes adequate coping ability • Engages in open communication with others
2. Provide education about diagnosis and treatment plan. a. Explain in simple terms what diagnostic tests to expect, how long they will take, and what will be experienced during each test. b. Review treatment plan, and encourage patient to ask questions.	2. Helping the patient to understand the diagnostic tests and treatment plan will help decrease his anxiety and promote cooperation.	
3. Assess his psychological reaction to his diagnosis/prognosis and how he has coped with past stresses.	3. This information provides clues in determining appropriate measures to facilitate coping.	
4. Provide information about institutional and community resources for coping with prostate cancer: social services, support groups, community agencies.	4. Institutional and community resources can help the patient and family cope with the illness and treatment on an ongoing basis.	

Nursing Diagnosis: Urinary retention related to urethral obstruction secondary to prostatic enlargement or tumor and loss of bladder tone due to prolonged distention/retention
Goal: Improved pattern of urinary elimination

Nursing Interventions	Rationale	Expected Outcomes
1. Determine patient's usual pattern of urinary function.	1. Provides a baseline for comparison and goal to work toward.	• Voids at normal intervals • Reports absence of frequency, urgency, or bladder fullness • Displays no palpable suprapubic distention after voiding • Maintains balanced intake and output
2. Assess for signs and symptoms of urinary retention: amount and frequency of urination, suprapubic distention, complaints of urgency and discomfort.	2. Voiding 20–30 mL frequently and output less than intake suggest retention.	
3. Catheterize patient to determine amount of residual urine.	3. Determines amount of urine remaining in bladder after voiding.	
4. Initiate measures to treat retention. a. Encourage assuming normal position for voiding. b. Recommend using Valsalva maneuver preoperatively, if not contraindicated. c. Administer prescribed cholinergic agent. d. Monitor effects of medication.	4. Promotes voiding: a. Usual position provides relaxed conditions conducive to voiding. b. Valsalva maneuver exerts pressure to force urine out of bladder. c. Stimulates bladder contraction. d. If unsuccessful, another measure may be required.	
5. Consult with primary provider regarding intermittent or indwelling catheterization; assist with procedure as required.	5. Catheterization will relieve urinary retention until the specific cause is determined; it may be an obstruction that can be corrected only surgically.	

(Continued)

(Continued)

6. Monitor catheter function; maintain sterility of closed system; irrigate as required.	6. Adequate functioning of catheter is to be ensured to empty bladder and to prevent infection.
7. Prepare patient for surgery if indicated.	7. Surgical removal of obstruction may be necessary.

Nursing Diagnosis: Deficient knowledge related to the diagnosis of: cancer, urinary difficulties, and treatment modalities
Goal: Understanding of the diagnosis and ability to care for self

Nursing Interventions	Rationale	Expected Outcomes
1. Encourage communication with the patient.	1. This is designed to establish rapport and trust.	• Discusses his concerns and problems freely • Asks questions and shows interest in his disorder • Describes activities that help or hinder recovery • Identifies ways of attaining/maintaining bladder control • Demonstrates satisfactory technique and understanding of catheter care • Lists signs and symptoms that must be reported should they occur (e.g., abnormal bleeding, infection)
2. Review the anatomy of the involved area.	2. Orientation to one's anatomy is basic to understanding its function.	
3. Be specific in selecting information that is relevant to the patient's particular treatment plan.	3. This is based on the treatment plan; because it varies with each patient, individualization is desirable.	
4. Identify ways to reduce pressure on the operative area after prostatectomy. a. Avoid prolonged sitting (in a chair, long automobile rides), standing, walking. b. Avoid straining, such as during exercises, bowel movement, lifting, and sexual intercourse.	4. This is to prevent bleeding; such precautions are in order for 6–8 weeks postoperatively.	
5. Familiarize patient with ways of attaining/maintaining bladder control.	5. These measures will help control frequency and dribbling and aid in preventing retention.	
a. Encourage urination every 2–3 hours; discourage voiding when supine.	a. By sitting or standing, patient is more likely to empty his bladder.	
b. Avoid drinking cola and caffeine beverages; urge a cutoff time in the evening for drinking fluids to minimize frequent voiding during the night.	b. Spacing the kind and amount of liquid intake will help to prevent frequency.	
c. Describe perineal exercises to be performed every hour.	c. Exercises will assist him in starting and stopping the urinary stream.	
d. Develop a schedule with patient that will fit into his routine.	d. A schedule will assist in developing a workable pattern of normal activities.	
6. Demonstrate catheter care; encourage his questions; stress the importance of position of urinary receptacle.	6. By requiring a return demonstration of care, collection, and emptying of the device, he will become more independent and also can prevent backflow of urine, which can lead to infection.	

Nursing Diagnosis: Imbalanced nutrition: less than body requirements related to decreased oral intake because of anorexia, nausea, and vomiting caused by cancer or its treatment
Goal: Maintain optimal nutritional status

Nursing Interventions	Rationale	Expected Outcomes
1. Assess the amount of food eaten.	1. This assessment will help determine nutrient intake.	• Responds positively to his favorite foods • Assumes responsibility for his oral hygiene • Reports absence of nausea and vomiting • Notes increase in weight after improved appetite
2. Routinely weigh patient.	2. Weighing the patient on the same scale under similar conditions can help monitor changes in weight.	
3. Elicit patient's explanation of why he is unable to eat more.	3. His explanation may present easily corrected practices.	

(Continued)

(Continued)

4. Cater to his individual food preferences (e.g., avoiding foods that are too spicy or too cold).	4. He will be more likely to consume larger servings if food is palatable and appealing.
5. Recognize effect of medication or radiation therapy on appetite.	5. Many chemotherapeutic agents and radiation therapy promote anorexia.
6. Inform patient that alterations in taste can occur.	6. Aging and the disease process can reduce taste sensitivity. In addition, smell and taste can be altered as a result of the body's absorption of by-products of cellular destruction (brought on by malignancy and its treatment).
7. Educate patient about appropriate oral hygiene interventions	7. Food will be more palatable and appealing following good oral hygiene.
8. Use measures to control nausea and vomiting. a. Administer prescribed antiemetic agents, around the clock if necessary. b. Provide oral hygiene after vomiting episodes. c. Provide rest periods after meals.	8. Prevention of nausea and vomiting can stimulate appetite.
9. Provide frequent small meals and a comfortable and pleasant environment.	9. Smaller portions of food are less acute to the patient.
10. Assess patient's ability to obtain and prepare foods.	10. Disability or lack of social support can hinder the patient's ability to obtain and prepare foods.

Nursing Diagnosis: Sexual dysfunction related to effects of therapy: chemotherapy, hormonal therapy, radiation therapy, surgery
Goal: Ability to resume/enjoy modified sexual functioning

Nursing Interventions	Rationale	Expected Outcomes
1. Determine from nursing history what effect patient's medical condition is having on his sexual functioning.	1. Usually, decreased libido and, later, impotence may be experienced.	• Describes the reasons for changes in sexual functioning • Discusses with appropriate health care personnel alternative approaches and methods of sexual expression • Includes partner in discussions related to changes in sexual function
2. Inform patient of the effects of prostate surgery, orchiectomy (when applicable), chemotherapy, irradiation, and hormonal therapy on sexual function.	2. Treatment modalities may alter sexual function, but each is evaluated separately with regard to its effect on a particular patient.	
3. Include his partner in developing understanding and in discovering alternative, satisfying close relations with each other.	3. The bond between a couple may be strengthened with new appreciation and support that had not been evident before the current illness.	

Nursing Diagnosis: Acute pain related to progression of disease and treatment modalities
Goal: Relief of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Evaluate nature of patient's pain, its location, and intensity using pain rating scale.	1. Determining nature and causes of pain and its intensity help to select proper pain relief modality and provide baseline for later comparison.	• Reports relief of pain • Expects exacerbations, reports their quality and intensity, and obtains relief • Uses pain relief strategies appropriately and effectively • Identifies strategies to avoid complications of analgesic use (e.g., constipation)
2. Avoid activities that aggravate or worsen pain.	2. Bumping the bed is an example of an action that can intensify the patient's pain.	
3. Because pain is usually related to bone metastasis, ensure that patient's bed has a bed board on a firm mattress. In addition, protect the patient from falls/injuries.	3. This will provide added support and is more comfortable. Protecting the patient from injury protects him from additional pain.	

(Continued)

(Continued)

4. Provide support for affected extremities.	4. More support, coupled with reduced movement of the part, helps in pain control.	
5. Prepare patient for radiation therapy if prescribed.	5. Radiation therapy may be effective in controlling pain.	
6. Administer analgesic or opioid agents at regularly scheduled intervals as prescribed.	6. Analgesic agents alter perception of pain and provide comfort. Regularly scheduled analgesics around the clock rather than PRN (as needed) provide more consistent pain relief.	
7. Initiate bowel program to prevent constipation.	7. Opioid analgesic agents and inactivity contribute to constipation.	

Nursing Diagnosis: Impaired physical mobility related to tissue hypoxia, malnutrition, and exhaustion and to spinal cord or nerve compression from metastases
Goal: Improved physical mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for factors causing limited mobility (e.g., pain, hypercalcemia, limited exercise tolerance).	1. This information offers clues to the cause; if possible, cause is treated.	• Achieves improved physical mobility • Relates that short-term goals are encouraging him because they are attainable
2. Provide pain relief by administering prescribed medications.	2. Analgesic/opioid agents allow the patient to increase his activity more comfortably.	
3. Encourage the use of assistive devices: cane, walker.	3. Support may offer the security needed to become mobile.	
4. Involve significant others in helping patient with range-of-motion exercises, positioning, and walking.	4. Assistance from partner or others encourages patient to repeat activities and achieve goals.	
5. Provide positive reinforcement for achievement of small gains.	5. Encouragement stimulates improvement of performance.	
6. Assess nutritional status.	6. See Nursing Diagnosis: Imbalanced nutrition: less than body requirements.	

Collaborative Problems: Hemorrhage, infection, bladder neck obstruction
Goal: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Alert the patient to changes that may occur (after discharge) and that need to be reported:	1. Certain changes signal beginning complications, which call for nursing and medical interventions.	• Experiences no bleeding or passage of blood clots • Reports no infection or pain around the catheter • Experiences normal frequency or urination • Reports normal urinary output • Maintains bladder control
a. Continued bloody urine; passing blood clots	a. Hematuria with or without blood clot formation may occur postoperatively.	
b. Pain; burning around the catheter	b. Indwelling urinary catheters may be a source of pain or infection.	
c. Frequency of urination	c. Urinary frequency may be caused by urinary tract infections or by bladder neck obstruction, resulting in incomplete voiding.	
d. Diminished urinary output	d. Bladder neck obstruction decreases the amount of urine that is voided.	
e. Increasing loss of bladder control	e. Urinary incontinence may be a result of urinary retention.	

(Jevtana injection) are treatments options for patients requiring care for the management of metastatic castration-resistant prostate cancer, which does not respond to sipuleucel-T or the usual treatment options (Simondsen & Kolesar, 2013).

Surgical Management

Radical prostatectomy is considered first-line treatment for prostate cancer and is used with patients whose tumor is confined to the prostate (McDougal et al., 2016). It is the complete surgical removal of the prostate, seminal vesicles, tips of the vas deferens, and often the surrounding fat, nerves, and blood vessels. Laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy have become the standard surgical approaches for localized cancer of the prostate. Although sexual impotence is a common side effect, these laparoscopic radical prostatectomy approaches result in low morbidity and more favorable postoperative outcomes, including improved quality of life and less sexual dysfunction if the nerves are spared. Surgical approaches are discussed in detail later in this chapter.

Radiation Therapy

Two major forms of radiation therapy are used to treat cancer of the prostate: teletherapy (external) and brachytherapy (internal). Teletherapy (external-beam radiation therapy [EBRT]) is prescribed by the radiation oncologist for a total dose over a certain time frame—for example, 28 treatments over 5½ weeks (Itano et al., 2016). It is a treatment option for patients with low-risk prostate cancer; progression-free survival is similar to that of low-risk patients treated with radical prostatectomy. Patients with intermediate- and high-risk cancers receive higher doses of EBRT. They may also be candidates both pelvic lymph node irradiation and androgen deprivation therapy (ADT) that entails surgical (orchiectomy) or medical castration (e.g., with luteinizing hormone–releasing hormone agonists) (NCCN, 2016b). Intensity-modulated radiation therapy (IMRT) is one method of delivery of EBRT. IMRT sets a dose for the target volume and restricts the dose to surrounding tissue. Another approach to delivery of radiation uses a computer-controlled robotic arm to deliver a course of radiotherapy (i.e., stereotactic radiosurgery) to localized prostate cancer. This method, referred to as the CyberKnife®, is now considered a safe and reliable method of delivering radiation to treat prostate cancer (Detti, Bonomo, Masi, et al., 2016).

Brachytherapy involves the implantation of interstitial radioactive seeds under anesthesia. It has become a commonly used monotherapy treatment option for early, clinically organ-confined prostate cancer. The surgeon uses ultrasound guidance to place 80 to 100 seeds (depending on the prostate volume), and the patient returns home after the procedure. Exposure of others to radiation is minimal, but the patient should avoid close contact with pregnant women and infants for up to 2 months. Radiation safety guidelines include straining urine for seeds and using a condom during sexual intercourse for 2 weeks after implantation to catch any seeds that pass through the urethra. This approach can be completed in 1 day, with little lost time from normal activities. Brachytherapy may be combined with EBRT with or without neoadjuvant ADT for patients considered at intermediate risk. High-risk patients are considered poor candidates for permanent brachytherapy (Itano et al., 2016).

Although cure rates with radiation are comparable to those of radical prostatectomy, radiation therapy possesses its own unique set of side effects, which differ depending on the method of radiation administration. Patients receiving EBRT or brachytherapy may experience inflammation of the rectum, bowel, and bladder (proctitis, enteritis, and cystitis) because of the proximity of these structures to the prostate and the radiation doses. Inflammation and mucosal loss at the bladder neck, prostate, and urethra can cause acute urinary dysfunction. Both irritative and obstructive urinary symptoms can cause pain with urination and ejaculation until the irritation subsides. Rectal urgency, diarrhea, and tenesmus may occur as a result of radiation of the anterior rectal wall. Late side effects include rectal proctitis, bleeding, and rectal fistula; painless hematuria; chronic interstitial cystitis; urethral stricture erectile dysfunction; and, rarely, secondary cancers of the rectum and bladder (Thakur, 2016).

Hormonal Strategies

The number of survivors of prostate cancer in the United States is estimated at 2 million; approximately one third of these men currently receive ADT (Simpson, 2015). ADT is commonly used to suppress androgenic stimuli to the prostate by decreasing the level of circulating plasma testosterone or interrupting the conversion to or binding of DHT. As a result, the prostatic epithelium atrophies (decreases in size). This effect is accomplished either by surgical castration (bilateral orchiectomy, removal of one or both of the testes), which has traditionally been the mainstay of hormonal treatment, or by medical castration with the administration of medications, such as luteinizing hormone–releasing hormone (LHRH) agonists. Bilateral orchiectomy decreases plasma testosterone levels significantly because approximately 93% of circulating testosterone is of testicular origin (7% is from the adrenal glands). Thus, the testicular stimulus required for continued prostatic growth is removed, resulting in prostatic atrophy.

However, orchiectomy often results in significant morbidity. Although the procedure does not cause the side effects associated with other hormonal therapies (described later), it is associated with considerable emotional impact. Because patients who have prostate cancer are living longer with the disease, health care providers are focusing on effective therapeutic modalities that promote an acceptable quality of life. Patients may be given the option for testicular prostheses to be placed during surgery.

LHRH agonists include leuprolide (Lupron) and goserelin (Zoladex). Additional hormonal manipulation with antiandrogens may be prescribed for patients who do not show adequate serum testosterone suppression (less than 50 ng/mL) with medical or surgical castration. Antiandrogen receptor antagonists include flutamide (Eulexin), bicalutamide (Casodex), and nilutamide (Nilandron). LHRH agonists suppress testicular androgen, whereas antiandrogen receptor antagonists cause adrenal androgen suppression. When LHRH agonists are initiated, a testosterone flare may occur, causing pain in bony metastatic disease. Antiandrogens given for the first 7 days may reduce this uncomfortable symptom.

The most common uses of LHRH agonists are as follows: (1) in the adjuvant and neoadjuvant setting in combination with radiation therapy, (2) after radical prostatectomy, and (3) in the treatment of recurrence indicated by an elevation in the PSA but without clinical or x-ray evidence. Medical and surgical castration causes hot flushing because these treatment modalities increase hypothalamic activity, which stimulates the thermoregulatory centers of the body (Baker, 2014); (Jones, 2016); (Scher, 2016).

The management of hormone-refractory prostate cancer remains somewhat controversial. Another category of medication used as a second-line hormonal intervention is the adrenal ablating drugs. Ketoconazole (Nizoral) is used to inhibit cytochrome P450 enzymes, which are required for the synthesis of androgens and other steroids. High-dose ketoconazole lowers testosterone by decreasing both testicular and endocrine production of androgen. Administration of this medication requires steroid supplementation to prevent adrenal insufficiency.

Hypogonadism is responsible for the adverse effects of ADT, which include vasomotor flushing, loss of libido, decreased bone density (resulting in osteoporosis and fractures), anemia, fatigue, increased fat mass, lipid alterations, decreased muscle mass, gynecomastia (increased breast tissue), and mastodynia (breast/nipple tenderness). Hypogonadism is associated with an increased risk of diabetes, resulting from insulin resistance, metabolic syndrome, and cardiovascular disease (McDougal et al., 2016).

Chemotherapy

Recent studies have shown clear benefits in terms of survival with chemotherapy treatment that includes a docetaxel-based regimen for non–androgen-dependent prostate cancer (NCCN, 2016b). Other studies are under way to determine the importance of the vascular endothelial growth factor system. Tumor angiogenesis is essential for tumor growth, including growth of prostate carcinomas and other high-grade cancers. Therefore, antiangiogenic treatment in combination with conventional therapies may play a future role in treatment. Gene-based therapy in prostate cancer is an emerging and promising adjuvant to conventional treatment strategies.

Possible complications related to chemotherapy are specific to the type of chemotherapy given (see Chapter 58, Chart 58-4).

Other Therapies

Cryosurgery of the prostate is used to ablate prostate cancer in patients who cannot tolerate surgery and in those with recurrent prostate cancer. Transperineal probes are inserted into the prostate under ultrasound guidance to freeze the tissue directly.

Keeping the urethral passage patent may require repeated TURPs. If this is impractical, catheter drainage is instituted by way of the suprapubic or transurethral route. For men with advanced prostate cancer, palliative measures are indicated. Although cure is unlikely with advanced prostate cancer, many men survive for long periods, free of debilitating symptoms.

Bone lesions that result from metastasis of prostate cancer can be very painful and result in pathologic fractures. Opioid and nonopioid medications are used to control bone pain. EBRT can be delivered to skeletal lesions to relieve pain. Radiopharmaceuticals, such as strontium or samarium, can be injected IV to treat multiple sites of bone metastasis. Antiandrogen therapies are used in an effort to reduce the circulating androgens. If antiandrogen therapies are not effective, medications such as prednisone have been effective in reducing pain and improving quality of life (Lycken, Garmo, Adolfsson, et al., 2013); (Rathkopf & Scher, 2013). Bisphosphonate therapy with pamidronate (Aredia) can be given to reduce the risk of pathologic fracture. In advanced prostate cancer, blood transfusions are given to maintain adequate hemoglobin levels when bone marrow is replaced by tumor.

More than one third of men with a diagnosis of prostate cancer elect to use some form of complementary and integrative health. Acupuncture has been used to treat both PE and erectile dysfunction with some limited, anecdotal success (Tsai, Liu, Chang, et al., 2014). Because research on many forms of complementary, alternative, and integrative health is lacking, patients often rely on anecdotal information to make decisions about its use. Nurses and other health care professionals play a vital role in assisting patients to locate and evaluate available information about these practices to ensure that harmful forms are avoided (Braun, Gupta, Birdsall, et al., 2013). The National Center for Complementary and Integrative Health (NCCIH) website can assist nurses in providing patients with evidence-based information (see the Resources section at the end of the chapter).

The Patient Undergoing Prostate Surgery

Prostate surgery may be indicated for the patient with BPH or prostate cancer. The objectives before prostate surgery are to assess the patient's general health status and to establish optimal kidney function. Prostate surgery should be performed before acute urinary retention develops and damages the upper urinary tract and collecting system or, in the case of prostate cancer, before cancer progresses.

Surgical Procedures

Several approaches can be used to remove the hypertrophied portion of the prostate gland: TURP, suprapubic prostatectomy, perineal prostatectomy, retropubic prostatectomy, TUIP, and laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy (see Table 46-4). With these approaches, all cancerous or hyperplastic tissue is removed, leaving behind only the capsule of the prostate.

Transurethral Resection of the Prostate

TURP, which is the most common procedure used, can be carried out through endoscopy. The prostate gland is removed in small chips with an electrical cutting loop (see Fig. 46-5A). This procedure eliminates the risk of transurethral resection syndrome (hyponatremia, hypovolemia). Transurethral resection syndrome is a potential but rare complication of TURP that occurs in approximately 2% of men who undergo the procedure (Lycken, et al., 2013); (Rathkopf & Scher, 2013) (see Chart 46-4).

TURP usually requires an overnight hospital stay. Urethral strictures are more frequent than with nontransurethral procedures, and repeated procedures may be necessary because the residual prostatic tissue grows back. TURP rarely causes erectile dysfunction but may trigger retrograde ejaculation, because removal of prostatic tissue at the bladder neck can cause the seminal fluid to flow backward into the bladder rather than forward through the urethra during ejaculation.

TABLE 46-4 Surgical Approaches for Treatment of Prostate Disorders

The surgical approach of choice depends on (1) the size of the gland, (2) the severity of the obstruction, (3) the age of the patient, (4) the condition of the patient, and (5) the presence of associated diseases.

Surgical Approach	Advantages	Disadvantages	Nursing Implications
Transurethral Resection (TURP) Removal of prostatic tissue by optical instrument introduced through urethra; used for glands of varying size. Ideal for patients who are poor surgical risks.	Avoids abdominal incision Safer for surgical-risk patient Shorter length of hospital stay and recovery periods Lower morbidity rate Causes less pain Can be used as a palliative approach with history of radiation therapy	Requires highly skilled surgeon. Recurrent obstruction, urethral trauma, and stricture may develop. Delayed bleeding may occur.	Monitor for hemorrhage. Observe for symptoms of urethral stricture (dysuria, straining, weak urinary stream).
Open Surgical Removal			
Suprapubic approach Removal of prostatic tissue through abdominal incision; can be used for gland of any size	Technically simple Offers wide area of exploration Permits exploration for cancerous lymph nodes Allows more complete removal of obstructing gland Permits treatment of associated bladder lesions	Requires surgical approach through the bladder Control of hemorrhage is difficult Urine may leak around the suprapubic tube Recovery may be prolonged and uncomfortable	Monitor for indications of hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube.
Perineal approach Removal of gland through an incision in the perineum; preferred approach for patients who are obese	Offers direct anatomic approach Permits gravity drainage Particularly effective for radical cancer therapy Allows hemostasis under direct vision Low mortality rate Low incidence of shock Ideal for patients with large prostate who are very old, frail, and poor surgical risks	Higher postoperative incidence of impotence and urinary incontinence Possible damage to rectum and external sphincter Restricted operative field Greater potential for contamination and infection of incision	Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.
Retropubic approach Low abdominal incision; bladder is not entered.	Avoids incision into the bladder Permits surgeon to see and control bleeding Shorter recovery period Less bladder sphincter damage Suitable for removal of large glands	Cannot treat associated bladder disease Increased incidence of hemorrhage from prostatic venous plexus; osteitis pubis	Monitor for hemorrhage. Anticipate posturinary leakage for several days after removing the catheter.
Transurethral Incision (TUIP) Urethral approach; 1–2 cuts are made in the prostate and prostate capsule to reduce pressure on the urethra and to reduce urethral constriction.	Results comparable to TURP Low incidence of erectile dysfunction and retrograde ejaculation No bladder neck contracture	Recurrent obstruction and urethral trauma Delayed bleeding	Monitor for hemorrhage.
Laparoscopic Radical Prostatectomy In this approach, 4–6 small (1 cm [0.5 inch]) incisions are made in the abdomen; laparoscopic instruments inserted through the incisions are used to dissect the prostate.	Minimally invasive technique Improved patient satisfaction and quality of life Shorter length of hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 400 mL Reduced infection risk Less scarring Better visualization of surgical field than other approaches	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation Long surgical time (4–5 hours)	Observe for symptoms of urethral stricture (dysuria), straining, weak urinary stream. Monitor for hemorrhage and shock. Provide meticulous aseptic care to area around suprapubic tube. Monitor for changes in bowel function. Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.

(Continued)

(Continued)

Robotic-Assisted Laparoscopic Radical Prostatectomy Involves using computer console and da Vinci. In this approach, 6 small (1 cm [0.5 inch]) incisions are made in the abdomen; laparoscopic instruments inserted through the incisions are used to dissect the prostate.	Minimally invasive technique Improved patient satisfaction and quality of life Shorter length of hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 150 mL Improved magnification of operative field, using a 3-dimensional view (includes, magnification, high resolution, and depth perception) Less postoperative pain Reduced risk of infection Less scarring Laparoscopic instruments have 6 degrees of movement with joints, allowing extensive range of motion and precision. Nerve sparing with less incontinence and sexual dysfunction	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation	Observe for symptoms of urethral stricture (dysuria), straining, weak urinary stream. Monitor for hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube. Monitor for changes in bowel function. Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Provide foam rubber ring for patient comfort in sitting. Anticipate urinary leakage around the wound for several days after the catheter is removed.

Chart 46-4

Transurethral Resection Syndrome

Transurethral resection syndrome is a rare but potentially serious complication of transurethral prostatectomy (TURP). Signs and symptoms are caused by neurologic, cardiovascular, and electrolyte imbalances associated with absorption of the solution used to irrigate the surgical site during the surgical procedure. Hyponatremia, hypovolemia, and occasionally hyperammonemia may occur.

Signs and Symptoms

- Collapse
- Headache
- Hypotension
- Lethargy and confusion
- Muscle spasms
- Nausea and vomiting
- Seizures
- Tachycardia

Interventions

- Discontinue irrigation.
- Administer diuretic agents as prescribed.
- Replace bladder irrigation with normal saline.
- Monitor intake and output.
- Monitor the patient's vital signs and level of consciousness.
- Differentiate lethargy and confusion of TURP syndrome from postoperative disorientation and hyponatremia.
- Maintain patient safety during times of confusion.
- Assess lung and heart sounds for indications of pulmonary edema, heart failure, or both as fluid moves back into the intravascular space.

Adapted from Brown, C. S. (2014). Dilutional hyponatremia in a community hospital setting: Case report. Intensive & Critical Care Nursing, 30(1), 1–5.

Suprapubic Prostatectomy

A suprapubic prostatectomy is an open surgical procedure (see Fig. 46-5B). Disadvantages include blood loss, the need for an abdominal incision, and the risks associated with any major abdominal surgical procedure (see Fig. 46-5B).

Perineal Prostatectomy

A perineal prostatectomy (see Fig. 46-5C) is practical when other approaches are not possible and is useful for an open biopsy. However, incontinence, sexual dysfunction, and rectal injury are more likely to occur with this approach.

Retropubic Prostatectomy

Retropubic prostatectomy is used more commonly than the suprapubic approach (see Fig. 46-5D). This procedure is suitable for large glands located high in the pelvis. Although blood loss can be better controlled and the surgical site is easier to visualize, infections can readily start in the retropubic space.

Transurethral Incision of the Prostate

TUIP is indicated when the prostate gland is small (30 g or less), and it is an effective treatment for many cases of BPH (see Fig. 46-5E). TUIP can be performed on an outpatient basis and has a lower complication rate than other more invasive prostate procedures.

Laparoscopic Radical Prostatectomy

A laparoscopic radical prostatectomy has fewer risks compared with open radical prostatectomy (Simpson, 2015).

Robotic-Assisted Laparoscopic Radical Prostatectomy

Robotic-assisted laparoscopic radical prostatectomy is a minimally invasive approach that uses a computer console and a robot to move instruments, replicating the movements of the surgeon's hands (Simpson, 2015); (Sohn, Lee, & Ahlering, 2013).

Pelvic Lymph Node Dissection

Pelvic lymph node dissection (PLND) is not always performed. It may be used in some patients to provide information for staging the tumor and to remove an area of microscopic metastasis. The planned treatment may influence the surgeon's

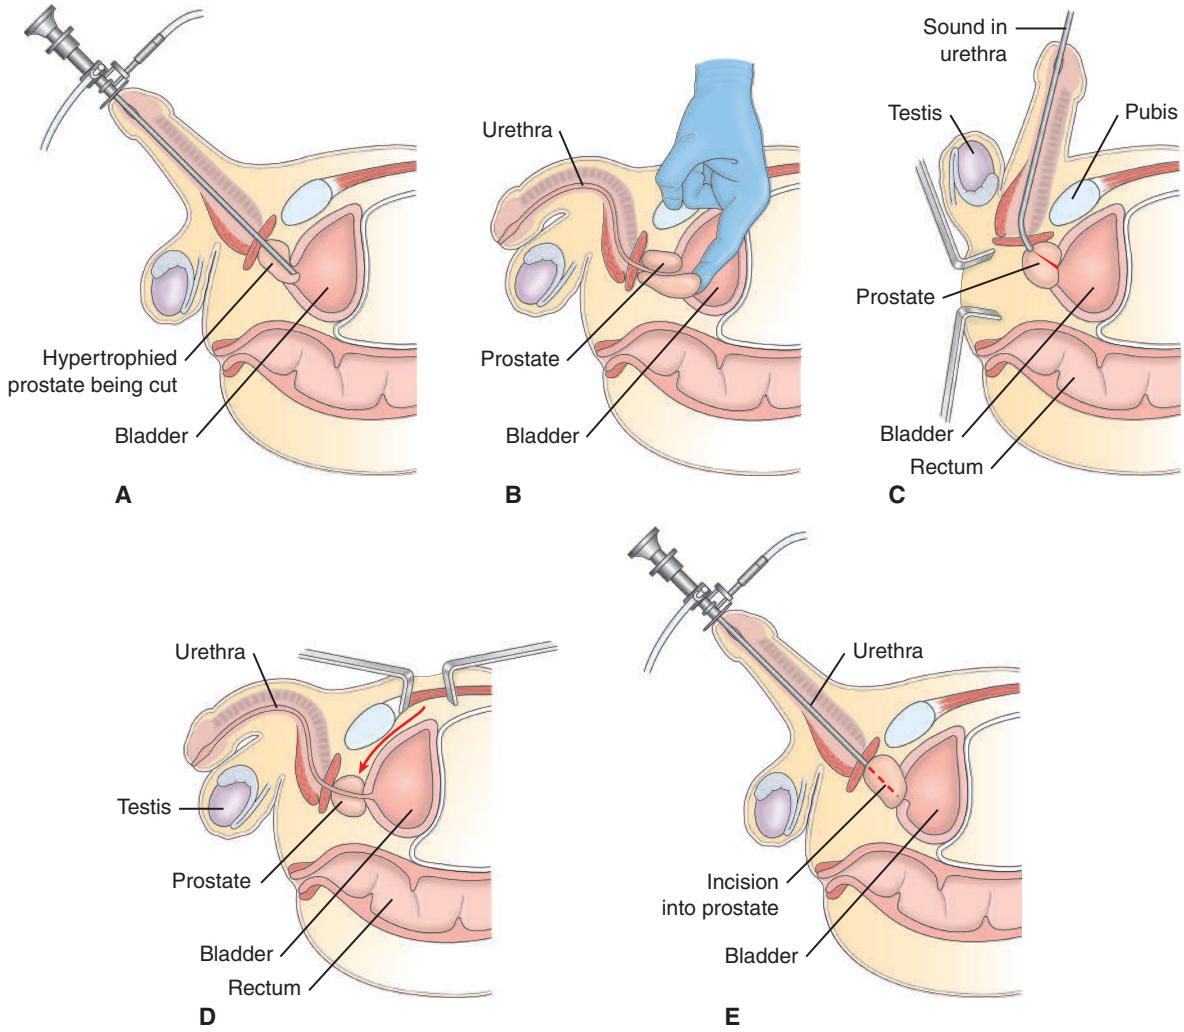

Figure 46-5 • Prostate surgery procedures. **A**. Transurethral resection of the prostate. A loop of wire connected with a cutting current is rotated in the cystoscope to remove shavings of prostate at the bladder orifice. **B**. Suprapubic prostatectomy. With an abdominal approach, the prostate is shelled out of its bed. **C**. Perineal prostatectomy. Two retractors on the left spread the perineal incision to provide a view of the prostate. **D**. Retropubic prostatectomy is performed through a low abdominal incision. Note two abdominal retractors and *arrow* pointing to the prostate gland. **E**. Transurethral incision of the prostate involves one or two incisions into the prostate to reduce pressure on the urethra.

decision to perform PLND and the extent (limited vs. extended) of the dissection. Dissection of nodes anterior and lateral to the external iliac vessels is associated with an increased risk of lymphedema (NCCN, 2016a).

Complications

Postoperative complications depend on the type of prostatectomy performed and may include hemorrhage, clot formation, catheter obstruction, and sexual dysfunction. All prostatectomies carry a risk of impotence because of potential damage to the pudendal nerves. In most instances, sexual activity may be resumed in 6 to 8 weeks, which is the time required for the prostatic fossa to heal. The anatomic changes in the posterior urethra can lead to retrograde ejaculation. During ejaculation, the seminal fluid goes into the bladder and is excreted with the urine. A vasectomy may be performed during surgery to prevent infection from spreading from the prostatic urethra through the vas and into the epididymis.

After total prostatectomy (usually for cancer), the risk of impotence is high. If this is unacceptable to the patient, options are available to produce erections sufficient for sexual intercourse: prosthetic penile implants, negative-pressure (vacuum) devices, and pharmacologic interventions (see earlier discussion and Table 46-2).

NURSING PROCESS

Patient Undergoing Prostatectomy

Assessment

The nurse assesses how the underlying disorder (BPH or prostate cancer) has affected the patient's lifestyle. Questions to ask during assessment include the following: Has the patient's activity level or activity tolerance changed? What is his presenting urinary problem (described in the patient's own words)? Has he experienced decreased force of urinary flow, decreased ability to initiate voiding, urgency, frequency, nocturia, dysuria, urinary retention, or hematuria? Does the patient report back pain, flank pain, and lower abdominal or suprapubic discomfort? Possible causes of such discomfort include infection, retention, and renal colic. Has the patient

experienced erectile dysfunction or changes in frequency or enjoyment of sexual activity?

The nurse obtains further information about the patient's family history of cancer and heart or kidney disease, including hypertension. Has he lost weight? Does he appear pale? Can he raise himself out of bed and return to bed without assistance? Can he perform usual activities of daily living? A comprehensive functional assessment helps determine how soon the patient will be able to return to normal activities after prostatectomy.

Diagnosis

Preoperative Nursing Diagnoses

Based on the assessment data, major preoperative nursing diagnoses may include the following:

- Anxiety about surgery and its outcome
- Acute pain related to bladder distention
- Deficient knowledge about factors related to the disorder and the treatment protocol

Postoperative Nursing Diagnoses

Based on the assessment data, major postoperative nursing diagnoses may include the following:

- Risk for imbalanced fluid volume
- Acute pain related to the surgical incision, catheter placement, and bladder spasms
- Deficient knowledge about postoperative care

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage and shock
- Infection
- Venous thromboembolism (VTE)
- Catheter obstruction
- Complications with catheter removal
- Urinary incontinence
- Sexual dysfunction

Planning and Goals

The major preoperative goals for the patient may include reduced anxiety and learning about his prostate disorder and the perioperative experience. The major postoperative goals may include maintenance of fluid volume balance, relief of pain and discomfort, ability to perform self-care activities, and absence of complications.

Preoperative Nursing Interventions

Reducing Anxiety

The patient is usually admitted to the hospital or surgical center on the morning of surgery. Because contact with the patient may be limited before surgery, the nurse must establish communication with the patient to assess his understanding of the diagnosis and of the planned surgical procedure. The nurse clarifies the nature of the surgery and expected postoperative outcomes. In addition, the nurse familiarizes the patient with the pre- and postoperative routines and initiates measures to reduce anxiety. Because the patient may be sensitive and embarrassed discussing problems related to the genitalia and sexuality, the nurse provides privacy and establishes a trusting and professional relationship. Guilt feelings often surface if the patient falsely assumes a cause-and-effect relationship between sexual practices and his current problems. He is encouraged to verbalize his feelings and concerns.

Relieving Discomfort

If the patient experiences discomfort before surgery, bed rest is prescribed, analgesic agents are given, and measures are initiated to relieve anxiety. If he is hospitalized, the nurse monitors his voiding patterns, watches for bladder distention, and assists with catheterization if indicated. An indwelling catheter is inserted if the patient has continuing urinary retention or if close monitoring is needed because of laboratory test results that indicate azotemia (accumulation of nitrogenous waste products in the blood). The catheter can help decompress the bladder gradually over several days, especially if the patient is an older adult and hypertensive and has diminished kidney function or urinary retention that has existed for many weeks. For a few days after the bladder begins draining, the blood pressure may fluctuate and kidney function may decline. If the patient cannot tolerate a urinary catheter, he is prepared for a cystostomy (and insertion of a suprapubic catheter).

Providing Education

Before surgery, the nurse reviews with the patient the anatomy of the affected structures and their function in relation to the urinary and reproductive systems, using diagrams and other educational aids as indicated. Web-based prostate cancer education both before and after surgery, along with phone and internet communication, promotes self-care management and support for patients and their partners and families (Song, Rini, Deal, et al., 2015). This education can occur during the preadmission testing visit, with the nurse in prescribed settings, or in the urologist's office. The nurse explains what will take place while the patient is prepared for diagnostic tests and then for surgery (depending on the type of prostatectomy planned). The nurse also reinforces information given by the surgeon about the type of incision, which varies with the surgical approach (see Table 46-4), and describes the likely type of urinary drainage system (urethral or suprapubic) and the recovery room procedure. The amount of information given is based on the patient's needs and questions. The nurse explains procedures expected to occur during the immediate perioperative period; answers questions the patient, family, or significant other may have; and provides emotional support. In addition, the nurse provides the patient with information about postoperative care and pain management.

Preparing the Patient

If the patient is scheduled for a prostatectomy, the preoperative preparation described in Chapter 4 is provided. Antiembolism stockings are applied before surgery and are particularly important to prevent VTE if the patient is placed in a lithotomy position during surgery. An enema is usually given at home on the evening before surgery or on the morning of surgery to prevent postoperative straining, which can induce bleeding.

Postoperative Nursing Interventions

Maintaining Fluid Balance

During the postoperative period, the patient is at risk for imbalanced fluid volume because of the irrigation of the surgical site during and after surgery. With irrigation of the urinary catheter to prevent its obstruction by blood clots, fluid may be absorbed through the open surgical site and retained, increasing the risk of excessive fluid retention, fluid imbalance, and water intoxication. The urine output and the amount of fluid used for irrigation must be closely monitored to determine whether irrigation fluid is being retained and to ensure an adequate urine output. An

intake and output record, including the amount of fluid used for irrigation, must be maintained. The patient is also monitored for electrolyte imbalances (e.g., hyponatremia), increasing blood pressure, confusion, and respiratory distress. These signs and symptoms are documented and reported to the surgeon. The risk of fluid and electrolyte imbalance is greater in older patients with pre-existing cardiovascular or respiratory disease.

Relieving Pain

After a prostatectomy, the patient is assisted to sit and dangle his legs over the side of the bed on the day of surgery. The next morning, he is assisted to ambulate. If pain is present, the cause and location are determined, and the severity of pain and discomfort is assessed (Carter, Miller, Murphy, et al., 2014). The pain may be related to the incision or may be the result of excoriation of the skin at the catheter site. It may be in the flank area, indicating a kidney problem, or it may be caused by bladder spasms. Bladder irritability can initiate bleeding and result in clot formation, leading to urinary retention.

Patients experiencing bladder spasms may report urgency to void, a feeling of pressure or fullness in the bladder, and bleeding from the urethra around the catheter. Medications that relax the smooth muscles can help ease the spasms, which can be intermittent and severe; these medications include flavoxate (Urispas) and oxybutynin (Ditropan). Warm compresses to the pubis or sitz baths may also relieve the spasms.

The nurse monitors the drainage tubing and irrigates the system as prescribed to relieve any obstruction that may cause discomfort. Usually, the catheter is irrigated with 50 mL of irrigating fluid at a time. It is important to make sure that the same amount is recovered in the drainage receptacle. Securing the catheter drainage tubing to the leg or abdomen can help decrease tension on the catheter and prevent bladder irritation. Discomfort may be caused by dressings that are too snug, saturated with drainage, or improperly placed. Analgesic agents are given as prescribed. The nurse notifies the primary provider if the analgesic medications do not relieve the patient's pain and obtains a prescription for new doses or different medications.

After the patient is ambulatory, he is encouraged to walk but not to sit for prolonged periods, because this increases intra-abdominal pressure and the possibility of discomfort and bleeding. Prune juice and stool softeners are provided to ease bowel movements and to prevent excessive straining. An enema, if prescribed, is given with caution to avoid rectal perforation.

Monitoring and Managing Potential Complications

After prostatectomy, the patient is monitored for major complications such as hemorrhage, infection, VTE, catheter problems, and sexual dysfunction.

Hemorrhage. Although patients are advised to discontinue all aspirin, nonsteroidal anti-inflammatory drugs, and platelet inhibitors 10 to 14 days before the surgery to prevent excessive bleeding, bleeding and hemorrhagic shock remain risks. The risk is increased with BPH because a hyperplastic prostate gland is very vascular. Bleeding may occur from the prostatic bed. Bleeding may also result in the formation of clots, which then obstruct urine flow. The drainage normally begins as reddish-pink and then clears to a light pink within 24 hours after surgery. Bright red bleeding with increased viscosity and numerous clots usually indicates arterial bleeding. Venous blood appears darker and less viscous. Arterial hemorrhage usually requires surgical intervention (e.g., suturing or transurethral coagulation of bleeding vessels), whereas venous bleeding may be controlled by applying prescribed traction to the catheter so that the balloon holding the catheter in place applies pressure to the prostatic fossa. The surgeon applies traction by securely taping the catheter to the patient's thigh if hemorrhage occurs. Less blood loss (150 mL) is expected with robotic-assisted laparoscopic radical prostatectomy, compared to the 500 to 900 mL loss that may occur with open prostatectomy.

Nursing management includes assistance in implementing strategies to stop the bleeding and to prevent or reverse hemorrhagic shock. If blood loss is extensive, fluids and blood component therapy may be given. If hemorrhagic shock occurs, treatments described in Chapter 8 are initiated.

Nursing interventions include closely monitoring vital signs; administering medications, IV fluids, and blood component therapy as prescribed; maintaining an accurate record of intake and output; and carefully monitoring drainage to ensure adequate urine flow and patency of the drainage system. The patient who experiences hemorrhage and his family are often anxious and benefit from explanations and reassurance about the event and the procedures that are performed.

Infection. After perineal prostatectomy, the surgeon usually changes the dressing on the first postoperative day. Further dressing changes may become the responsibility of the nurse in the inpatient setting or the home care nurse upon discharge. Careful aseptic technique is used because the potential for infection is great. Dressings can be held in place by a double-tailed, T-binder bandage or a padded athletic supporter. The tails cross over the incision to give double thickness and then each tail is drawn up on either side of the scrotum to the waistline and fastened.

Rectal thermometers, rectal tubes, and enemas are avoided because of the risk of injury and bleeding in the prostatic fossa. After the perineal sutures are removed, the perineum is cleansed as indicated. A heat lamp may be directed to the perineal area to promote healing. The scrotum is protected with a towel while the heat lamp is in use. Sitz baths are also used to promote healing.

UTIs and epididymitis are possible complications after prostatectomy. The patient is assessed for their occurrence; if they occur, the nurse administers antibiotic agents as prescribed. Because the risk of infection continues after discharge from the hospital, the patient and family need to be educated to monitor for signs and symptoms of infection (fever, chills, sweating, myalgia, dysuria, urinary frequency, and urgency). The patient and family are instructed to contact the urologist if these symptoms occur.

Venous Thromboembolism. Patients undergoing prostatectomy are at risk for VTE, including deep vein thrombosis and pulmonary embolism; therefore, the nurse assesses the patient frequently after surgery for manifestations of VTE. Early postoperative ambulation is essential to reduce the risk of VTE. Medical and nursing management of VTE are described in Chapters 12 and 24, respectively. In addition, if the patient is at high risk for clot formation, additional antithrombotic interventions may be prescribed (Goodman, 2013).

Potential Catheter Problems. After TURP, the catheter must drain well; an obstructed catheter produces distention of the prostatic capsule and resultant hemorrhage. Furosemide (Lasix) may be prescribed to promote urination and initiate postoperative diuresis, thereby helping to keep the catheter patent.

The nurse observes the lower abdomen to ensure that the catheter has not become blocked. A distinct, rounded swelling above the pubis is a manifestation of an overdistended bladder. If the nurse ascertains that the client's bladder is distended, a portable bladder scanner may be used to determine if urine retention is a problem (see Chapter 45).

The drainage bag is monitored for bloody urine, and the dressings and surgical incision are examined for bleeding. The color of the urine is carefully noted and documented; a change in color from pink to amber indicates reduced bleeding. Blood pressure, pulse, and respirations are monitored and compared with baseline preoperative vital signs to detect hypotension. The nurse also observes the patient for restlessness, diaphoresis, pallor, any drop in blood pressure, and an increasing pulse rate.

Drainage of the bladder may be accomplished by gravity through a closed sterile drainage system. A three-way drainage system is useful in irrigating the bladder and preventing clot formation (see Fig. 46-6). Continuous irrigation may be used with TURP. Some urologists leave an indwelling catheter attached to a dependent drainage system. Gentle irrigation of the catheter may be prescribed to remove any obstructing clots.

If the patient complains of pain, the tubing is examined. The drainage system is irrigated with irrigating fluid (usually 50 mL), if indicated and prescribed, to clear any obstruction.

Nursing Alert: The amount of fluid recovered in the drainage bag must equal the amount of fluid instilled. Overdistention of the bladder should be avoided because it can induce secondary hemorrhage by stretching the coagulated blood vessels in the prostatic capsule.

To prevent traction on the bladder, the drainage tube (not the catheter) is secured to the inner thigh. If a cystostomy catheter is in place, it is secured to the abdomen. The nurse explains the purpose of the catheter to the patient and assures him that the urge to void results from the presence of the catheter and from bladder spasms. Reassurance is given to the patient that medication (anticholinergics) will be given to control his bladder spasms. He is cautioned not to pull on the catheter, because this causes bleeding and subsequent catheter blockage, which leads to urinary retention.

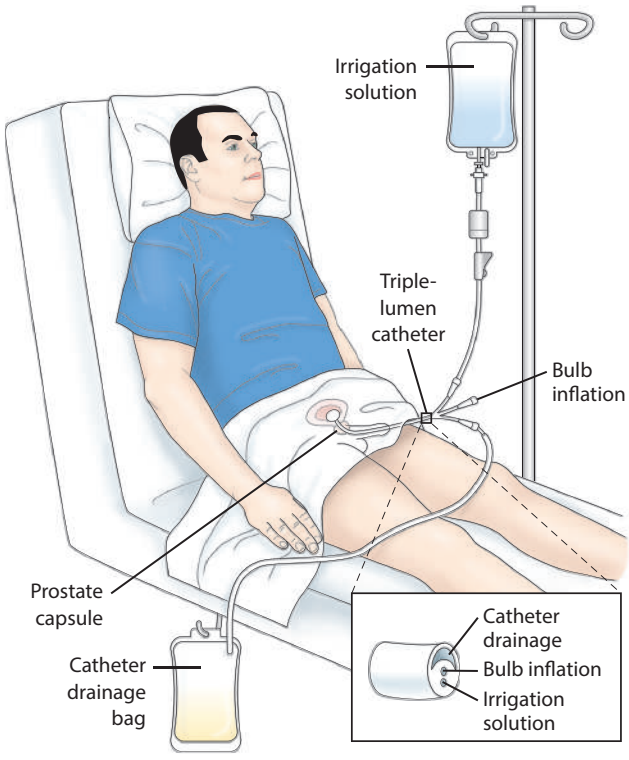

Figure 46-6 • A three-way system for bladder irrigation.

After the catheter is removed (usually when the urine appears clear), urine may leak around the wound for several days in the patient who has undergone perineal, suprapubic, or retropubic surgery. The cystostomy tube may be removed before or after the urethral catheter is removed. Some urinary incontinence may occur after catheter removal, and the patient is informed that this is likely to subside over time.

Urinary Incontinence. Postoperative urinary incontinence is a complication that can be reduced through the use of a surgical technique called puboprostatic ligament-sparing, or through the use of a male sling (Sandhu, 2015). Even without these techniques, current surgical procedures have decreased the incidence of urinary incontinence following surgery. Factors associated with postoperative continence are younger age, preservation of both neurovascular bundles, absence of an anastomotic stricture, eversion of the bladder neck, and a smaller prostate volume. The nurse can encourage the patient who experiences incontinence to take steps to prevent incontinence, improve continence, anticipate leakage, and cope with lack of complete control (Dorey, 2013). Preventing incontinence involves increasing voiding frequency, avoiding positions that encourage the urge to void, and decreasing fluid intake prior to activities. Promoting continence involves pelvic floor exercises (see the Educating Patients About Self-Care section that follows), biofeedback, and electrical stimulation. Anticipating leakage may entail lifestyle modifications such as using absorbent pads and carrying extra clothes to prevent urinary accidents; this can improve confidence when bathroom access is limited. It also helps to know the location of public bathrooms. Coping long term with complete lack of control may involve collagen injections, artificial sphincter implants, medications, and leg bags (Dorey, 2013); (McDougal et al., 2016).

Sexual Dysfunction. Depending on the type of surgery, the patient may experience sexual dysfunction related to erectile dysfunction, decreased libido, and fatigue. These issues may become a concern to the patient soon after surgery or in the weeks to months of rehabilitation. With nerve-sparing radical prostatectomy, the likelihood of recovering the ability to have erections is better for men who are younger and men in whom both neurovascular bundles are spared. A decrease in libido is usually related to the impact of the surgery on the body. Reassurance that the usual level of libido will return after recuperation from surgery is often helpful to the patient and his partner. The patient should be aware that he may experience fatigue during rehabilitation from surgery. This fatigue may also decrease his libido and alter his enjoyment of usual activities.

Several options to restore erectile function are discussed with the patient by the surgeon or urologist. These options may include medications, surgically placed implants, or negative-pressure devices. PDE-5 inhibitors (see Table 46-3) may be effective for treatment of erectile dysfunction in men after radical prostatectomy, especially if the neurovascular bundles have been preserved. They may also improve erectile

function in men with partial or moderate erectile dysfunction after radiation therapy for localized prostate cancer.

Nursing interventions include assessing for sexual dysfunction after surgery. Providing a private and confidential environment to discuss issues of sexuality is important. The emotional challenges of prostate surgery and its consequences need to be carefully explored with the patient and his partner. Providing the opportunity to discuss these issues can be very beneficial to the patient. For patients who have significant difficulty adjusting to sexual dysfunction, a referral to a sex therapist may be indicated.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The length of the hospital stay for the patient undergoing prostatectomy depends on the surgical approach used and ranges from 1 to 2 days for robotic-assisted laparoscopic prostatectomy to 3 to 5 days for open prostatectomy. The patient and family require education about how to manage the drainage system, how to assess for complications, and how to promote recovery. The nurse provides verbal and written education about the need to maintain the drainage system and to monitor urinary output; about wound care; and about strategies to prevent complications, such as infection, bleeding, and thrombosis. In addition, the patient and family need to know about signs and symptoms that should be reported to the primary provider (e.g., blood in urine, decreased urine output, fever, change in wound drainage, calf tenderness).

As the patient recovers and drainage tubes are removed, he may become discouraged and depressed because he cannot regain bladder control immediately. Furthermore, urinary frequency and burning may occur after the catheter is removed. Educating the patient about the following exercises may help him regain urinary control:

- Tense the perineal muscles by pressing the buttocks together, hold this position, and then relax. This exercise can be performed 10 to 20 times each hour while sitting or standing (Itano et al., 2016).
- Try to interrupt the urinary stream after starting to void; wait a few seconds and then continue to void.

Perineal exercises should continue until the patient gains full urinary control. The patient is educated to urinate as soon as he feels the first urge to do so. It is important to let the patient know that regaining urinary control is a gradual process; he may continue to "dribble" after being discharged from the hospital, but this should gradually diminish (usually within 1 year). The urine may be cloudy for several weeks after surgery but should clear as the prostate area heals.

While the prostatic fossa heals (6 to 8 weeks), the patient should avoid activities that produce Valsalva effects (straining, heavy lifting) because they may increase venous pressure and produce hematuria. He should avoid long motor trips and strenuous exercise, which increase the tendency to bleed. He should also know that spicy foods, alcohol, and coffee may cause bladder discomfort. The patient should be cautioned to drink enough fluids to avoid dehydration, which increases the tendency for a blood clot to form and obstruct the flow of urine. Signs of complications, such as bleeding, passage of blood clots, a decrease in the urinary stream, urinary retention, or symptoms of UTIs, should be reported to the primary provider (see Chart 46-5). Patients who have undergone robotic-assisted prostatectomy are often able to return to their usual activities in approximately 7 to 10 days (Sohn et al., 2013).

Continuing and Transitional Care. Referral for home, community-based or transitional care may be indicated if the patient is an older adult or has other health problems, if the patient and family cannot provide care in the home, or if the patient lives alone without available supports. The nurse making a home visit assesses the patient's physical status (cardiovascular and respiratory status, fluid and nutritional status, patency of the urinary drainage system, wound and nutritional status) and provides catheter and wound care, if

Chart 46-5 HOME CARE CHECKLIST

Postprostatectomy Care

At the completion of home care education, the patient and/or caregiver will be able to:

- Name the procedure that was performed and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Locate list of names and telephone numbers of resource personnel involved in care (e.g., health care professionals, home care nurse, urinary catheter/dressing supply vendor).
- Identify the equipment necessary and how to obtain medical supplies to carry out dressing changes, wound care, and other prescribed regimens.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., increased activity and ambulation, perineal exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
  - Describe measures to relieve postoperative pain and discomfort (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
  - Demonstrate appropriate care of urinary catheter and collection receptacle.
  - Demonstrate appropriate dressing change/wound care.
  - When appropriate, demonstrate performance of perineal muscle exercises to facilitate bladder control.
- State the name, dose, side effects, frequency, and schedule for all medications.
- Identify signs and symptoms of complications that should be reported to surgeon (e.g., decreased output, blood or clots in urine or urine drainage system, change in wound drainage, fever or symptoms of urinary tract infections, calf tenderness).
- Explain treatment plan and importance of follow-up care to all health care providers.
- State time and date of follow-up appointments, therapy, and testing.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g. friends, relatives, faith community).
  - Identify phone numbers of support groups for people with cancer and their caregivers/families.
  - State meeting locations and times for support groups.
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

indicated. The nurse reinforces previous education, assesses the ability of the patient and family to manage required care, and encourages the patient to ambulate and to carry out perineal exercises as prescribed. The patient may need to be reminded that return of bladder control may take time.

The patient is reminded about the importance of routine health screening and other health promotion activities. If the prostatectomy was performed to treat prostate cancer, the patient and family are also instructed about the importance of follow-up and monitoring with the primary provider.

Evaluation

Expected preoperative patient outcomes may include:

1. Demonstrates reduced anxiety
2. States that pain and discomfort are decreased
3. Relates understanding of the surgical procedure and postoperative course and practices perineal muscle exercises and other techniques useful in facilitating bladder control

Expected postoperative patient outcomes may include the following:

1. Reports relief of discomfort
2. Exhibits fluid and electrolyte balance
   a. Irrigation fluid and urinary output are within parameters determined by surgeon
   b. Experiences no signs or symptoms of fluid retention
3. Participates in self-care measures
   a. Increases activity and ambulation daily
   b. Produces urine output within normal ranges and consistent with intake
   c. Performs perineal exercises and interrupts urinary stream to promote bladder control
   d. Avoids straining and lifting heavy objects
4. Is free of complications
   a. Maintains vital signs within normal limits
   b. Exhibits wound healing, without signs of inflammation or hemorrhage
   c. Maintains acceptable level of urinary elimination
   d. Maintains optimal drainage of catheter and other drainage tubes
   e. Reports understanding of changes in sexual function

DISORDERS AFFECTING THE TESTES AND ADJACENT STRUCTURES

Orchitis

Orchitis is a rare, acute inflammatory response of one or both testes as a complication of systemic infection or as an extension of an associated epididymitis caused by bacterial, viral, spirochetal, or parasitic organisms. Micro-organisms may reach the testes through the blood, lymphatic system, or, more commonly, by traveling through the urethra, vas deferens, and epididymis; bacteria usually spread from an associated epididymitis in sexually active men. Causative organisms include *Neisseria gonorrhoeae, Chlamydia trachomatis, E. coli, Klebsiella, Pseudomonas aeruginosa, Staphylococcus* species, and *Streptococcus* species.

Signs and symptoms of orchitis include fever; pain, which may range from mild to severe; tenderness in one or both testicles; bilateral or unilateral testicular swelling; penile discharge; blood in the semen; and leukocytosis.

Treatment of orchitis is based on whether the causative organism is bacterial or viral. Bacterial orchitis is treated with antibiotic agents and supportive comfort measures. If the cause of the orchitis is an STI, the partner should be treated as well. Viral orchitis is treated using supportive treatments of rest, elevation of the scrotum, ice packs to reduce scrotal edema, analgesic agents, and anti-inflammatory medications. Bilateral orchitis can cause sterility in some men. Mumps vaccination is recommended for postpubertal men who have not had mumps or received inadequate immunization in childhood. Orchitis develops in approximately 30% of postpubertal men with mumps 4 to 6 days after parotitis starts, and one third of men have some testicular atrophy.

Epididymitis

Epididymitis is an infection of the epididymis, which usually spreads from an infected urethra, bladder, or prostate. The incidence is less than 1 in 1000 males per year. Prevalence is greatest in men 19 to 35 years of age. Acute epididymitis occurs bilaterally in 5% to 10% of affected patients (McDougal et al., 2016). Risk factors for epididymitis include recent surgery or a procedure involving the urinary tract, participation in high-risk sexual practices, personal history of an STI, past prostate infections or UTIs, lack of circumcision, history of an enlarged prostate, and the presence of a chronic indwelling urinary catheter.

Pathophysiology

A causative organism can be identified in 80% of patients. In prepubertal males, older men, and men who are homosexual, the predominate causal organism is *E. coli,* although in older men, the condition may also be a result of urinary obstruction. In sexually active men 35 years and younger, the pathogens usually are related to bacteria associated with STIs (e.g., *C. trachomatis, N. gonorrhoeae*). The infection moves in an upward direction, through the urethra and the ejaculatory duct, and then along the vas deferens to the epididymis (Taylor, 2015).

Clinical Manifestations

Epididymitis often slowly develops over 1 to 2 days, beginning with a low-grade fever, chills, and heaviness in the affected testicle. The testicle becomes increasingly tender to pressure and traction. The patient may report unilateral pain, soreness in the inguinal canal along the course of the vas deferens, and pain and swelling in the scrotum and the groin. The epididymis becomes increasingly swollen, with extreme pain in the lower abdomen and pelvis. Occasionally, there may be discharge from the urethra, blood in the semen, pus (pyuria) and bacteria (bacteriuria) in the urine, and pain during intercourse and ejaculation. The patient may report urinary frequency, urgency, or dysuria, and testicular pain aggravated by bowel movement.

Assessment and Diagnostic Findings

Laboratory assessment includes urinalysis, complete blood cell count, Gram stain of urethral drainage, urethral culture or deoxyribonucleic acid (DNA) probe, and referral for syphilis and HIV testing in sexually active patients. Acute testicular pain should never be ignored, and it should be distinguished from testicular torsion, which is a surgical emergency.

Medical Management

The selection of an antibiotic depends on the causative organism; if epididymitis is associated with an STI, the patient's partner should also receive antimicrobial therapy. The spermatic cord may be infiltrated with a local anesthetic agent to relieve pain if the patient is seen within the first 24 hours after onset of pain. Supportive interventions also include reduction in physical activity, scrotal support and elevation, ice packs, anti-inflammatory agents, analgesics (including nerve blocks), and sitz baths. Urethral instrumentation (e.g., catheter insertion) is avoided. The patient is observed for scrotal abscess formation as well.

In chronic epididymitis, a 4- to 6-week course of antibiotic therapy for bacterial pathogens is prescribed. An epididymectomy (excision of the epididymis from the testis) may be performed for patients who have recurrent, refractory, incapacitating episodes of this infection. With long-term epididymitis, the passage of sperm may be obstructed. If the obstruction is bilateral, infertility may result.

Nursing Management

Bed rest is prescribed, and the scrotum is elevated with a scrotal bridge or folded towel to prevent traction on the spermatic cord, to promote venous drainage, and to relieve pain. Antimicrobial agents are given as prescribed until the acute inflammation subsides. Intermittent cold compresses to the scrotum may help ease the pain. Later, local heat or sitz baths may help resolve the inflammation. Analgesic medications are given for pain relief as prescribed.

The nurse instructs the patient to avoid straining, lifting, and sexual stimulation until the infection is under control. He should continue taking analgesic agents and antibiotics as prescribed and using ice packs if necessary to relieve discomfort. He needs to know that it may take 4 weeks or longer for the inflammation to resolve.

Testicular Torsion

Testicular torsion is a surgical emergency requiring immediate diagnosis to avoid loss of the testicle. Torsion of the testis is rotation of the testis, which twists the blood vessels in the spermatic cord and therefore impedes the arterial and venous supply to the testicle and surrounding structures in the scrotum. The patient presents with sudden pain in the testicle, developing over 1 to 2 hours, with or without a predisposing event. Nausea, lightheadedness, and swelling of the scrotum may develop. On physical examination, testicular tenderness, an elevated testis, a thickened spermatic cord, and a swollen, painful scrotum may be present. If the torsion cannot be reduced manually, surgery to untwist the spermatic cord and anchor both testes in their correct position to prevent recurrence should occur within 6 hours of the onset of symptoms in order to save the testis. After 6 hours of impaired blood supply, the risk of loss of the testicle increases.

Testicular Cancer

Although only accounting for about 1% of all cancers in men, testicular cancer is the most common cancer diagnosed in men between 15 and 35 years of age; approximately 8400 new cases and 380 deaths occur in the United States annually (ACS, 2015). It is the second most common malignancy in those 35 to 39 years of age. For unknown reasons, worldwide incidence of testicular tumors has more than doubled in the past 40 years. Testicular cancer incidence rates are highest in developed countries such as New Zealand (7.8), UK (6.3), Australia (6.1), Sweden (5.6), USA (5.2), Poland (4.9), and Spain (3.8) per 100,000 men. India has the lowest incidence—0.5 per 100,000 men (Shanmugalingam, Soultati, Chowdhury, et al., 2013). Because of advances in cancer therapy, testicular cancer is a highly treatable and usually curable form of cancer. The 5-year relative survival rate for all testicular cancers is more than 95% and approaches 99% if the cancer has not spread outside of the testes (ACS, 2015). After treatment, most patients with testicular cancer have a near-normal life expectancy.

Classification of Testicular Tumors

The testicles contain several types of cells, each of which may develop into one or more types of cancer. The type of cancer cell determines the appropriate treatment and affects the prognosis. Testicular cancer is classified as germinal or nongerminal (stromal). Secondary testicular cancers may also occur.

Germinal Tumors

Germinal tumors make up approximately 90% of all cancers of the testis; germinal tumors are further classified as seminomas or nonseminomas. These cancers grow from the germ cells that produce sperm, thus the name *germinal tumors.* Seminomas are slow-growing forms of testicular cancer that are usually found in men in their 30s and 40s (ACS, 2015); (NCCN, 2016c). Although seminomas can spread to the lymph nodes, the cancer is usually localized in the testes. Nonseminomas are more common and tend to grow more quickly than seminomas. Nonseminomas are often made up of different cell types and are identified according to the cells in which they start to grow. Nonseminoma testicular cancers include choriocarcinomas (rare), embryonal carcinomas, teratomas, and yolk sac tumors. It is crucial to distinguish between seminomas and nonseminomas because the differences affect prognosis and treatment.

Nongerminal Tumors

Nongerminal tumors account for less than 10% of testicular cancers. These cancers may develop in the supportive and hormone-producing tissues, or stroma, of the testicles. The two main types of stromal tumors are Leydig cell tumors and Sertoli cell tumors. Although these tumors infrequently spread beyond the testicle, a small number metastasize and tend to be resistant to chemotherapy and radiation therapy.

Secondary Testicular Tumors

Secondary testicular tumors are those that have metastasized to the testicle from other organs. Lymphoma is the most common cause of secondary testicular cancer. Cancers may also spread to the testicles from the prostate gland, lung, skin (melanoma), kidney, and other organs. The prognosis with these cancers is usually poor because they typically also spread to other organs. Treatment depends on the specific type of cancer (ACS, 2015).

Risk Factors

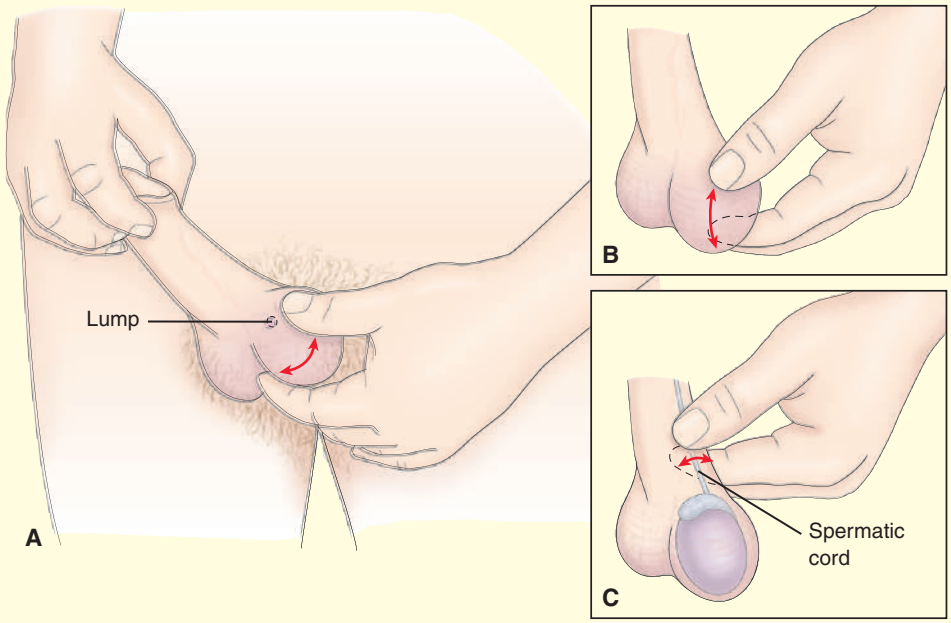
Risk factors for testicular cancer include cryptorchidism (undescended testicles), family history of testicular cancer, and personal history of testicular cancer (ACS, 2015); (Fuller, 2014). Other risk factors include race and ethnicity: Caucasian American men have a five times greater risk than African American men and more than two to three times greater

risk than Asian, Native American, and Hispanic American men. The risk of developing testicular cancer is higher in HIV-positive men (ACS, 2015). Occupational hazards, including exposure to chemicals encountered in mining, oil and gas production, and leather processing, have been suggested as possible risk factors. No evidence has linked testicular cancer to prenatal exposure to diethylstilbestrol or to vasectomy (ACS, 2015).

Clinical Manifestations

The symptoms appear gradually, with a mass or lump on the testicle and usually painless enlargement of the testis. The patient may report heaviness in the scrotum, inguinal area, or lower abdomen. Backache (from retroperitoneal node extension), abdominal pain, weight loss, and general weakness may result from metastasis. Enlargement of the testis without pain is a significant diagnostic finding. Some testicular tumors tend to metastasize early, spreading from the testis to the lymph nodes in the retroperitoneum and to the lungs.

Assessment and Diagnostic Findings



Educating young men about testicular cancer and the need for urgent evaluation of any mass or enlargement or unexplained testicular pain is key to early detection (Fuller, 2014). Education about TSE, starting in adolescence, alerts men to the importance of seeking medical attention if a testicle becomes indurated, enlarged, atrophied, nodular, or painful (see Chart 46-6). TSE should be performed monthly. Testicular cancers generally grow rapidly and are easily detected against a typically smooth and homogeneous texture. Annual testicular examination by a clinician can reveal signs and lead to early diagnosis and treatment of testicular cancer. Promoting awareness of this disease is an important health promotion intervention; men should seek medical evaluation for signs or symptoms of testicular cancer without delay (Akar & Bebis, 2014). Any suspicious testicular mass warrants prompt evaluation with a thorough history and physical examination, focusing on palpation of the affected testicle.

The tumor markers alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-hCG) may be elevated in patients

Chart 46-6 PATIENT EDUCATION

Testicular Self-Examination

Testicular self-examination is to be performed once a month. The test is neither difficult nor time-consuming. A convenient time is usually after a warm bath or shower when the scrotum is more relaxed.

The nurse instructs the patient to:

1. Use both hands to palpate the testis. The normal testicle is smooth and uniform in consistency.
2. Place the index and middle fingers under the testis and the thumb on top; roll the testis gently in a horizontal plane between the thumb and fingers (**A**).
3. Feel for any evidence of a small lump or abnormality.
4. Follow the same procedure and palpate upward along the testis (**B**).
5. Locate and palpate the epididymis (**C**), a cordlike structure on the top and back of the testicle that stores and transports sperm. In addition, locate and palpate the spermatic cord.
6. Repeat the examination for the other testis, epididymis, and spermatic cord. It is normal to find that one testis is larger than the other.
7. If you find any evidence of a small, pealike lump or if the testis is swollen (possibly from an infection or tumor), consult your primary provider.

Adapted from Weber, J. R., & Kelley, J. H. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

with testicular cancer. Tumor marker levels in the blood are used for diagnosis, staging, and monitoring the response to treatment. Blood chemistry, including lactate dehydrogenase, is also necessary.

A chest x-ray to assess for metastasis in the lungs and a transscrotal testicular ultrasound will be performed. Microscopic analysis of tissue is the only definitive way to determine if cancer is present, but it is usually performed at the time of surgery rather than as a part of the diagnostic workup to reduce the risk of promoting spread of the cancer (ACS, 2015). Inguinal orchiectomy is the standard way to establish the diagnosis of testicular cancer. Other staging tests to determine the extent of the disease in the retroperitoneum, pelvis, and chest include an abdominal/pelvic CT scan and chest CT scan (if the abdominal CT or chest x-ray is abnormal). A brain MRI and bone scan may be obtained if indicated (NCCN, 2016c). Discussion of the option to bank sperm should take place prior to orchiectomy and treatment.

Medical Management

Testicular cancer—one of the most curable solid tumors—is highly responsive to treatment. Early-stage disease is curable more than 95% of the time; thus, prompt diagnosis and treatment are essential. The NCCN practice consensus guidelines for testicular cancer are used to guide diagnostic workup, primary treatment, follow-up, and salvage therapy (treatment given when the cancer does not respond to standard treatment) for both seminomas and nonseminomas (NCCN, 2016c). The goals of management are to eradicate the disease and achieve a cure. Therapy is based on the cell type, the stage of the disease, and risk classification tables (determined as good, intermediate, and poor risk). Primary treatment includes removal of the affected testis by orchiectomy through an inguinal incision with a high ligation of the spermatic cord. The patient is offered the option of implantation of a testicular prosthesis during the orchiectomy. Although most patients experience no impairment of endocrine function after unilateral orchiectomy for testicular cancer, some patients have decreased hormonal levels, suggesting that the unaffected testis is not functioning normally. Retroperitoneal lymph node dissection (RPLND) may be performed after orchiectomy to diagnose and prevent lymphatic spread of the cancer. Alternatives to the more invasive open RPLND for early-stage germ cell testicular cancer include nerve-sparing and laparoscopic RPLND, which improve sexual function and promote rapid recovery (Hanna & Einhorn, 2014). Although libido and orgasm are usually unimpaired after RPLND, ejaculatory dysfunction with resultant infertility may develop. Two thirds of men who are newly diagnosed with testicular cancer may be considering future fatherhood, and sperm quality is reduced in men with testicular cancer; therefore, sperm banking before treatment may be considered (Martin, Turner, Bourne, et al., 2013). Half of patients will not recover fertility as a result of radiation therapy, cytotoxic therapy, unilateral excision of a testis, and RPLND. Counseling about fertility issues may help the patient make the appropriate choices (Brand, Williams, & Braybrooke, 2015).

Radiation therapy is more effective with seminomas than with nonseminomas. Postoperatively, radiation may be used in early-stage seminomas. It is delivered only to the affected side; the other testis is shielded from radiation to preserve fertility. Radiation is also used in patients whose disease does not respond to chemotherapy and in those for whom lymph node surgery is not recommended.

Chemotherapy may be used for seminomas, nonseminomas, and advanced metastatic disease. Cisplatin (Platinol-AQ) can be used in combination with other chemotherapeutic agents, such as etoposide (Toposar), bleomycin (Blenoxane), paclitaxel (Taxol), ifosfamide (Ifex), and vinblastine (Velban), and results in a high percentage of complete remissions. With nonseminomas, aggressive surgical resection of all residual masses following chemotherapy is standard therapy. Good results may also be obtained by combining different types of treatment, including surgery, radiation therapy, and chemotherapy. Even with metastatic testicular cancer, the prognosis is favorable because of advances in treatment. However, for patients who do not respond to high-dose salvage chemotherapy, the cancer is nearly always incurable.

A patient with a history of one testicular tumor has a greater chance of developing subsequent tumors. Late relapse of testicular cancer is currently defined as tumor recurrence more than 2 years after complete remission following primary treatment that included chemotherapy. The most common site of recurrence is the retroperitoneum. Follow-up studies include chest x-rays, excretory urography, radioimmunoassay of beta-hCG and AFP levels, and examination of lymph nodes.

Long-term side effects associated with treatment for testicular cancer include renal insufficiency from kidney damage, hearing problems, gonadal damage, peripheral neuropathy, and, rarely, secondary cancers. Management of a patient with testicular carcinoma is therapy aimed at cure followed by close monitoring to detect and promptly treat any recurrences (NCCN, 2016c). Investigations of new medications, combinations of chemotherapeutic agents, and stem cell transplantation are ongoing.

Nursing Management

Nursing management includes assessment of the patient's physical and psychological status and monitoring of the patient for response to and possible effects of surgery, chemotherapy, and radiation therapy (see Chapter 58). Pre- and postoperative care is described in Chapters 4 and 6, respectively. In addition, because the patient may have difficulty coping with his condition, issues related to body image and sexuality should be addressed.

Patients may be required to endure a long course of therapy and will need encouragement to maintain a positive attitude. After completing treatment, patients enter a follow-up surveillance period. Nurses educate these cancer survivors about the importance of adhering to follow-up appointments for early detection of cancer recurrence (most often occurring within 2 years posttreatment) and evaluation of late effects of treatment (including secondary cancers). Additional concerns include infertility, cardiotoxicity, neurotoxicity, nephrotoxicity, pulmonary toxicity, and metabolic syndrome; and alterations in quality of life (Russell, 2014); (Schover, van der Kaaij, van Dorst, et al., 2014). The nurse carefully assesses cultural aspects of care related to testicular cancer and its treatment (see Chart 46-7). The nurse reminds the patient about the importance of performing TSE in the treated or remaining testis. The patient is encouraged to participate in healthy behaviors, including smoking cessation, healthy diet, minimization of alcohol intake, and cancer screening activities. Most experts agree that couples should use birth control for 18 to 24 months after the last cycle of chemotherapy as this is the usual period of time after treatment for sperm to return to normal (Brand et al., 2015).

Chart 46-7 NURSING RESEARCH PROFILE

Surviving Testicular Cancer

Saab, M., Noureddine, S., Hujer, H. A., et al. (2014). Surviving testicular cancer: The Lebanese lived experience. Nursing Research, 63(3), 203–209.

Purpose

There is limited research and other literature available about what it means to live with testicular cancer. Although there are a few studies on survivors of testicular cancer in the United States and in several other European countries, there are no studies on men residing in the Arab region, particularly men in the country of Lebanon. The purpose of this study was to describe the experience of Lebanese survivors of testicular cancer and to obtain an understanding of the psychosexual dimensions of their experience.

Design

A hermeneutic, phenomenologic, qualitative research design was used to interview eight men recruited from the clinics of a urologist and an oncologist. The inclusion criteria specified that the participant: (1) was a resident of Lebanon who was of Lebanese nationality, as it was believed that the participant's cultural background played a major role in shaping their experiences, (2) was between 18 and 50 years of age, (3) was amenable to sharing personal information about the experience, (4) was willing to consent to digitally recording the interview, and (5) was willing to provide informed consent. A purposive sampling method was used. Prior to initiating the interview, the researcher asked several icebreaker questions about the participant's state of health and engagement in various types of daily activities. The main interview question was: Tell me about your life since you were diagnosed with testicular cancer. Specifically, the researchers asked participants about their lives since being diagnosed and receiving treatment, about their personal relationships, how their sex life, fertility, and sexual performance was affected, and if any problems were occurring. To ensure privacy for the interview, the researcher met with the men in a place of the participant's choice. Interviews were conducted in the participants' homes, workplaces, researcher's office, and one was held by participant request in the researcher's car. After each interview field notes were written by the researcher.

Findings

The study participants were 32–50 years of age, with a mean age of 41 years. The participants were interviewed approximately 6 years after they had completed treatment. Five men reported undergoing a unilateral orchiectomy with chemotherapy, two reported only a bilateral orchiectomy, and one had a bilateral orchiectomy with radiation therapy. The participants were primarily businessmen, managers, skilled workers, an engineer and a bank employee. Six participants were married and two were identified as single. Six themes emerged from the interview data: (1) cancer perception in the Lebanese culture, (2) "do not show, do not tell," (3) the cancer experience is a turning point, (4) fertility, manhood and relationships, (5) coping with cancer, (6) preserved aspects of life.

Nursing Implications

It is important for nurses and other health care providers to address the patients' need for education and the cultural aspects of care related to testicular cancer and its treatment. The topics of fertility and sexuality must be included in all educational programs since these two topics were major areas of concern to the participants. Since fertility was a key determinant to the man's sexual identity, the need to discuss the option of sperm banking was viewed as an important care recommendation. The need for support groups with possible contact between newly diagnosed men and testicular cancer survivors, sexual counseling, and instruction on testicular self-examination during adolescence and young adulthood were important components to integrate into health care practice.

Hydrocele

A hydrocele is a collection of fluid most commonly located between the visceral and parietal layers of the tunica vaginalis of the testis, although it may also collect within the spermatic cord. This condition is the most common cause of scrotal swelling. At birth, 1 in 10 infants has a hydrocele, which usually resolves without treatment within the first year of life. Acute hydroceles primarily develop in adults older than 40 years; they may occur in association with inflammation (e.g., radiation therapy), infection, epididymitis, local injury, or systemic infectious disease (e.g., mumps). Chronic hydroceles may occur related to the imbalance between fluid secretion and reabsorption in the tunica vaginalis. On physical examination, an easily transilluminated, painless, extratesticular mass is found. Hydrocele can be differentiated from a hernia by transillumination; a hydrocele transmits light, whereas a hernia does not. Ultrasonography is recommended for large hydroceles to differentiate them from testicular tumors (Crawford, 2014).

Treatment is usually not required unless the hydrocele is large, bulky, tense, or uncomfortable; compromises testicular circulation; or causes an undesirable appearance. Treatment may involve surgical excision or needle aspiration. Surgical excision (hydrocelectomy) may be performed in an outpatient setting under general or spinal anesthesia with the goal of prevention of recurrence by excising the tunica vaginalis or sclerosing the visceral and parietal layers. Surgical excision involves resection or suturing together the two layers. A drainage tube may be required, and the patient is advised to wear a bulky dressing over the incisional site for a few days after the procedure. To reduce swelling, ice packs are applied to the scrotal area during the first 24 hours. A scrotal athletic supporter may be worn for a period of time postoperatively for comfort and support. Surgical risks include hematoma in the loose scrotal tissues, infection, or injury to the scrotum.

Needle aspiration is another option used to remove the fluid in the scrotum. Because it is common for fluid to reaccumulate, this treatment may be followed by the injection of a sclerosing agent to prevent this recurrence. This option may be used for men who are poor surgical risks. Potential risks include infection and scrotal pain.

Varicocele

A varicocele is an abnormal dilation of the pampiniform venous plexus and the internal spermatic vein in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord). Varicoceles occur in approximately 15% to 20% of healthy adult men and 40% of infertile men; the large majority (95%) are in the left testicle because incompetent valves are more common in the left internal

spermatic veins (Grossman & Porth, 2014). Although men may report scrotal pain, tenderness, heaviness in the inguinal area, and infertility, varicoceles are often asymptomatic.

If the varicocele is mild and fertility is not an issue, no treatment is required, and a scrotal support is usually sufficient to relieve symptoms of heaviness. If the condition results in ongoing distressing symptoms or fertility is an issue, the varicocele can be corrected surgically. Postprocedural education and care include an ice pack applied to the scrotum for the first few hours after surgery to relieve edema, dressing removal after 48 hours, nonstrenuous exercise for the first 2 days, scrotal support, pain control, and reporting complications such as infection and hematoma.

Vasectomy

Vasectomy, or male sterilization, involves the surgical interruption of both vas deferens—the tubes that carry the sperm from the testicles and epididymis to the seminal vesicles—to prevent fertilization of an egg after ejaculation. During the outpatient procedure, the surgeon exposes the vas deferens through a small surgical opening or puncture in the scrotum using a sharp, curved hemostat (see Fig. 46-7). The vas is then ligated (cut) or cauterized (burned), with the severed ends occluded by ties or clips to seal the lumens and then placed back into the scrotum. A section of the vas deferens may or may not be removed. The spermatozoa, which are manufactured in the testes, cannot travel up the vas deferens after this surgery (McDougal et al., 2016).

Because seminal fluid is manufactured predominantly in the seminal vesicles and prostate gland, which are unaffected by vasectomy, no noticeable decrease in the amount of ejaculate occurs (volume decreases approximately 3%), even though it contains no spermatozoa. Because the sperm cells have no exit, they are resorbed into the body. A vasectomy usually has no effect on sexual potency, erection, ejaculation, or production of male hormones and provides no protection against STIs.

Couples who were once worried about pregnancy resulting from contraceptive failure often report a decrease in concern and an increase in spontaneous sexual arousal after vasectomy. Concise and factual preoperative explanations may minimize or relieve the patient's concerns related to pain and reduced masculinity. The patient is advised that he will be sterile but that potency will not be altered after a bilateral vasectomy. On rare occasions, a spontaneous reanastomosis of the vas deferens occurs, making it possible to impregnate a partner.

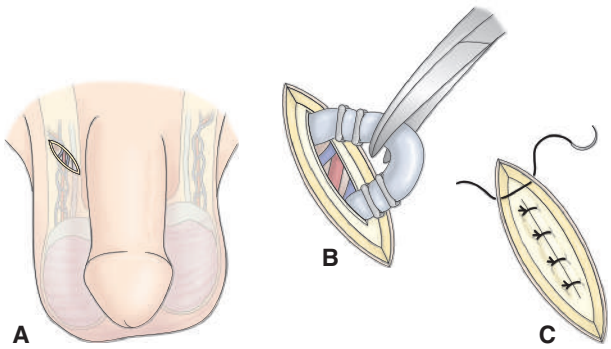


Figure 46-7 • A vasectomy is a resection of the vas deferens to prevent passage of sperm from the testes to the urethra during ejaculation. **A**. An incision or small puncture is made to expose the vas deferens. **B**. The vas deferens is isolated and severed. **C**. The severed ends are occluded with ligatures or clips, or the lumen of each vas is sealed by electrocautery and the incision is sutured closed. (Suturing may not be required if a puncture approach has been used.)

Complications of vasectomy include scrotal ecchymoses and swelling, superficial wound infection, vasitis (inflammation of the vas deferens), epididymitis or epididymo-orchitis, hematomas, chronic pain, and spermatic granuloma. A spermatic granuloma is an inflammatory response to the collection of sperm leaking from the severed end of the proximal vas deferens into the scrotal tissue. A painless small lump is formed, which usually does not require surgical intervention.

Nursing Management

Nursing education focuses on self-management of swelling and discomfort post vasectomy. Applying ice bags intermittently to the scrotum for several hours after surgery can reduce swelling and relieve discomfort. The nurse advises the patient to wear snug cotton underwear or a scrotal support for added comfort and support. Explanation of expected discoloration of the scrotal skin and superficial swelling may alleviate anxiety and concerns. These conditions may be relieved by sitz baths.

Sexual intercourse may be resumed as desired, usually after 1 week. Fertility remains for a varying time after vasectomy until the spermatozoa stored distally in the seminal vesicles have been evacuated. Sterility is often achieved after 10 to 20 ejaculations following the vasectomy procedure but may take longer. A reliable method of contraception should be used until infertility is confirmed by examination of an ejaculate specimen in the urologist's office at a follow-up appointment, usually 4 to 8 weeks after the vasectomy.

Vasovasostomy (Sterilization Reversal)

Although men choosing to undergo vasectomy should not consider the surgical procedure as reversible, microsurgical techniques can be used to reverse a vasectomy (vasovasostomy) and restore patency to the vas deferens. Many men have sperm in their ejaculate after a reversal, and 50% to 70% can impregnate a partner. The success of the procedure depends on the vasectomy method performed and the amount of time since the vasectomy. The procedure can be very costly, is not covered by insurance, is not permanent with occlusion of the vas recurring 2 or more years after vasovasostomy, and results in sperm counts at lower than prevasectomy levels (Lindsey, Herrela, Goodman, et al., 2015).

Semen Cryopreservation (Sperm Banking)

Storing fertile semen in a sperm bank before a vasectomy is an option for men who experience a major life change and may want to father a child at a later time. In addition, if a man has just sustained an injury to the spinal cord or is about to undergo a procedure or treatment (e.g., radiation therapy to the pelvis, chemotherapy, orchiectomy) that may affect his fertility, sperm banking may be considered (Kelvin, 2015). This procedure usually requires several visits to the facility where the sperm is stored under hypothermic conditions. The semen is obtained by masturbation and collected in a sterile container for storage. Insurance carriers rarely cover the cost of semen collection and banking. The costs of semen cryopreservation vary according to facility, method of sperm retrieval, number of specimens, and length of time in storage, making the process cost-prohibitive for some men.

DISORDERS AFFECTING THE PENIS

Phimosis

Phimosis is a condition in which the foreskin (prepuce) cannot be retracted over the glans in uncircumcised males. With the decrease in routine circumcision of newborns, early instruction should be given to parents about cleansing the foreskin and the need for retraction to cleanse the glans. If the glans is not cleaned, secretions accumulate, causing inflammation of the glans penis (balanitis), which can later lead to adhesions and fibrosis. Phimosis often develops in adults as a result of inflammation, edema, and constriction because of poor hygiene or underlying medical conditions such as diabetes. The thickened secretions (smegma) can become encrusted with urinary salts and calcify, forming calculi in the prepuce and increasing the risk of penile carcinoma. Treatment for phimosis secondary to inflammation is the application of steroidal cream to the foreskin to soften and correct the narrowness, resulting in decreased constriction. Although phimosis is the most common indication for adult circumcision, it is rarely necessary to surgically correct the condition by loosening or removing the foreskin.

Paraphimosis is a condition in which the foreskin, once retracted over the glans, cannot be returned to its usual position. Chronic inflammation under the foreskin leads to formation of a tight ring of skin when the foreskin is retracted behind the glans, causing venous congestion, edema, and enlargement of the glans, which makes the condition worse. As the condition progresses, arterial occlusion and necrosis of the glans may occur. Paraphimosis usually can be treated by firmly compressing the glans for 5 minutes to reduce the tissue edema and size and then pushing the glans back while simultaneously moving the foreskin forward (manual reduction). The constricting skin ring may require incision under local anesthesia. Circumcision is usually indicated after the inflammation and edema subside (Keane & Graham, 2016).

Cancer of the Penis

Penile cancer is rare, occurring in less than 1% of cancers among men in the United States. It accounts for an estimated 1290 new cancer cases and 300 expected deaths each year (ACS, 2015). The 5-year survival rates for cancer localized to the penis approaches 80%, but this statistic drops to 52% if the lymph nodes are involved and to 18% if the cancer has spread beyond the inguinal lymph nodes (Keane & Graham, 2016). Penile cancer is much more common in some parts of Africa and South America, where it accounts for up to 10% of cancers in men. In rural India, the rate of penile cancer is higher (3/100000 men) than in urban population (0.7-2.3/100000), which accounts more than 6% of all cancers in Indian population.

Because the penis contains different cell types, penile cancer can arise in each type of cell, which determines the prognosis. Types of penile cancer include squamous cell carcinoma (most common; 95% of cases), epidermoid penile cancer, verrucous carcinoma, adenocarcinoma, in situ carcinomas (erythroplasia of Queyrat and Bowen disease), basal cell penile cancer, melanoma, and sarcomas (McDougal et al., 2016). Several risk factors for penile cancer have been identified, including lack of circumcision, poor genital hygiene, phimosis, HPV, smoking, ultraviolet light treatment of psoriasis on the penis, increasing age (two thirds of cases occur in men older than 65 years), penile metastasis secondary to bladder cancer, lichen sclerosus, and balanitis xerotica obliterans (Kumar, Bhattacharyya, Mandal, et al., 2014); (Turner, Drudge-Coates, & Henderson, 2013). However, the exact cause remains unclear. Because penile cancer is rare, there has been little improvement in diagnostic and staging tests, understanding of risk factors, and development of treatment modalities.

Clinical Manifestations

The penile lesion usually alerts the patient to the presence of penile cancer; however, men may delay seeking treatment for more than a year because of embarrassment, fear, or lack of understanding. Common clinical presentations are a painless lump, ulcer, or wartlike growth on the skin of the penis; a change in skin color such as a red rash, bluish growths, or whitish patches; and malodorous and persistent discharge in late stages.

Assessment and Diagnostic Findings

Penile cancer involves the glans most frequently (48%), followed by lesions of the foreskin (21%), the coronal sulcus (6%), the penile shaft (less than 2%), the urethra, and regional or distant lymph nodes (McDougal et al., 2016). A thorough physical examination is necessary, including assessment and palpation of the penis and the inguinal lymph nodes. The size, location, borders, consistency, fixation, and character and time of onset of the penile lesions should be noted. Incisional or excisional biopsy is performed to determine the cell types of the penile cancer. Further staging tests using ultrasonography, MRI, or CT scan may be obtained to determine the extent of local lesions, if metastatic disease is present, and treatment options.

Prevention

The best way to reduce the risk of penile cancer is to avoid known risk factors whenever possible (ACS, 2015). Avoidance of sexual practices that are likely to result in HPV infection may reduce the risk of penile cancer. Gardasil, a vaccine that protects against infection with HPV, the cause of 90% of genital warts, is recommended for males 9 through 26 years old (CDC, 2015). Although uncircumcised men have a greater incidence of penile cancer than circumcised men, the more important factor in preventing penile cancer is good genital hygiene. Circumcision is not recommended as a prevention strategy (ACS, 2015).

Medical Management

Treatment varies depending on the type and stage of penile cancer, location of the lesion, overall physical health, and personal preferences about treatments and side effects. Treatment emphasis is on minimizing the cancer's invasiveness and preserving organ function (Khoo, 2013). The goal of treatment in invasive penile cancer is complete excision with adequate margins. Surgery is the most common treatment method used in all forms of the disease. Depending on the stage and invasiveness of the cancer, therapeutic options may include simple excision, electrodesiccation and curettage, cryosurgery, Mohs surgery (microscopically controlled surgery), yttrium aluminum garnet (YAG) laser surgery, wide local excision, circumcision, and surgical removal of part of the penis or the entire penis (penectomy). Organ-sparing surgical approaches are preferable. Partial penectomy is preferred to total penectomy because patients can then participate in sexual intercourse, stand for urination, and maintain cosmesis.

Modern reconstructive surgical techniques are providing more options for patients. The shaft of the penis can still respond to sexual arousal with an erection and has the sensory capacity for orgasm and ejaculation. Total penectomy is indicated if the tumor is not amenable to conservative treatment. After a total penectomy, the patient may still experience orgasm with stimulation of the perineum and scrotal area.

Topical chemotherapy with 5-fluorouracil cream or biologic therapy may also be effective. Radiation therapy is used to treat small squamous cell carcinomas of the penis and for palliation in advanced tumors or cases of lymph node metastasis.

Penile cancer spreads primarily to the inguinal lymph nodes; thus, appropriate lymph node management plays a significant role in survival. Because enlarged inguinal lymph nodes are caused by inflammation in 50% of cases, patients who present with enlarged lymph nodes should undergo treatment of the primary lesion followed by a 4- to 6-week course of oral broad-spectrum antibiotic agents. Persistent enlarged lymph nodes after antibiotic therapy should be considered to be metastatic disease and treated with either a sentinel lymph node biopsy (to determine presence of cancer) or with pelvic and bilateral inguinal lymph node dissection. If extensive pelvic lymph node involvement is present, the patient should receive adjuvant or neoadjuvant chemotherapy and postoperative radiation therapy (Khoo, 2013).

Priapism

Priapism, a relatively uncommon disorder, is defined as a persistent penile erection that may or may not be related to sexual stimulation. The penis becomes large, hard, and painful. Priapism results from either neural or vascular causes, including sickle cell disease, leukemic cell infiltration, polycythemia, spinal cord tumors or injury, and tumor invasion of the penis or its vessels. It may also occur with use of vasoactive agents that affect the central nervous system, antihypertensive agents, antipsychotic and antidepressant medications, substances injected into the penis to treat erectile dysfunction, alcohol, and cocaine. There are three forms of priapism: ischemic (veno-occlusive; low flow), nonischemic (high flow), and stuttering (intermittent).

The ischemic form, which is described as nonsexual, persistent erection with little or no cavernous blood flow, must be treated promptly to prevent permanent damage to the penis. The goal of therapy is to improve venous drainage of the corpora cavernosa to prevent ischemia, fibrosis, and impotence. The initial treatment is directed at relieving the erection, preventing penile damage and simultaneously treating the underlying disease. Recommended treatment is aspiration of the corpora cavernosa (with or without irrigation) or intracavernous injection of sympathomimetic agents (e.g., phenylephrine). Repeated injections may be needed to resolve priapism. Surgical shunts are used to reestablish penile circulation if repeated injections of the sympathomimetic are ineffective (McDougal et al., 2016).

Nonischemic priapism and stuttering are generally not considered emergencies and often resolve without treatment. Conservative treatment (e.g., application of ice and site-specific compression to the injury) may be used. If repeated episodes occur, surgical shunting is considered. Patients with the intermittent form of priapism may be instructed in intracavernosal self-injection of phenylephrine.

Peyronie's Disease

Peyronie's disease is an acquired, benign condition that involves the buildup of fibrous plaques in the sheath of the corpus cavernosum. These plaques are not visible when the penis is relaxed. However, when the penis is erect, curvature occurs that can be painful and can make sexual intercourse difficult or impossible. Peyronie's disease typically begins between 45 and 65 years of age. Medical management in the first year of active disease includes systemic, topical, intralesional, or extracorporeal techniques, with 50% of men experiencing spontaneous resolution. Surgical removal of mature plaques is used to treat severe disease. Patients should be fully informed of available treatment options and their likely outcomes (McDougal et al., 2016).

Urethral Stricture

Urethral stricture is a condition in which a section of the urethra is narrowed. It can occur congenitally or from a scar along the urethra. Traumatic injury to the urethra (e.g., from instrumentation or infections) can result in strictures that restrict urine flow and decrease the urinary stream, leading to spraying or double stream, postvoiding dribbling, and dilation of the proximal urethra and prostatic ducts. Prostatitis is a common complication. Treatment involves dilation of the urethra or, in severe cases, urethrotomy (surgical removal of the stricture). Antimicrobial agents are necessary for resolution of UTIs, followed by long-term prophylactic therapy until the stricture is corrected. Treatment should not be considered successful until at least 1 year has passed, because strictures may recur anytime during that period (Keane & Graham, 2016).

Circumcision

Circumcision is the surgical excision of the foreskin (prepuce) of the glans penis. According to the CDC, approximately 80% of men are circumcised in the United States, and circumcision is one of the oldest surgical procedures performed worldwide (CDC, 2015). In India, 13.5% of men are circumcised (Morris, Wamai, Henebeng, et al., 2016). There is controversy about the guidelines to determine the validity of male circumcision as a prevention of disease transmission (Earp, 2015). In adults, circumcision may be indicated as part of treatment for phimosis, paraphimosis, and recurrent infections of the glans and foreskin. It also may be performed at the patient's request.

The primary method of circumcision in adults is surgical excision. Postoperatively, a petrolatum (Vaseline) gauze dressing is applied and changed as indicated. The patient is observed for bleeding. Because considerable pain may occur after circumcision, analgesic agents are given as needed.

Abnormal Breast Conditions in Males

Gynecomastia

Gynecomastia is the most common breast condition in the males. Adolescent boys can be affected because of hormones secreted by the testes. This type of gynecomastia is virtually always benign and resolves spontaneously in 1 to 2 years. Gynecomastia can also occur in older men and usually presents as a firm, tender mass underneath the areola. In these patients, gynecomastia may be diffuse and related to the use of certain medications (e.g., digitalis, ranitidine [Zantac]). It may also be associated with certain conditions, including feminizing testicular tumors,

infection in the testes, and liver disease resulting from factors such as alcohol abuse or a parasitic infection.

Patients in their late teens to late 40s presenting with idiopathic (unknown cause) gynecomastia should have a testicular examination and possibly a testicular ultrasound performed. Treatment of the enlarged breast tissue is based on patient preference and is usually reserved for those men who cannot tolerate the cosmetic appearance of the breast or who have severe pain associated with the condition. Mammography and ultrasound are utilized if there is a concern about malignancy. Observation is acceptable in most cases because gynecomastia may resolve on its own. Surgical removal of the tissue through a small incision around the areola is the best treatment option. Liposuction performed by a plastic surgeon is another possibility, although this does not allow for pathologic examination of the tissue

CRITICAL THINKING EXERCISES

1. Identify the priorities, approach, and techniques you would use to perform a health assessment on a 24-year-old male graduate student from a tribal community of North East India who speaks Hindi as a second language and who has been diagnosed with squamous cell carcinoma of the penis. How will your priorities, approach, and techniques integrate cultural considerations into the nursing care?
2. A 65-year-old male patient who has a history of thyroid disease, hypertension, and type II diabetes is diagnosed with prostate cancer with a Gleason score of 4 post biopsy. What evidence-based information would you provide to the patient and his spouse to assist in preventing postoperative complications during the recovery period? Identify the evidence for and the criteria used to evaluate the strength of the evidence for the nursing care identified.
3. You are caring for a 30-year-old man who has been recently advised by his urologist to undergo a circumcision due to repeated episodes of epididymitis. What is the evidence base for his treatment options? Identify the criteria used to evaluate the strength of the evidence. How would you explain the various treatment options to the patient and his significant other?

Burns, Reconstruction, and Cosmetic Surgery

Chapter 47 Assessment and Management of Burn Injury, Reconstruction, and Cosmetic Surgery 1509

CHAPTER 47

Assessment and Management of Burn Injury, Reconstruction, and Cosmetic Surgery

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the factors that affect the severity of burn injury.
2. Describe the local and systemic effects of a major burn injury.
3. Compare priorities of care and potential complications for each phase of burn recovery.
4. Plan fluid replacement requirements during the emergent/resuscitative phase of a burn injury.
5. Discuss the nurse's role in burn wound management during the acute/intermediate phase of burn care.
6. Use the nursing process as a framework of care for the patient with burns.
7. Recognize the psychosocial challenges associated with burn injuries and identify strategies for intervention.
8. Identify the management and nursing care of patients undergoing plastic and cosmetic procedures.

GLOSSARY

autograft: a graft derived from one part of a patient's body and used on another part of that same patient's body
carboxyhemoglobin: a compound of carbon monoxide and hemoglobin, formed in the blood with exposure to carbon monoxide
collagen: a protein present in skin, tendon, bone, cartilage, and connective tissue
contracture: shrinkage of burn scar through collagen maturation
débridement: removal of foreign material and devitalized tissue until surrounding healthy tissue is exposed
derma filler: substances used to augment soft tissues to replace the lost subcutaneous fat
donor site: the area from which skin is taken to provide a skin graft for another part of the body
eschar: devitalized tissue resulting from a burn or wound
escharotomy: a linear excision made through eschar to release constriction of underlying tissue
excision: surgical removal of tissue
fasciotomy: an incision made through the fascia to release constriction of underlying muscle
gender reassignment: a gender affirmation surgery that involves genital reconstruction to change the genitalia from one gender to another
homograft: a graft transferred from one human (living or cadaveric) to another human; also called *allograft*
liposuction: a surgical intervention in which excess subcutaneous fat is removed using special cannula to achieve aesthetic body contour
skin rejuvenation: measures to bring back the lost contour and glow
xenograft: a graft obtained from an animal of a species other than that of the recipient (e.g., pigskin); also called *heterograft*

Introduction

Burn injuries are painful, costly, disfiguring, require intensive and extensive rehabilitation therapy, and are often associated with long-term disability. Advances in burn care that include optimal fluid resuscitation, infection control, early excision and grafting, an enhanced team approach, and the emergence of specialized burn centers have contributed to significant improvements in morbidity and mortality of patients with burns (Meyerson, Coffey, Jones, et al. 2015); (Sen, Palmieri, & Greenhalgh, 2015). The role of the nurse in the interdisciplinary treatment team includes provision of holistic evidence-based care during all phases of burn injury recovery to optimize patient outcomes.

Overview of Burn Injury

Incidence

A burn injury can affect people of all ages and socioeconomic groups. It is estimated that 300,000 deaths occur all over the globe due to burns. Out of this >95% deaths occur in middle and low income countries of the South East Asia Region. In India, 7 million people sustain burn injuries every year. Out of this, 0.14 million people die and 2.4 lakh people become crippled. A higher proportion of females die than males (Bhansali, Gandhi, Sahastrabudhe et al., 2017).

A long-term study done in a tertiary care center showed that 95% of burns were due to thermal and scalds injury. 3.8% sustained electrical burns and only 0.2% suffered chemical burns. Out of the 3179 patients admitted with burns, 54.51% of them died. Death among female patients was 40% more than that of males. Mortality rate was higher with older people. The study revealed that the survival rate is dependent on the percentage of BSA. The survival rate for patients with 30–52% BSA was 44% whereas for patients with BSA above 52–80%, survival rate reduced to mere 3% (Bhansali, et al., 2017).

Patients with burns have particularly prolonged hospital lengths of stay (LOS). Many patients require multiple surgical interventions, extensive pain control, immobilization and rehabilitation, and prolonged intravenous (IV) medication regimens, particularly with antibiotics and opioids.

Gerontologic Considerations

The skin of the older adult is thinner and less elastic, which affects the depth of injury and its ability to heal. Delayed wound healing, another consequence of aging, is associated with higher morbidity and mortality (Nitzschke, Aden, Serio-Melvin, et al., 2014). Pulmonary function becomes impaired with age; therefore, airway exchange, lung elasticity, and ventilation may be altered and can be exacerbated by a history

of smoking. Decreased cardiac output, coronary artery disease, and decreased cardiovascular compensatory response may increase the risk of complications in older adult patients with burn injuries. There may be a fine line between adequate fluid resuscitation and fluid overload in this population. Decreased kidney and hepatic function can impact medication dosing due to altered medication clearance. Malnutrition may impact morbidity and mortality in older adults, especially those who are institutionalized. Additionally, older patients may have varying degrees of mental capacity on admission or through the course of care, making assessment of pain, anxiety, and delirium a challenge for the burn team.

A recent retrospective review of 1461 patients with burns admitted to a burn center between 2006 and 2015 revealed the Lethal Dose 50 (LD50) (i.e., lethal burn dose) for patients over 65 years of age is 35% of the TBSA, unchanged in the last 30 years, despite advances in burn care. Although there was no significant difference in incidence of pneumonia, bacteremia, sepsis, wound infection, kidney injury, abdominal compartment syndrome (ACS), acute respiratory distress syndrome (ARDS), or deep vein thrombosis (DVT), there was a statistical increase in LOS, gastrointestinal (GI) bleeding, and mortality when compared to patients less than 65 years of age. Furthermore older adult patients displayed impaired capacity for wound healing, impaired immune response, increased risk for multiple organ failure, an inability to respond to stressors, and profound alterations in metabolism (Jeschke, Patsouris, Stanojcic, et al., 2015).

Comorbidities and the resultant treatment polypharmacy (i.e., multiple medication prescriptions) contribute to in-hospital complications as well as increase the need for discharge to a facility other than the patient's home after acute recovery (Justiniano, Coffey, Evans, et al., 2015). Nurses need to assess an older adult patient's ability to safely perform activities of daily living (ADLs), assist older adult patients and families to modify their environment to ensure safety, and make referrals as needed.

Prevention

Burns are preventable. An important goal of nurses in community and home settings is to provide education about the prevention of burn injury (see Chart 47-1). Nurses should capitalize on the teachable moment, an opportunity using a recent injury event, as a prime time people "are likely to be more receptive to accept guidance on how to change their behavior to avoid future injury" (Klas, Smith, Matherly, et al., 2015, p. 434). High-risk behaviors such as alcohol consumption and alcohol abuse often precipitate many burn injuries (Sen et al., 2015). The World Health Organization (WHO) recommends heightened awareness of the burden of burn injury and risk factors as imperatives to develop an effective burn prevention program (WHO, 2014).

Outlook for Survival and Recovery

WHO (2014) estimated 265,000 annual deaths worldwide are caused by burns, the majority occurring in middle- to low-income populations, while nonfatal burns are a leading cause of morbidity including disfigurement, disability, and social stigma. The strongest predictors for mortality in burn injuries included increased percent of TBSA burned, presence of inhalation injury, and increased age. Provision of evidenced-based, multidisciplinary, holistic care is crucial to improving both survival and recovery, culminating in re-integration of the survivor into society.

Chart 47-1 HEALTH PROMOTION

Burn Prevention

- Advise that matches and lighters be kept out of the reach of children.
- Emphasize the importance of never leaving children unattended around fire or in bathroom/bathtub.
- Educate about the installation and maintenance of smoke and carbon monoxide detectors on every level of the home and changing batteries annually on birthday.
- Recommend the development and practice of a home exit fire drill with all members of the household.
- Advocate setting the water heater temperature no higher than 48.9°C (120°F).
- Educate about the perils of smoking in bed, smoking while using home oxygen, or falling asleep while smoking.
- Caution against using flammable liquids to start fires and/or throwing flammable liquids onto an already burning fire.
- Warn of the danger of removing the radiator cap from a hot car engine.
- Recommend avoidance of overhead electrical wires and underground wires when working outside.
- Advise that hot irons and curling irons be kept out of the reach of children.
- Discourage running electric cords under carpets or rugs.
- Recommend storage of flammable liquids well away from a fire source, such as a pilot light.
- Educate about the importance of being aware of loose clothing when cooking over a stovetop or flame.
- Recommend having a working fire extinguisher in the home and knowing how to use it.

Great strides in research on treatment have helped to increase the survival rate of patients with burn injuries. Long-term outcomes can now be evaluated because patients with very large burns are surviving their injuries. Improvements in fluid resuscitation, infection control, nutrition delivery, early burn excision (i.e., surgical removal of tissue), wound closure, modulation of the metabolic response, and development of burn centers have contributed to the survivability and recovery from burn injuries (Rousseau, Massion, Laungani, et al., 2014); (Snell, Loh, Mahambrey, et al., 2013). Continued research and advances in the areas of critical care, rehabilitation, and psychosocial and scar management are essential for continued progress in burn care.

Severity

The severity of each burn injury is determined by multiple factors. These factors include age of the patient; depth of the burn; amount of surface area of the body that is burned; the presence of inhalation injury; presence of other injuries; location of the injury in areas such as the face, the perineum, hands, or feet; and the presence of comorbid conditions. Even in specialized burn centers, adults with more than 40% TBSA burned are at high risk for mortality and morbidity (Jeschke et al., 2015). Careful assessment enables the burn team to estimate the likelihood of survival and develop an individualized plan of care for each patient.

Age

Young children and older adults continue to have increased morbidity and mortality when compared to other age groups with similar injuries and present a challenge for the burn team. Thinner skin at both ends of the age spectrum leads to deeper

burns with more complications. This is an important factor when determining the severity of injury and possible outcome for the patient.

Burn Depth

Burns are classified according to the depth of tissue destruction as depicted in Table 47-1. First-degree burns are superficial injuries that involve only the outermost layer of skin. These burns are erythematous, but the epidermis is intact; if rubbed, the burned tissue does not separate from the underlying dermis. This is known as a negative Nikolsky's sign. A typical first-degree burn is a sunburn or superficial scald.

Second-degree burns involve the entire epidermis and varying portions of the dermis. They are painful and are typically associated with blister formation. Healing time depends on the depth of dermal injury and typically ranges from 2 to 3 weeks. Hair follicles and skin appendages remain intact.

Third-degree (full-thickness) burns involve total destruction of the epidermis, dermis, and, in some cases, damage of underlying tissue. Wound color ranges widely from pale white to red, brown, or charred. The burned area lacks sensation because nerve fibers are damaged. The wound appears leathery and dry due to the destruction of the microcirculation; hair follicles and sweat glands are destroyed. The severity of this burn is often deceiving to patients because they have no pain in the injury area (see Fig. 47-1).

Fourth-degree burns (deep burn necrosis) are those injuries that extend into deep tissue, muscle, or bone (see Fig. 47-2) (Kearns, Cairns, Holmes, et al., 2013).

Figure 47-1 • Third-degree (full-thickness) burn to arm and upper back with surrounding second-degree (partial-thickness) burn. Used with permission from University of Texas Medical Branch, Galveston, TX.

Burn depth determines whether spontaneous re-epithelialization will occur. Determining burn depth can be difficult even for the experienced burn care provider. The following factors are considered in determining the depth of a burn: how the injury occurred, causative agent (such as flame or scalding liquid), temperature and duration of contact with the causative agent, and thickness of the skin at the injury site.

TABLE 47-1 Characteristics of Burns According to Depth

Causes	Skin Involvement	Clinical Manifestations	Wound Appearance	Recuperative Course and Treatment
First Degree (Superficial)				
Sunburn Low-intensity flash Superficial scald	Epidermis	Tingling Hyperesthesia (hypersensitivity) Pain that is soothed by cooling Peeling Itching	Reddened; blanches with pressure; dry Minimal or no edema Possible blisters	Complete recovery within a few days Oral pain medications, cool compresses, skin lubricants (e.g., ointments, emollients); topical antimicrobial agents not indicated
Second Degree (Partial Thickness)				
Scalds Flash flame Contact	Epidermis, portion of dermis	Pain Hyperesthesia Sensitive to air currents	Blistered, mottled red base; disrupted epidermis; weeping surface Edema	Recovery in 2–3 weeks Some scarring and depigmentation possible; may require grafting
Third Degree (Full Thickness)				
Flame Prolonged exposure to hot liquids, Electric current or Chemical Contact	Epidermis, dermis, and sometimes subcutaneous tissue; may involve connective tissue, and muscle	Insensate Shock Myoglobinuria (red pigment in urine) and possible hemolysis (blood cell destruction) Possible contact points (entrance or exit wounds in electrical burns)	Dry; pale white, red brown, leathery, or charred Coagulated vessels may be visible. Edema	Eschar may slough Grafting necessary Scarring and loss of contour and function
Fourth Degree (Full Thickness That Includes Fat, Fascia, Muscle, and/or Bone)				
Prolonged exposure or high voltage electrical injury	Deep tissue, muscle and bone	Shock Myoglobinuria (red pigment in urine) and possible hemolysis (blood cell destruction)	Charred	Amputations likely Grafting of no benefit, given depth and severity of wound(s)

Figure 47-2 • Fourth-degree burn to second digit. Used with permission from University of Texas Medical Branch, Galveston, TX.

Extent of Body Surface Area Injured

Various methods are used to estimate the TBSA affected by burns; among them are the rule of nines, the Lund and Browder method, and the palmer method. These tools assist the treatment team in making decisions about the plan of care, which may include transfer of the patient to a burn center. Burn centers are hospital based and are specially equipped with the resources and personnel to treat patients with burns from the time of injury through their rehabilitation. Burn center designation is jointly conferred by the ABA and the American College of Surgeons (ABA, 2014). Chart 47-2 provides the criteria for referral to a burn center.

Rule of Nines

The most common method used to estimate the extent of burns in adults is the rule of nines (see Fig. 47-3). This system is based on anatomic regions, each representing approximately 9% of the TBSA, allowing clinicians to quickly obtain an estimate of burn size. If a portion of an anatomic area is burned, the TBSA is calculated accordingly—for example, if approximately half of one arm were burned, the TBSA burned would be 4.5% (Kearns et al., 2013).

Chart 47-2

American Burn Association Criteria for Referral to a Burn Center

- Partial-thickness burns covering 10% of total body surface area or greater
- Burns involving the face, hands, feet, genitalia, perineum, or major joints
- Third-degree burns
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders
- Any patients with burns and concomitant trauma
- Children with burn injuries in facilities that do not specialize in pediatric care
- Patients who will require special social, emotional, or long-term rehabilitation

Adapted from American Burn Association. (2011). Advanced burn life support (ABLS) course provider manual 2011. Chicago, IL: Author.

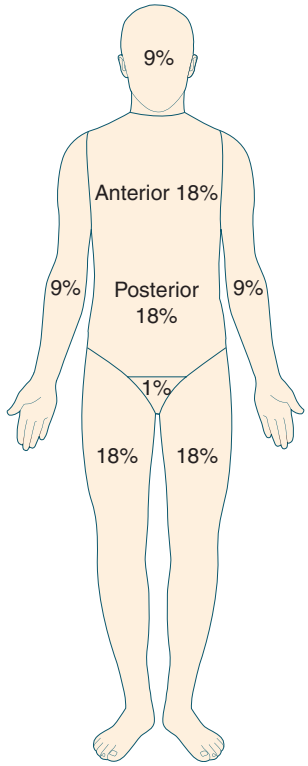

Figure 47-3 • The rule of nines. Estimated percentage of total body surface area (TBSA) in the adult is calculated by sectioning the body surface into areas with a numerical value related to nine. (*Note*: The anterior and posterior head total 9% of TBSA.)

Lund and Browder Method

A more precise method of estimating the extent of a burn is the Lund and Browder method (Kearns et al., 2013), which recognizes the percentage of surface area of various anatomic parts, especially the head and legs, as it relates to the age of the patient. By dividing the body into very small areas and providing an estimate of the proportion of TBSA accounted for by each body part, clinicians can obtain a reliable estimate of TBSA burned. The initial evaluation is made on arrival of the patient to the hospital and should be revised within the first 72 hours, because demarcation of the wound and its depth present themselves more clearly by this time. The Lund and Browder chart is readily available in both printed and electronic formats.

Palmer Method

In patients with scattered burns, the Palmer method may be used to estimate the extent of the burns. The size of the patient's hand, including the fingers, is approximately 1% of that patient's TBSA (ABA, 2011).

Pathophysiology

Burn injuries are very traumatic injuries as the initial injury can evolve and worsen over time. Burn injury is the result of a chemical injury or heat transfer from one site to another, causing tissue destruction through coagulation, protein denaturation, or ionization of cellular contents. The burn wound is not homogenous; rather, tissue necrosis occurs at the center of the

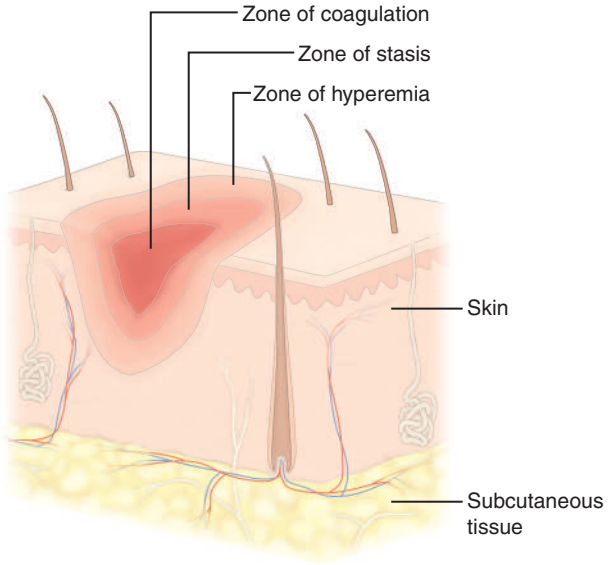

Figure 47-4 • Zones of burn injury. Each burned area has three zones of injury. The zone of coagulation (the innermost area, where cellular death occurs) sustains the most damage. The zone of stasis (the middle area) has a compromised blood supply, inflammation, and tissue injury. The zone of hyperemia (the outermost area) sustains the least damage.

injury with regions of tissue viability toward the periphery. The central area of the wound is termed the *zone of coagulation* due to the characteristic coagulation necrosis of cells that occurs (see Fig. 47-4). The surrounding zone, the *zone of stasis,* describes an area of injured cells that may remain viable but, with persistent ischemia, will undergo necrosis within 24 to 48 hours. The outermost zone, the *zone of hyperemia,* sustains minimal injury and may fully recover spontaneously over time.

The skin and the mucosa of the upper airways are the most common sites of tissue destruction, although deep tissues, including the viscera, can be damaged by electrical burns (see Chart 47-3) or by prolonged contact with a heat or chemical source. The release of local mediators and changes in blood flow, tissue edema, and infection can cause progression of the burn injury.

Another potential mechanism of burn injury is radiation exposure. This has received increased attention because of threats of terrorism and recent world events. Radiation injuries produce two detrimental effects. The first is a thermal effect, which results in cutaneous burn injuries. The second effect is damage to the cellular deoxyribonucleic acid (DNA), which may be localized or affect the whole body. Morbidity and mortality are dose dependent (see Chapter 61). Treatment for the cutaneous injury is the same as other burns discussed in this chapter.

The depth of a burn injury depends on the temperature of the burning agent and the duration of contact with the agent. In adults, exposure to temperatures of 54°C (130°F) for 30 seconds will result in burn injury. At 60°C (140°F), tissue destruction occurs in 5 seconds (this is a common setting for home water heaters; see Chart 47-1 for discussion of appropriate water heater setting). At 71°C (160°F) or higher, a full-thickness burn occurs instantaneously (ABA, 2011).

Major burn injuries, those that affect more than 30% TBSA, produce both local and systemic effects characterized by burn wound edema, generalized edema formation in noninjured tissue, increased metabolic rate (hypermetabolism), hyperdynamic circulation, increased oxygen and glucose consumption, catabolism of muscle and bone, immune dysfunction, insulin resistance, and impaired organ perfusion (Flores, Stockton, Roberts, et al., 2015); (Snell et al., 2013). Severe injuries ultimately encompass changes in pathophysiology of all body systems as presented in Table 47-2 and Figure 47-5. Initially, these responses are compensatory adaptive responses to the burn injury, but quickly become counterproductive events negatively impacting recovery (Abdullahi & Jeschke, 2014). These pathologic responses are also seen in trauma, but the magnitude, duration, and severity are significantly higher with burn injuries.

TABLE 47-2 Pathophysiologic Changes with Severe Burns

Body System	Physiologic Changes
Cardiovascular	Cardiac depression, edema, hypovolemia
Pulmonary	Vasoconstriction, edema
Gastrointestinal	Impaired motility and absorption, vasoconstriction, loss of mucosal barrier function with bacterial translocation, increased pH
Kidney	Vasoconstriction
Other	Altered thermoregulation, immunodepression, hypermetabolism

Adapted from Abdullahi, A., & Jeschke, M. G. (2014). Nutrition and anabolic pharmacotherapies in the care of burn patients. Nutrition in Clinical Practice, 29(5), 621–630; Snell, J. A., Loh N. W., Mahambrey, T, et al. (2013). Clinical review: The critical care management of the burn patient. Critical Care, 17(5), 241.

Cardiovascular Alterations

When a burn injury occurs, there is an immediate decrease in cardiac output that precedes the loss of plasma volume, although the exact mechanism why this occurs is unknown. Due to vasoconstrictive compensatory responses secondary to plasma volume loss, the workload of the heart and oxygen demand increase.

Hypovolemia is the immediate consequence of ensuing plasma volume loss and results in decreased perfusion and oxygen delivery. As fluid loss continues due to capillary leakage, and vascular volume decreases, cardiac output continues to decrease and the blood pressure drops. This is the onset of burn shock. Burn shock is initially a type of hypovolemic shock. The systemic inflammation causes the release of free oxygen radicals that increase capillary permeability, causing increased plasma loss and subsequent peripheral edema. As a compensatory response to intravascular fluid loss, the sympathetic nervous system releases catecholamines, resulting in an increase in peripheral resistance (vasoconstriction) and an increase in pulse rate that further decreases tissue perfusion.

Prompt, appropriate fluid resuscitation maintains the blood pressure in the low to normal range and improves cardiac output (see later discussion). But, despite adequate fluid resuscitation, cardiac filling pressures (central venous pressure, pulmonary artery pressure, and pulmonary artery wedge pressure) remain low during the initial burn shock period. Unlike traumatic injuries, which are often characterized by blood loss, only plasma is lost in the burn injury. If adequate IV fluids are not given to maintain vascular volume, distributive shock occurs (see Chapter 8).

Generally, the greatest volume of fluid leak occurs in the first 24 to 36 hours after the burn, peaking by 6 to 8 hours. As the capillaries begin to regain their integrity, burn shock resolves and fluid returns to the vascular compartment. Intrinsic

Chart 47-3

Electrical Burns

Electrical injuries are devastating and complex burns. Heat generated by electricity is directly responsible for tissue damage, but unlike most thermal burns, visual examination is not predictive of burn size and severity. It is helpful to know the circumstances of the injury to anticipate potential tissue damage and complications. Superficial injuries present themselves as contact points on physical examination. Deep tissue injuries may not be visible on initial clinical presentation but in most circumstances should be assumed on presentation so that timely intervention may be initiated. Mechanisms of injury include flash, conductive, and lightning injury.

Flash Injury

An electrical flash generates light and heat. Injury is caused by the heat generated to exposed areas, or by flames from ignition of clothing. Flash burns are thermal burns and have fewer complications; patients with flash injuries have shorter lengths of hospital stay than those with conductive injuries.

Conductive Injury

Conductive electrical injuries occur when the current overcomes the skin's resistance and travels through the body. The amount and severity of tissue damage is directly proportional to the strength of the current (voltage), duration of contact with the source, which organs lay along the pathway of current, and whether the current is direct or alternating. Conduction of electricity through the nerves and vessels and along the outside of bones generates heat, causing damage to adjacent tissues and direct injury to the peripheral nerves. Deep muscle injury may be present without injury to superficial muscles, masking the true extent of the injury. In addition, electrical current immediately contracts muscles as it travels through the body causing possible skeletal and joint injuries in high-voltage contact. Although the majority of reported electrical injuries are high voltage (>1000 volts) injuries, significant physical and psychological morbidity also occur with low voltage (<1000 volts) injuries as well.

Entrance and exit wounds or contact points can help identify the probable current path and therefore anticipated tissue and organ involvement. Direct current (DC) travels in one direction, is associated with an explosion and likely concomitant trauma from the blast. Alternating current (AC) passes back and forth from the point of contact, through the body and back to the source many times per second and can hold the victim to it, increasing contact time. Compartment syndrome is common with electrical injuries due to the edema that results from injured tissue compounded by the large fluid volumes required for resuscitation to prevent kidney failure. As a result, invasive decompressive therapies such as fasciotomies, nerve releases, ocular releases, and laparotomies may be required.

Lightning Injury

Lightning injuries can result from a direct strike, a high-voltage DC injury that is usually fatal, or a side flash wherein the current discharges from an object nearby through the air to an adjacent object or person. Side flashes are the most common cause of injury and result in immediate deep polarization of the entire myocardium with possible cardiac arrest. Respiratory arrest is also expected because electric current can temporarily inactivate the brain's respiratory center. People struck by lightning may suffer from various debilitating long-term symptoms including memory loss, attention deficits, sleep disorders, chronic pain, numbness, dizziness, stiffness in joints, irritability, fatigue, weakness, muscle spasms, and depression.

Management

Resuscitation fluid calculations based on total body surface area are inaccurate in conductive electrical injuries, including some lightning injuries. It is difficult to quantify the extent of tissue injury without surgical exploration because the damage may not be visible on physical examination. Serum creatinine kinase levels are useful in determining the degree of muscle injury in the early phases of care. Myoglobinuria, common with muscle damage, may cause kidney failure if not treated. IV fluid administration titrated to a higher target of urine output per hour than usual may be indicated until the urine is no longer red. It is common practice to add 50 mEq of sodium bicarbonate per liter of IV fluid in an effort to assist in alkalinizing the urine. Serum myoglobin and urine myoglobin levels may be monitored as indicators of the need for continued resuscitation.

Finally, the surgical treatment of an electrical injury is as complex as the injury itself. Vasculature is commonly affected; thus, progressive tissue necrosis occurs over time. Sequential surgical débridement may be necessary, using caution to preserve viable tissue.

diuresis will begin and continue for several days to 2 weeks in the previously healthy adult.

Fluid and Electrolyte Alterations

Edema forms rapidly after a burn injury. A superficial burn will cause edema to form within 4 hours, whereas a deeper burn will continue to form edema up to 18 hours post-injury. This is caused by increased perfusion to the injured area in the presence of increased capillary permeability and reflects the amount of microvascular and lymphatic damage to the tissue. In burns greater than 30% TBSA, inflammatory mediators stimulate local and systemic reactions resulting in extensive shift of intravascular fluid, electrolytes, and proteins into the surrounding interstitium (Snell et al., 2013).

Nursing Alert: For patients in the emergent/resuscitative phase, nurses should do a primary survey and monitor circulation. As the taut, burned tissue becomes unyielding to the edema underneath its surface, it begins to act like a tourniquet, especially if the burn is circumferential. As edema increases, pressure on small blood vessels in the distal extremities causes an obstruction of blood flow and consequent tissue ischemia and compartment syndrome. See Chapter 38 for discussion of compartment syndrome. Patients in the acute/intermediate phase must be monitored for the development of venous thromboembolism (VTE).

Treatments for edema may include elevation of the extremity or, in severe cases, removal of eschar (i.e., devitalized tissue) via escharotomy (i.e., surgical incision through eschar), or

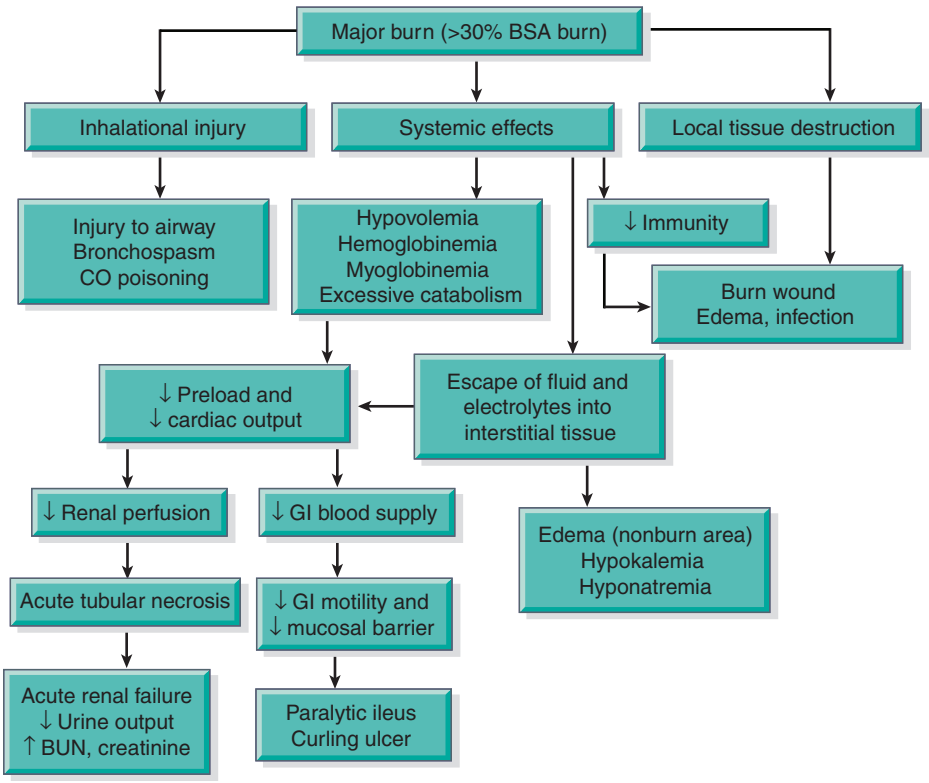

Figure 47-5 • Pathophysiology of major burn injury.

decompression of edema formation via fasciotomy (i.e., surgical incision through fascia to relieve constricted muscle) to restore tissue perfusion (see Figs. 47-6 and 47-7).

Reabsorption of edema begins at about 4 hours post-injury and is complete by 4 days post-burn injury. However, the rate of reabsorption depends on the depth of injury to the tissue. Although adequate fluid resuscitation is paramount to maintaining tissue perfusion, excessive fluid administration increases edema formation in both burned and nonburned tissue causing ischemia and necrosis.

Immediately after burn injury, hyperkalemia (excessive potassium) may result from massive cell destruction. Hypokalemia (potassium depletion) may occur later with fluid shifts and inadequate potassium replacement. Serum sodium levels vary in response to fluid resuscitation. Hyponatremia (serum sodium depletion) may be present as a result of plasma loss or may also occur during the first week of the acute phase, as water shifts from the interstitial space and returns to the vascular space.

At the time of burn injury, some red blood cells may be destroyed and others damaged, resulting in anemia. Despite

Figure 47-6 • Escharotomy of forearm. Used with permission from University of Texas Medical Branch, Galveston, TX.

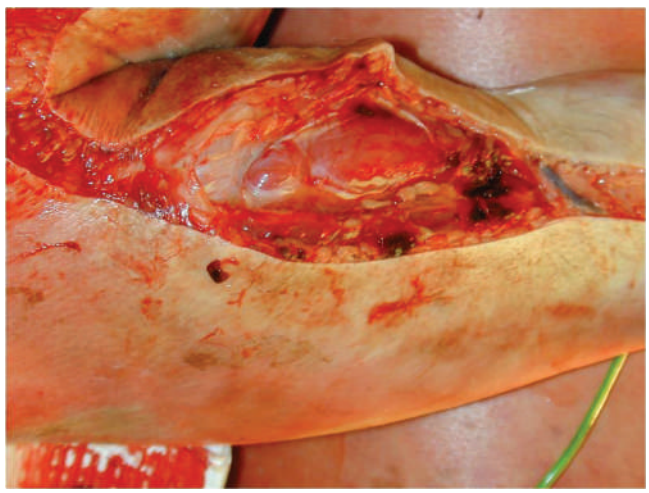

Figure 47-7 • Fasciotomy of upper arm. Used with permission from University of Texas Medical Branch, Galveston, TX.

this, the hematocrit may be elevated due to plasma loss. Abnormalities in coagulation, including a decrease in platelets (thrombocytopenia) and prolonged clotting and prothrombin times, also occur.

Pulmonary Alterations

Inhalation injury is caused by inhalation of thermal and/or chemical irritants. Inhalation injuries are categorized as upper airway injury (above the glottis) or lower airway injury (below the glottis). Injuries above the vocal cords can be thermal or chemical, whereas injuries below the vocal cords are usually chemical (ABA, 2011). Approximately 6% to 30% of patients admitted to burn centers have an inhalation injury (ABA, 2011). The presence of inhalation injury is important to recognize. History of the injury, such as a flame injury occurring in an enclosed space, and clinical signs such as singed facial hair or carbonaceous sputum should be considered indicators for the presence of a smoke inhalation injury. Bronchoscopy is considered the standard test for definitive diagnosis as initial chest x-rays appear normal. The extent of damage is directly related to the temperature and the concentration of toxic gases.

Upper Airway Injury

Upper airway injury is obstructive and is caused by severe upper airway edema from direct thermal injury or secondary edema from face or neck burns in the early post-burn period. Because of the cooling effect of rapid vaporization in the oropharynx, direct heat injury does not normally occur below the level of the glottis. However, with steam exposure, thermal injury to the lower airways is possible because the upper airway cannot effectively protect the lower airway from steam.

Lower Airway Injury

Inhalation injury below the glottis results from inhaling the products of incomplete combustion or noxious gases and is often the source of death at the scene of a fire. Smoke inhalation injuries cause loss of ciliary action, trigger an inflammatory response causing hypersecretion, and produce severe mucosal edema and possibly bronchospasm. Alveolar surfactant production is reduced, resulting in atelectasis (collapse of alveoli). Expectoration of carbon particles in the sputum is the cardinal sign of this injury.

Noxious gases, such as carbon monoxide and hydrogen cyanide, contribute to lower airway injuries. Carbon monoxide poisoning is a factor in most fatalities at the scene of a fire as it combines with hemoglobin and displaces oxygen to form carboxyhemoglobin. The affinity of hemoglobin for carbon monoxide is 200 times greater than that for oxygen, and if significant quantities of carbon monoxide are present, then tissue hypoxia will occur (ABA, 2011). Treatment is administration of 100% oxygen to displace the carbon monoxide molecules bound to hemoglobin. Hydrogen cyanide is a systemic toxin also associated with mortality. Signs and symptoms of hypoxia in light of normal arterial oxygen tension (PaO_2) is an indicator of cyanide poisoning (Snell et al., 2013).

Bronchoconstriction (caused by release of histamine, serotonin, and thromboxane [a powerful vasoconstrictor]) and chest constriction secondary to circumferential torso burns can contribute to deterioration. Even without pulmonary injury, hypoxia may be present. Early in the post-burn period, catecholamine release in response to the stress of the burn injury alters peripheral blood flow, thereby reducing oxygen delivery to the periphery. Later, hypermetabolism and continued catecholamine release lead to increased tissue oxygen consumption, which can also lead to hypoxia. To ensure that adequate oxygen is available to the tissues, supplemental oxygen may be needed. Restrictive pulmonary excursion may occur with full-thickness burns encircling the thorax resulting in decreased tidal volume. In such situations, an escharotomy may be necessary to restore adequate chest excursion.

Kidney Alterations

Kidney function may be altered as a result of decreased blood volume post-burn injury due to the compensatory response to intravascular volume loss. Adequate fluid volume replacement can restore renal blood flow, increasing the glomerular filtration rate and urine volume. Additionally, destruction of red blood cells at the injury site results in free hemoglobin in the urine. If muscle damage occurs (e.g., from electrical burns), myoglobin is released from the muscle cells and excreted by the kidneys causing the urine to be red. If there is inadequate blood flow through the kidneys caused by the hemoglobin and myoglobin occluding the renal tubules, acute tubular necrosis and acute kidney injury will occur (see Chapter 44). Increased abdominal pressure from the injury can also cause kidney ischemia.

Immunologic Alterations

The immunologic defenses of the body are greatly altered by a burn injury. The skin is the largest barrier to infection, and when it is compromised, the patient is continually exposed to the environment. The burn injury itself produces systemic release of cytokines and other substances that cause leukocyte and endothelial cell dysfunction. Burn centers provide an infection-controlled environment to protect the patient and minimize exposure to potentially harmful organisms.

Thermoregulatory Alterations

Integumentary loss also results in an inability to regulate body temperature. Patients with burn injuries may, therefore, exhibit low body temperatures in the early hours after injury. Hostler, Weaver, Ziembicki, et al. (2013) found that hypothermia (i.e., core temperature less than 36.5°C [97.7°F]), on admission of patients to the hospital was an independent predictor of mortality. Intraoperative hypothermia, exacerbated by exposure during prolonged surgeries, combined with general anesthesia's blunting of metabolic and neurologic hypothermic responses, also poses challenges to successfully treating patients with major burns (Davis, Rodriquez, Quintana, et al., 2013). Burn centers have heat panels at the bedside as additional heating sources to help maintain the patient's body temperature through environmental warming. After the initial few hours, persistent increases in baseline core temperature ensues as part of the physiologic and metabolic response to a burn injury (Snell et al., 2013).

Gastrointestinal Alterations

Patients who are critically ill, including those with burns, are predisposed to altered GI motility. Impaired enteric nerve and smooth muscle function, inflammation, surgery, medications such as vasopressors, and inadequate tissue perfusion are some causes of GI dysfunction. Indicators of GI organ ischemia include increased bladder pressure, increasing serum lactate, and feeding intolerance (Trexler, Lundy, Chung, et al., 2014). Three of the most common GI alterations in patients with burns are paralytic ileus (absence of intestinal peristalsis), Curling's ulcer, and

translocation of bacteria. Decreased peristalsis and bowel sounds are manifestations of paralytic ileus. Gastric distention and nausea may lead to vomiting; therefore, gastric decompression is advised. Gastric bleeding secondary to massive physiologic stress may be signaled by occult blood in the stool, regurgitation of "coffee ground" material from the stomach, or bloody vomitus. These signs suggest gastric or duodenal erosion (Curling's ulcer).

Patients with large TBSA burns are also at risk for life-threatening ACS due to large volumes of fluid required for resuscitation, fluid shifts to the interstitium causing edema formation, and decreased abdominal wall compliance due to eschar formation. Increased pressure in the abdominal cavity contributes to GI tract and abdominal organ ischemia (see Chapter 8).

Management of Burn Injury

Burn care is typically categorized into three phases of care: emergent/resuscitative, acute/intermediate, and rehabilitation. Although priorities exist for each of the phases, assessment and management of problems and complications will overlap. Table 47-3 summarizes the priorities of care for each phase.

Emergent/Resuscitative Phase

On-the-Scene Care

The first step in management is to remove the patient from the source of injury and stop the burning process while preventing injury to the rescuer. Rescue workers' priorities include establishing an airway, supplying oxygen (100% oxygen if carbon monoxide poisoning is suspected), inserting at least one large-bore IV line, and covering the wound with a clean, dry cloth or gauze. Continuous irrigation of chemical injury must begin immediately. Chart 47-4 describes the procedures and care required at the burn scene. The outward physical appearance of the person who has been burned is often distracting, but it is the internal systemic effects that pose greater threats to life.

An immediate primary survey of the patient is carried out to assess the ABCDEs: *a*irway (A) with consideration given to protecting the cervical spine, gas exchange or *b*reathing (B), *c*irculatory and *c*ardiac status (C), *d*isability (D) including neurologic deficit, and *e*xpose and *e*xamine (E) while maintaining a warm environment (ABA, 2011).

Chart 47-4

Emergency Procedures at the Burn Scene

- **Extinguish the flames or remove from source.** When clothing catches fire, the flames can be extinguished if the person drops to the floor or ground and rolls ("stop, drop, and roll"); anything available to smother the flames, such as a blanket, rug, or coat, may be used. The older adult, or others with impaired mobility, could be instructed to "stop, sit, and pat" to prevent concomitant musculoskeletal injuries. Standing still forces the person to breathe flames and smoke, and running fans the flames. If the burn source is electrical, the electrical source must be disconnected safely before moving the patient.
- **Cool the burn.** After the flames are extinguished, the burned area and adherent clothing are soaked with *cool* water, *briefly,* to cool the wound and halt the burning process. However, *never* apply ice directly to the burn, *never* wrap the person in ice, and *never* use cold soaks or dressings for longer than several minutes; such procedures may worsen tissue damage and lead to hypothermia in people with large burns.
- **Remove restrictive objects.** If possible, remove clothing immediately. Adherent clothing may be left in place once cooled. Other clothing and all jewelry, including all piercings, should be removed to allow for assessment and to prevent constriction secondary to rapidly developing edema.
- **Cover the wound.** The burn should be covered as quickly as possible to minimize bacterial contamination, maintain body temperature, and decrease pain by preventing air currents from coming in contact with the injured surface. Any clean, dry cloth can be used as an emergency dressing. Ointments and salves should *not* be used. Other than the dressing, no medication or material should be applied to the burn wound at the scene.
- **Irrigate chemical burns.** Chemical burns resulting from contact with a corrosive material are irrigated immediately. Most chemical laboratories have a high-pressure shower for such emergencies. If such an injury occurs at home, brush off the chemical agent, remove clothes immediately, and rinse all areas of the body that have come in contact with the chemical. Rinsing can occur in the shower or any other source of continuous running water. If a chemical gets in or near the eyes, the eyes should be flushed with cool, clean water immediately. Outcomes for the patient with chemical burns are significantly improved by rapid, sustained flushing of the injury at the scene.

TABLE 47-3 Phases of Burn Care

Phase	Duration	Priorities
Emergent/resuscitative	From onset of injury to completion of fluid resuscitation	• Primary survey: A, B, C, D, E • Prevention of shock • Prevention of respiratory distress • Detection and treatment of concomitant injuries • Wound assessment and initial care
Acute/intermediate	From beginning of diuresis to near completion of wound closure	• Wound care and closure • Prevention or treatment of complications, including infection • Nutritional support
Rehabilitation	From major wound closure to return to individual's optimal level of physical and psychosocial adjustment	• Prevention and treatment of scars and contractures • Physical, occupational, and vocational rehabilitation • Functional and cosmetic reconstruction • Psychosocial counseling

Adapted from American Burn Association. (2011). Advanced burn life support (ABLS) course provider manual 2011. Chicago, IL: Author; Serghiou, M. A., Ott, S., Whitehead, C., et al. (2012). Comprehensive rehabilitation of the burn patient. In D. Herndon (Ed.). Total burn care (4th ed.). Edinburgh: Saunders Elsevier.

Nursing Alert: Airway patency and breathing must be assessed during the initial minutes of emergency care. Immediate therapy is directed toward establishing a patent airway and giving humidified 100% oxygen. If qualified personnel and equipment are available and the victim has severe respiratory distress and/or airway edema, the rescuers must insert an endotracheal tube and initiate mechanical ventilation.

Nursing Alert: No food or fluid is given by mouth, and the patient is placed in a position that will prevent aspiration of vomitus, because nausea and vomiting may occur and protection of the airway is always a priority.

The secondary survey focuses on obtaining a history, the completion of the total body system assessment, initial fluid resuscitation, and provision of psychosocial support of the conscious patient (see Chapter 60) (ABA, 2011).

Medical Management

Long-term outcomes are impacted by the quality of care received in the first few hours after injury (Kearns et al., 2013). Initially, the patient is transported to the nearest emergency department (ED) so that lifesaving measures can be initiated, and early referral to a burn center is made if indicated.

Initial priorities in the ED remain airway, breathing, and circulation. For mild pulmonary injury, 100% humidified oxygen is given, and the patient is encouraged to cough so that secretions can be expectorated or removed by suctioning. For more severe situations, it may be necessary to remove secretions by bronchial suctioning and to give bronchodilators and mucolytic agents. It is essential to continuously monitor airway patency, because a previously stable airway may rapidly deteriorate as edema increases and toxic effects of smoke inhalation become apparent.

Once urgent respiratory needs are appropriately addressed, fluid resuscitation is initiated in burns greater than 20% TBSA to maintain adequate organ perfusion. Baseline weight and laboratory test results are obtained, and these parameters must be monitored closely in the immediate post-burn (resuscitation) period. Both under-resuscitation and over-resuscitation with IV fluids are associated with poor outcomes. Shock, ischemic complications, and multiple organ dysfunction syndrome (MODS) occur with under-resuscitation (see Chapter 8), and heart failure and pulmonary edema occur with over-resuscitation (see Chapter 23).

In order to facilitate fluid administration, peripheral IV access may be initially obtained; however, in larger burns, central venous access is recommended due to the large volume required. TBSA is calculated and fluid resuscitation with lactated Ringers (LR) should be initiated using ABA fluid resuscitation formulas. LR is the crystalloid of choice because its pH and osmolality most closely resemble human plasma.

The ABA (2011) fluid resuscitation formula for adults within 24 hours post thermal or chemical burn is as follows:

2 mL LR × patient's weight in kilograms × %TBSA second-, third-, and fourth-degree burns

For adults with electrical burns:

4 mL LR × patient's weight in kilograms × % TBSA second-, third-, and fourth-degree burns

Other commonly recommended formulas for fluid resuscitation (Gupta, Asirvatham, Reddy, et al., 2021) are as follows:

- Evans formula: 1 mL NS/kg/% TBSA and 1 mL colloid/kg/% TBSA plus 2 L of 5% dextrose
- Brookes formula: 1.5 mL crystalloid/kg/% TBSA and 0.5 mL colloid/kg/% TBSA plus 2 L of 5% dextrose
- Modified Parkland formula: 4 mL RL/kg/% TBSA

The infusion is regulated so that one half of the total calculated volume is given in the first 8 hours post-burn injury. The second half of the calculated volume is given over the next 16 hours. Timing is one of the most important considerations in calculating fluid needs in the first 24 hours post burn. The starting point is the time of injury—not the time of arrival to the treating facility (ABA, 2011).

These formulas are only a guideline. It is imperative that the rate of infusion be titrated hourly as indicated by physiologic monitoring of the patient's response. For adults, a urine output of 0.5 to 1 mL/kg/h is used as an indication of appropriate resuscitation in thermal and chemical injuries, whereas in electrical injuries a urine output of 75 to 100 mL/h is the goal (ABA, 2011). Other indicators such as blood pressure and heart rate are not useful in assessing adequate intravascular volume in patients with major burns.

After adequate respiratory function and circulatory status have been established, the patient is assessed for cervical spine and/or head injuries if involved in a traumatic or electrical injury. All clothing and jewelry are removed because they may contain chemicals, retain heat, or become constrictive as edema rapidly develops. For chemical burns, flushing of the exposed areas with copious amounts of clean water is continued. The patient is checked for contact lenses. These are removed immediately if chemicals have come in contact with the eyes or if facial burns have occurred. In addition, the eyes are examined promptly for injury to the corneas. An ophthalmologist may be consulted for complete assessment via fluorescent staining to assess for corneal damage.

The patient's temperature must be monitored because hypothermia may develop rapidly and manipulation of the environment may be necessary. A temperature less than 35°C (95°F) causes vasoconstriction, which may increase tissue ischemia and necrosis.

It is important to validate an account of the burn scenario provided by the patient, witnesses at the scene, and first responders. Information should include the time and the source of the burn injury, the scene of injury (particularly if the patient was in an enclosed space), length of exposure, prior treatment, and any history of concomitant traumatic injury. A history of preexisting medical conditions, allergies, medications, and the use of drugs, alcohol, and tobacco is obtained to assist with the treatment plan.

An indwelling urinary catheter is inserted to permit accurate monitoring of urine output and as a measure of kidney function and fluid needs for patients with moderate to severe burns. If the burn exceeds 20% to 25% TBSA, a nasogastric tube is inserted and connected to low intermittent suction. All patients who are intubated should have a nasogastric tube inserted to decompress the stomach, and to prevent vomiting and aspiration. Often, patients with large burns become nauseated as a result of the GI effects of the burn injury, such as paralytic ileus, and the effects of medications such as opioids.

Clean sheets are placed under and over the patient to protect the burn wound from contamination, maintain body

temperature, and reduce pain caused by air currents passing over exposed nerve endings. Baseline height, weight, arterial blood gases, hematocrit, serum electrolytes, blood alcohol level, drug panel, urinalysis, and chest x-rays may be obtained. Because poor tissue perfusion accompanies burn injuries, only IV analgesia is given in small repeated doses, which is crucial for pain reduction in the emergent phase. If the patient has an electrical burn, a baseline electrocardiogram is also obtained and continuous cardiac monitoring is initiated. Because burns are contaminated wounds, tetanus prophylaxis is given if the patient's immunization status is not current or is unknown.

Nursing Alert: If necessary, a blood pressure cuff can be placed around a patient's burned extremity. The cuff must be of the correct size with accommodations made for edema.

Although the major focus of care during the emergent phase is physical stabilization, the nurse must also attend to the patient's and the family's psychological needs. Anxiety accompanies burn injuries and must be addressed on an ongoing basis. Burn injury is a crisis—one that causes varying emotional responses that may result in conflicts that may cause ethical dilemmas (see Chart 47-5). The patient's and family's coping abilities and available supports are assessed. The nurse must consider special circumstances surrounding the burn injury when providing care. Examples include cases of abuse, neglect, suicide attempts, and injury/death of other family members or friends from the same event.

Nursing Management

Nursing assessment in the emergent phase of burn injury focuses on the major priorities for any trauma patient; the burn wound is a secondary consideration to stabilization of airway,

Chart 47-5 ETHICAL DILEMMA

How Much is Enough and What is Comfort Care?

Case Scenario

A 66-year-old man was transported to the nearest burn center, where you work as a staff nurse. He was drinking beer and cooking steaks on top of a propane grill. He inexplicably threw lighter fluid on the grill and it engulfed his upper torso and face in flames. He sustained a full-thickness burn to 42% of his body (face, neck, both arms, and chest). He was awake at the scene of injury when paramedics arrived and indicated a past medical history of hypertension, hypercholesterolemia, and gout. He was in little pain at the time due to the depth of the burn injury; however, he was asking the team questions related to the survivability of his injury, "Am I going to die?"

Given the extensiveness of his facial burns, he was intubated upon admission to the burn center. Family arrived, and the burn surgeon explained the extent of injury. A decision was made to proceed with care and assess his progress post resuscitation. They were prepared for a future decision regarding withdrawal of care if survival becomes futile.

Initial resuscitation has occurred, and approximately 4 days post burn, the patient begins to show signs of acute kidney injury. He has had one surgical procedure for débridement and grafting to his chest, and although grafts are intact, they do not look healthy. He is showing increased signs of discomfort and pain due to the operative procedure and the addition of another wound (the new donor site). In a team meeting, the family decides that they do not want to initiate hemodialysis and therefore place the patient on comfort measures. Approximately 3 days later, he remains on comfort care and has increased signs of restlessness and pain. You are caring for the patient and request that the physician prescribe an increase in pain medication from 5 mg morphine to 8 mg IV. Within 2 hours after administration, the patient expired without discomfort. Six months later, the facility is contacted by an attorney and informed that the family is taking legal action against you and the physician for performing euthanasia on the patient.

Discussion

Clinicians on burn teams commonly face these types of ethical dilemmas. Whenever possible, the team should attempt to elicit the patient's wishes as early as possible, including any advance directives. It is important to collaborate and communicate with the family regarding end of life care. Although the family agreed to "comfort care," there may have been ambiguity regarding what this entails. The problem in this case is that due to absence of pain, it is often difficult for a patient to understand the severity of their burn injury. The patient begins to experience increased pain as care progresses, and increased medication is expected. As the medication is increased to relieve pain and suffering but death ensued, the *Doctrine of Double Effect* comes into play. The medication given relieved the pain and suffering but the "bad" effect or death occurred. In such cases, the outcome may be predicted but it is not the intention of the intervention.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have preeminence as you proceeded to work with this family?
- Would you describe your role in this case as complicit with assisted suicide, active euthanasia, or providing palliation? What distinction, if any, might there be among these three acts? Do you believe that this was a survivable injury?
- Describe how the ethical principles of autonomy, beneficence, and nonmaleficence may intersect or be at odds with each other in this case (Chapter 2, Chart 2-3). As a member of the burn team when the patient arrived at your facility, what could you have done differently to ensure that the patient's autonomy was preserved before he was intubated?
- What were the "intentions" in this case? How might intentionality be instrumental in making this act of titrating medications that provided palliation morally defensible? Is this nursing intervention morally defensible according to the principle of double effect (see Chapter 2, Chart 2-3)?
- Note that the American Nurses Association (2015) *Code of Ethics* clearly states that nurses should not *intentionally* cause a patient's death.

breathing, and circulation. Respiratory status is monitored closely, and pulses are evaluated, particularly in areas of circumferential burn injury to an extremity. Cardiac monitoring is indicated initially if the patient has a history of cardiac disease, electrical injury, or respiratory conditions. Vital signs and hemodynamic status are monitored closely with awareness of expected abnormalities consistent with burn injury such as tachycardia and tachypnea.

If all extremities are burned, determining blood pressure may be difficult. A clean dressing applied under the blood pressure cuff protects the wound from contamination. Because increasing edema makes blood pressure difficult to auscultate, a Doppler (ultrasound) device or a noninvasive electronic blood pressure device may be helpful. In patients with severe burns, an arterial catheter is used for blood pressure measurement and for collecting blood specimens. Peripheral pulses of burned extremities are checked frequently, either by palpation or the use of a Doppler if necessary. Elevation of burned extremities above the level of the heart is necessary to decrease edema. Large-bore IV catheters (e.g., 14 to 18 gauge) and an indwelling urinary catheter are inserted, if not already in place, and the nurse's assessment must include hourly assessment of intake and urine output.

Red-colored urine suggests the presence of hemochromogens from damage to red blood cells and myoglobin resulting from muscle damage. These are associated with deep burns caused by electrical injury or prolonged contact with heat or flame. Glycosuria, a common finding in the early post-burn hours, results from the release of liver glycogen stores in response to stress.

The nurse assists with calculating the patient's expected fluid requirements and monitoring the patient's response to fluid resuscitation. Nurse-driven resuscitation protocols can improve patient outcomes in the emergent/resuscitative phase (Fahlstrom, Boyle, & Makic, 2013). Nursing responsibilities include administration of fluids, strict monitoring of fluid intake and output, monitoring patient response, and notifying the treatment team of significant assessment findings and any abnormal laboratory values.

To help guide treatment, the following are essential: documentation of body temperature, body weight, and pre-burn weight; history of allergies, tetanus immunization, past medical and surgical history, and current illnesses; and a list of current medications. A head-to-toe assessment is performed, focusing on signs and symptoms of concomitant illness, associated injury, or developing complications. Assessing the extent of the burn wound using the rule of nines or facilitated with anatomic diagrams (described previously) is performed. In addition, the nurse works with the primary provider to clinically assess the initial areas of full- and partial-thickness injury. Psychosocial considerations of the patient and family and communication with the treatment team are imperative early in the course of care.

Nursing care of the patient during the emergent/resuscitative phase of burn injury is detailed in Chart 47-6.

Acute/Intermediate Phase

The acute/intermediate phase of burn care follows the emergent/resuscitative phase and begins 48 to 72 hours after the burn injury. During this phase, attention is directed toward continued assessment and maintenance of respiratory and circulatory status, fluid and electrolyte balance, and GI and kidney function. Infection prevention, burn wound care (e.g., wound cleaning and débridement, topical antibacterial therapy, application of dressings, and wound grafting), pain management, modulation of the hypermetabolic response, and early positioning/mobility are priorities at this stage and are discussed in detail in the following sections.

Medical Management

Pulmonary complications are common in burn injury. Airway obstruction caused by upper airway edema can take as long as 48 hours to develop. Changes detected by x-ray and arterial blood gas analysis may occur as the effects of resuscitative fluid and the chemical reactions of smoke ingredients with lung tissues become apparent. Diagnosis is largely based on history and clinical presentation, monitoring of arterial blood gases with carboxyhemoglobin levels, and direct observation of the airway by fiberoptic bronchoscopy (Dries & Endorf, 2013). To lessen the effects of upper airway edema, elevation of the patient's head of the bed may be helpful. Stridor and dyspnea are ominous because they are late signs of impending airway obstruction. Early protective intubation to maintain airway patency should be considered as obstruction may occur very rapidly. However, intubation and mechanical ventilation are significant contributors to pulmonary infections. Ideally, the best practice is to remove the endotracheal tube as soon as possible so that a route for pathogens is not accessible to the lungs.

Late pulmonary complications secondary to inhalation injuries include mucosal sloughing of the airway and casts formed from cellular debris, which can lead to obstruction, increased secretions, inflammation, atelectasis, airway ulceration, pulmonary edema, and tissue hypoxia (Snell et al., 2013). Pneumonia, acute lung injury (ALI), and ARDS may also occur.

Ventilator-associated pneumonia (VAP) is one complication of any patient who is hospitalized and mechanically ventilated, and is particularly exacerbated in the patient with an inhalation injury. It affects as many as 10% to 20% of patients on mechanical ventilation longer than 48 hours. See Chapter 11, Chart 11-11, for discussion of "bundled" strategies to prevent VAP and Chapter 12 for discussion of respiratory failure and ARDS.

As capillaries regain integrity, 48 or more hours after the burn, fluid moves from the interstitial to the intravascular compartment and intrinsic diuresis begins. If cardiac or kidney function is inadequate, fluid overload may occur and symptoms of heart failure may result (see Chapter 23). Administration of fluids and electrolytes continues cautiously during this phase of burn care due to fluid shifts, evaporative fluid loss from large burn wounds, and the patient's physiologic responses to the burn injury. Blood components are given as needed to treat surgical blood loss and anemia.

Hyperthermia is common in patients after burn shock resolves. A resetting of the core body temperature in patients who are severely burned results in a body temperature a few degrees higher than normal for several weeks after the burn. This can be compounded by body temperature increases from sepsis.

Central venous, peripheral arterial, or specialty catheters may be required for monitoring hemodynamics. It is not uncommon for patients with major burns to have multiple invasive line sites due to the amount and frequency of fluid and medication that need to be given. Whenever possible, burned areas of the body are avoided as insertion sites for invasive lines.

One of the most important medical interventions for patients with burns that has positively impacted mortality is early excision. Through surgical excision, the necrotic tissue is removed and underlying viable tissue is preserved. Early excision of dead tissue with wound closure and/or application

Chart 47-6 PLAN OF NURSING CARE

Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury

NURSING DIAGNOSIS: Impaired gas exchange related to carbon monoxide poisoning, smoke inhalation, and upper airway obstruction
GOAL: Maintenance of adequate tissue oxygenation

Nursing Interventions	Rationale	Expected Outcomes
1. Provide 100% humidified oxygen.	1. Humidification provides moisture to injured tissues; supplemental oxygen increases alveolar oxygenation.	• Absence of dyspnea • Arterial oxygen saturation >95% by pulse oximetry • Arterial blood gas levels within normal limits • Respiratory rate, pattern, and breath sounds normal
2. Assess breath sounds, and respiratory rate, rhythm, depth, and symmetry of chest excursion. Monitor patient for signs of hypoxia. Report abnormalities to primary provider	2. These factors provide baseline data of assessment and evidence of increasing respiratory compromise.	
3. Observe for the following: a. Erythema or blistering of lips or buccal mucosa b. Singed nasal hairs c. Burns of face, neck, or chest d. Increasing hoarseness e. Soot in sputum or tracheal tissue in respiratory secretions	3. These signs indicate possible inhalation injury and risk of respiratory dysfunction.	
4. Monitor arterial blood gas values, pulse oximetry readings, and carboxyhemoglobin levels.	4. Increasing $PaCO_2$ and decreasing PaO_2 and O_2 saturation may indicate need for mechanical ventilation.	
5. Prepare to assist with intubation and escharotomies of chest.	5. Intubation allows airway protection and mechanical ventilation. Escharotomy enables adequate chest excursion in circumferential chest burns.	

NURSING DIAGNOSIS: Ineffective airway clearance related to edema and effects of smoke inhalation
GOAL: Maintain patent airway and adequate airway clearance

Nursing Interventions	Rationale	Expected Outcomes
1. Maintain patent airway through proper patient positioning, removal of secretions, and artificial airway if needed.	1. A patent airway is crucial to respiration.	• Patent airway • Respiratory secretions are minimal, colorless, and thin
2. Provide humidified oxygen as prescribed.	2. Humidification liquefies secretions and facilitates expectoration.	
3. Encourage patient to turn, cough, and deep breathe. Encourage patient to use incentive spirometry. Suction as needed.	3. These activities promote mobilization and removal of secretions.	

NURSING DIAGNOSIS: Deficient fluid volume related to increased capillary permeability and evaporative losses from the burn wound
GOAL: Restoration of optimal fluid and electrolyte balance and perfusion of vital organs

Nursing Interventions	Rationale	Expected Outcomes
1. Monitor vital signs, hemodynamics, and urine output, as well as strict intake and output and daily weight.	1. Hypovolemia is a major risk immediately after the burn injury. Overresuscitation might cause fluid overload.	• Urine output between 0.5 and 1.0 mL/kg/h (30–50 mL/h; 75–100 mL/h if electrical burn injury) • Mean arterial pressure ≥60 mm Hg • Voids clear yellow urine with specific gravity within normal limits • Serum electrolytes within normal limits
2. Maintain IV lines and regulate fluids at appropriate rates, as prescribed.	2. Adequate fluids are necessary for perfusion of vital organs and maintenance of fluid and electrolyte balance.	
3. Observe for symptoms of deficiency or excess of serum sodium, potassium, calcium, phosphorus, and bicarbonate.	3. Rapid shifts in fluid and electrolyte status are possible in the post-burn period.	
4. Elevate head of patient's bed, and elevate burned extremities.	4. Elevation promotes venous return.	
5. Notify physician immediately of decreased urine output and hemodynamic changes.	5. Rapid fluid shifts must be detected early to prevent complications.	

(Continued)

(Continued)

NURSING DIAGNOSIS: Hypothermia related to loss of skin microcirculation and open wounds
GOAL: Maintenance of adequate body temperature

Nursing Interventions	Rationale	Expected Outcomes
1. Assess core body temperature frequently.	1. Frequent temperature assessments help detect hypothermia.	• Body temperature remains >37°C (98.6°F) • Absence of chills or shivering
2. Provide a warm environment by increasing room temperature or adjunct therapies as needed (overbed warmers, blankets, heat lamps, etc.)	2. Minimizes energy expenditure.	
3. Work quickly when wounds must be exposed.	3. Limiting exposure minimizes evaporative heat loss from wound.	

NURSING DIAGNOSIS: Acute pain related to tissue and nerve injury
GOAL: Control of pain

Nursing Interventions	Rationale	Expected Outcomes
1. Use pain intensity scale to assess pain level. Differentiate restlessness due to pain from restlessness due to hypoxia.	1. Pain level provides baseline for evaluating effectiveness of pain relief measures. Hypoxia can cause similar signs and must be ruled out before analgesic medication is given.	• States pain level is decreased and is acceptable to patient's pain goal • Absence of nonverbal cues of pain
2. Administer IV analgesics as prescribed and assess for effectiveness.	2. IV administration is necessary because of altered tissue perfusion from burn injury.	
3. Provide emotional support and reassurance.	3. Fear and anxiety increase the perception of pain.	

NURSING DIAGNOSIS: Anxiety related to fear and the emotional impact of burn injury
GOAL: Minimization of patient's and family's anxiety

Nursing Interventions	Rationale	Expected Outcomes
1. Assess patient's and family's understanding of burn injury, coping skills, and family dynamics.	1. Previous successful coping strategies can be fostered for use in the present crisis. Assessment allows planning of individualized interventions.	• Patient and family verbalize understanding of emergent burn care • Patient and family's anxiety levels will be minimized
2. Explain all procedures to the patient and the family in clear, simple terms.	2. Increased understanding alleviates fear of the unknown. High levels of anxiety may interfere with understanding of complex explanations.	
3. Consider administering prescribed antianxiety medications if the patient remains extremely anxious despite nonpharmacologic interventions.	3. Anxiety levels during the emergent phase may exceed the patient's coping abilities.	

COLLABORATIVE PROBLEMS: Acute respiratory failure, distributive shock, acute kidney injury, compartment syndrome, paralytic ileus, Curling's ulcer
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
Acute Respiratory Failure		
1. Assess for increasing dyspnea, stridor, changes in respiratory patterns.	1. Such signs reflect deteriorating respiratory status.	• Breathes spontaneously with adequate tidal volume • Arterial blood gas values within acceptable limits • Chest x-ray findings normal • Absence of cerebral signs of hypoxia
2. Monitor pulse oximetry, arterial blood gas values.	2. Abnormal findings may indicate respiratory failure.	
3. Monitor chest x-ray results.	3. X-ray may disclose pulmonary injury.	

(Continued)

(Continued)

4. Assess for restlessness, confusion, difficulty attending to questions, or decreasing level of consciousness.	4. Such manifestations may indicate cerebral hypoxia.	
5. Report deteriorating respiratory status immediately to primary provider.	5. Acute respiratory failure is life threatening, and immediate intervention is required.	
6. Prepare to assist with intubation or escharotomies as indicated.	6. Intubation allows mechanical ventilation. Escharotomies allow adequate chest excursion with respirations.	
Distributive Shock		
1. Assess for decreasing urine output and alterations in vital signs and hemodynamics.	1. Such signs and symptoms may indicate distributive shock and inadequate intravascular volume.	• Urine output between 0.5 and 1.0 mL/kg/h (30–50 mL/h; 75–100 mL/h if electrical burn injury) • Blood pressure within patient's normal range • Hemodynamics remain within normal limits • No signs or symptoms of impaired perfusion
2. Assess for progressive edema as fluid shifts occur.	2. As fluid shifts into the interstitial spaces in burn shock, edema occurs and may compromise tissue perfusion.	
3. Adjust fluid resuscitation in collaboration with the primary provider in response to physiologic findings.	3. Optimal fluid resuscitation prevents distributive shock and improves patient outcomes.	
Acute Kidney Injury		
1. Monitor urine output, blood urea nitrogen (BUN), and serum creatinine levels.	1. These values reflect renal function.	• Adequate urine output • BUN and serum creatinine values remain normal
2. Report decreased urine output or increased BUN and creatinine values to primary provider.	2. These laboratory values indicate possible kidney failure.	
3. Assess urine for hemoglobin or myoglobin. Administer increased fluids as prescribed.	3. Hemoglobin or myoglobin in the urine predisposes patient to increased risk of kidney failure. Fluids help to flush hemoglobin and myoglobin from renal tubules.	
Compartment Syndrome		
1. Assess peripheral pulses frequently with Doppler ultrasound device if needed.	1. Pulse assessments are crucial to assess for adequate perfusion.	• Peripheral pulses detectable • Signs of adequate peripheral perfusion
2. Assess warmth, capillary refill, sensation, and movement of extremity frequently. Compare affected with unaffected extremity.	2. These assessments may signal worsening peripheral perfusion.	
3. Remove blood pressure cuff after each reading.	3. Cuff may act as a tourniquet as extremities swell.	
4. Elevate burned extremities.	4. Elevation reduces edema formation.	
5. Report loss of pulse or sensation or presence of pain to primary provider immediately.	5. These signs and symptoms may indicate impaired tissue perfusion.	
6. Prepare to assist with escharotomies.	6. Escharotomies relieve the constriction caused by edema.	
Paralytic Ileus		
1. Auscultate for bowel sounds, abdominal distention.	1. Presence of bowel sounds indicates normal peristalsis. Abdominal distention reflects inadequate decompression.	• Normal bowel sounds • Absence of abdominal distention
2. Maintain nasogastric tube on low intermittent suction until bowel sounds resume.	2. This measure relieves gastric and abdominal distention.	
Curling's Ulcer		
1. Assess gastric aspirate and stools for blood.	1. Blood indicates possible gastric or duodenal ulcer bleeding.	• Gastric aspirate and stools do not contain blood
2. Administer histamine-2 blockers and/or antacids as prescribed.	2. Such medications reduce gastric acidity and risk of ulceration.	

of biologic or synthetic wound covering reduces the effects of inflammatory mediators that cause pathophysiologic abnormalities (Rousseau et al., 2014).

Infection Prevention

There are multifactorial reasons why patients with burns incur some of the highest risks for health care–associated infections (HAIs). These reasons may include loss of the barrier function of the skin for protection against invasive microorganisms; necrotic tissue in burn eschar combines with serum proteins to produce an environment conducive to bacterial growth; and the effects of thermal injury compromise both cell-mediated and systemic intrinsic immunity, thus promoting an environment conducive to pathogen proliferation (Abdullahi & Jeschke, 2014). Pathogens can be transmitted directly by health care staff through contact or droplets, or indirectly through the environment or equipment (Meyerson et al., 2015). It is, therefore, critical that the nurse prioritizes infection prevention in the plan of care.

Causative agents of burn infections may include bacteria, fungi, or viruses. Common sources of potential contamination in a burn unit that require hypervigilance include hydrotherapy equipment, direct or indirect contamination from health care workers' hands, environmental surfaces, and translocation of microorganisms from other body systems—most notably, the GI tract. Whether the burn wound is healing through spontaneous re-epithelialization or is being prepared for skin grafting, it must be protected from pathogens. Infection impedes burn wound healing by promoting excessive inflammation and damaging tissue. Clinical signs of infection include progressive erythema, warmth, tenderness, and malodorous exudate.

A multiple-strategy approach is crucial in prevention and control of burn wound infections. Such strategies include (Mayhall, 2012):

- The use of barrier techniques (e.g., gowns, gloves, eye protection, and masks if needed)
- Environmental cleaning with periodic cultures of patient care equipment (with special attention to hydrotherapy equipment)
- Application of appropriate topical antimicrobial agents
- Appropriate use of systemic antibiotic and antifungal agents (careful use and close monitoring of culture sensitivities are needed due to increasing challenges of antibiotic resistance in health care environments)
- Early excision and closure of the burn wound
- Control of hyperglycemia (with insulin as indicated, even in a patient without a prior diagnosis of diabetes)
- Management of the hypermetabolic response (see Chapter 8)

There are varying practices in the burn community regarding environmental and patient cultures for surveillance. In some burn centers, patients may be cultured on admission to screen for the presence of methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci. Wounds are generally cultured on admission, with each surgical case, and for clinical suspicion of infection. Antimicrobial therapy is tailored to culture results.

Wound Cleaning

Proper management of burn wounds is required to prevent wound deterioration. The goal of wound care is to remove nonviable tissue and wound exudate, and eliminate previously applied topical agents. Gentle cleaning with mild soap, water, and a washcloth can prevent infection by decreasing bacteria and debris on the wound surface. Hair in and around the burn area, except the eyebrows, should be clipped short or shaved.

Various processes are used to clean the burn wound. Patients who are hemodynamically unstable may have their wounds washed at the bedside, whereas patients who are ambulatory may shower. The wounds of patients who are nonambulatory can be cleaned using shower carts—mobile stretchers made with removable sides, drainage holes, and positioning capabilities. Retractable shower hoses suspended from walls and ceilings provide the nurse with easy access to a clean water source for washing the wounds. Whatever method is used, the goal is to protect the wound from acute proliferation of pathogenic organisms on the surface and invasion of deeper tissues until either spontaneous healing or skin grafting can be achieved. Strategies for the prevention of cross-contamination include the use of plastic liners, water filters, and thorough decontamination of equipment.

Patient comfort and ability to participate in the prescribed treatment are important considerations. During bathing, patient participation is encouraged to promote exercise of the extremities. At the time of wound cleaning, all skin is inspected for any signs of redness, breakdown, or local infection. This also provides the nurse an opportunity for patient education. Encouraging family presence during wound care can improve patient and family satisfaction, nursing communication, and optimize patient outcomes (see Chart 47-7) (Bishop, Walker, & Spivak, 2013).

During treatment, the patient is continuously assessed for signs of hypothermia. The temperature of the water is maintained at 37.8°C (100°F), and the temperature of the room should be maintained between 26.6° and 29.4°C (80° and 85°F) to prevent hypothermia. Other assessment considerations include patient fatigue, changes in hemodynamic status, and pain unrelieved by analgesic medications or relaxation techniques.

Topical Antibacterial Therapy

Variations in topical wound care for nonsurgical burn wounds exist among burn centers across the country, and choices are made based on the individualized needs of each patient. The goal of topical therapy is to provide a dressing with the following characteristics:

- Is effective against gram-positive and gram-negative organisms and fungi
- Penetrates the eschar but is not systemically toxic
- Is cost-effective, available, and acceptable to the patient
- Is easy to apply and remove, and decreases the frequency of dressing changes, decreases pain, and minimizes nursing time

No single topical medication is universally effective, and the use of different agents at different times in the post-burn period may be necessary.

Nursing Alert: Prudent use and alternation of antimicrobial agents can result in reduction of resistant strains of bacteria, greater effectiveness of the agents, and a decreased risk of sepsis. Table 47-4 describes selected topical antimicrobial agents.

Wound Dressing

After the prescribed topical agents are applied, the wound is covered with several layers of dry dressings with lighter dressing over joints to allow for mobility. Dressings may also need to be modified to accommodate splints or other positioning devices. Circumferential dressings should always be applied distally to proximally in order to promote return of excess fluid to the central circulation. If the hand or foot is burned, the fingers and

Chart 47-7 NURSING RESEARCH PROFILE

Family Presence During Dressing Changes in the Burn Unit

Bishop, S. M., Walker, M. D., & Spivak, I. M. (2013). Family presence in the adult burn intensive care unit during dressing changes. Critical Care Nurse, 33(1), 14–23.

Purpose

Severe burn injuries are often devastating events that can disrupt family dynamics. Staff working in burn units have traditionally forbidden visitation during dressing changes, even though the American Association of Critical Care Nurses and the American College of Critical Care Medicine both recommend family presence during procedures. However, there is no evidence that family presence during dressing changes in burn units has any effect on patient satisfaction with care. This quality improvement project sought to find out if family presence during dressing changes would have any association with patient satisfaction and rates of infections.

Design

The setting for this quality improvement project was a five-bed burn intensive care unit located within a 404-bed urban level 1 trauma center, which admits, on average, 130 patients with burns each year. This academic medical center utilizes a patient- and family-centered care (PFCC) model. The central tenet of the PFCC model is that the patient is a reflection of the family unit and that the family is central to the patient's well-being. Core concepts inherent in this model include dignity and respect, collaboration, participation, and information sharing. Although there was no research-based evidence that demonstrated that family presence during dressing changes would improve patient satisfaction, tenets of the PFCC model supported that this would be the case. Patients and their family members were invited to observe dressing changes, and, if they consented, were instructed in appropriate infection control protocols. Patient satisfaction scores on key Press Ganey Likert scale metrics were used pre- and postimplementation to find if patient satisfaction improved postintervention. Likewise, rates of hospital care–associated infections (HAIs) pre- and postintervention were compared.

Findings

Thirty seven Press Ganey patient satisfaction survey results obtained postintervention (March 2009 through December 2011) were compared to thirty five survey results obtained pre-intervention (January 2007 through February 2009). Each of the six metrics that were selected as indicative of satisfaction were higher postintervention, including "staff attitudes toward visitors," "nurses kept you informed," "overall rating of nursing care," "included in decisions regarding treatment," "instructions for care at home," and "extent felt ready for discharge." The rate of HAIs dropped from 13.5 per 1000 patient days in 2008 to 6.25 per 1000 patient days in 2011.

Nursing Implications

The results from this quality improvement project support the continued study of family presence during dressing changes in burn units. Family presence during dressing changes could potentially diminish anxiety in the patient, which could mitigate the pain experienced by the patient. Furthermore, most patients with burns rely upon family members to aid with dressing changes once they are discharged to the home setting. Involving family members in the dressing change process earlier may facilitate their comfort in taking on this vitally important caretaking responsibility.

TABLE 47-4 Overview of Select Topical Antimicrobial Agents Used for Burn Wounds

Agent	Indication/Comment	Application	Nursing Implications
General			
Antimicrobial ointment	Antibacterial coverage and promotion of a moist wound environment	Apply 1/16-inch layer of ointment with a clean glove daily.	Ensure removal of old ointment at the time of wound cleaning prior to applying a new layer. Monitor closely for signs and symptoms of local infection.
Specific Agents			
Silver sulfadiazine 1% (Silvadene) water-soluble cream	Bactericidal agent for many gram-positive and gram-negative organisms, as well as yeast and *Candida albicans* Minimal penetration of eschar	Apply 1/16-inch layer of cream with a clean glove 1–3 times daily.	Anticipate formation of pseudo-eschar (proteinaceous gel), which can be removed.
Mafenide acetate 5%–10% (Sulfamylon) hydrophilic-based solution or cream	Antimicrobial agent for gram-positive and gram-negative organisms Diffuses through eschar and avascular tissue (e.g., cartilage)	Apply twice a day with a clean glove as prescribed.	Is a strong carbonic anhydrase inhibitor and may cause metabolic acidosis. Application may cause considerable pain initially.
Silver nitrate 0.5% aqueous solution	Effective against most strains of *Staphylococcus* and *Pseudomonas* and many gram-negative organisms. Does not penetrate eschar	Apply solution to gauze dressing and place over wound. Keep the dressing wet but covered with dry gauze and dry blankets to decrease vaporization.	Monitor serum sodium (Na^+) and potassium (K^+) levels, and replace as prescribed. Silver nitrate solution is hypotonic and acts as a wick for sodium and potassium. Protect bed linens and clothing from contact with silver nitrate, which stains everything it touches.
Silver-impregnated dressings (sheets or mesh)	Broad antimicrobial effects (product specific) Delivers a uniform, antimicrobial concentration of silver ions to the burn wound.	Apply directly to wound. Cover with absorbent secondary dressing if needed.	May produce a pseudo-eschar from silver after application. Can be left in place for several days (product specific).

toes should be wrapped individually to promote mobility and function while healing.

Burns to the face may be left open to air once they have been cleaned and the topical agent has been applied. Careful attention is required to ensure that the topical agent does not come in contact with the eyes or mouth. A light dressing can be applied to the face to absorb excess exudates if needed.

Occlusive dressings, gauze, and a topical antimicrobial agent may be used over areas with new skin grafts to protect the new graft and promote an optimal condition for its adherence to the recipient site. Ideally, these surgical dressings remain in place for 3 to 5 days, at which time they are removed for examination of the graft. When occlusive dressings are applied, precautions are taken to prevent two body surfaces from touching, such as fingers or toes, ear and scalp, the areas under the breasts, any point of flexion, or between the genital folds. Functional body alignment positions are maintained by using splints or by regular repositioning of the patient.

Nursing Alert: Dressings can impede circulation if they are wrapped too tightly. The peripheral pulses must be checked frequently and burned extremities elevated. If the patient's pulse is diminished, this is a critical situation and must be addressed immediately.

Dressings that adhere to the wound bed may be removed more comfortably and with less damage to healing tissue by moistening the dressing with water. The patient may participate in removing the dressings, providing some degree of control over this painful procedure. The wounds are then cleaned and débrided to remove any remaining topical agent, exudate, and nonviable tissue. Sterile scissors and forceps may be used to trim loose eschar and encourage separation of devitalized tissue. During this procedure, the wound and surrounding skin are carefully inspected. Documentation should include color, odor, size, exudate, signs of re-epithelialization, any changes from the previous dressing change, and other key characteristics.

Vacuum Dressing

Vacuum dressing works by applying negative pressure by closed dressing system with the suction apparatus. It is applied in wounds with excessive exudates so that wound healing is facilitated (see Fig. 47-8). It also minimizes the sloughing and edema around the wound, and thereby increases the blood flow to the wound.

One disadvantage with negative-pressure application is that there is a huge loss of vitamins such as vitamins A, C, and E, and minerals such as copper and zinc. These elements are essential for wound healing. Hence, they need to be supplemented in higher proportion than in other wound treatment modalities (Hourigan, Omaye, Keen, et al., 2016).

Wound Débridement

The goals of débridement (the removal of *devitalized* tissue) are:

- Removal of devitalized tissue or burn eschar in preparation for grafting and wound healing
- Removal of tissue contaminated by bacteria and foreign bodies, thereby protecting the patient from invasion of bacteria

There are four types of débridement—natural, mechanical, chemical, and surgical.

Natural Débridement

With natural débridement, the devitalized tissue separates from the underlying viable tissue spontaneously. Bacteria present at the interface of the burned tissue and the viable tissue gradually liquefy the fibrils of collagen that hold the eschar in place. Collagen is a protein present in skin, tendon, bone, cartilage, and connective tissue. Proteolytic and other natural enzymes cause this phenomenon. The process may take weeks to months to occur.

Figure 47-8 • The vacuum dressing by creation of negative pressure in the wound dressing.

Mechanical Débridement

Mechanical débridement involves the use of surgical tools to separate and remove the eschar. This technique can be performed by physicians, specially trained nurses, or physical therapists and is usually done with daily dressing changes. If bleeding occurs, hemostatic agents or pressure can be applied to achieve hemostasis. Dressing changes and wound cleaning aid the removal of wound debris. Wet-to-dry dressings are not advocated in burn care because of the possibility of removing viable cells along with necrotic tissue.

Chemical Débridement

Topical enzymatic agents are available to promote débridement of burn wounds. Because such agents usually do not have antimicrobial properties, they may be used together with topical antibacterial therapy to protect the patient from bacterial invasion. Heavy metals such as silver can deactivate débriding agents; therefore, caution is necessary to ensure that the topical antimicrobial agent does not interfere with the chemical débridement. Alternating topical medications with dressing changes may also be considered.

Surgical Débridement

Early surgical excision to remove devitalized tissue along with early burn wound closure is now recognized as one of the most important factors contributing to survival in a patient with a major burn injury. Surgical débridement is carried out before the natural separation of eschar occurs. This may be performed as soon as possible after the burn, once the patient is hemodynamically stable and edema has decreased. Ideally, the wound is then covered immediately with a skin graft (if necessary) and a dressing. If the wound bed is not ready for a skin graft at the time of excision, a temporary biologic or

synthetic dressing may be used until a skin graft can be applied during a subsequent surgery.

The use of surgical excision carries with it risks and complications, especially with large burns. The procedure creates a high risk of extensive blood loss and lengthy operating and anesthesia times. Furthermore, blood losses sustained during surgical procedures, wound care, and ongoing hemolysis exacerbate anemia. Blood transfusions may be required periodically to maintain adequate hemoglobin levels for oxygen delivery to the myocardium. See Chapter 26 for discussion of blood component therapy.

When conducted in a timely and efficient manner, surgical excision results in shorter lengths of hospital stay and possibly a decreased risk of complications from invasive burn wound sepsis. Once débrided, granulation tissue fills the space created by the wound, creates a barrier to bacteria, and serves as a bed for epithelial cell growth. A wound covering is then applied to keep the wound bed moist and promote the granulation process.

Wound Grafting

The patient with deep partial- or full-thickness burns may be a candidate for skin grafting to decrease the risk of infection; prevent further loss of protein, fluid, and electrolytes through the wound; and minimize evaporative heat loss. Special attention is warranted when grafting the face (for cosmetic, functional, and psychological reasons); functional areas, such as the hands and feet; and areas that involve joints. Grafting permits earlier functional ability and reduces scar contractures (shrinkage of burn scar through collagen maturation). When burns are very extensive, the order in which areas are grafted is chosen based on the ability to achieve wound closure as soon as possible; therefore, the chest and abdomen or back may be grafted first to reduce the total body burn surface area.

Autografts

Autografting remains the preferred autologous method for definitive burn wound closure after excision. Autografts are the ideal means of covering burn wounds because the grafts are the patient's own skin and therefore are not rejected by the patient's immune system. They can be split-thickness, full-thickness, or epithelial grafts. Because the donor site (the area from which skin is taken to provide the autograft) for a full-thickness graft includes both the epidermis and dermis, its use must be cautiously considered because the donor site cannot heal spontaneously.

Split-thickness autografts are most commonly used and can be applied in sheets (see Fig. 47-9), or they can be expanded by meshing so that they cover more than a given donor site area (see Fig. 47-10). Skin meshers enable the surgeon to cut tiny slits into a sheet of donor skin, making it possible to expand to cover larger areas with smaller amounts of donor skin. These expanded grafts adhere to the recipient site more easily than sheet grafts and prevent the accumulation of blood, serum, air, or purulent material under the graft that would prevent revascularization and adherence. However, any kind of graft other than a sheet graft contributes to scar formation as it heals. The use of expanded grafts may be necessary in large wounds but should be viewed as a compromise in terms of cosmesis.

If blood, serum, air, fat, or necrotic tissue is present between the recipient site and the graft, there may be partial or total loss of the graft. Infection, mishandling of the graft, sheer injury

Figure 47-9 • Split-thickness sheet graft. Used with permission from University of Texas Medical Branch, Galveston, TX.

Figure 47-10 • Split-thickness meshed graft. Used with permission from University of Texas Medical Branch, Galveston, TX.

with mobilization or trauma during dressing changes account for most other instances of graft loss. The use of split-thickness grafts allows the remaining donor site to retain sweat glands and hair follicles, minimizing healing time.

Cultured epithelial autograft (CEA) has emerged as an important procedure in the management of massive burns. In burns that cover more than 90% TBSA, CEA may be the only option because the availability of nonburned skin as donor sites will not be sufficient for grafting. CEA involves obtaining full-thickness biopsies of the patient's unburned skin that are cultured to promote growth of keratinocytes. The final product is available approximately 3 weeks later for grafting (see Fig. 47-11). Meticulous attention is required to CEA applied to body surfaces because it is very fragile and prone to graft loss. Optimal application of CEA requires aggressive, early application of allograft to prepare and protect the wound bed (Kym, Yim, Yoon, et al., 2015). CEA can be cost prohibitive and requires extended LOS.

Care of the Graft Site Protection is key in caring for skin grafts postoperatively. Occlusive dressings are commonly used initially after grafting to immobilize the graft and support a

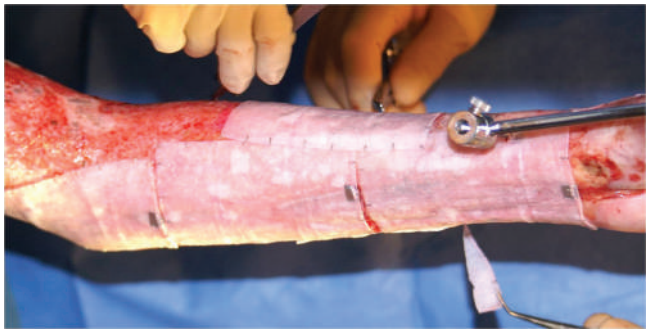

Figure 47-11 • Application of cultured epithelial autologous grafts. Used with permission from University of Texas Medical Branch, Galveston, TX.

humid environment. Occupational therapists may construct splints to immobilize newly grafted areas. Homograft, xenograft, or synthetic dressings (discussed later) may also be used to protect fragile grafts.

The first dressing change is usually performed 2 to 5 days after surgery, or earlier in the case of clinical signs of infection or bleeding. Infection, bleeding beneath the graft, and shearing forces are the most common reasons for graft loss in the early postoperative period. The patient is positioned and turned carefully to avoid disturbing the graft or putting pressure on the graft site. If an extremity has been grafted, it is elevated to minimize edema. The patient may begin exercising the grafted area 5 to 7 days after surgery. This may vary with individual burn center's protocols.

Care of the Donor Site The donor site is a clean wound created in a surgical environment. After the donor skin is excised, a hemostatic agent such as thrombin or epinephrine may be applied directly to the site to promote hemostasis. A myriad of dressings are available to cover donor sites. Donor sites must remain clean, dry, and free from pressure. Because a donor site is usually a partial-thickness wound, it is very painful and an additional potential site of infection. With proper care, the donor site should heal spontaneously within 7 to 14 days in a previously healthy, nonsmoking adult.

Homografts and Xenografts

Homografts (or allografts) and xenografts (or heterografts) are also referred to as biologic dressings and are intended as temporary wound coverage. Homografts are skin obtained from recently deceased or living humans other than the patient. Xenografts consist of skin taken from animals (usually pigs). Therefore, the body's immune response will eventually reject them as a foreign substance.

Biologic dressings protect the wound from physical trauma and loss of fluid, protein and heat; provide pain relief; and hasten re-epithelialization and, therefore, healing (Hermans, 2014). In extensive burns, they provide temporary wound coverage and protection of granulation tissue until autografting is possible. They may also be used as a test graft in preparation for autografting to determine if the bed will accept the graft. Once the biologic dressing appears to be "taking," or adhering to the granulating surface with minimal underlying exudation, the patient is ready for an autologous skin graft. As a temporary dressing, they also decrease the wound's evaporative water and protein loss, provide an effective barrier for entry of bacteria, and decrease pain by protecting nerve endings. Biologic dressings can be left open or covered. They stay in place for varying lengths of time but are removed in instances of infection or rejection. Another advantage of biologic dressings is that fewer dressing changes may be required.

Homografts tend to be the most expensive biologic dressings. They are available from skin banks in fresh and cryopreserved (frozen) forms. Homografts are thought to provide the best infection control of all biologic or biosynthetic dressings available. Revascularization occurs within 48 hours, and the graft may be left in place for several weeks.

Pigskin, an effective xenograft, is available from commercial suppliers. It is available fresh, frozen, or lyophilized (freeze-dried) for longer shelf life. Pigskin is used for temporary covering of clean wounds such as superficial partial-thickness wounds and donor sites. Although pigskin does not vascularize, it adheres to clean superficial wounds, providing pain control and reducing evaporative fluid loss while the underlying wound re-epithelializes (Lee, Dibildox, Jimenez, et al., 2012).

When grafting is not possible, skin substitutes have been created that surgically replace the epidermis and the dermis either temporarily or permanently. Each provides advantages and disadvantages that are important to consider in product selection.

Biosynthetic and Synthetic Dressings

Problems with availability, sterility, and cost have prompted the search for biosynthetic and synthetic dressings, which may eventually replace biologic dressings as temporary wound coverings. One widely used synthetic dressing is Biobrane® a dual-layer dressing of nylon and silicone (Jeschke, Finnerty, Shahrokhi, et al., 2013). The material is porous, semi-transparent, and sterile. It has an indefinite shelf life and is less costly than homograft or xenograft. Like biologic dressings, Biobrane® protects the wound from fluid loss and bacterial invasion and decreases pain at the site. It can remain in place until spontaneous re-epithelialization and wound healing occur, alleviating pain associated with frequent dressing changes. It can also be laid on top of a wide-meshed autograft to protect the wound until the autograft epithelium grows to close the interstices. As the Biobrane® gradually separates, it is trimmed away, leaving a healed wound (see Fig. 47-12).

Pain Management

A burn injury is considered one of the most painful types of trauma that a patient can experience. The nature of the injury

Figure 47-12 • Biobrane® applied to hand and forearm. Used with permission from University of Texas Medical Branch, Galveston, TX.

may expose nerve endings; and the patient may require multiple débridements, surgeries, and treatments. Moving, changing position, and receiving occupational and physical therapy cause additional discomfort. Adequate pain management must address background, procedural, and breakthrough pain.

Background pain is a continuous level of discomfort even when the patient is inactive or not undergoing any procedures. The goal of treatment is to provide a long-acting analgesic agent that will provide even coverage for this long-term discomfort. It is helpful to use escalating doses when initiating the medication to reach the level of pain control that is acceptable to the patient and facilitates participation in their recovery. The use of patient-controlled analgesia gives control to the patient and achieves this goal. Breakthrough pain is described as acute, intense, and episodic. It is generally related to an activity or movement of the affected area. Short-acting agents are used for breakthrough pain to achieve pain control if needed. Procedural pain is discomfort that occurs with procedures such as daily wound treatments, invasive line insertions, and physical and occupational therapy. The goal is to plan proper analgesia that will place the patient in a state of comfort throughout the procedure.

Most severe burns are a combination of partial- and full-thickness burns that influence the amount of pain the patient experiences. Superficial and partial-thickness burns are very painful because the nerve endings are not covered, resulting in excruciating pain with exposure to temperature, pressure, air currents, and movement. In a full-thickness burn, the nerve endings are destroyed, and upon admission there is numbness and decreased sensation to that area. Thus, the patient often underestimates severe injuries. Memories of the pain patients experience may persist for a long time. Educating patients and their families about burn pain and its relationship to the depth of injury as well as the pain management plan is an important priority for the nurse.

Pharmacologic treatment for the management of burn pain includes the use of opioids, nonsteroidal anti-inflammatory drugs, anxiolytics, and anesthetic agents. These and other pain management strategies are discussed in Chapter 9. Treatment of anxiety with benzodiazepines may be used along with opioids. The use of anesthetics in a nonoperative setting (i.e., moderate sedation) requires administration and monitoring by qualified personnel. Recent advances include the use of agents with rapid onset and short duration, which have been very effective in pain control during a planned procedure. In the provision of holistic patient care, the use of nonpharmacologic pain and anxiety interventions must not be overlooked. Nonpharmacologic therapies include relaxation techniques, distraction, guided imagery, hypnosis, therapeutic touch, humor, music therapy, and more recently virtual reality techniques.

Modulation of Hypermetabolism

Burn injuries produce profound metabolic abnormalities fueled by the exaggerated stress response to the injury. The body's response has been classified as hyperdynamic, hypermetabolic, and hypercatabolic. Hypermetabolism can affect morbidity and mortality by increasing the risk of infection and slowing the healing rate. Early nutritional support is essential to recovery for the patient with burns in order to attenuate the hypercatabolism and hypermetabolism that occurs (Abdullahi & Jeschke, 2014). Improvements in cellular defense, mucosal barrier function of the GI tract, and decreased inflammation have been seen with immune-modulating nutritional support (Sen et al., 2015).

Nutrition should be provided upon arrival to the burn center and may require placement of a feeding tube to deliver adequate calories. Patients who are critically ill may even have their feedings continued intraoperatively if the airway is protected. Several formulas exist for estimating the daily metabolic expenditure and caloric requirements of patients with burn injuries. Carbohydrates are the most important energy source and should account for 55% to 60% of nutrition delivery to decrease protein catabolism (Abdullahi & Jeschke, 2014). Fat, although a required nutrient, should be provided in more limited quantities. When the oral route is used, high-protein, high-calorie meals and supplements are given. Dietary consultations are useful in helping patients meet their nutritional needs. Daily calorie counts aid in assessing the adequacy of nutritional intake.

Early excision and grafting of the burn wound is one of the most important factors in ameliorating hypermetabolism by removing eschar, thereby lessening the effects of inflammatory mediators. Appropriate manipulation of environmental temperatures may decrease energy expenditure by the patient. Insulin therapy in patients with burns is needed to treat the hyperglycemia that occurs from accelerated gluconeogenesis and is beneficial in muscle protein synthesis. Oxandrolone (Oxandrin), an anabolic steroid, is commonly given to patients with burns because it improves protein synthesis and metabolism. Administration of propranolol (Inderal) (a beta-blocker) decreases heart rate and blocks harmful catecholamine effects. Lastly, exercise is described as an essential adjunct in the plan of care for patients with burns, because it attenuates the hypermetabolic response and increases lean muscle mass (Abdullahi & Jeschke, 2014).

Nursing Management

Nursing management of the patient in the acute/intermediate phase is focused on the following priorities: restoring fluid balance, preventing infection, modulating hypermetabolism, promoting skin integrity, relieving pain and discomfort, promoting mobility, strengthening coping strategies, supporting patient and family processes, and monitoring and managing complications.

Restoring Normal Fluid Balance

To reduce the risk of fluid overload and consequent heart failure and pulmonary edema, daily weights and careful calculation of intake and output measurement are utilized to guide therapy. Changes in physical assessment and hemodynamic indicators are also useful in evaluating the patient's response to treatment.

Preventing Infection

The patient with burns is at risk for infection from multiple sources, which may include open wounds, lung injury, GI ischemia, and indwelling catheters. Therapeutic interventions are complex due to the patient's altered physiology. Signs of infection including increased temperature, tachycardia, tachypnea, and leukocytosis may be present in the patient with burns without underlying infection, making infections more difficult to recognize.

A major part of the nurse's role during the acute phase of burn care is detection and prevention of infection. The nurse is responsible for providing a clean environment, including the promotion of protective isolation interventions. The nurse protects the patient from sources of contamination, including other patients, staff members, visitors, and equipment. Patients can inadvertently promote migration of microorganisms from one burned area to another by touching their wounds or dressings. Bed linens can also spread infection through either colonization with wound microorganisms or fecal

contamination. Regular bathing of unburned areas and changing of linens can help prevent infection. Fresh flowers, plants, and fresh fruit baskets are not permitted in the patient's room because of the risk of microorganism growth. Invasive lines and tubing must be routinely changed according to CDC recommendations, and prompt removal of all indwelling catheters when no longer indicated can prevent HAIs.

Modulating Hypermetabolism

The nurse collaborates with the dietitian or nutrition support team to develop a plan that meets the needs of the patient. Family members may be encouraged to bring nutritious and favorite foods to the hospital. High-calorie nutritional supplements may be necessary. Nutritional intake must be accurately documented. Vitamin and mineral supplements may be prescribed.

If caloric goals cannot be met by oral feeding, a feeding tube is inserted and used for continuous or bolus feedings of specific formulas. The volume of residual gastric secretions should be checked to ensure absorption. The patient should be weighed each day and the results tracked to properly assess appropriate weight parameters and to attenuate catabolism of lean muscle mass.

Promoting Skin Integrity

Wound care is usually the single most time-consuming element of burn care after the emergent phase. The primary provider prescribes the desired topical antibacterial agents and specific biologic, biosynthetic, or synthetic wound coverings and plans for surgical excision and grafting. The nurse needs to make astute assessments of wound status, use creative approaches to wound dressings, and support the patient during the emotionally distressing and significantly painful experience of wound care.

Assessment of the burn wound requires an experienced eye, hand, and sense of smell. Important wound assessment features include size, color, odor, presence of eschar and exudate, epithelial buds (small pearl-like clusters of cells on the wound surface), bleeding, granulation tissue, the status of graft take, healing of the donor site, and the condition of the surrounding skin. Any significant changes in the wound are reported to the primary provider because they may indicate burn wound infection and require immediate intervention.

The nurse also assists the patient and family by providing instruction, support, and encouragement to take an active part in dressing changes and wound care when appropriate. Discharge planning needs for wound care must be anticipated early in the course of burn management, and the strengths of the patient and family are assessed and used in preparing for the patient's eventual discharge and home care needs. Family presence during dressing changes promotes feelings of readiness for discharge (see Chart 47-7) (Bishop et al., 2013).

Relieving Pain and Discomfort

Pain management continues to be a priority during the acute phase of burn recovery. Frequent assessment of pain is required, and analgesic and anxiolytic medications are given as prescribed. To increase its effectiveness, analgesic medication is provided before the pain becomes severe. Nonpharmacologic interventions can be used to alter the patient's perceptions of and responses to pain. Frequent reassessment of responses to interventions, whether pharmacologic or nonpharmacologic, is essential.

Post-burn pruritus (itching) affects almost all patients with burns and is one of the most distressing symptoms in the post-burn period. Oral antipruritic agents, environmental conditions, frequent lubrication of the skin with water or silica-based lotion, and diversion activities all help to promote comfort in this phase. The instructions "pat, don't scratch" must be reinforced with patients in order to prevent further discomfort and infectious complications. Although gabapentin (Neurontin) had been prescribed to treat both pain and pruritus in patients' post burns, results from a recent double-blinded, randomized controlled trial does not support its effectiveness (Wibbenmeyer, Eid, Liao, et al., 2014).

Lack of sleep and rest interfere with healing, comfort, and restoration of energy. If necessary, sleep aids are prescribed on a regular basis in addition to analgesic and anxiolytic agents.

Promoting Physical Mobility

An early priority is to prevent complications of immobility. Deep breathing, turning, and proper positioning are essential nursing practices that prevent atelectasis and pneumonia, control edema, and prevent pressure ulcers and contractures. Specialty beds may be useful, and early mobility is strongly encouraged. If the lower extremities are burned, elastic pressure bandages should be applied before the patient is placed in an upright position to promote venous return and minimize edema formation. A review of over 36,000 patients with burns showed a DVT rate of 0.8%. Risk factors that were identified included a TBSA greater than 20%, previous history of DVT, African American race, and use of blood transfusions and mechanical ventilation (Satahoo, Parikh, Naranjo, et al., 2015).

The burn wound is in a dynamic state for at least 1 year after wound closure. During this time, aggressive efforts must be made to prevent contracture and hypertrophic scarring. Both passive and active range-of-motion exercises are initiated from the day of admission and are continued after grafting within prescribed limitations. Splints or functional devices may be applied to the extremities for contracture control. The nurse monitors the splinted areas for signs of vascular insufficiency, nerve compression, and skin breakdown. Occupational and physical therapists are consulted to develop a patient-specific plan of care throughout hospitalization and recovery.

Strengthening Coping Strategies

Much of the patient's energy goes into maintaining vital physical functions and wound healing in the early post-burn weeks, leaving little emotional energy for coping. In the acute phase of burn care, the patient is facing the reality of the burn injury. Grief, depression, anger, regression, and manipulative behavior are common responses of patients who have burn injuries. Withdrawal from participation in required treatments and regression must be viewed with an understanding that such behavior may help the patient cope with an enormously stressful event.

The patient may experience feelings of anger. At times, the anger may be directed inward because of a sense of guilt, perhaps for causing the fire or even for surviving when others perished. The anger may also be directed outward toward those who escaped unharmed or those who are now providing care. One way to help the patient handle these emotions is to enlist someone to whom the patient can express feelings without fear of retaliation. A nurse, social worker, psychiatric liaison nurse, peer supporter or counselor who is not involved in direct care activities may fill this role successfully.

Patients with burn injuries are very dependent on health care team members during the long period of treatment and recovery. However, even when physically unable to contribute much to self-care, they should be included in decisions regarding care and encouraged to assert their individuality in terms of preferences and recognition of their unique identities.

As the patient improves in mobility and strength, the nurse works with the patient to set realistic expectations for self-care and planning for the future. Many patients respond positively to the use of contractual agreements and other strategies that recognize their independence, set expectations for behavior, and encourage positive communication.

Supporting Patient and Family Processes

The burn injury has tremendous psychological, economic, and life-altering impact on the patient and family. The nurse is instrumental in providing support to the patient and family as they adapt to the burn injury. Referrals for social services or psychological counseling should be made as appropriate. This support continues into the rehabilitation phase. Some burn centers offer a structured peer support program in which a patient who has survived a burn injury visits the patient while hospitalized to provide psychosocial support. Many patients appreciate the opportunity to be able to share their experience with another person who has had a burn injury.

Patients who experience major burns are commonly sent to burn centers far from home. Because burn injuries are sudden and unexpected, family roles are disrupted. If the primary caregiver or wage earner in the family is injured, roles may change, which adds more stress to the family. Therefore, both the patient and the family need thorough information regarding the patient's burn care and expected course of treatment. Barriers to learning and preferred learning styles are assessed and considered. This information is used to tailor education activities. Patient and family education is a priority and is best provided with a multimedia approach.

Monitoring and Managing Potential Complications

Acute Respiratory Failure and Acute Respiratory Distress Syndrome

The patient's respiratory status is monitored closely for increased difficulty in breathing, change in respiratory pattern, or onset of adventitious (abnormal) breath sounds. Typically, at this stage, signs and symptoms of injury to the respiratory tract become apparent. As described previously, signs of hypoxia, diminished breath sounds, wheezing, tachypnea, stridor, and sputum tinged with soot (or in some cases containing sloughed tracheal tissue) are among the many possible findings. Medical management of the patient with acute respiratory failure requires intubation and mechanical ventilation (if not already in use). If ARDS has developed, higher oxygen levels, positive end-expiratory pressure, and pressure support are used with mechanical ventilation to promote gas exchange across the alveolar–capillary membrane (see Chapters 11 and 12).

Heart Failure and Pulmonary Edema

If the cardiac and renal systems cannot compensate for the excess vascular volume as fluid shifts back to the intravascular space, heart failure and pulmonary edema may result. The patient is assessed for signs of heart failure, including decreased cardiac output, oliguria, jugular vein distention, persistent edema, and the onset of an S_3 or S_4 heart sound. If invasive hemodynamic monitoring is used, increasing central venous, pulmonary artery, and pulmonary artery wedge pressures indicate increased fluid volume.

Crackles in the lungs and increased difficulty with breathing may indicate pulmonary edema, which should be reported promptly to the primary provider. In the meantime, the patient is positioned comfortably, with the head of the bed raised (if not contraindicated by other treatments or injuries) to promote lung expansion and gas exchange. Management of this complication includes providing supplemental oxygen, administering IV diuretic agents, carefully assessing the patient's response, and providing vasoactive medications, if indicated (see Chapter 23).

Sepsis

Sepsis is a leading cause of morbidity and mortality in patients with burn injuries. The signs of early sepsis are subtle and require a high index of suspicion and very close monitoring of changes in the patient's status. One of the challenges in the recognition of sepsis is the lack of definition of sepsis in the population of patients with burns. Because patients with burns are hypermetabolic, this results in tachycardia, tachypnea, and elevated body temperature. These physiologic norms in patients with burns make the diagnosis of sepsis more challenging. A recent retrospective study of burn admissions over a 5-year period found that temperature less than 36°C (96.8°F), heart rate greater than 130 bpm, base deficit less than −6 mEq/L, a mean arterial pressure less than 60 mm Hg, serum glucose greater than 150 mg/dL, and utilization of vasopressors were predictive of sepsis in patients with burns (Mann-Salinas, Baun, Meininger, et al., 2013). See Chapter 8 for treatment recommendations for sepsis.

Rehabilitation Phase

Rehabilitation begins immediately after the burn has occurred and often extends for years after the initial injury. For nurses who care for patients with burns, this can be one of the more physically demanding and challenging phases. One important focus of the burn team is to evaluate the patient carefully for late complications related to burn injuries as described in Table 47-5.

Burn rehabilitation is comprehensive, complex, and requires a multidisciplinary approach to optimize the patient's physical and psychosocial recovery related to the injury. As patients begin to recover, they become more aware of the injuries and the challenges they face. Individualized plans of care that are specific to the severity and location of injury are developed and reevaluated frequently. The increased survival of patients with significant burn injuries has translated into the need for additional and comprehensive burn rehabilitation programs worldwide. The ultimate goal is to return patients to the highest level of function possible within the context of their injuries. Occupational and physical therapists are essential to optimize patient goals and outcomes.

Psychological Support

A patient's outlook, motivation, and support system are important to their overall well-being and ability to progress through the rehabilitation phase. Psychiatric disorders may have contributed to the cause of the burn injury itself. Examples include self-inflicted burns, suicide attempts, or intentional infliction on one individual by another in cases of abuse. These are a few examples that illustrate the critical need for psychosocial resources in burn recovery. Although psychiatric disorders are not contributory to all burn injuries, the life-altering nature of burn injuries almost always causes temporary or permanent impairment of psychosocial adaptation.

In the acute phase of the injury, acute shock, terror, disbelief, confusion, and anxiety are common. Patients may be at risk for delirium and may experience temporary psychoses. Patients may be confused from medications they are taking, but they have an underlying sense of fear, anxiety, and pain. Early consultation with mental health professionals will assist to best meet individual needs, which may include pharmaceutical interventions with concurrent counseling.

TABLE 47-5 Complications in Rehabilitation Phase of Burn Care

Complications	Contributing Factors	Interventions
Neuropathies and nerve entrapment	Electrical injury, large deep burns, improper positioning, edema, scar tissue	Assess peripheral pulses and sensation (neurovascular checks). Prevent edema and pressure by elevation, positioning, and prevention of constricting dressings. Assess splints for proper fit and application. Consult OT and PT departments for positioning.
Wound breakdown and/or pressure ulcer formation	Shearing, pressure, inadequate nutrition	Protect wound from pressure and shearing forces. Educate patient about importance of good nutrition.
Hypertrophic scarring	Partial- and full-thickness burns	Keep skin pliable and soft by using emollients. Apply pressure garments as prescribed. Massage.
Contractures	Partial- and full-thickness burns	Maintain position of joints in alignment. Perform gentle range-of-motion exercises. Consult OT and PT departments for exercises and positioning recommendations.
Joint instability	Burn wound, burn scar, and contractures	Maintain appropriate joint positioning through appropriate application of splints. Monitor joint pinning if indicated.
Complex pain	Trauma and burns	Provide adequate pain management. Consult OT and PT departments for exercises and desensitization. Promote gentle motion of affected extremities.

OT, occupational therapy; PT, physical therapy.

The rehabilitation phase may present a new set of challenges. While the patient is physically recovering, the reality and impact of the injury begin to set in as patients recognize that survival is expected. Patients may experience devastating grief and loss. The sense of loss may originate from physical injury, loss of control from the forced dependency on others for care, or loss of family members/friends who may have perished in the injury. In residential fires, survivors may have lost their homes and all of their possessions.

Posttraumatic stress disorder (PTSD) is the most common psychiatric disorder in patients with burns, with a prevalence of 8% to 30% (Hobbs, 2014). Other psychological disorders that may be experienced by patients with burns include anxiety, depression, and sleep disturbances.

As recovery progresses, discharge planning must include strategies to assist the patient in reintegrating into their home, community, workplace, and school. For many patients, issues regarding quality of life may become very real at this point in recovery. This is an emotional time as the patient and family begin to live with new physical limitations and challenges in relationships. In addition to preparing the patient's support system, the patient and family must also prepare for the reactions from strangers.

Organizations that provide support for reintegration are able to offer education and training geared specifically to patients with burn injuries. Workshops on application of makeup to reduce the appearance of scars can benefit those with obvious facial scarring is just one example of strategies available to assist patients with burns who have body image disturbances. Cultural influences play a strong factor in this process, because some cultures are particularly sensitive to physical appearance, which is reinforced by current media. The role of the nurse is to encourage patients to voice their concerns, provide empathy, and provide them with assistive resources.

Abnormal Wound Healing

Partial-thickness wounds involving the epidermis and superficial dermis tend to heal without scarring. Deeper wounds will likely develop scarring of variable degrees. As with other disorders, risk factors may be stratified as modifiable or nonmodifiable. For example, a nonmodifiable risk factor for scarring is heredity, because some patients are simply more prone to hypertrophic scar formation. The focus of patient education for nurses must be on how to best change or adapt risk factors that are modifiable. Patients should be strongly encouraged to follow occupational therapist recommendations for scar prevention and management.

Normal scarring occurs in a superficial tissue injury and begins forming within 7 to 10 days post-injury and progresses over the next 6 to 12 months. Abnormal scarring occurs after a longer period of wound healing and may form either hypertrophic or keloid scars.

Hypertrophic and Keloid Scars

Hypertrophic scars form within the boundaries of the initial wound and push outward on the perimeter of the wound. They are common in areas over joints and in the younger population. The scar becomes red (because of its hypervascular nature), raised, and hard.

Keloid scars are irregularly formed and extend beyond the margins of the original wound. They are large, nodular, and ropelike, often causing itching and tenderness. They are more common in dark-pigmented skin, uncommon in children and older adults, and have familial tendencies.

Prevention and Treatment of Scars

Preventive treatment modalities are used to prevent scar contractures and excess hypertrophic tissue. Compression is introduced early in burn wound treatment. Elastic bandage wraps are used initially to help promote adequate circulation, but they can also be used as the first form of compression for scar management, followed by elasticized tubular bandages until the patient can be measured for a customized garment. Application of elastic pressure garments loosens collagen bundles and encourages parallel orientation of the collagen to the skin surface. As pressure continues over time, collagen

restructures and vascularity decreases. Although this therapy is somewhat controversial, pressure has shown to be beneficial in controlling scar formation over time. Garments are worn continuously (i.e., 23 hours per day).

Many areas of the body are difficult to compress due to the contours or location of the injury. Inserts, such as silicone sheets, are helpful for these small troublesome areas and are placed beneath the garment or compression dressing to enhance scar compression. Gentle superficial scar massage can be performed with a moisturizer several times a day.

Burn reconstruction is a treatment option after scars have matured and is discussed within the first few years after injury. This decision requires individualized planning, realistic expectations, and patience. The treatment team and the patient will ultimately decide on the best approach for long-term functionality and cosmesis.

NURSING PROCESS

Care of the Patient During the Rehabilitation Phase

Assessment

The nurse obtains information about the patient's education level, occupation, leisure activities, cultural background, religion, and family interactions. The patient's self-concept, mental status, emotional response to the injury and subsequent hospitalization, level of intellectual functioning, previous hospitalizations, response to pain and pain relief measures, and sleep pattern are also essential components of a comprehensive assessment. Information about the patient's general self-concept, self-esteem, and coping strategies in the past are valuable in assessing emotional needs.

Ongoing physical assessments related to rehabilitation goals include range of motion of affected joints, functional abilities in ADLs, early signs of skin breakdown, evidence of neuropathies (nerve damage), activity tolerance, and quality or condition of healing skin. The patient's participation in care and ability to demonstrate self-care in such areas as ambulation, eating, wound cleaning, toileting, and applying pressure wraps are documented on a regular basis.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses may include the following:

- Activity intolerance related to pain with exercise, limited joint mobility, muscle wasting, and limited endurance
- Disturbed body image related to altered physical appearance and self-concept
- Impaired physical mobility due to contractures or hypertrophic scarring
- Deficient knowledge about postdischarge home care and recovery needs

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Inadequate psychological adaptation to burn injury

Planning and Goals

The major goals for the patient include increased mobility and participation in ADLs; adaptation and adjustment to alterations in body image, self-concept, and lifestyle; increased understanding and knowledge of the injury, treatment, and planned follow-up care; and absence of complications.

Nursing Interventions

Promoting Activity Tolerance

The extensive physical rehabilitation can be painful and acute for the patient. Strategies to maintain motivation and participation may be beneficial during this critical phase. The nurse incorporates physical and occupational therapy exercises in the patient's care to prevent muscle atrophy and to maintain the mobility required for daily activities. The patient's activity tolerance, strength, and endurance gradually increase if activity occurs over increasingly longer periods. Fatigue and pain tolerance are monitored and used to determine the amount of activity to be encouraged on a daily basis. Activities such as family visits and recreational therapy (e.g., video games, radio, television) can provide diversion, improve the patient's outlook, and increase tolerance for physical activity. In older adult patients and those with chronic illnesses and disabilities, rehabilitation must take into account preexisting functional abilities and limitations.

The nurse must schedule care in such a way that the patient has periods of rest and uninterrupted sleep. A good time for planned patient rest is after the stress of dressing changes and exercise, while pain interventions and sedatives are still effective. This plan must be communicated to family members and other care providers. The patient may have insomnia related to frequent nightmares about the burn injury or other fears and anxieties about the outcome of the injury. The nurse reassures the patient and administers agents, as prescribed, to promote sleep. Reducing metabolic stress by relieving pain, preventing chilling or fever, and promoting the physical integrity of all body systems help the patient conserve energy for therapeutic activities and wound healing.

Improving Body Image and Self-Concept

Patients who have survived burn injuries may lack the benefit of anticipatory grief often seen in a patient who is approaching surgery or dealing with the terminal illness of a loved one. As care progresses, the patient who is recovering from burns becomes aware of daily improvement and begins to exhibit basic concerns: Will I be disfigured or be disabled? How long will I be in the hospital? What about my job and family? Will I ever be independent again? How will this injury affect my sexual relationships? How can I pay for my care? Was my burn the result of my carelessness? Where will I live now?

When caring for a patient with a burn injury, the nurse needs to be aware that there are prejudices and misunderstandings in society about those who are viewed as different. Opportunities and accommodations available to others are often denied to those who are disfigured by scarring associated with burn injury. These include social participation, employment, prestige, various roles, and status. The health care team must actively promote a healthy body image and self-concept in patients with burn injuries so that they can accept or challenge others' perceptions of those who are disfigured or disabled. Survivors themselves must show others who they are, how they function, and how they want to be treated.

Promoting Physical Mobility Through Preventing Contractures or Hypertrophic Scar Formation

With early and aggressive physical and occupational therapy, contractures or hypertrophic scars are rarely a long-term complication. However, surgical intervention is indicated if full range of motion in the patient with burns is not achieved. See Chapter 38 for a discussion of range of motion exercises. Range of

motion exercises need to be started as early as possible following burn injury for prevention of contractures and deformities.

Monitoring and Managing Potential Complications

Impaired Psychological Adaptation to the Burn Injury. Some patients, particularly those with limited coping skills or psychological function, or a history of psychiatric problems before the burn injury, may not achieve adequate psychological adaptation to the burn injury. Psychological counseling or psychiatric referral may be made to assess the patient's emotional status, to help the patient develop coping skills, and to intervene if major psychological issues or ineffective coping is identified.

Promoting Home, Community-Based, and Transitional Care

Educating the Patient about Self-Care. The focus of rehabilitative interventions is directed toward outpatient care, home care, or care in a rehabilitation center. This includes wound care, dressing changes, pain management, nutrition, prevention of complications, and other care needs. Information and written instructions are provided about specific exercises and the use of pressure garments and splints. The patient and family are provided education to assist them in their continued care needs after discharge (see Chart 47-8).

Chart 47-8 HOME CARE CHECKLIST

The Patient with a Burn Injury

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the burn injury and treatment on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State how to contact all members of the treatment team (e.g., interdisciplinary burn team, health care providers, home care professionals, and durable medical equipment and supply vendor).
- State the name, dose, side effects, frequency, and schedule for all medications.
- Demonstrate psychosocial adaptation and social integration through verbalizing understanding of the following:
  - Changes in lifestyle and emotional adjustment to injury take time. It is not uncommon for patients to report nightmares or "flashbacks" of the injury. If this becomes disruptive, it should be discussed with the treatment team.
  - Resume previous interests and activities gradually.
  - Burn care such as dressing, medicines, and treatment is very expensive; therefore, it is advised to contact some NGO or good samaritan for financial help.
- Demonstrate adaptation of the home environment, assisted as needed by team members.
- State burn skin precautions:
  - Wear sunblock with the highest sun protection factor (SPF) possible to protect exposed burned skin from the sun. Light-colored clothing, long pants, and long-sleeved shirts may also be necessary to protect from the sun.
  - Wear wide-brimmed hats if face or ears have been burned to protect the area from the sun.
  - Avoid further trauma to burned skin; leave blisters that may form intact.
  - Lubricate healed burned skin with mild lotion (as prescribed); avoid scratching.
  - Use only mild soap and lotion (i.e., products without perfume) on burned areas. Keeping skin clean overall is important to support good hygiene and prevent infection.
  - Avoid tight clothing over burned areas so as not to restrict movement or irritate newly healed areas.
  - Select white cotton, loose-fitting clothing so that dyes in colored clothes do not irritate healing skin.
  - Wear clothing and gloves to protect healing skin from unnecessary bruises, bumps, and scratches.
  - Be aware that tolerance to extremes in temperatures may be affected.
  - Itching is a normal, uncomfortable part of healing and burn recovery; do not scratch, pat areas; apply mild moisturizers to decrease itching from dryness. Medications for itching can be discussed with the treatment team.
- Demonstrate wound care technique:
  - Take prescribed pain medications if needed 30 min prior to wound care to achieve maximum effectiveness.
  - Use mild soap, water, and a clean washcloth to clean wounds.
  - Apply prescribed topical medications and dressings as instructed.
  - Inspect wounds carefully with each dressing change for signs of infection, including increased redness, swelling, drainage, or foul odor.
- State aspects of ADLs and exercise:
  - Perform as much of own care as possible.
  - Adhere to the exercise regimen given by the therapists.
  - Although physical rehabilitation is tiring, daily participation is essential.
  - Plan for adequate rest and sleep.
  - When at rest, swollen limbs should be elevated.
- Describe approaches to controlling pain (e.g., take analgesics as prescribed; use nonpharmacologic interventions).
- States changes in diet necessary to promote health (e.g., nutrient rich foods, rather than empty calories).
- States changes in fluid intake needed to prevent constipation associated with the use of analgesic medications.
- Discusses management of burn scar:
  - Massage with mild lotion or cream to stretch skin to maintain/increase its elasticity.
  - Wear compression garments 23 hours a day if instructed.
  - Discoloration of the skin for many months is an expected normal part of healing.
- Discuses resumption of sexual relations:
  - Resumption of sexual relationships is the rule rather than the exception and should occur when comfortable for all.
  - Expect sensitivity of and around the genital area for several months if these areas were burned.
- States correct use of medical devices:
  - Follow occupational therapist's instructions for splint use and cleaning.
  - Use crutches, walkers, or other assistive devices as instructed.
  - If devices such as shower chairs or grab bars are needed in the home, this should be arranged prior to discharge.
- State time and date of follow-up appointments, therapy, and testing:
  - Keep a list of questions to ask team members.
  - Bring medications, or a list of current medications, to each visit for the team to review.
- Identify sources of support (e.g. friends, relatives, faith community, burn support groups, and caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

Continuing and Transitional Care. After discharge, care by a multidisciplinary treatment team is necessary. Some patients may require the services of an inpatient rehabilitation center before returning home. Patients should receive follow-up from a burn center when possible for periodic evaluation by the burn team, modification of outpatient treatment plan, and evaluation for reconstructive surgery. Many patients require outpatient physical or occupational therapy several times a week. The nurse coordinates all aspects of care and ensures that the patient's needs are met. Such coordination is an important aspect of assisting the patient to achieve independence.

Some patients may require referral for transitional care after discharge. The nurse assesses the patient's physical and psychological status as well as the adequacy of the home setting for safe and adequate care. The nurse monitors the patient's progress; assesses adherence to the plan of care; and assists the patient and family with wound care, exercises, and other physical needs. Patients experiencing difficulties with psychosocial adjustments are identified and appropriate referrals are made.

Evaluation

Expected patient outcomes may include:

1. Demonstrates adequate activity tolerance
   a. Has energy available to perform daily activities
   b. Shows gradual increased tolerance and endurance in physical activities
   c. Obtains adequate sleep and rest daily
2. Adapts to altered body image
   a. Verbalizes accurate description of alterations in body image and accepts physical appearance
   b. Demonstrates interest in resources that may improve function and perception of body appearance (e.g., cosmetics, wigs, and prostheses as appropriate)
   c. Socializes with significant others, peers, and usual social group
   d. Seeks and achieves return to role in family, school, and community as a contributing member
3. Demonstrates physical mobility adequate to perform ADLs
   a. Demonstrates range of motion appropriate for injury
   b. Absence of complications from wound healing
4. Demonstrates knowledge of required self-care and follow-up care
   a. Verbalizes detailed plan for follow-up care
   b. Demonstrates ability to perform or direct wound care and prescribed exercises
   c. Returns for follow-up appointments as scheduled
   d. Identifies resource people and agencies to contact for specific problems
5. Exhibits no complications
   a. Exhibits psychosocial adaptation to burn injury
   b. Verbalizes understanding of diagnosis and treatment plan

Outpatient Burn Care

The increased availability of outpatient surgery and access to expert burn care in outpatient settings make this option possible for the treatment of minor burns as well as follow-up for the patient with more severe burns who is discharged. The goals for treatment in an outpatient setting may include burn wound management, pain management, scar and reconstructive care, psychosocial care, and rehabilitation. However, a number of factors must be considered when determining if outpatient care is appropriate for the patient: age, past medical history, extent and depth of the burn, location of the burn wounds, availability of family support systems and community resources, the patient's ability and willingness to adhere to a therapeutic regimen, distance from home, and availability of transportation from home to the outpatient setting.

The frequency of follow-up visits is individualized. The initial outpatient visit for a discharged patient with burn injuries is usually scheduled within 2 to 3 days after hospital discharge. Follow-up appointments will vary and over time decrease in frequency, based on the patient's needs. Patient and family education is paramount and should include verbal and written instructions as well as return demonstration of the wound or scar care required. The importance of notifying the outpatient setting about early complications and of keeping follow-up appointments is emphasized to the patient and family. Physical therapy and occupational therapy are often provided in the outpatient burn setting. The rehabilitation goals are to increase range of motion, strengthen muscles, and build the patient's activity tolerance. This is accomplished by a specific plan of care and includes routine visits for up to 2 years or more following the injury.

Adaptation to lifestyle changes and emotional status should be assessed during the outpatient visits and proper referrals made for counseling services. These assessments may be difficult to recognize due to the infrequent nature of the visits; therefore, it is helpful to incorporate family response and interactions into the assessment. The health care team must also be alert to issues of substance abuse, safety concerns, suicidal thoughts, depression, and PTSD.

PLASTIC, RECONSTRUCTIVE, AND COSMETIC PROCEDURES

The word plastic comes from a Greek word meaning "to form." Plastic or reconstructive procedures are performed to reconstruct or alter congenital or acquired defects to restore or improve the body's form and function. Often the terms plastic and reconstructive are used interchangeably. This type of surgery includes closure of wounds, removal of skin tumors, repair of soft tissue injuries or burns, correction of deformities, and repair of cosmetic defects. Plastic surgery can be used to repair many parts of the body and numerous structures, such as bone, cartilage, fat, fascia, mucous membrane, muscle, nerve, and cutaneous structures. Bone inlays and transplants for deformities and nonunion can be performed, muscle can be transferred, nerves can be reconstructed and spliced, and cartilage can be replaced. As important as any of these measures is the reconstruction of the cutaneous tissues around the neck and the face; this is usually referred to as *aesthetic* or *cosmetic surgery*.

Cosmetic procedures are generally considered to be ones that correct defects that are not life threatening or caused by disease. An example would be removal of a benign mole or sebaceous cyst from the face. Most health insurance plans do not cover procedures deemed to be cosmetic, and these procedures can be expensive. Procedures that are performed to correct a surgical defect, such as removal of a skin cancer or correction of a significant congenital defect such as a cleft lip, are generally covered by insurance.

Wound Coverage: Grafts and Flaps

Various surgical techniques, including skin grafts and flaps, are used to cover skin wounds.

Skin Grafts

Skin grafting is a technique in which a section of skin is detached from its own blood supply and transferred as free tissue to a distant (recipient) site. Skin grafting can be used to repair almost any type of wound and is the most common form of reconstructive surgery.

Skin grafts are commonly used to repair surgical defects such as those that result from excision of skin tumors, to cover areas denuded of skin (e.g., burns), and to cover wounds in which insufficient skin is available to permit wound closure. They are also used when primary closure of the wound increases the risk of complications or when primary wound closure would interfere with function.

Skin grafts types, selection, and nursing management are detailed in the earlier part of this chapter on burn wound management.

Grafts are also referred to by their thickness. A skin graft may be a split-thickness (i.e., thin, intermediate, or thick) or a full-thickness graft, depending on the amount of dermis included in the specimen. A split-thickness graft can be cut at various thicknesses and is commonly used to cover large wounds or defects for which a full-thickness graft or flap is impractical (see Fig. 47-13). A full-thickness graft consists of epidermis and the entire dermis without the underlying fat. It is used to cover wounds that are too large to be closed directly (Urden, Stacy, & Lough, 2014).

Flaps

Another form of wound coverage is provided by flaps. A flap is a segment of tissue that remains attached at one end (i.e., a base or pedicle) while the other end is moved to a recipient area. Its survival depends on functioning arterial and venous blood supplies and lymphatic drainage in its pedicle or base (Clark, Wang, & Terris, 2015). A flap differs from a graft in that a portion of the tissue is attached to its original site and retains its blood supply. An exception is the free flap, which is described later.

Flaps may consist of skin, mucosa, muscle, adipose tissue, omentum, and bone. They are used for wound coverage and provide bulk, especially when bone, tendon, blood vessels, or nerve tissue is exposed. Flaps are used to repair defects caused by congenital deformity, trauma, or tumor ablation (removal, usually by excision) in an adjacent part of the body (Clark et al., 2015).

Flaps offer an aesthetic solution because a flap retains the color and texture of the donor area; is more likely to survive than a graft; and can be used to cover nerves, tendons, and blood vessels. However, several surgical procedures are usually required to advance a flap. The major complication is necrosis of the pedicle or base as a result of failure of the blood supply.

A striking advance in reconstructive surgery is the use of free flaps or free tissue transfer achieved by microvascular techniques. A free flap is completely severed from the body and transferred to another site. A free flap receives early vascular supply from microvascular anastomosis with vessels at the recipient site. The procedure usually is completed in one step, eliminating the need for a series of surgical procedures to move the flap. Microvascular surgery allows surgeons to use a variety of donor sites for tissue reconstruction (Clark et al., 2015).

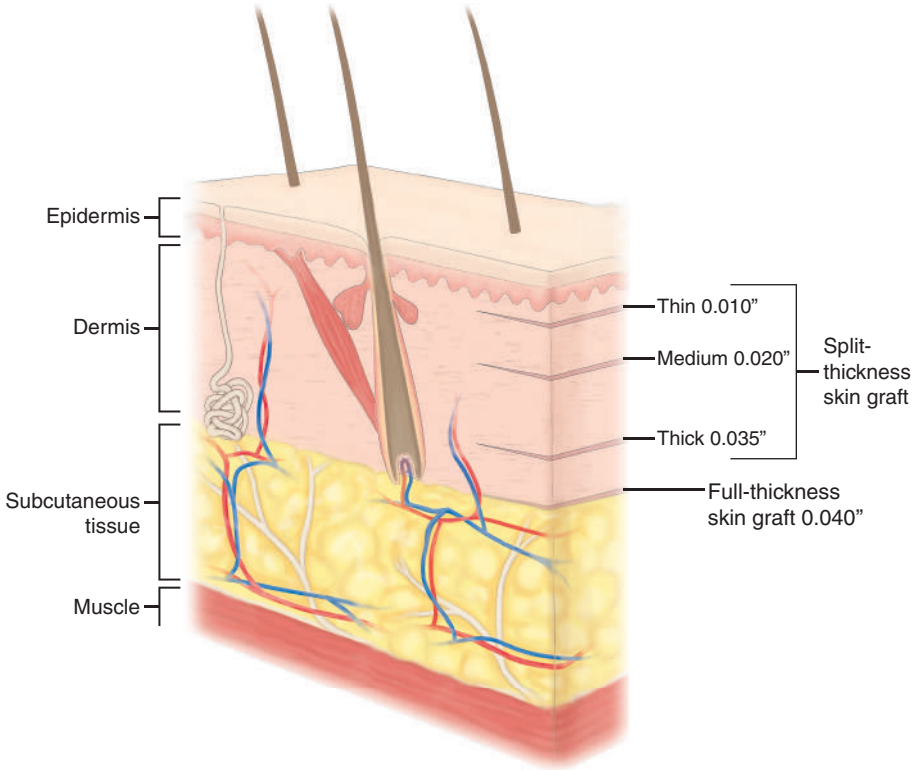

Figure 47-13 • Layers of skin appropriate for split and full thickness graft.

Cosmetic Procedures

Chemical Face Peeling

Chemical face peeling involves application of a chemical mixture to the face for superficial destruction of the epidermis and the upper layers of the dermis to treat fine wrinkles, keratoses, and pigment problems. It is especially useful for wrinkles at the upper and lower lip, forehead, and periorbital areas. The type of chemical used depends on the planned depth of the peel. The patient who is conscious feels a burning sensation that continues for 12 to 24 hours. Frequent small doses of analgesic and tranquilizing agents are prescribed to keep the patient comfortable. The most common complications include discoloration of the skin, infection of the burned area, persistent sensory changes or itching, and occasionally permanent scarring of the skin (Arif, 2015).

Dermabrasion

Dermabrasion is a form of skin abrasion used to treat acne scarring, aging, and sun-damaged skin. A special instrument (e.g., motor-driven wire brush, diamond-impregnated disc) is used. The epidermis and some superficial dermis are removed by a sanding-type action, and enough of the dermis is preserved to allow re-epithelization of the treated areas. Results are best in the face because it is rich in intradermal epithelial elements (Hession & Graber, 2015).

Patients with a history of herpes simplex viral infection are typically prescribed prophylactic antiviral medications (e.g., valacyclovir [Valtrex]) preprocedurally so that the physiologic stress of the procedure is less likely to cause a cutaneous herpes eruption. Tretinoin cream (Renova) may be prescribed with instructions to apply it 2 to 3 weeks preoperatively; this is associated with accelerating re-epithelialization post dermabrasion. Patients must be educated preprocedurally about the postprocedural dressing regimen and when to return to the primary provider to have dressing changes performed (Wong, Arnold, & Boeckman, 2016).

Facial Reconstructive Surgery

Reconstructive procedures on the face are individualized to the patient's needs and desired outcomes. They are performed to repair deformities or restore normal function. They may vary from closure of small defects to complicated procedures involving implantation of prosthetic devices to conceal a large defect or reconstruct a lost part of the face (e.g., nose, ear, jaw). Each surgical procedure is customized and involves a variety of incisions, flaps, and grafts. Multiple surgical procedures may be required.

The process of facial reconstruction is often slow and tedious. Because a person's facial appearance affects self-esteem so greatly, this type of reconstruction is often a very emotional experience for the patient.

Face-Lift

Rhytidectomy (face-lift) is a surgical procedure that removes soft tissue folds and minimizes cutaneous wrinkles on the face. It is performed to create a more youthful appearance. Psychological preparation requires that the patient recognize the limitations of surgery and the fact that miraculous rejuvenation will not occur. The patient is informed that the face may appear bruised and swollen after the dressings are removed and that several weeks may pass before the edema subsides. Corticosteroids (e.g., methylprednisolone) and vitamin C are prescribed postoperatively to minimize edema. Prophylactic antibiotic agents such as cephalexin (Keflex) may also be prescribed postoperatively (Warren & Neligan, 2013).

Laser Treatment of Cutaneous Lesions

Lasers are devices that amplify or generate highly specialized light energy. They can mobilize immense heat and power when focused at close range and are valuable tools in providing dermatologic abrasion therapy. The laser modalities used for this purpose today include scanned carbon dioxide laser, pulsed carbon dioxide laser, pulsed erbium/yttrium-aluminum-garnet (Er:YAG) laser, fractional Er:YAG laser resurfacing, combination carbon dioxide and Er:YAG lasers, and fractionated photothermolysis (Husain & Alster, 2016).

Each of these lasers is a precise surgical instrument that vaporizes and excises water-containing tissues with minimal damage. Because the beams used can seal blood and lymphatic vessels, they create a dry surgical field that makes many procedures easier and quicker. Therefore, these lasers are generally safe to use on patients with bleeding disorders or those receiving anticoagulant therapy. They are primarily used to improve the appearance of facial wrinkles, although they are also useful in removing epidermal nevi, tattoos, certain warts, skin cancer, ingrown toenails, and keloids. Incisions made with the laser beam heal and scar much like those made by a scalpel. Patients with a history of herpes simplex viral infection typically receive preprocedural antiviral prophylaxis (Husain & Alster, 2016).

Nursing Management

The majority of dermatologic and reconstructive procedures are performed in the physician's office or in an outpatient surgical department; therefore, most care takes place in the home. Most procedures, except very extensive reconstruction, are performed under local anesthesia or moderate sedation, therefore requiring a very short recovery time. Unless there are complications, the patient does not need hospitalization. The nurse must prepare both the patient and family for what to expect during the postoperative recovery time. Table 47-6 lists a few of the nursing considerations that must be reviewed in educating the patient and family.

Reconstructive Surgeries of the Congenital Defects

Reconstructive surgeries of the congenital defects have seen greater advancement in recent years. The congenital anomalies are one of the important causes for morbidity worldwide. These disorders are responsible for whopping 57.7 million disability-adjusted life years worldwide (WHO, 2013). Other than congenital heart disease, cleft lip, cleft palate, and hand abnormalities are major conditions requiring repair to maintain a reasonable quality of life. Affordability and accessibility to surgical correction is a major issue in low-income countries like India.

Reconstructive surgeries for polydactyly, syndactyly, and other types of hand and foot deformities give promising results.

Gender Reassignment

Gender reassignment surgery is a gender reaffirmation procedure that involves genital reconstruction to change

TABLE 47-6 Nursing Considerations in Cosmetic Procedures

Nursing Consideration	Interventions and Patient Education
Maintaining airway and pulmonary function	Cosmetic surgeries involving the face and neck can cause considerable swelling; bandages can restrict breathing or eating. Check dressings frequently, and ensure that no constriction occurs as swelling develops.
Relieving pain and achieving comfort	Procedures that involve a large surface area will cause considerable pain. Cool compresses or ice packs will relieve the burning of dermabrasion or chemical peels. Oral analgesic agents should be given regularly to control pain.
Maintaining adequate nutrition	When the face is involved, the patient may be unable to fully open the mouth, and chewing may be painful. Provide soft or liquid diet that is high in protein to assist with healing.
Enhancing communication	Depending on the type of cosmetic procedure, a nonverbal method of communication might be necessary until pain and swelling have subsided.
Improving self-concept	Recovery time from cosmetic procedures is slow. Expected results will take weeks to become apparent. Persons of color will experience increased pigmentation long after the initial wounds have healed. Helping patients to understand postoperative expectations will allow them to feel more comfortable with the healing process.
Promoting family coping	Most cosmetic procedures are performed in an outpatient facility; therefore, family members are integral to postoperative care. They should understand what to expect as the patient emerges from the procedure room: the type of dressings that will be in place, the skin care plan that is prescribed, and how to cope with the patient's pain.
Monitoring and managing potential complications	Infection is the most common complication, but excessive pain, nerve damage, and emotional distress about appearance are also common. If opioid analgesic agents are used, there may be gastrointestinal upset, mental status changes, or allergic reaction to the medication. Alert the caregiver to signs of these complications and how and when to report changes in status.

the genitalia from one gender to another. Transgenders may require gender reassignment surgery. Gender dysphoria is a condition classified in DSM-V as a type of mismatch between the perceived gender identity and the assigned biological sex. Individuals are attracted to the other sex and try to dress up and behave in confirmation to the opposite sex. During the time of puberty, they may experience intense anxiety and depression. Karyotyping may be performed to establish genetic abnormality before planning for gender reassignment procedure. Atypical sexual behaviors of the assigned sex or gender dysphoria is not an absolute indication for sex reassignment surgery as it involves lot of physical as well as psychological complications.

There are two types of sex reassignment procedure: male-to-female (MTF) and female-to-male surgery. Female-to-male surgery is a procedure that involves removal of the male sexual organ and reconstruction of a new vagina and breasts. After the surgery for adequate breast development and enhancement of the body shape, female hormones will be administered for at least 6 months (Gupta & Murarka, 2009). Counseling sessions with a psychologist need to be continued postsurgery as depression and suicidal ideations are very common.

Female-to-male surgery involves hormonal treatment, prosthetic implant, and reconstruction of functional phallus and urethra. Female-to-male gender reassignment surgery usually achieves lesser success due to the difficulty of creating a functioning penis from the much smaller clitoral tissue available in the female genitals. Apart from the genital organs, breasts also need to be surgically altered.

Legal Mandates for Gender Reassignment

Approval from two psychiatrists and psychologists and a certificate from a gynecologist are mandatory. Before the gender reassignment surgery, counseling sessions for 6 months with a qualified psychologist is a legal precondition (Gupta & Murarka, 2009). During these sessions, the risks involved are discussed. Parents and the young patients suffering from gender dysphoria need to be explained about the possible failure to achieve the desired results and other psychological disturbances.

Legal and Ethical Issues in Plastic Surgery

Plastic reconstructive surgeries are commonly performed to improve the functional and aesthetic appeal. Complications may arise following the procedures performed for the sole purpose of improving the look. Whenever the outcome of surgery is not in expected lines, it may attract legal suits against the treating surgeon and the team. An enormous amount of money and scarce medical resources are spent. The Government of India has not set the gender reassignment surgeries and other cosmetic procedures in the list of priority and these are not covered under health insurance schemes.

Autonomy and confidentiality are important aspects of legal and ethical issues in plastic reconstructive surgery. Nurses and health care professionals need to maintain a high degree of confidentiality about the treatment modalities and individual identities. Photographs taken for comparison purposes need to be taken and published after taking informed consent.

Skin Rejuvenation

Aging, heredity, stress, and excessive exposure to sunlight may lead to wrinkles, acne, scars, and loss of firmness and healthy glow. Skin rejuvenation refers to measures taken to bring back the lost contour and glow. There are numerous treatment modalities as well as over-the-counter cosmetic preparations.

Common skin rejuvenation treatments include chemical peels, laser, intense pulse light, ablative laser treatment, mechanical ablation, microneedling, dermafillers, and botulinum toxin. The skin rejuvenation therapies help in removing the scars, pigmentation, and sagging of the skin. Most of the skin conditions require multimodality and a series of treatment for excellent outcomes. Other than these therapies, cosmetic products such as moisturizers, lactic acids, humectants, retinoids, and antioxidants are widely used for aesthetic look (Grunebaum & Baumann, 2014). Stem cells derived from autologous adipose tissues, microfat, platelet therapies, and nanofat are effective in skin rejuvenation (Pourang, Rockwell, & Karim, 2020).

Derma Fillers

Derma fillers are substances used to augment soft tissues and to replace the lost subcutaneous fat. They are injectable materials used to lift up the sagging skin or facial folds that occur due to aging, heredity, or other reasons. Various types of derma fillers are available. Based on the origin, they can be classified as autograft, allograft, heterograft, and biosynthetic material. Temporary fillers are commonly biodegradable and last less than a year. Semipermanent materials such as cultured human fibroblasts may last from 1 to 2 years. Permanent derma fillers are synthetic and nonbiodegradable.

Some of the commonly used fillers are human collagen, porcine collagen, hyaluronic acids, autologous fats, and synthetic polymers. Usually, these products are injected superficially under the skin or a little beneath the dermal layer or deeply above the periosteal layers. Derma fillers may be used in augmenting the buttocks and breasts, lip enhancement, buccal cavity closure, correcting the skin folds, and correcting some skin diseases. They can be used alone or along with botulinum toxins.

Nursing Concerns

The procedure should be carried out with informed consent. The possible complications need to be explained. Preprocedure photographs are usually taken to compare the postprocedure effect. Nurses need to identify whether there is a history of allergy in the patients.

In the postprocedural phase, the nurse needs to instruct the patient not to massage or disturb the injected area for at least 6 hours. Strenuous exercises and exposure to extreme temperatures may also be avoided for at least 6 hours. On the day of the procedure, the patient has to sleep with the head end slightly elevated. Common complications are anaphylaxis, erythema, necrosis, and granuloma formation (Vedamurthy, 2008).

Liposuction

Liposuction is a surgical intervention in which excess subcutaneous fat is removed using a special cannula to achieve aesthetic body contour. It is otherwise called liposculpture or lipoplasty. Along with liposuction, lifestyle changes such as regular exercise, balanced diet, smoking, and alcohol cessation are important to achieve an optimal outcome. There are different types of liposuction, viz., suction-assisted liposuction, power-assisted liposuction, ultrasound-assisted liposuction, laser-assisted liposuction, and water-assisted liposuction.

Nurses need to assess the lifestyle and history of allergies before the procedure. Prior to the procedure, padding of the areas at risk for injury needs to be done. Post procedure, nurses should remain alert for possible thromboembolism as well as fat embolism. Nurse need to assist the patient to put on the compressive stockings. They should remain alert for fat embolism by observing for hypoxia, fever, tachypnea, and bilateral x-ray changes (Oliver, Pathan, & Mosahebi, 2016).

CRITICAL THINKING EXERCISES

1. A 45-year-old man sustains a steam burn while working on an offshore oil platform. He sustains third-degree burns over 65% of his body. He has delayed transportation to the nearest burn center. What should be the priorities of the first responders on the scene? On arrival to the treating facility, the patient's temperature is 35.2°C (95.3°F), and his weight is 62 kg. How should the treatment team at the burn treating facility prioritize this patient's care?
2. A 34-year-old woman is preparing dishes for a small birthday party of her son. In the process of cooking, the pressure pan burst and the contents of pan fell all over her right hand and forearm, and abdomen and anterior thighs. She is transported to the hospital for care. Using the rule of nines, what is her estimated TBSA? Based on the best evidence, what type of fluid should be used for resuscitation and why? What other information would you need to calculate her fluid requirements in the emergent/resuscitative phase?
3. A 69-year-old man was found down in the hallway of his apartment by firefighters, who extracted him from the smoke-filled building after being called to the scene by neighbors. He does not sustain obvious cutaneous burns. Upon interview and examination, he is tachypneic and exhibits hoarseness when speaking. You note singed nasal hair and lips. What is your immediate concern? What treatment should you expect the physician to prescribe first? Based on the current best evidence, what tests or procedures would most likely be prescribed to assist in the diagnosis and management of this patient?

CHAPTER 48

Assessment of Neurologic Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the structures and functions of the central and peripheral nervous systems.
2. Differentiate between pathologic changes that affect motor control and those that affect sensory pathways.
3. Compare and contrast the functioning of the sympathetic and parasympathetic nervous systems.
4. Explain the significance of physical assessment to the diagnosis of neurologic dysfunction.
5. Identify changes in neurologic function associated with aging and their impact on neurologic assessment findings.
6. Discuss diagnostic tests used for assessment of suspected neurologic disorders and the related nursing implications.

GLOSSARY

agnosia: loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile
ataxia: inability to coordinate muscle movements, resulting in difficulty in walking, talking, and performing self-care activities
autonomic nervous system: division of the nervous system that regulates the involuntary body functions
axon: portion of the neuron that conducts impulses away from the cell body
Babinski reflex (sign): a reflex action of the toes; in adults is indicative of abnormalities in the motor control pathways leading from the cerebral cortex
clonus: abnormal movement marked by alternating contraction and relaxation of a muscle occurring in rapid succession
delirium: an acute, confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death
dendrite: portion of the neuron that conducts impulses toward the cell body
flaccidity: displaying lack of muscle tone; limp, floppy
parasympathetic nervous system: division of the autonomic nervous system active primarily during nonstressful conditions, controlling mostly visceral functions
position (postural) sense: awareness of position of parts of the body without looking at them; also referred to as proprioception
reflex: an automatic response to stimuli
rigidity: increase in muscle tone at rest characterized by increased resistance to passive stretch
Romberg test: test for cerebellar dysfunction that can be done with the patient seated or standing; inability to maintain position for 20 seconds is a positive test
spasticity: sustained increase in tension of a muscle when it is passively lengthened or stretched
sympathetic nervous system: division of the autonomic nervous system with predominantly excitatory responses; the "fight-or-flight" system
vertigo: illusion of movement in which the individual or the surroundings are sensed as moving

Introduction

Nurses in many practice settings encounter patients with altered neurologic function. Disorders of the nervous system can occur at any time during the lifespan and can vary from mild, self-limiting symptoms to devastating, life-threatening disorders. Nurses must be skilled in the general assessment of neurologic function and be able to focus on specific areas as needed. Assessment requires knowledge of the anatomy and physiology of the nervous system and an understanding of the array of tests and procedures used to diagnose neurologic disorders. Knowledge about the nursing implications and interventions related to assessment and diagnostic testing is also essential.

Anatomic and Physiologic Overview

The nervous system consists of two major parts: the central nervous system (CNS), including the brain and spinal cord, and the peripheral nervous system, which includes the cranial nerves, spinal nerves, and autonomic nervous system. The function of the nervous system is to control motor, sensory, autonomic, cognitive, and behavioral activities. The brain itself contains more than 100 billion cells that link the motor and sensory pathways, monitor the body's processes, respond to the internal and external environment, maintain homeostasis, and direct all psychological, biologic, and physical activity through complex chemical and electrical messages (Klein & Stewart-Amidei, 2012).

Cells of the Nervous System

The basic functional unit of the brain is the neuron (see Fig. 48-1). It is composed of dendrites, a cell body, and an axon. The dendrites are branch-type structures for receiving electrochemical messages. The axon is a long projection that carries electrical impulses away from the cell body. Some axons have a myelinated sheath that increases speed of conduction. Nerve cell bodies occurring in clusters are called *ganglia* or *nuclei.* A cluster of cell bodies with the same function is called a *center* (e.g., the respiratory center). Neurons are supported, protected, and nourished by glial cells, which are 50 times greater in number than neurons (Hickey, 2014).

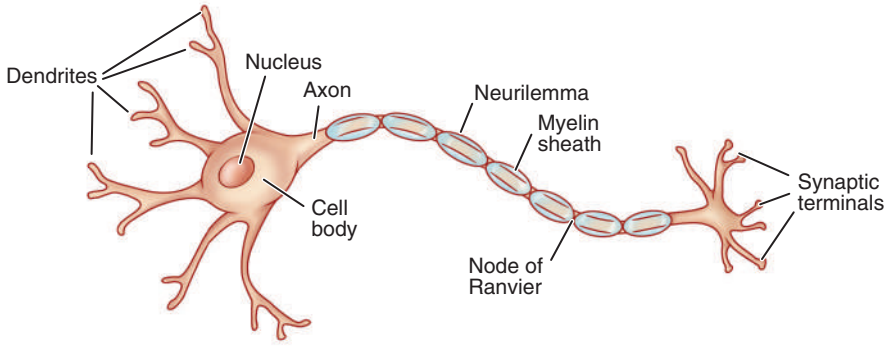

Figure 48-1 • Neuron.

Neurotransmitters

Neurotransmitters communicate messages from one neuron to another or from a neuron to a target cell, such as muscle or endocrine cells. Neurotransmitters are manufactured and stored in synaptic vesicles. As an electrical action potential moves along the axon and reaches the nerve terminal, neurotransmitters are released into the synapse. The neurotransmitter is transported across the synapse, binding to receptors on the postsynaptic cell membrane. A neurotransmitter can either excite or inhibit activity of the target cell. Usually, multiple neurotransmitters are at work in the neural synapse. The source and action of major neurotransmitters are described in Table 48-1. Once released, enzymes either destroy the neurotransmitter or reabsorb it into the neuron for future use.

Many neurologic disorders are due, at least in part, to an imbalance in neurotransmitters. For example, Parkinson disease develops from decreased availability of dopamine, whereas acetylcholine binding to muscle cells is impaired in myasthenia gravis (Porth, 2014). All brain functions are modulated through neurotransmitter receptor site activity, including memory and other cognitive processes (Hickey, 2014).

Ongoing research is evaluating diagnostic tests that can detect abnormal levels of neurotransmitters in the brain. Positron emission tomography (PET), for example, can detect dopamine, serotonin, and acetylcholine. Single-photon emission computed tomography (SPECT), similar to PET, can detect changes in some neurotransmitters, such as dopamine in Parkinson disease (Fischbach & Dunning, 2015). Both PET and SPECT are discussed in more detail later in this chapter.

The Central Nervous System

The Brain

The brain accounts for approximately 2% of the total body weight; in an average young adult, the brain weighs approximately 1400 g, whereas in an average older adult, the brain weighs approximately 1200 g (Hickey, 2014). The brain is divided into three major areas: the cerebrum, the brain stem, and the cerebellum. The cerebrum is composed of two hemispheres, the thalamus, the hypothalamus, and the basal ganglia. The brain stem includes the midbrain, pons, and medulla. The cerebellum is located under the cerebrum and behind the brain stem (see Fig. 48-2).

Cerebrum

The outside surface of the hemispheres has a wrinkled appearance that is the result of many folded layers or convolutions called *gyri,* which increase the surface area of the brain, accounting for the high level of activity carried out by such a small-appearing organ. Between each gyrus is a sulcus or fissure that serves as an anatomic division. In between the cerebral hemispheres is the great longitudinal fissure that separates the cerebrum into the right and left hemispheres. The two hemispheres are joined at the lower portion of the fissure

TABLE 48-1 Major Neurotransmitters

Neurotransmitter	Source	Action
Acetylcholine (major transmitter of the parasympathetic nervous system)	Many areas of the brain; autonomic nervous system	Usually excitatory; parasympathetic effects sometimes inhibitory (stimulation of heart by vagal nerve)
Serotonin	Brain stem, hypothalamus, dorsal horn of the spinal cord	Inhibitory; helps control mood and sleep, inhibits pain pathways
Dopamine	Substantia nigra and basal ganglia	Usually inhibitory; affects behavior (attention, emotions) and fine movement
Norepinephrine (major transmitter of the sympathetic nervous system)	Brain stem, hypothalamus, postganglionic neurons of the sympathetic nervous system	Usually excitatory; affects mood and overall activity
Gamma-aminobutyric acid	Spinal cord, cerebellum, basal ganglia, some cortical areas	Inhibitory
Enkephalin, endorphin	Nerve terminals in the spine, brain stem, thalamus and hypothalamus, pituitary gland	Excitatory; pleasurable sensation, inhibits pain transmission

Adapted from Porth, C. M. (2014). Essentials of pathophysiology (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

by the corpus callosum. The external or outer portion of the hemispheres (the cerebral cortex) is made up of gray matter approximately 2 to 5 mm in depth; it contains billions of neuron cell bodies, giving it a gray appearance. White matter makes up the innermost layer and is composed of myelinated nerve fibers and neuroglia cells that form tracts or pathways connecting various parts of the brain with one another. These pathways also connect the cortex with lower portions of the brain and spinal cord. The cerebral hemispheres are divided into pairs of lobes as follows (see Fig. 48-2):

- *Frontal*—the largest lobe, located in the front of the brain. The major functions of this lobe are concentration, abstract thought, information storage or memory, and motor function. It contains Broca area, which is located in the left hemisphere and is critical for motor control of speech. The frontal lobe is also responsible in large part for a person's affect, judgment, personality, and inhibitions (Hickey, 2014).
- *Parietal*—a predominantly sensory lobe posterior to the frontal lobe. This lobe analyzes sensory information and relays the interpretation of this information to other cortical areas and is essential to a person's awareness of body position in space, size and shape discrimination, and right–left orientation (Hickey, 2014).
- *Temporal*—located inferior to the frontal and parietal lobes, this lobe contains the auditory receptive areas and plays a role in memory of sound and understanding of language and music.
- *Occipital*—located posterior to the parietal lobe, this lobe is responsible for visual interpretation and memory.

The corpus callosum (see Fig. 48-3), a thick collection of nerve fibers that connects the two hemispheres of the brain, is responsible for the transmission of information from one side of the brain to the other. Information transferred includes sensation, memory, and learned discrimination. Right-handed people and some left-handed people have cerebral dominance on the left side of the brain for verbal, linguistic, arithmetic, calculation, and analytic functions. The nondominant hemisphere is responsible for geometric, spatial, visual, pattern, and musical functions. Nuclei for cranial nerves I and II are also located in the cerebrum.

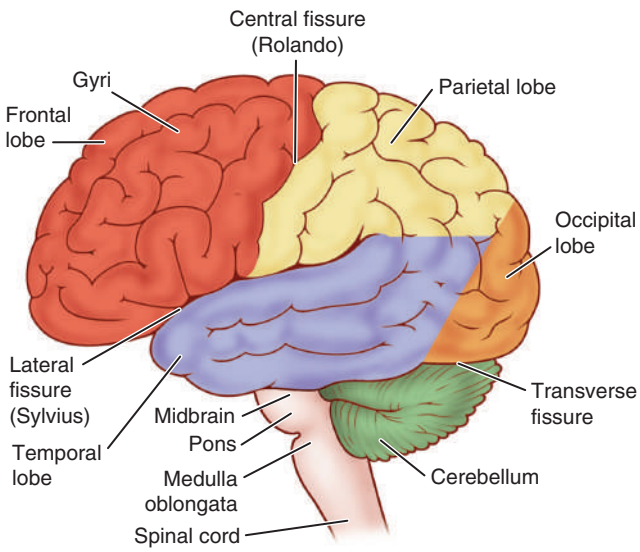

Figure 48-2 • View of the external surface of the brain showing lobes, cerebellum, and brain stem.

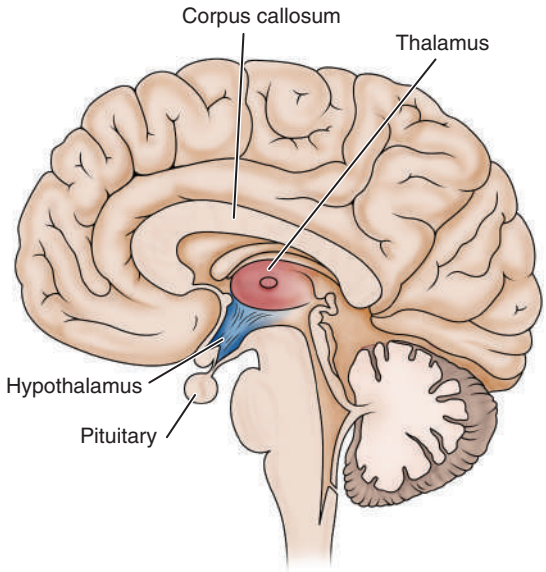

Figure 48-3 • Medial view of the brain.

The thalami lie on either side of the third ventricle and act primarily as a relay station for all sensation except smell. All memory, sensation, and pain impulses pass through this section of the brain. The hypothalamus (see Fig. 48-3) is located anterior and inferior to the thalamus, and beneath and lateral to the third ventricle. The infundibulum of the hypothalamus connects it to the posterior pituitary gland. The hypothalamus plays an important role in the endocrine system because it regulates the pituitary secretion of hormones that influence metabolism, reproduction, stress response, and urine production. It works with the pituitary to maintain fluid balance through hormonal release and maintains temperature regulation by promoting vasoconstriction or vasodilatation. In addition, the hypothalamus is the site of the hunger center and is involved in appetite control. It contains centers that regulate the sleep–wake cycle, blood pressure, aggressive and sexual behavior, and emotional responses (i.e., blushing, rage, depression, panic, and fear). The hypothalamus also controls and regulates the autonomic nervous system. The optic chiasm (the point at which the two optic tracts cross) and the mammillary bodies (involved in olfactory reflexes and emotional response to odors) are also found in this area.

The basal ganglia are masses of nuclei located deep in the cerebral hemispheres that are responsible for control of fine motor movements, including those of the hands and lower extremities.

Brain Stem

The brain stem consists of the midbrain, pons, and medulla oblongata (see Fig. 48-2). The midbrain connects the pons and the cerebellum with the cerebral hemispheres; it contains sensory and motor pathways and serves as the center for auditory and visual reflexes. Cranial nerves III and IV originate in the midbrain. The pons is situated in front of the cerebellum between the midbrain and the medulla and is a bridge between the two halves of the cerebellum, and between the medulla and the midbrain. Cranial nerves V through VIII originate in

the pons. The pons also contains motor and sensory pathways. Portions of the pons help regulate respiration.

Motor fibers from the brain to the spinal cord and sensory fibers from the spinal cord to the brain are located in the medulla. Most of these fibers cross, or decussate, at this level. Cranial nerves IX through XII originate in the medulla. Reflex centers for respiration, blood pressure, heart rate, coughing, vomiting, swallowing, and sneezing are also located in the medulla. The reticular formation, responsible for arousal and the sleep–wake cycle, begins in the medulla and connects with numerous higher structures.

Cerebellum

The cerebellum is posterior to the midbrain and pons, and below the occipital lobe (see Fig. 48-2). The cerebellum integrates sensory information to provide smooth coordinated movement. It controls fine movement, balance, and position (postural) sense or proprioception (awareness of position of extremities without looking at them).

Structures Protecting the Brain

The brain is contained in the rigid skull, which protects it from injury. The major bones of the skull are the frontal, temporal, parietal, occipital, and sphenoid bones. These bones join at the suture lines (see Fig. 48-4) and form the base of the skull. Indentations in the skull base are known as fossae. The anterior fossa contains the frontal lobe, the middle fossa contains the temporal lobe, and the posterior fossa contains the cerebellum and brain stem.

The meninges (fibrous connective tissues that cover the brain and spinal cord) provide protection, support, and nourishment. The layers of the meninges are the dura mater, arachnoid, and pia mater (see Fig. 48-5):

- *Dura mater*—the outermost layer; covers the brain and the spinal cord. It is tough, thick, inelastic, fibrous, and gray. There are three major extensions of the dura: the falx cerebri, which folds between the two hemispheres; the tentorium, which folds between the occipital lobe and cerebellum to form a tough, membranous shelf; and the falx cerebelli, which is located between the right and left side of the cerebellum. When excess pressure occurs in the cranial cavity, brain tissue may be compressed against these dural folds or displaced around them, a process called *herniation*. A potential space exists between the dura and the skull, and between the periosteum and the dura in the vertebral column, known as the epidural space. Another potential space, the subdural space, also exists below the dura. Blood or an abscess can accumulate in these potential spaces.
- *Arachnoid*—the middle membrane; an extremely thin, delicate membrane that closely resembles a spider web (hence the name *arachnoid*). The arachnoid membrane has cerebrospinal fluid (CSF) in the space below it, known as the subarachnoid space. This membrane has arachnoid villi, which are unique finger-like projections that absorb CSF into the venous system. When blood or bacteria enter the subarachnoid space, the villi become obstructed and *communicating* hydrocephalus (increased size of ventricles) may result.
- *Pia mater*—the innermost, thin, transparent layer that hugs the brain closely and extends into every fold of the brain's surface.

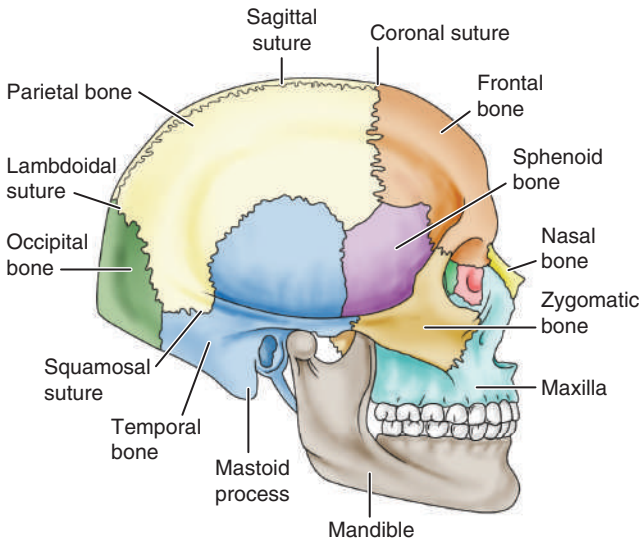

Figure 48-4 • Bones and sutures of the skull.

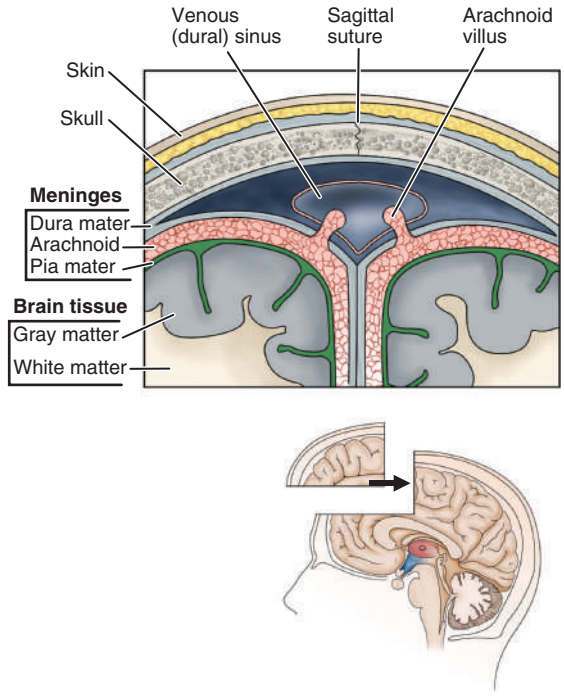

Figure 48-5 • Meninges and related structures.

Cerebrospinal Fluid

CSF is a clear and colorless fluid that is produced in the choroid plexus of the ventricles and circulates around the surface of the brain and the spinal cord. There are four ventricles: the right and left lateral and the third and fourth ventricles. The two lateral ventricles open into the third ventricle at the interventricular foramen (also known as the foramen of Monro). The third and fourth ventricles connect via the aqueduct of Sylvius. The fourth ventricle drains CSF into the subarachnoid space on the surface of the brain and spinal cord, where it is absorbed by the arachnoid villi. Blockage of the flow of CSF anywhere in the ventricular system produces *obstructive* hydrocephalus.

CSF is important in immune and metabolic functions in the brain. It is produced at a rate of about 500 mL/day; the ventricles and subarachnoid space contain approximately 150 mL of

fluid (Hickey, 2014). The composition of CSF is similar to other extracellular fluids (such as blood plasma), but the concentrations of the various constituents differ. A laboratory analysis of CSF indicates color (clear), specific gravity (normal 1.007), protein count, cell count, glucose, and other electrolyte levels (see Table A-5 in Appendix A). Normal CSF contains a minimal number of white blood cells and no red blood cells. The CSF may also be tested for immunoglobulins or the presence of bacteria. A CSF sample may be obtained through a lumbar puncture or intraventricular catheter (Hickey, 2014).

Cerebral Circulation

The brain does not store nutrients and requires a constant supply of oxygen. These needs are met through cerebral circulation; the brain receives approximately 15% of the cardiac output, or 750 mL per minute of blood flow. Brain circulation is unique in several aspects. First, arterial and venous vessels are not parallel as in other organs in the body; this is due in part to the role the venous system plays in CSF absorption. Second, the brain has collateral circulation through the circle of Willis (see later discussion), allowing blood flow to be redirected on demand. Third, blood vessels in the brain have two rather than three layers, which may make them more prone to rupture when weakened or under pressure.

Arteries

Arterial blood supply to the anterior brain originates from the common carotid artery, which is the first bifurcation off the aorta. The internal carotid arteries arise at the bifurcation of the common carotid. Branches of the internal carotid arteries (the anterior and middle cerebral arteries) and their connections (the anterior and posterior communicating arteries) form the circle of Willis (see Fig. 48-6).

The vertebral arteries branch from the subclavian arteries to supply most of the posterior circulation of the brain. At the level of the brain stem, the vertebral arteries join to form the basilar artery. The basilar artery divides to form the two branches of the posterior cerebral arteries. Functionally, the posterior and anterior portions of the circulation usually remain separate. However, the circle of Willis can provide collateral circulation through communicating arteries if one of the vessels supplying it becomes occluded or is ligated.

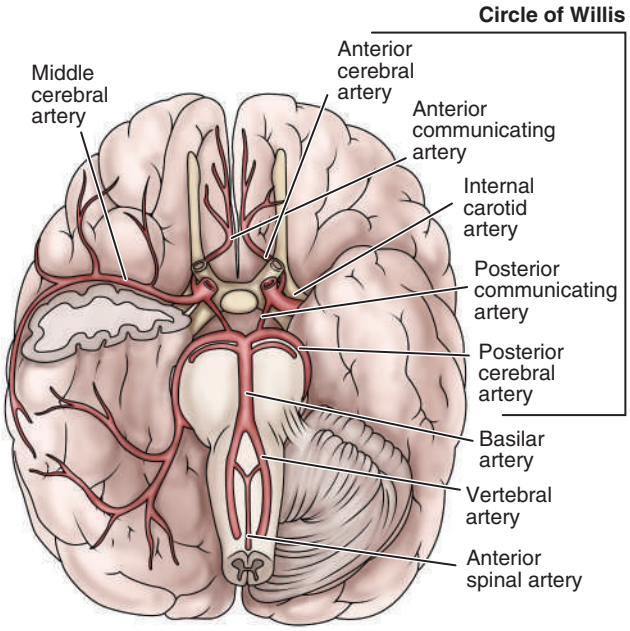

Figure 48-6 • Arterial blood supply of the brain, including the circle of Willis, as viewed from the ventral surface.

The bifurcations along the circle of Willis are frequent sites of aneurysm formation. Aneurysms are outpouchings of the blood vessel due to vessel wall weakness. Aneurysms can rupture and cause a hemorrhagic stroke. See Chapter 50 for a more detailed discussion of aneurysms.

Veins

Venous drainage for the brain does not follow the arterial circulation as in other body structures. The veins reach the brain's surface, join larger veins, and then cross the subarachnoid space and empty into the dural sinuses, which are the vascular channels embedded in the dura (see Fig. 48-5). The network of the sinuses carries venous outflow from the brain and empties into the internal jugular veins, returning the blood to the heart. Cerebral veins are unique, because unlike other veins in the body, they do not have valves to prevent blood from flowing backward and depend on both gravity and blood pressure for flow.

Blood–Brain Barrier

The CNS is inaccessible to many substances that circulate in the blood plasma (e.g., dyes, medications, and antibiotic agents) because of the blood–brain barrier. This barrier is formed by the endothelial cells of the brain's capillaries, which form continuous tight junctions, creating a barrier to macromolecules and many compounds. All substances entering the CSF must filter through the capillary endothelial cells and astrocytes. The blood–brain barrier has a protective function but can be altered by trauma, cerebral edema, and cerebral hypoxemia; this has implications for treatment and selection of medications for CNS disorders (Hickey, 2014).

The Spinal Cord

The spinal cord is continuous with the medulla, extending from the cerebral hemispheres and serving as the connection between the brain and the periphery. Approximately 45 cm (18 inches) long and about the thickness of a finger, it extends from the foramen magnum at the base of the skull to the lower border of the first lumbar vertebra, where it tapers to a fibrous band called the *conus medullaris*. Continuing below the second lumbar space are the nerve roots that extend beyond the conus, which are called the *cauda equina* because they resemble a horse's tail. Meninges surround the spinal cord.

In a cross-sectional view, the spinal cord has an H-shaped central core of nerve cell bodies (gray matter) surrounded by ascending and descending tracts (white matter) (see Fig. 48-7). The lower portion of the H is broader than the upper portion and corresponds to the anterior horns. The anterior horns contain cells with fibers that form the anterior (motor) root and are essential for the voluntary and reflex activity of the muscles they innervate. The thinner posterior (upper horns) portion contains cells with fibers that enter over the posterior (sensory) root and thus serve as a relay station in the sensory/reflex pathway.

The thoracic region of the spinal cord has a projection from each side at the crossbar of the H-shaped structure of gray matter called the *lateral horn*. It contains the cells that give rise to the autonomic fibers of the sympathetic division. The fibers

leave the spinal cord through the anterior roots in the thoracic and upper lumbar segments.

The Spinal Tracts

The white matter of the spinal cord is composed of myelinated and unmyelinated nerve fibers. The fast-conducting myelinated fibers form bundles; fiber bundles with a common function are called *tracts*.

There are six ascending tracts (see Fig. 48-7). Two tracts, known as the fasciculus cuneatus and gracilis or the posterior columns, conduct sensations of deep touch, pressure, vibration, position, and passive motion from the same side of the body. Before reaching the cerebral cortex, these fibers cross to the opposite side in the medulla. The anterior and posterior spinocerebellar tracts conduct sensory impulses from muscle spindles, providing necessary input for coordinated muscle contraction. They ascend uncrossed and terminate in the cerebellum. The anterior and lateral spinothalamic tracts are responsible for conduction of pain, temperature, proprioception, fine touch, and vibratory sense from the upper body to the brain. They cross to the opposite side of the cord and then ascend to the brain, terminating in the thalamus (Klein & Stewart-Amidei, 2012).

There are eight descending tracts (see Fig. 48-7). The anterior and lateral corticospinal tracts conduct motor impulses to the anterior horn cells from the opposite side of the brain, cross in the medulla, and control voluntary muscle activity. The three vestibulospinal tracts descend uncrossed and are involved in some autonomic functions (sweating, pupil dilation, and circulation) and involuntary muscle control. The corticobulbar tract conducts impulses responsible for voluntary head and facial muscle movement and crosses at the level of the brain stem. The rubrospinal and reticulospinal tracts conduct impulses involved with involuntary muscle movement.

Vertebral Column

The bones of the vertebral column surround and protect the spinal cord and normally consist of 7 cervical, 12 thoracic, and 5 lumbar vertebrae, as well as the sacrum (a fused mass of 5 vertebrae), and terminate in the coccyx. Nerve roots exit from the vertebral column through the intervertebral foramina (openings). The vertebrae are separated by discs, except for the first and second cervical, the sacral, and the coccygeal vertebrae. Each vertebra has a ventral solid body and a dorsal segment or arch, which is posterior to the body. The arch is composed of two pedicles and two laminae supporting seven processes.

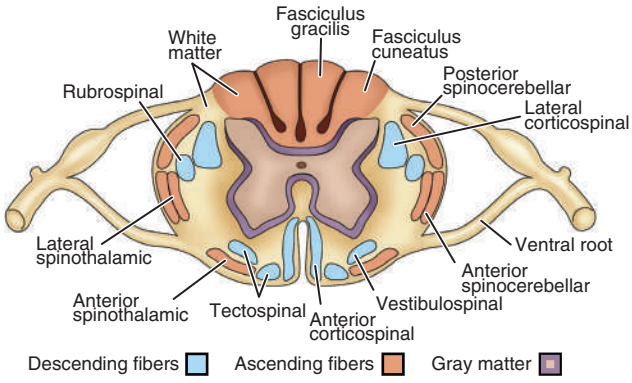

Figure 48-7 • Cross-sectional diagram of the spinal cord showing major spinal tracts.

The vertebral body, arch, pedicles, and laminae all encase and protect the spinal cord.

The Peripheral Nervous System

The peripheral nervous system includes the cranial nerves, the spinal nerves, and the autonomic nervous system.

Cranial Nerves

Twelve pairs of cranial nerves emerge from the lower surface of the brain and pass through openings in the base of the skull. Three cranial nerves are entirely sensory (I, II, VIII), five are motor (III, IV, VI, XI, and XII), and four are mixed sensory and motor (V, VII, IX, and X). The cranial nerves are numbered in the order in which they arise from the brain (see Fig. 48-8). The cranial nerves innervate the head, neck, and special sense structures. Table 48-2 identifies primary functions of the cranial nerves.

Spinal Nerves

The spinal cord is composed of 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve has a ventral root and a dorsal root. The dorsal roots are sensory and transmit sensory impulses from specific areas of the body known as dermatomes (see Fig. 48-9) to the dorsal horn ganglia. The sensory fiber may be somatic, carrying information about pain, temperature, touch, and position sense (proprioception) from the tendons, joints, and body surfaces; or visceral, carrying information from the internal organs.

The ventral roots are motor and transmit impulses from the spinal cord to the body; these fibers are also either somatic or visceral. The visceral fibers include autonomic fibers that control the cardiac muscles and glandular secretions.

Autonomic Nervous System

The autonomic nervous system regulates the activities of internal organs such as the heart, lungs, blood vessels, digestive organs, and glands (see Fig. 48-10). Maintenance and restoration of internal homeostasis is largely the responsibility of the autonomic nervous system. There are two major divisions:

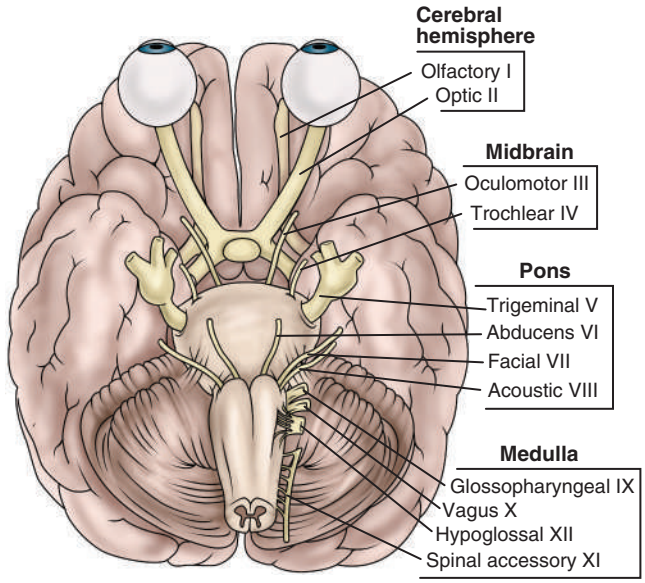

Figure 48-8 • Diagram of the base of the brain showing location of the cranial nerves.

TABLE 48-2 Cranial Nerves

Cranial Nerve	Type	Function
I (olfactory)	Sensory	Sense of smell
II (optic)	Sensory	Visual acuity and visual fields
III (oculomotor)	Motor	Muscles that move the eye and lid, pupillary constriction, lens accommodation
IV (trochlear)	Motor	Muscles that move the eye
V (trigeminal)	Mixed	Facial sensation, corneal reflex, mastication
VI (abducens)	Motor	Muscles that move the eye
VII (facial)	Mixed	Symmetry of facial expression and muscle movement in upper and lower face, salivation and tearing, taste, sensation in the ear
VIII (acoustic)	Sensory	Hearing and equilibrium
IX (glossopharyngeal)	Mixed	Taste, sensation in pharynx and tongue, pharyngeal muscles, swallowing
X (vagus)	Mixed	Muscles of pharynx, larynx, and soft palate; sensation in external ear, pharynx, larynx, thoracic and abdominal viscera; parasympathetic innervation of thoracic and abdominal organs
XI (spinal accessory)	Motor	Sternocleidomastoid and trapezius muscles
XII (hypoglossal)	Motor	Movement of the tongue

the sympathetic nervous system, with predominantly excitatory responses (most notably the "fight-or-flight" response), and the parasympathetic nervous system, which controls mostly visceral functions.

The autonomic nervous system innervates most body organs. Although usually considered part of the peripheral nervous system, this system is regulated by centers in the spinal cord, brain stem, and hypothalamus.

The hypothalamus is the major subcortical center for the regulation of autonomic activities, serving an inhibitory–excitatory role. The hypothalamus has connections that link the autonomic system with the thalamus, the cortex, the olfactory apparatus, and the pituitary gland. Located here are the mechanisms for the control of visceral and somatic reactions that were originally important for defense or attack and are associated with emotional states (e.g., fear, anger, and anxiety); for the control of metabolic processes, including fat, carbohydrate, and water metabolism; for the regulation of body temperature, arterial pressure, and all muscular and glandular activities of the gastrointestinal tract; for control of genital functions; and for the sleep cycle.

The autonomic nervous system is separated into the anatomically and functionally distinct sympathetic and parasympathetic divisions. Most of the tissues and the organs under autonomic control are innervated by both systems. For example, the parasympathetic division causes contraction (stimulation) of the urinary bladder muscles and a decrease (inhibition) in heart rate, whereas the sympathetic division produces relaxation (inhibition) of the urinary bladder and an increase (stimulation) in the rate and force of the heartbeat. Table 48-3 compares the sympathetic and the parasympathetic effects on the different systems of the body.

Sympathetic Nervous System

The sympathetic division of the autonomic nervous system is best known for its role in the body's fight-or-flight response. Under stress from either physical or emotional causes, sympathetic

TABLE 48-3 Effects of the Autonomic Nervous System

Structure or Activity	Parasympathetic Effects	Sympathetic Effects
Pupil of the Eye	Constricted	Dilated
Circulatory System		
Rate and force of heartbeat	Decreased	Increased
Blood vessels		
In heart muscle	Constricted	Dilated
In skeletal muscle	[a]	Dilated
In abdominal viscera and the skin	[a]	Constricted
Blood pressure	Decreased	Increased
Respiratory System		
Bronchioles	Constricted	Dilated
Rate of breathing	Decreased	Increased
Digestive System		
Peristaltic movements of digestive tube	Increased	Decreased
Muscular sphincters of digestive tube	Relaxed	Contracted
Secretion of salivary glands	Thin, watery saliva	Thick, viscid saliva
Secretions of stomach, intestine, and pancreas	Increased	[a]
Conversion of liver glycogen to glucose	[a]	Increased
Genitourinary System		
Urinary bladder		
Muscle walls	Contracted	Relaxed
Sphincters	Relaxed	Contracted
Muscles of the uterus	Relaxed; variable	Contracted under some conditions; varies with menstrual cycle and pregnancy
Blood vessels of external genitalia	Dilated	[a]
Integumentary System		
Secretion of sweat	[a]	Increased
Pilomotor muscles	[a]	Contracted (goose flesh)
Adrenal Medulla	[a]	Secretion of epinephrine and norepinephrine

[a]No direct effect.

impulses increase greatly. As a result, the bronchioles dilate for easier gas exchange; the heart's contractions are stronger and faster; the arteries to the heart and voluntary muscles dilate, carrying more blood to these organs; peripheral blood vessels constrict, making the skin feel cool but shunting blood to essential organs; the pupils dilate; the liver releases glucose for quick energy; peristalsis slows; hair stands on end; and perspiration increases. The main sympathetic neurotransmitter is norepinephrine (noradrenaline). A sympathetic discharge releases epinephrine (adrenalin)—hence, the term *adrenergic* is often used to refer to this division.

Sympathetic neurons are located primarily in the thoracic and lumbar segments of the spinal cord, and their axons, or the preganglionic fibers, emerge by way of anterior nerve roots from the eighth cervical or first thoracic segment to the second or third lumbar segment. A short distance from the cord, these fibers diverge to join a chain, composed of 22 linked ganglia, that extends the entire length of the spinal column, adjacent to the vertebral bodies on both sides. Some form multiple synapses with nerve cells within the chain. Others traverse the chain without making connections or losing continuity to join large "prevertebral" ganglia in the thorax, the abdomen, or the pelvis or one of the "terminal" ganglia in the vicinity of an organ, such as the bladder or the rectum at the end of the colon (see Fig. 48-10). Postganglionic nerve fibers originating in the sympathetic chain rejoin the spinal nerves that supply the extremities and are distributed to blood vessels, sweat glands, and smooth muscle tissue in the skin. Postganglionic fibers from the prevertebral plexuses (e.g., the cardiac, pulmonary, splanchnic, and pelvic plexuses) supply structures in the head and neck, thorax, abdomen, and pelvis, respectively, having been joined in these plexuses by fibers from the parasympathetic division.

The adrenal glands, kidneys, liver, spleen, stomach, and duodenum are under the control of the giant celiac plexus, commonly known as the solar plexus. This receives its sympathetic nerve components by way of the three splanchnic nerves, composed of preganglionic fibers from nine segments of the spinal cord (T4 to L1), and is joined by the vagus nerve, representing the parasympathetic division. From the celiac plexus, fibers of both divisions travel along the course of blood vessels to their target organs.

Certain syndromes are distinctive to the sympathetic nervous system. For example, sympathetic storm is a syndrome associated with changes in level of consciousness, altered vital signs, diaphoresis, and agitation that may result from hypothalamic stimulation of the sympathetic nervous system following traumatic brain injury (Fischbach & Dunning, 2015).

Parasympathetic Nervous System

The parasympathetic nervous system functions as the dominant controller for most visceral functions; the primary neurotransmitter is acetylcholine. During quiet, nonstressful conditions, impulses from parasympathetic fibers (cholinergic) predominate. The fibers of the parasympathetic system are located in two sections: one in the brain stem and the other from spinal segments below L2. Because of the location of these fibers, the parasympathetic system is referred to as the craniosacral division, as distinct from the thoracolumbar (sympathetic) division of the autonomic nervous system.

The parasympathetic nerves arise from the midbrain and the medulla oblongata. Fibers from cells in the midbrain travel with the third oculomotor nerve to the ciliary ganglia, where postganglionic fibers of this division are joined by those of the sympathetic system, creating controlled opposition, with a delicate balance maintained between the two at all times.

Motor and Sensory Pathways of the Nervous System

Motor Pathways

The corticospinal tract begins in the motor cortex, a vertical band within each frontal lobe, and controls voluntary movements of the body. The exact locations within the brain at which the voluntary movements of the muscles of the face,

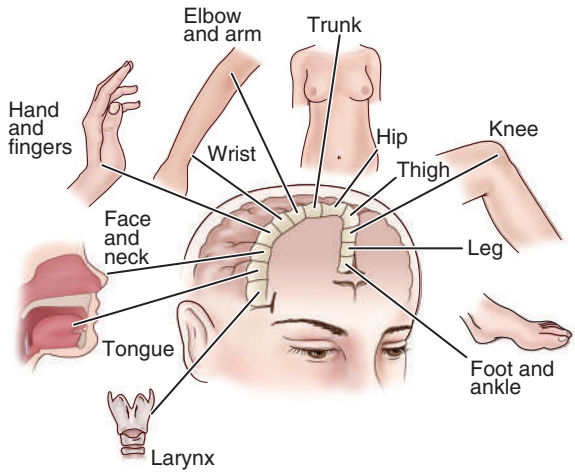

Figure 48-11 • Diagrammatic representation of the cerebrum showing locations for control of motor movement of various parts of the body.

thumb, hand, arm, trunk, and leg originate are known (see Fig. 48-11). To initiate movement, these particular cells must send the stimulus along their fibers. Stimulation of these cells with an electric current also results in muscle contraction. En route to the pons, the motor fibers converge into a tight bundle known as the internal capsule. A comparatively small injury to the internal capsule results in a more severe paralysis than does a larger injury to the cortex itself.

At the medulla, the corticospinal tracts cross to the opposite side, continuing to the anterior horn of the spinal cord, in proximity to a motor nerve cell. Until this point, neurons are known as upper motor neurons. As they connect to motor fibers of the spinal nerves, they become lower motor neurons. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle.

Involuntary motor activity is also possible and is mediated through reflex arcs. Synaptic connections between anterior horn cells and sensory fibers that have entered adjacent or neighboring segments of the spinal cord serve as protective mechanisms. These connections are seen during deep tendon reflex testing.

Upper and Lower Motor Neurons

The voluntary motor system consists of two groups of neurons: upper motor neurons and lower motor neurons. Upper motor neurons originate in the cerebral cortex, the cerebellum, and the brain stem. Their fibers make up the descending motor pathways, are located entirely within the CNS, and modulate the activity of the lower motor neurons. Lower motor neurons are located either in the anterior horn of the spinal cord gray matter or within cranial nerve nuclei in the brain stem. Axons of lower motor neurons in both sites extend through peripheral nerves and terminate in skeletal muscle. Lower motor neurons are located in both the CNS and the peripheral nervous system.

The motor pathways from the brain to the spinal cord, as well as from the cerebrum to the brain stem, are formed by upper motor neurons. They begin in the cortex of one side of the brain, descend through the internal capsule, cross to the opposite side in the brain stem, descend through the corticospinal tract, and synapse with the lower motor neurons in the cord. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle. The clinical features of lesions of upper and lower motor neurons are discussed in the following sections and in Table 48-4.

TABLE 48-4 Comparison of Upper Motor Neuron and Lower Motor Neuron Lesions

Upper Motor Neuron Lesions	Lower Motor Neuron Lesions
Loss of voluntary control	Loss of voluntary control
Increased muscle tone	Decreased muscle tone
Muscle spasticity	Flaccid muscle paralysis
No muscle atrophy	Muscle atrophy
Hyperactive and abnormal reflexes	Absent or decreased reflexes

Upper motor neuron lesions

Upper motor neuron lesions can involve the motor cortex, the internal capsule, the spinal cord gray matter, and other structures of the brain through which the corticospinal tract descends. If the upper motor neurons are damaged or destroyed, as frequently occur with stroke or spinal cord injury, paralysis (loss of voluntary movement) results. However, because the inhibitory influences of intact upper motor neurons are impaired, reflex (involuntary) movements are uninhibited, and hence hyperactive deep tendon reflexes, diminished or absent superficial reflexes, and pathologic reflexes such as a Babinski response occur. Severe leg spasms can occur as the result of an upper motor neuron lesion; the spasms result from the preserved reflex arc, which lacks inhibition along the spinal cord below the level of injury. There is little or no muscle atrophy, and muscles remain permanently tense, exhibiting spastic paralysis.

Paralysis associated with upper motor neuron lesions can affect a whole extremity, both extremities, or an entire half of the body. *Hemiplegia* (paralysis of an arm and leg on the same side of the body) can be the result of an upper motor neuron lesion. If hemorrhage, an embolus, or a thrombus destroys the fibers from the motor area in the internal capsule, the arm and the leg of the opposite side become stiff, weak, or paralyzed, and the reflexes are hyperactive (see further discussion of hemiplegia in Chapter 50). If both legs are paralyzed, the condition is called *paraplegia*. If all four extremities are paralyzed, the condition is called *tetraplegia* (quadriplegia).

Lower motor neuron lesions

A patient is considered to have lower motor neuron damage if a motor nerve is damaged between the spinal cord and muscle. The result of lower motor neuron damage is muscle paralysis. Reflexes are lost, and the muscle becomes flaccid (limp) and atrophied from disuse. If the patient has injured the spinal trunk and it can heal, the use of muscles connected to that section of the spinal cord may be regained. However, if the anterior horn motor cells are destroyed, the nerves cannot regenerate and the muscles are never useful again.

Flaccid paralysis and atrophy of the affected muscles are the principal signs of lower motor neuron disease. Lower motor neuron lesions can be the result of trauma, infection (poliomyelitis), toxins, vascular disorders, congenital malformations, degenerative processes, and neoplasms. Compression of nerve roots by herniated intervertebral discs is a common cause of lower motor neuron dysfunction.

Coordination of Movement

The motor system is complex, and motor function depends not only on the integrity of the corticospinal tracts but also on other pathways from the basal ganglia and cerebellum that control and coordinate voluntary motor function. The smoothness, accuracy, and strength that characterize the muscular movements of a normal person are attributable to the influence of the cerebellum and the basal ganglia.

Through the action of the cerebellum, the contractions of opposing muscle groups are adjusted in relation to each other to maximal mechanical advantage; muscle contractions can be sustained evenly at the desired tension and without significant fluctuation, and reciprocal movements can be reproduced at high and constant speed, in stereotyped fashion and with relatively little effort.

The basal ganglia play an important role in planning and coordinating motor movements and posture. Complex neural connections link the basal ganglia with the cerebral cortex. The major effect of these structures is to inhibit unwanted muscular activity.

Impaired cerebellar function, which may occur as a result of an intracranial injury or some type of an expanding mass (e.g., a hemorrhage, an abscess, or a tumor), results in loss of muscle tone, weakness, and fatigue. Depending on the area of the brain affected, the patient has different motor symptoms or responses. The patient may demonstrate abnormal flexion, abnormal extension, or flaccid posturing. Flaccidity (lack of muscle tone) preceded by abnormal posturing in a patient with cerebral injury indicates severe neurologic impairment, which may herald brain death (Klein & Stewart-Amidei, 2012); (Posner, Saper, Schiff, et al., 2007). See Figure 49-2 in Chapter 49 for further explanation of posturing.

Destruction or dysfunction of the basal ganglia leads not to paralysis but to muscle rigidity, disturbances of posture, and difficulty initiating or changing movement. The patient tends to have involuntary movements. These may take the form of coarse tremors, most often in the upper extremities, particularly in the distal portions; athetosis, which is movement of a slow, squirming, writhing, twisting type; or chorea, marked by spasmodic, purposeless, irregular, uncoordinated motions of the trunk and the extremities, and facial grimacing. Disorders affecting basal ganglia activity include Parkinson and Huntington diseases (see Chapter 53).

Sensory System Function

Receiving Sensory Impulses

Afferent impulses travel from their points of origin to their destinations in the cerebral cortex via the ascending pathways directly, or they may cross at the level of the spinal cord or in the medulla, depending on the type of sensation carried. Knowledge of these pathways is important for neurologic assessment and for understanding symptoms and their relationship to various lesions.

Sensory impulses convey sensations of heat, cold, and pain; position; and vibration. The axons enter the spinal cord by way of the posterior root, specifically in the posterior gray columns of the spinal cord, where they connect with the cells of secondary neurons. Pain and temperature fibers (located in the spinothalamic tract) cross immediately to the opposite side of the cord and course upward to the thalamus. Fibers carrying sensations of touch, light pressure, and localization do not connect immediately with the second neuron but ascend the cord for a variable distance before entering the gray matter and completing this connection. The axon of the secondary neuron traverses the cord, crosses in the medulla, and proceeds upward to the thalamus.

Position and vibratory sensations are produced by stimuli arising from muscles, joints, and bones. These stimuli are conveyed, uncrossed, all the way to the brain stem by the axon of the primary neuron. In the medulla, synaptic connections are made with cells of the secondary neurons, whose axons cross to the opposite side and then proceed to the thalamus.

Integrating Sensory Impulses

The thalamus integrates all sensory impulses except olfaction. It plays a role in the conscious awareness of pain and the recognition of variation in temperature and touch. The thalamus is responsible for the sense of movement and position as well as the ability to recognize the size, shape, and quality of objects. Sensory information is relayed from the thalamus to the parietal lobe for interpretation.

Sensory Losses

Destruction of a sensory nerve results in total loss of sensation in its area of distribution (see Fig. 48-9). Lesions affecting the posterior spinal nerve roots may impair tactile sensation, causing intermittent severe pain that is referred to their areas of distribution. Destruction of the spinal cord yields complete anesthesia below the level of injury. Selective destruction or degeneration of the posterior columns of the spinal cord is responsible for a loss of position and vibratory sense in segments distal to the lesion, without loss of touch, pain, or temperature perception. A cyst in the center of the spinal cord causes dissociation of sensation—loss of pain at the level of the lesion. This occurs because the fibers carrying pain and temperature cross within the cord immediately on entering; thus, any lesion that divides the cord longitudinally divides these fibers. Other sensory fibers ascend the cord for variable distances, some even to the medulla, before crossing, thereby bypassing the lesion and avoiding destruction. Lesions in the thalamus or parietal lobe result in impaired touch, pain, temperature, and proprioceptive sensations.

Assessment of the Nervous System

Health History

An important aspect of the neurologic assessment is the history of the present illness. The initial interview provides an excellent opportunity to systematically explore the patient's current condition and related events while simultaneously observing overall appearance, mental status, posture, movement, and affect. Depending on the patient's condition, the nurse may need to rely on yes-or-no answers to questions, a review of the medical record, input from witnesses or the family, or a combination of these.

Neurologic disorders may be stable or progressive, characterized by symptom-free periods as well as fluctuations in symptoms. The health history therefore includes details about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members.

Common Symptoms

The symptoms of neurologic disorders are as varied as the disease processes. Symptoms may be subtle or intense,

fluctuating or permanent, inconvenient or devastating. This chapter discusses the most common signs and symptoms associated with neurologic disease; the relationship of specific signs and symptoms to a particular disorder is presented in later chapters in this unit.

Pain

Pain is considered an unpleasant sensory perception and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Pain is therefore considered multidimensional and entirely subjective. Pain can be acute or chronic. In general, acute pain lasts for a relatively short period of time and remits as the pathology resolves. In neurologic disease, acute pain may be associated with brain hemorrhage, spinal disc disease (Jarvis, 2015), or trigeminal neuralgia. In contrast, chronic or persistent pain extends for long periods of time and may represent a broader pathology. This type of pain can occur with many degenerative and chronic neurologic conditions (e.g., multiple sclerosis). See Chapter 9 for a more detailed discussion of pain.

Seizures

Seizures are the result of abnormal electrical discharges in the cerebral cortex, which then manifest as an alteration in sensation, behavior, movement, perception, or consciousness. The alteration may be short, such as in a blank stare that lasts only a second, or of longer duration, such as a tonic–clonic grand mal seizure that can last several minutes. The seizure activity reflects the area of the brain affected. Seizures can occur as isolated events, such as when induced by a high fever, alcohol or drug withdrawal, or hypoglycemia. A seizure may also be the first obvious sign of a brain lesion (Hickey, 2014).

Dizziness and Vertigo

Dizziness is an abnormal sensation of imbalance or movement. It is fairly common in the older adult and a common complaint encountered by health professionals (Jarvis, 2015). Dizziness can have a variety of causes, including viral syndromes, hot weather, roller-coaster rides, and middle ear infections, to name a few. One difficulty confronting health care providers when assessing dizziness is the vague and varied terms that patients use to describe the sensation.

About 50% of all patients with dizziness have vertigo, or the illusion of movement in which the individual or the surroundings are sensed as moving, usually as rotation (Jarvis, 2015). Vertigo is usually a manifestation of vestibular dysfunction. It can be so severe as to result in spatial disorientation, lightheadedness, loss of equilibrium (staggering), and nausea and vomiting.

Visual Disturbances

Visual defects that cause people to seek health care can range from the decreased visual acuity associated with aging to sudden blindness caused by glaucoma. Normal vision depends on functioning visual pathways through the retina and optic chiasm and the radiations into the visual cortex in the occipital lobes. Lesions of the eye itself (e.g., cataract), lesions along the pathway (e.g., tumor), or lesions in the visual cortex (e.g., stroke) interfere with normal visual acuity. Abnormalities of eye movement (as in the nystagmus associated with multiple sclerosis) can also compromise vision by causing diplopia or double vision. See Chapter 42 for a more detailed discussion of disorders that affect vision.

Muscle Weakness

Muscle weakness is a common manifestation of neurologic disease. It frequently coexists with other symptoms of disease and can affect a variety of muscles, causing a wide range of disability. Weakness can be sudden and permanent, as in stroke, or progressive, as in neuromuscular diseases such as amyotrophic lateral sclerosis. Any muscle group can be affected.

Abnormal Sensation

Abnormal sensation is a neurologic manifestation of both central and peripheral nervous system disease. Altered sensation can affect small or large areas of the body. It is frequently associated with weakness or pain and is potentially disabling. Lack of sensation places a person at risk for falls and injury.

Past Health, Family, and Social History

The nurse may inquire about any family history of genetic diseases (see Chart 48-1). A review of the medical history, including a system-by-system evaluation, is part of the health history. The nurse should be aware of any history of trauma or falls that may have involved the head or spinal cord. Questions regarding the use of alcohol, medications, and illicit drugs are also relevant. The history-taking portion of the neurologic assessment is critical and, in many cases of neurologic disease, leads to an accurate diagnosis.

Physical Assessment

The neurologic examination is a systematic process that includes a variety of clinical tests, observations, and assessments designed to evaluate the neurologic status of a complex system. Many neurologic rating scales exist (Herndon, 2006), and some of the more common ones are discussed in this chapter.

The brain and spinal cord cannot be examined as directly as other systems of the body. Therefore, much of the neurologic examination is an indirect evaluation that assesses the function of the specific body part or parts controlled by the nervous system. A neurologic assessment is divided into five components: consciousness and cognition, cranial nerves, motor system, sensory system, and reflexes. One or more components may become the priority assessment, depending on the patient's condition. For example, motor, sensory, and reflex assessments are the priority in patients with spinal injury, whereas in a patient who is comatose, the cranial nerves and level of consciousness become the priority.

Assessing Consciousness and Cognition

Cerebral abnormalities may cause disturbances in mental status, intellectual functioning, thought content, and emotional status. There may also be alterations in language abilities as well as lifestyle. The examiner must also be aware of the patient's overall level of consciousness and any changes over time (Posner et al., 2007).

The examiner records and reports specific observations regarding mental status, intellectual function, thought content, and emotional status, all of which permit comparison by others over time. Alterations should be described in specific and nonjudgmental terms. The use of terms such as "inappropriate" or "demented" is avoided, because they often mean different things to different people and are therefore not useful when describing behavior. Analysis and the conclusions that may be drawn from these findings usually depend on the examiner's knowledge of neuroanatomy, neurophysiology, and neuropathology.

Chart 48-1 GENETICS IN NURSING PRACTICE

Neurologic Disorders

Several neurologic disorders are associated with genetic abnormalities. Neurologic impairment is noted with many other genetic illnesses. Some examples include:

Autosomal Dominant:

- Cerebral arteriopathy
- Familial Alzheimer disease
- Huntington disease
- Myotonic dystrophies
- Neurofibromatosis
- Von Hippel–Lindau syndrome

Autosomal Recessive:

- Canavan disease
- Familial dysautonomia
- Friedreich's ataxia

X Linked:

- Duchenne muscular dystrophy
- Fragile X syndrome

Inheritance pattern is not distinct; however, there is a genetic predisposition for the disease:

- Amyotrophic lateral sclerosis (ALS)
- Epilepsy
- Neural tube defects (e.g., spina bifida, anencephaly)
- Parkinson disease
- Tourette syndrome

Other genetic disorders that also impact the neurologic system:

- Bipolar disease
- Downs syndrome
- Phenylketonuria (PKU)
- Schizophrenia
- Tay–Sachs disease
- Tuberous sclerosis complex

Nursing Assessments

Family History Assessment Specific to Neurologic Disorders

- Assess for other similarly affected relatives with neurologic impairment.
- Inquire about age of onset (e.g., present at birth—spina bifida; developed in childhood—Duchenne muscular dystrophy; developed in adulthood—Huntington disease, Alzheimer disease, ALS).
- Inquire about the presence of related conditions such as intellectual disability and/or learning disabilities (neurofibromatosis type 1).

Patient Assessment

- Assess for the presence of other physical features suggestive of an underlying genetic condition, such as skin lesions seen in neurofibromatosis (café au lait spots).
- Assess attention span, and the presence of hyperactivity or withdrawn behavior.
- Assess for other congenital abnormalities (e.g., cardiac, ocular).
- Inspect for presence of freckles in the axillary or inguinal areas.
- Assess for presence of uncoordinated movement of extremities, muscle twitching, or history of seizures.
- Assess for poor or hyperactive muscle tone.
- Assess for episodes of forgetfulness or uncharacteristic changes in behavior or mood.
- Inspect for disproportionate facial features (fragile X or Downs syndrome).
- Observe for presence of "tics" or uncontrolled body movement.
- Ask about history of seizures or head trauma.

Mental Status

An assessment of mental status begins by observing the patient's appearance and behavior, noting dress, grooming, and personal hygiene. Posture, gestures, movements, and facial expressions often provide important information about the patient. Does the patient appear to be aware of and interact with the surroundings?

Assessing orientation to time, place, and person assists in evaluating mental status. Does the patient know what day it is, what year it is, and the name of the Prime Minister of India? Is the patient aware of where he or she is? Is the patient aware of who the examiner is and of their purpose for being in the room? Assessment of immediate and remote memory is also important. Is the capacity for immediate memory intact? See Chapter 62.

Intellectual Function

A person with an average intelligence quotient (IQ) can repeat seven digits without faltering and can recite five digits backward. The examiner might ask the patient to count backward from 100 or to subtract 7 from 100, then 7 from that, and so forth (referred to as serial 7s). The capacity to interpret well-known proverbs tests abstract reasoning, which is a higher intellectual function—for example, does the patient know what is meant by "a stitch in time saves nine"? The intellectual function of patients with damage to the frontal cortex appears intact until one or more tests of intellectual capacity are performed. Questions designed to assess this capacity might include the ability to recognize similarities—for example, how are a mouse and dog or pen and pencil alike? Can the patient make judgments about situations—for example, if the patient arrives home without a house key, what alternatives are there?

Thought Content

During the interview, it is important to assess the patient's thought content. Are the patient's thoughts spontaneous, natural, clear, relevant, and coherent? Does the patient have any fixed ideas, illusions, or preoccupations? What are their insights into these thoughts? Preoccupation with death or morbid events, hallucinations, and paranoid ideation are examples of unusual thoughts or perceptions that require further evaluation.

Emotional Status

An assessment of consciousness and cognition also includes the patient's emotional status. Is the patient's affect (external manifestation of mood) natural and even, or irritable and angry, anxious, apathetic or flat, or euphoric? Does their mood fluctuate normally, or does the patient unpredictably swing from joy to sadness during the interview? Is affect appropriate to words and thought content? Are verbal communications consistent with nonverbal cues?

Language Ability

The person with normal neurologic function can understand and communicate in spoken and written language. Does the patient answer questions appropriately? Can he or she read a sentence from a newspaper and explain its meaning? Can the patient write their name or copy a simple figure that the examiner has drawn? A deficiency in language function is called *aphasia*. Different types of aphasia result from injury to different parts of the brain (see Table 48-5). See Chapter 50 for a detailed discussion of aphasia.

Impact on Lifestyle

The nurse assesses the impact of any impairment on the patient's lifestyle. Issues to consider include the limitations imposed on the patient by any cognitive deficit and the patient's role in society, including family and community roles. The plan of care that the nurse develops needs to address and support adaptation to the neurologic deficit and continued function to the extent possible within the patient's support system.

Level of Consciousness

Consciousness is the patient's wakefulness and ability to respond to the environment. Level of consciousness is the most sensitive indicator of neurologic function. To assess level of consciousness, the examiner observes for alertness and ability to follow commands.

If the patient is not alert or able to follow commands, the examiner observes for eye opening; verbal response and motor response to stimuli, if any; and the type of stimuli needed to obtain a response. Noxious stimuli should be used first, then painful stimuli if no response is observed. In the patient with decreased level of consciousness, motor and cranial nerve functions become the priority assessments, because abnormalities can indicate the area of involvement in the absence of responsiveness. See Chapter 49 for further discussion of changes in level of consciousness.

Examining the Cranial Nerves

Cranial nerves are assessed when level of consciousness is decreased, with brain stem pathology, or in the presence of peripheral nervous system disease (Weber & Kelley, 2014). Right and left cranial nerve functions are compared throughout the examination.

For the procedural guidelines for assessing cranial nerve function, refer to Procedural Guidelines 48-1.

Examining the Motor System

Motor Ability

A thorough examination of the motor system includes an assessment of muscle size and tone as well as strength, coordination, and balance. The patient is instructed to walk across the room, if possible, while the examiner observes posture and gait. The muscles are inspected, and palpated if necessary, for their size and symmetry. Any evidence of atrophy or involuntary movements (tremors, tics) is noted. Muscle tone (the tension present in a muscle at rest) is evaluated by palpating various muscle groups at rest and during passive movement. Resistance to these movements is assessed and documented. Abnormalities in tone include spasticity (increased muscle tone), rigidity (resistance to passive stretch), and flaccidity.

TABLE 48-5 Types of Aphasia and Region of Brain Involved

Type of Aphasia	Brain Area Involved
Auditory receptive	Temporal lobe
Visual receptive	Parietal and occipital area
Expressive speaking	Inferior-posterior frontal areas
Expressive writing	Posterior frontal area

Muscle Strength

Assessing the patient's ability to flex or extend the extremities against resistance tests muscle strength. The function of an individual muscle or group of muscles is evaluated by placing the muscle at a disadvantage. The quadriceps, for example, is a powerful muscle responsible for straightening the leg. Once the leg is straightened, it is exceedingly difficult for the examiner to flex the knee. If the knee is flexed and the patient is asked to straighten the leg against resistance, weakness can be elicited. The evaluation of muscle strength compares the sides of the body to each other. For example, the right upper extremity is compared to the left upper extremity. Subtle differences in strength may be evaluated by testing for drift. For example, both arms are out in front of the patient with palms up; drift is seen as pronation of the palm, indicating a subtle weakness that may not have been detected on the resistance examination.

Clinicians use a five-point scale to rate muscle strength. A 5 indicates full power of contraction against gravity and resistance or normal muscle strength; 4 indicates fair but not full strength against gravity and a moderate amount of resistance or slight weakness; 3 indicates just sufficient strength to overcome the force of gravity or moderate weakness; 2 indicates the ability to move but not to overcome the force of gravity or severe weakness; 1 indicates minimal contractile power (weak muscle contraction can be palpated but no movement is noted) or very severe weakness; and 0 indicates no movement (Jarvis, 2015).

Nursing Alert: When recording muscle strength, a stick figure is used as a precise form to document findings. The five-point scale is used to rate and record distal and proximal strength in both upper and lower extremities. Figure 48-12 provides further details.

Assessment of muscle strength may be as detailed as necessary. One may quickly test the strength of the proximal muscles of the upper and lower extremities, always assessing both sides by comparing one side to the other. The strength of the finer muscles that control the function of the hand (hand grasp) and the foot (dorsiflexion and plantar flexion) can then be assessed.

Balance and Coordination

Cerebellar and basal ganglia influence on the motor system is reflected in balance control and coordination. Coordination in the hands and upper extremities is tested by having the patient perform rapid, alternating movements and point-to-point testing. First, the patient is instructed to pat their thigh as fast as possible with each hand separately. Then, the patient is instructed to alternately pronate and supinate the hand as rapidly as possible. Last, the patient is asked to touch each of the fingers with the thumb in a consecutive motion. Speed, symmetry, and degree of difficulty are noted. Point-to-point testing is accomplished by having the patient touch the

Procedural Guidelines 48-1

Nursing Procedure for Assessing Cranial Nerve Function

Equipment

- Tongue depressor
- Flashlight
- Sugar and salt samples
- Watch
- Cotton-tipped swab
- Cotton swabs
- Snellen chart
- Ophthalmoscope
- Samples of familiar odors
- Tuning fork
- Tubes of hot and cold water

Implementation

Nursing Actions	Rationale
1. Explain procedure to patient.	1. Knowledge increases patient comfort and cooperation.
2. Perform hand hygiene.	2. Asepsis is essential to prevent infection.
3. Assess cranial nerve (CN) I (olfactory). With eyes closed, patient is asked to identify familiar odors (coffee, tobacco). Each nostril is tested separately.	3. The significant finding is anosmia (loss of sense of smell).
4. Assess CN II (optic). Assess vision using a Snellen eye chart. Assess visual fields. Perform ophthalmoscopic examination.	4. Significant findings include hemianopias (visual field defects) and decreased visual acuity or blindness.
5. Assess CN III (oculomotor). Test for eye movement toward the nose; inspect for conjugate movements and nystagmus. Evaluate papillary size, and test for pupillary reactivity to light; inspect ability to open eyelids.	5. Significant findings include dysconjugate gaze; gaze weakness or paralysis; double vision; dilated pupil, with or without impaired pupillary reaction to light; and inability to open the affected eyelid.
6. Assess CN IV (trochlear). Test for upward eye movement; inspect for conjugate movements and nystagmus.	6. Significant findings include dysconjugate gaze, gaze weakness or paralysis, and double vision.
7. Assess CN V (trigeminal). Have patient close the eyes. Touch cotton to forehead, cheeks, and jaw. Sensitivity to superficial pain is tested in these same three areas by using the sharp and dull ends of a broken tongue blade. Alternate between the sharp point and the dull end. Patient reports "sharp" or "dull" with each movement. If responses are incorrect, test for temperature sensation. Test tubes of cold and hot water are used alternately. While patient looks up, lightly touch a wisp of cotton against the temporal surface of each cornea. A blink and tearing are normal responses. Have patient clench and move the jaw from side to side. Palpate the masseter and temporal muscles, noting strength and equality.	7. Significant findings include impaired or absent corneal reflex, facial numbness, and jaw weakness.
8. Assess CN VI (abducens). Test for lateral eye movement; inspect for conjugate movement.	8. Significant findings include dysconjugate gaze, gaze weakness or paralysis, and double vision.
9. Assess CN VII (facial). Observe for symmetry while patient performs facial movements: smiles, whistles, elevates eyebrows, frowns, tightly closes eyelids against resistance (examiner attempts to open them). Observe face for flaccid paralysis (shallow nasolabial folds). Have patient extend tongue. Test ability to discriminate between sugar and salt.	9. Significant findings include facial weakness, inability to completely close the eyelid, and impaired taste.
10. Assess CN VIII (acoustic). Perform whisper or watch-tick test. Test for lateralization (Weber test). Test for air and bone conduction (Rinne test). Assess balance with eyes open and then closed for 20 seconds (Romberg test).	10. Significant findings include decreased hearing or deafness and impaired balance.
11. Assess CN IX (glossopharyngeal). Assess patient's ability to swallow and discriminate between sugar and salt on posterior third of the tongue.	11. Significant findings include dysphagia (difficulty swallowing) and impaired taste.
12. Assess CN X (vagus). Depress a tongue blade on posterior tongue, or stimulate posterior pharynx to elicit gag reflex. Note any hoarseness in voice. Check ability to swallow. Have patient say "ah." Observe for symmetric rise of uvula and soft palate.	12. Significant findings include weak or absent gag reflex, dysphagia, aspiration, hoarseness, and dysarthria (slurred speech).
13. Assess CN XI (spinal accessory). While patient shrugs shoulders against resistance, palpate and note strength of trapezius muscles. As patient turns head against opposing pressure of the examiner's hand, palpate and note strength of each sternocleidomastoid muscle.	13. Significant findings include weak or absent shoulder shrug and inability to turn the head to the side.
14. Assess CN XII (hypoglossal). While patient protrudes the tongue, note any deviation or tremors. Test the strength of the tongue by having patient move the protruded tongue from side to side against a tongue depressor.	14. Significant findings include dysphagia and dysarthria.

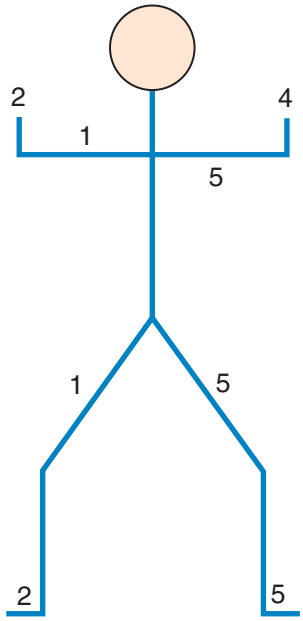

Figure 48-12 • A stick figure may be used to record muscle strength.

examiner's extended finger and then their own nose. This is repeated several times.

Coordination in the lower extremities is tested by having the patient run the heel down the anterior surface of the tibia of the other leg. Each leg is tested in turn. Ataxia is an incoordination of voluntary muscle action, particularly of the muscle groups used in activities such as walking or reaching for objects. Tremors (rhythmic, involuntary movements) noted at rest or during movement suggest a problem in the anatomic areas responsible for balance and coordination.

The Romberg test is a screening test for balance that can be done with the patient seated or standing. The patient can be seated or stand with feet together and arms at the side, first with eyes open and then with both eyes closed for 20 seconds (Bader, Littlejohns, & Olson, 2016); (Weber & Kelley, 2014). The examiner stands close to support the standing patient if he or she begins to fall. Slight swaying is normal, but a loss of balance is abnormal and is considered a positive Romberg test. Additional cerebellar tests for balance in the patient who is ambulatory include hopping in place, alternating knee bends, and heel-to-toe walking (both forward and backward).

Examining the Sensory System

The sensory system is even more complex than the motor system, because sensory modalities are more widespread throughout the central and peripheral nervous systems. The sensory examination is largely subjective and requires the cooperation of the patient. The examiner should be familiar with dermatomes that represent the distribution of the peripheral nerves that arise from the spinal cord (see Fig. 48-9) (Jarvis, 2015).

Assessment of the sensory system involves tests for tactile sensation, superficial pain, temperature, vibration, and position sense (proprioception). During the sensory assessment, the patient's eyes are closed. Simple directions and reassurance that the examiner will not hurt or startle the patient encourage the cooperation of the patient.

Tactile sensation is assessed by lightly touching a cotton wisp or fingertip to corresponding areas on each side of the body. The sensitivity of proximal parts of the extremities is compared with that of distal parts, and the right and left sides are compared.

Pain and temperature sensations are transmitted together in the lateral part of the spinal cord, so it is unnecessary to test for temperature sense in most circumstances. Determining the patient's sensitivity to a sharp object can assess superficial pain perception. However, pain sensation is usually reserved for patients who do not respond to or cannot discriminate touch stimulation. The patient is asked to differentiate between the sharp and dull ends of a broken wooden cotton swab or tongue blade; using a safety pin is inadvisable because it breaks the integrity of the skin. Both the sharp and dull sides of the object are applied with equal intensity at all times, and the two sides are compared. In the patient with an altered level of consciousness alternate methods of assessing pain may need to be used (see Chart 48-2) (Arbour, Gelinas, Loiselle, et al., 2015); (Poulsen, Brix, Andersen, et al., 2016).

Chart 48-2 NURSING RESEARCH PROFILE

BIS Monitoring for Pain Assessment

Arbour, C., Gelinas, C., Loiselle, C. G., et al. (2015). An exploratory study of the Bilateral Bispectral Index for pain detection in traumatic brain injured patients with altered level of consciousness. Journal of Neuroscience Nursing, 47(3), 166–177.

Purpose

The purpose of neurologic assessment is to identify alterations in neurologic function so that interventions may be implemented in a timely manner, but accurate assessment is not always possible in patients with an altered level of consciousness. This study sought to validate the bilateral bispectral index system (BIS) for pain assessment in patients with Traumatic Brain Injury (TBI) with an altered level of consciousness.

Design

The study used a repeated measure within-subject design utilizing a convenience sample of patients with TBI. Pain behaviors and BIS readings were observed during two procedures, one being noninvasive blood pressure monitoring the other during turning. Participants were observed for 1 minute before for a baseline, then during, and at 15 minutes after the two procedures.

Findings

The sample included 25 participants 18 years of age and older with Glasgow Coma Scores of 3 to 13 who were in ICU between 24 hours and 30 days. Stable BIS readings were found during the use of the noninvasive blood pressure monitoring. There was a significant increase in bilateral BIS from baseline during turning as well as an increase in observed pain behaviors (+3.00). However, only increased BIS readings recorded in the right hemisphere of the brain correlated with the pain behaviors of participants, those with a left-sided TBI.

Nursing Implications

More research is needed but nurses should know that there is potential for the use of bilateral BIS monitoring in the assessment of pain in patients who are nonverbal. This study provides beginning evidence that bilateral BIS has the potential for pain detection in those with a left-sided lesion.

Vibration and proprioception are transmitted together in the posterior part of the cord. Vibration may be evaluated through the use of a low-frequency (128 or 256 Hz) tuning fork. The handle of the vibrating fork is placed against a bony prominence, and the patient is asked if he or she feels a sensation and is instructed to signal the examiner when the sensation ceases. Common locations used to test for vibratory sense include the distal joint of the great toe and the proximal thumb joint. If the patient does not perceive the vibrations at the distal bony prominences, the examiner progresses upward with the tuning fork until the patient perceives the vibrations. As with all measurements of sensation, a side-to-side comparison is made.

Position sense or proprioception may be determined by asking the patient to close both eyes and indicate, as the great toe or index finger is alternately moved up and down, in which direction movement has taken place. Vibration and position sense are often lost together, frequently in circumstances in which all other sensation remains intact.

Integration of sensation in the brain is evaluated by testing two-point discrimination. When the patient is touched with two sharp objects simultaneously, are they perceived as two or as one? If touched simultaneously on opposite sides of the body, the patient should normally report being touched in two places. If only one site is reported, the one not being recognized is said to demonstrate extinction. Another test of higher cortical sensory ability is tactile identification. The patient is instructed to close both eyes and identify an object (e.g., key, coin) that is placed in one hand by the examiner; inability to identify an object by touch is known as tactile agnosia or astereognosis. Agnosia is the general loss of ability to recognize objects through a particular sensory system. The patient can also be shown a familiar object and asked to identify it by name; inability to identify a visualized object is known as visual agnosia. Each of these dysfunctions implicates a different part of the brain (see Table 48-6).

Decreased or absent sensations occur with problems anywhere along the sensory pathway. Sensory deficits resulting from peripheral neuropathy or spinal cord injury follow anatomic dermatomes. Destructive lesions of the brain may affect sensation on an entire side of the body. Stroke affecting a portion of the sensory cortex will produce altered sensory discrimination.

Examining the Reflexes

Reflexes are involuntary contractions of muscles or muscle groups in response to a stimulus. Reflexes are classified as deep tendon, superficial, or pathologic. Testing reflexes enables the examiner to assess involuntary reflex arcs that depend on the presence of afferent stretch receptors, spinal or brain stem synapses, efferent motor fibers, and a variety of modifying influences from higher levels.

Deep Tendon Reflexes

A reflex hammer is used to elicit a deep tendon reflex. The handle of the hammer is held loosely between the thumb and index finger, allowing a full swinging motion. The wrist motion is similar to that used during percussion. The extremity is positioned so that the tendon is slightly stretched. This requires a sound knowledge of the location of muscles and their tendon attachments. The tendon is then struck briskly (see Fig. 48-13), and the response is compared with that on the opposite side of the body. A wide variation in reflex response may be considered normal; however, it is more important that the reflexes be symmetrically equivalent. When the comparison is made, both sides should be equivalently relaxed and each tendon struck with equal force.

Valid findings depend on several factors: proper use of the reflex hammer, proper positioning of the extremity, and a patient who is relaxed (Jarvis, 2015). If the reflexes are symmetrically diminished or absent, the examiner may use isometric contraction of other muscle groups to increase reflex activity. For example, if lower extremity reflexes are diminished or absent, the patient is instructed to lock the fingers together and pull in opposite directions. Having the patient clench the jaw or press the heels against the floor or examining table may similarly elicit more reliable biceps, triceps, and brachioradialis reflexes.

The absence of reflexes is significant, although ankle jerks (Achilles reflex) may be normally absent in older adults. Deep tendon reflex responses are often graded on a scale of 0 to 4+, with 2+ considered normal (see Chart 48-3) but scale ratings are highly subjective. Findings can be recorded as a fraction, indicating the scale range (e.g., 2/4). Some examiners prefer to use the terms *present, absent,* and *diminished* when describing reflexes. As with muscle strength recording, a stick figure may be used to record numerical findings.

Biceps reflex

The biceps reflex is elicited by striking the biceps tendon over a slightly flexed elbow (see Fig. 48-13A). The examiner supports the forearm at the elbow with one arm while placing the thumb against the tendon and striking the thumb with the

TABLE 48-6 Types of Agnosia and Corresponding Sites of Lesions

Type of Aphasia	Brain Area Involved
Visual	Occipital lobe
Auditory	Temporal lobe (lateral and superior portions)
Tactile	Parietal lobe
Body parts and relationships	Parietal lobe (posteroinferior regions)

Chart 48-3

Documenting Reflexes

Deep tendon reflexes are graded on a scale of 0–4:

0 No response
1+ Diminished (hypoactive)
2+ Normal
3+ Increased (may be interpreted as normal)
4+ Hyperactive (hyperreflexia)

The deep tendon responses and plantar reflexes are commonly recorded on stick figures. The arrow points downward if the plantar response is normal and upward if the response is abnormal.

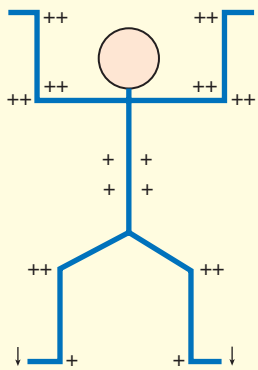

Figure 48-13 • Techniques for eliciting major reflexes. **A**. Eliciting the biceps reflex. **B**. Eliciting the triceps reflex. **C**. Eliciting the patellar reflex. **D**. Eliciting the Achilles reflex. Parts **A–D** from Weber, J., & Kelley, J. (2014). Health assessment in nursing (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

reflex hammer. The normal response is flexion at the elbow and contraction of the biceps.

Triceps reflex

To elicit a triceps reflex, the patient's arm is flexed at the elbow and hanging freely at the side. The examiner supports the patient's arm and identifies the triceps tendon by palpating 2.5 to 5 cm (1 to 2 inches) above the elbow. A direct blow on the tendon (see Fig. 48-13B) normally produces contraction of the triceps muscle and extension of the elbow.

Brachioradialis reflex

With the patient's forearm resting on the lap or across the abdomen, the brachioradialis reflex is assessed. A gentle strike of the hammer 2.5 to 5 cm (1 to 2 inches) above the wrist results in flexion and supination of the forearm (Jarvis, 2015).

Patellar reflex

The patellar reflex is elicited by striking the patellar tendon just below the patella. The patient may be in a sitting or a lying position. If the patient is supine, the examiner supports the legs to facilitate relaxation of the muscles (see Fig. 48-13C). Contractions of the quadriceps and knee extension are normal responses.

Achilles reflex

To elicit an Achilles reflex, the foot is dorsiflexed at the ankle and the hammer strikes the stretched Achilles tendon (see Fig. 48-13D). This reflex normally produces plantar flexion. If the examiner cannot elicit the ankle reflex and suspects that the patient cannot relax, the patient is instructed to kneel on a chair or similar elevated, flat surface. This position places the ankles in dorsiflexion and reduces any muscle tension in the gastrocnemius. The Achilles tendons are struck in turn, and plantar flexion is usually demonstrated (Jarvis, 2015).

Clonus

When reflexes are hyperactive, a movement called clonus may be elicited. If the foot is abruptly dorsiflexed, it may continue to "beat" two or three times before it settles into a position of rest. Occasionally with CNS system disease, this activity persists, and the foot does not come to rest while the tendon is being stretched but persists in repetitive activity. The unsustained clonus associated with normal but hyperactive reflexes is not considered pathologic. Sustained clonus always indicates the presence of CNS disease and requires further evaluation.

Superficial Reflexes

The major superficial reflexes include corneal, palpebral, gag, upper/lower abdominal, cremasteric (men only), and perianal. These reflexes are graded differently than the motor reflexes and are noted to be present (+) or absent (–). Of these, only the corneal, gag, and plantar reflexes are commonly tested.

The corneal reflex is tested carefully using a clean wisp of cotton and lightly touching the outer corner of each eye on the sclera. The reflex is present if the action elicits a blink. A stroke or brain injury might result in loss of this reflex, either unilaterally or bilaterally. Loss of this reflex indicates the need for eye protection and possible lubrication to prevent corneal damage.

The gag reflex is elicited by gently touching the back of the pharynx with a cotton-tipped applicator, first on one side of the uvula and then the other. Positive response is an equal elevation of the uvula and "gag" with stimulation. Absent response on one or both sides can be seen following a stroke and requires careful evaluation and treatment of the resultant swallowing dysfunction to prevent aspiration of food and fluids.

Pathologic Reflexes

Pathologic reflexes are seen in the presence of neurologic disease; they often represent emergence of earlier reflexes that disappeared with maturity of the nervous system. A pathologic reflex indicative of CNS disease affecting the corticospinal tract is the Babinski reflex (sign). In a person with an intact CNS, if the lateral aspect of the sole of the foot is stroked, the toes contract and draw together. However, in a person who has CNS disease of the motor system, the toes fan out and draw back (Jarvis, 2015). This is normal in newborns but represents a serious abnormality in adults. Other pathologic reflexes include the suck (sucking motions in response to touching the lips), snout (lip pursing in response to touching the lips), palmar (grasp in response to stroking the palm), and palmomental (contraction of the facial muscle in response to stimulation of the thenar eminence near the thumb) reflexes in adults. These reflexes often signify progressive nervous system degeneration (Klein & Stewart-Amidei, 2012).

Gerontologic Considerations

During the normal aging process, the nervous system undergoes many changes and is more vulnerable to illness. Age-related changes in the nervous system vary in degree and must be distinguished from those due to disease. It is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation. For example, although diminished strength and agility are a normal part of aging, localized weakness can only be attributed to disease.

Structural and Physiologic Changes

As the brain ages, neurons are lost, leading to a decrease in the number of synapses and neurotransmitters. This results in slowed nerve conduction and response time. Brain weight is decreased, and the ventricle size increases to maintain cranial volume. Cerebral blood flow and metabolism are reduced, leading to slower mental functions. Temperature regulation becomes less efficient. In the peripheral nervous system, myelin is lost, resulting in a decrease in conduction velocity in some nerves. Visual and auditory nerves degenerate, leading to loss of visual acuity and hearing. Taste buds atrophy, and nerve cell fibers in the olfactory bulb degenerate (Jarvis, 2015). Nerve cells in the vestibular system of the inner ear, cerebellum, and proprioceptive pathways also degenerate, leading to balance difficulties. Deep tendon reflexes can be decreased or in some cases absent. Hypothalamic function is modified such that stage IV sleep is reduced. There is an overall slowing of autonomic nervous system responses. Pupillary responses are reduced or may not appear at all in the presence of cataracts.

Motor Alterations

Reduced nerve input into muscle contributes to an overall reduction in muscle bulk, with atrophy most easily noted in the hands. Changes in motor function often result in decreased strength and agility, with increased reaction time. Gait is often slowed and wide based. These changes can create difficulties in maintaining balance, predisposing the older person to falls.

Sensory Alterations

Tactile sensation is dulled in the older adult due to a decrease in the number of sensory receptors. There may be difficulty in identifying objects by touch, because fewer tactile cues are received from the bottom of the feet and the person may become confused about body position and location (Bates & Wolbers, 2014).

Sensitivity to glare, decreased peripheral vision, and a constricted visual field occur due to degeneration of visual pathways, resulting in disorientation, especially at night when there is little or no light in the room. Because the older adult takes longer to recover visual sensitivity when moving from a light to dark area, nightlights and a safe and familiar arrangement of furniture are essential.

Loss of hearing can contribute to confusion, anxiety, disorientation, misinterpretation of the environment, feelings of inadequacy, and social isolation. A decreased sense of taste and smell may contribute to weight loss and disinterest in food. A decreased sense of smell may present a safety hazard, because older adults living alone may be unable to detect household gas leaks or fires. Smoke and carbon monoxide detectors—important in every residence—are critical for the older adult.

Temperature Regulation and Pain Perception

The older adult patient may feel cold more readily than heat and may require extra covering when in bed; a room temperature somewhat higher than usual may be desirable. Reaction to painful stimuli may be decreased with age. Because pain is an important warning signal, caution must be used when hot or cold packs are used. The older patient may be burned or suffer frostbite before being aware of any discomfort. Complaints of pain such as abdominal discomfort or chest pain may be more serious than the patient's perception might indicate and thus require careful evaluation. In older adults, two common pain syndromes that affect the neurologic system are diabetic and postherpetic neuropathies. These frequently occur due to the high rate of these comorbid conditions in older adults. See Chapter 31 for a discussion of diabetic neuropathy.

Mental Status

Although mental processing time decreases with age, memory, language, and judgment capacities remain intact. Change in mental status should never be assumed to be a normal part of aging. Delirium is an acute confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death. Older age is a risk, but delirium is also seen in patients who have underlying CNS damage or are experiencing an acute condition such as infection, adverse medication reaction, or dehydration. Drug toxicity and depression may produce impairment of attention and memory and should be evaluated as a possible cause of mental status change. The Confusion Assessment Method (CAM) is a commonly used screening tool (Inouye, van Dyck, Alessi, et al., 1990); (Layne, Haas, Davidson, et al., 2015) (see Chapter 62, Chart 62-7). Delirium must be differentiated from dementia, which is a chronic and irreversible deterioration of cognitive status. See Chapter 62, Table 62-3 for further discussion of delirium and dementia.

Nursing Implications

Nursing care for patients with age-related changes to the nervous system and for patients with long-term neurologic disability who are aging should include the modifications described previously. In addition, the consequences of any neurologic deficit and its impact on overall function such as activities of daily living, the use of assistive devices, and individual coping should be assessed and considered in planning patient care. Fall risk must be evaluated and fall prevention measures instituted for the patient who is hospitalized as well as in the home.

The nurse must understand the altered responses and the changing needs of the older adult patient before providing education. Visual and hearing deficits require adaptations in activities such as preoperative education, diet therapy, and education about new medications. When using visual materials for education or menu selection, adequate lighting without glare, contrasting colors, and large print are used to offset visual difficulties caused by rigidity and opacity of the lens in the eye and slower pupillary reaction. Procedures and preparations needed for diagnostic tests are explained, taking into account the possibility of impaired hearing and slowed responses in the older adult. Even with hearing loss, the older adult patient often hears adequately if the speaker uses a low-pitched, clear voice; shouting only makes it harder for the patient to understand the speaker. Providing auditory and visual cues aids understanding; if the patient has a significant hearing or visual loss, assistive devices, a signer, an interpreter, or a translator may be needed.

Providing instruction at an unrushed pace and using reinforcement enhance learning and retention. Material should be short, concise, and concrete. Vocabulary is matched to the patient's ability, and terms are clearly defined. The older adult patient requires adequate time to receive and respond to stimuli, learn, and react. These measures allow comprehension, memory, and formation of association and concepts.

Diagnostic Evaluation

A wide range of diagnostic studies may be performed in patients with altered neurologic function. The nurse should educate the patient about the purpose, what to expect, and any possible side effects related to these examinations prior to testing. Women who are premenopausal are advised to practice effective contraception before and for several days after any diagnostic procedure using contrast, and the woman who is breast-feeding is instructed to stop for the time period recommended by the nuclear medicine department (Pagana & Pagana, 2013). The nurse should note trends in results, because they provide information about disease progression as well as the patient's response to therapy.

Computed Tomography Scanning

Computed tomography (CT) scanning uses a narrow x-ray beam to scan body parts in successive layers. The images provide cross-sectional views of the brain, distinguishing differences in tissue densities of the skull, cortex, subcortical structures, and ventricles. An intravenous (IV) contrast agent may be used to highlight differences further. The brightness of each slice of the brain in the final image is proportional to the degree to which it absorbs x-rays. The image is displayed on an oscilloscope or television monitor and is photographed and stored digitally (Fischbach & Dunning, 2015). CT scanning is usually performed first without contrast material and then with IV contrast, if needed. The patient lies on an adjustable table with the head in a headrest while the scanning system rotates around the head and produces cross-sectional images. The patient must lie with the head held perfectly still without talking or moving the face, because head motion distorts the image. CT scanning is quick and painless and uses a small amount of radiation to produce images; it has a high degree of sensitivity for detecting lesions.

Brain lesions have a different tissue density from the surrounding normal brain tissue. Abnormalities detected on brain CT include tumor or other masses, infarction, hemorrhage, displacement of the ventricles, and cortical atrophy (Fischbach & Dunning, 2015). CT angiography allows visualization of blood vessels; in some situations, this eliminates the need for formal angiography. Whole-body CT scanners allow cross-sections of the spinal cord to be visualized. The injection of a water-soluble iodinated contrast agent into the subarachnoid space through lumbar puncture improves the visualization of the spinal and intracranial contents on these images. The CT scan, along with magnetic resonance imaging (MRI), has largely replaced myelography as a diagnostic procedure for the diagnosis of herniated lumbar discs.

Nursing Interventions

Essential nursing interventions include preparation for the procedure and patient monitoring. Preparation includes educating the patient about the need to lie quietly throughout the procedure. A review of relaxation techniques may be helpful for patients with claustrophobia. Sedation can be used if agitation, restlessness, or confusion interferes with a successful study. Ongoing patient monitoring during sedation is necessary. If a contrast agent is used, the patient must be assessed before the CT scan for an iodine/shellfish allergy, because the contrast agent used may be iodine based. Kidney function must also be evaluated because the contrast material is cleared through the kidneys. A suitable IV line for contrast injection and a period of fasting (usually 4 hours) are required prior to the study. Patients who receive an IV contrast agent are monitored during and after the procedure for allergic reactions and changes in kidney function (Fischbach & Dunning, 2015). Fluid intake is also encouraged after IV contrast to facilitate contrast clearance through the kidney.

Magnetic Resonance Imaging

MRI uses a powerful magnetic field to obtain images of different areas of the body. The magnetic field causes the hydrogen nuclei (protons) within the body to align like small magnets in a magnetic field. In combination with radiofrequency pulses, the protons emit signals, which are converted to images. An MRI scan can be performed with or without a contrast agent and can identify a cerebral abnormality earlier and more clearly than other diagnostic tests (Fischbach & Dunning, 2015). It can provide information about the chemical changes within cells, allowing the clinician to monitor a tumor's response to treatment. It is particularly useful in the diagnosis of brain tumor, stroke, and multiple sclerosis and does not involve ionizing radiation. An MRI scan may take an hour or longer to complete, so its use in emergency situations is limited.

Several MRI applications allow imaging of brain blood flow and metabolism via special imaging techniques added to the MRI. Such techniques include diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), magnetic resonance spectroscopy, and fluid attenuation inversion recovery (FLAIR) (Fischbach & Dunning, 2015). Magnetic resonance angiography (MRA) allows separate visualization of the cerebral vasculature without the administration of an arterial contrast agent. Both MRI and CT images are used as tools to plan and direct surgical intervention.

Nursing Interventions

Patient preparation includes providing education and obtaining an adequate history. Ferromagnetic substances in the body may become dislodged by the magnet, so history of working with metal fragments must be reviewed. The patient is questioned about any implants of any metal objects (e.g., aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants will be inactivated by MRI; therefore, other imaging procedures are considered. A complete list of metal compatibility may be found on MRI manufacturer Web sites.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) must be removed. This includes medication patches that have a metal backing and metallic lead wires; these can cause burns if not removed (Fischbach & Dunning, 2015). No metal objects may be brought into the room where the MRI is located; this includes oxygen tanks, IV poles, ventilators, or even stethoscopes. The magnetic field generated by the unit is so strong that any metal-containing items will be strongly attracted and literally can be pulled away with such force that they fly like projectiles toward the magnet. There is a risk of severe injury and death. Further, damage to expensive equipment may occur.

Nursing Alert: For patient safety, the nurse prevents any patient care equipment containing metal or metal parts (e.g., portable oxygen tanks) from entering the room where the MRI is located. The nurse also assesses the patient for the presence of medication patches with foil backing (such as nicotine patches) that may cause a burn while an MRI scan is being performed.

For the MRI, the patient lies with the head in a frame on a flat platform that is moved into a tube housing the magnet (see Fig. 48-14). The tube is narrow; persons with a wide girth may not fit into the scanner. Patients who are unable to lie flat will not be able to tolerate an MRI. The scanning process is painless, but the patient hears loud thumping of the magnetic coils as the magnetic field is being pulsed. Patients may experience claustrophobia while inside the narrow tube; sedation may be prescribed in these circumstances. "Open" MRI machines are less claustrophobic than the other devices and are available in many locations. However, the images produced on these machines are sometimes not so detailed, and traditional devices are preferred for accurate diagnosis. The patient may be educated about the use of relaxation techniques while in the scanner. The patient is informed that he or she will be able to talk to the staff during the scan through a microphone inside the scanner (Fischbach & Dunning, 2015).

Figure 48-14 • Technician explains what to expect during a magnetic resonance imaging procedure.

Positron Emission Tomography

PET is a computer-based nuclear imaging technique that produces images of actual organ functioning. The patient either inhales a radioactive gas or is injected with a radioactive substance that emits positively charged particles. When these positrons combine with negatively charged electrons (normally found in the body's cells), the resultant gamma rays can be detected by a scanning device that produces a series of two-dimensional views at various levels of the brain. This information is integrated by a computer and gives a composite picture of the brain at work.

PET permits the measurement of blood flow, tissue composition, and brain metabolism and thus indirectly evaluates brain function. The brain is one of the most metabolically active organs, consuming 80% of the glucose the body uses (Bader et al., 2016). PET measures this activity in specific areas of the brain and can detect changes in glucose use.

PET is useful in showing metabolic changes in the brain (Alzheimer disease), locating lesions (brain tumor, epileptogenic lesions), identifying blood flow and oxygen metabolism in patients with strokes, distinguishing tumor from areas of necrosis, and revealing biochemical abnormalities associated with mental illness. The isotopes used have a very short half-life and are expensive to produce, requiring specialized equipment for production. Improvement in the scanning procedure and production of isotopes, as well as the advent of reimbursement by third-party payers, has increased the clinical applications of PET studies.

Nursing Interventions

Key nursing interventions include patient preparation, which involves explaining the test and educating the patient about inhalation techniques and the sensations (e.g., dizziness, lightheadedness, and headache) that may occur. The IV injection of the radioactive substance produces similar side effects. Relaxation exercises may reduce anxiety during the test.

Single-Photon Emission Computed Tomography

SPECT is a three-dimensional imaging technique that uses radionuclides and instruments to detect single photons. It is a perfusion study that captures a moment of cerebral blood flow at the time of injection of a radionuclide. Gamma photons are emitted from a radiopharmaceutical agent given to the patient and are detected by a rotating gamma camera or cameras; the image is sent to a minicomputer. This approach allows areas behind overlying structures or background to be viewed, greatly increasing the contrast between normal and abnormal tissue. It is relatively inexpensive, and the duration is similar to that of a CT scan.

SPECT is useful in detecting the extent and location of abnormally perfused areas of the brain, thus allowing detection, localization, and sizing of stroke (before it is visible by CT scan); localization of seizure foci in epilepsy; detection of tumor progression (Fischbach & Dunning, 2015); and evaluation of perfusion before and after neurosurgical procedures.

Nursing Interventions

The nursing interventions for SPECT primarily include patient preparation and patient monitoring. Providing education about what to expect before the test can allay anxiety and ensure patient cooperation during the test. Pregnancy and breast-feeding are contraindications to SPECT.

The nurse may need to accompany and monitor the patient during transport to the nuclear medicine department for the scan. Patients are monitored during and after the procedure for allergic reactions to the radiopharmaceutical agent.

Cerebral Angiography

Cerebral angiography is an x-ray study of the cerebral circulation with a contrast agent injected into a selected artery. A valuable tool in investigating vascular disease or anomalies, it is used to determine vessel patency, identify presence of collateral circulation, and provide detail on vascular anomalies that can be used in planning interventions. With the advent of additional imaging techniques, formal cerebral angiography is less frequently performed.

Cerebral angiograms are performed by threading a catheter through the femoral artery in the groin and up to the desired vessel. Alternatively, direct puncture of the carotid artery may be performed. X-ray images are obtained as the contrast agent flows through the vessels; the carotid and vertebral arterial systems are visualized, as well as venous drainage. Arterial access may also be used for interventional procedures, such as placing coils in an aneurysm or arteriovenous malformation.

Nursing Interventions

Prior to the angiography, the patient's blood urea nitrogen and creatinine should be checked to ensure the kidneys will be able to excrete the contrast agent. The patient should be well hydrated, and clear liquids are usually permitted up to the time of the test. The patient is instructed to void immediately before the test, and locations of the appropriate peripheral pulses are marked with a felt-tip pen. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

After the hair in the groin is clipped and prepared, a local anesthetic agent is given to minimize pain at the insertion site and to reduce arterial spasm. A catheter is introduced into the femoral artery, flushed with heparinized saline, and filled with contrast agent. Fluoroscopy is used to guide the catheter to the appropriate vessels. Neurologic assessment is conducted during and immediately following cerebral angiography to observe for embolism or arterial dissection that may occur during the test. Signs of these complications include new onset of alterations in the level of consciousness, weakness on one side of the body, motor or sensory deficits, and speech disturbances.

Nursing care after cerebral angiography includes observation of the injection site for bleeding or hematoma formation (a localized collection of blood). Because a hematoma at the puncture site or embolization to a distal artery affects peripheral pulses, the peripheral pulses that were marked prior to the test are monitored frequently. The color and temperature of the involved extremity are assessed to detect possible embolism (Fischbach & Dunning, 2015). Fluids are encouraged to facilitate clearance of the contrast through the kidney. The nurse also monitors for an allergic reaction to the contrast agent.

Myelography

A myelogram is an x-ray of the spinal subarachnoid space taken after the injection of a contrast agent into the spinal subarachnoid space through a lumbar puncture. The water-based contrast agent disperses upward through the CSF to outline the spinal subarachnoid space and shows any distortion of the spinal cord or spinal dural sac caused by tumors, cysts, herniated vertebral discs, or other lesions. Myelography is performed infrequently today because of the sensitivity of CT and MRI scanning (Fischbach & Dunning, 2015).

Nursing Interventions

The patient is educated about what to expect during the procedure and made aware that changes in position may be made during the procedure. After myelography, the patient lies in bed with the head of the bed elevated 30 to 45 degrees. The patient is advised to remain in bed in the recommended position for 3 hours or as prescribed. Drinking liberal amounts of fluid for rehydration and replacement of CSF may decrease the incidence of post–lumbar puncture headache. The blood pressure, pulse, respiratory rate, and temperature are monitored, as well as the patient's ability to void. Untoward signs include headache, fever, stiff neck, photophobia (sensitivity to light), seizures, and signs of chemical or bacterial meningitis (Hickey, 2014).

Noninvasive Carotid Flow Studies

Noninvasive carotid flow studies use ultrasound imagery and Doppler measurements of arterial blood flow to evaluate carotid and deep orbital circulation. The graph produced indicates blood velocity. Increased blood velocity can indicate stenosis or partial

obstruction. These tests are often obtained before more invasive tests such as arteriography or are used as screening tools. Carotid Doppler, carotid ultrasonography, oculoplethysmography, and ophthalmodynamometry are four common noninvasive vascular techniques that permit evaluation of arterial blood flow and detection of arterial stenosis, occlusion, and plaques. These vascular studies allow noninvasive imaging of extra- and intracranial circulation (Fischbach & Dunning, 2015).

Transcranial Doppler

Transcranial Doppler uses the same noninvasive techniques as carotid flow studies but records the blood flow velocities of the intracranial vessels. Arterial flow velocities can be measured through thin areas of the temporal and occipital bones of the skull. A handheld Doppler probe emits a pulsed beam; the signal is reflected by the moving red blood cells within the blood vessels. Transcranial Doppler is a noninvasive technique that is helpful in assessing vasospasm (a complication following subarachnoid hemorrhage), altered cerebral blood flow found in occlusive vascular disease, other cerebral pathology, and brain death.

Nursing Interventions

When a carotid flow study or transcranial Doppler is scheduled, the procedure is described to the patient. The patient is informed that this is a noninvasive test, that a handheld transducer will be placed over the neck and the orbits of the eyes, and that a water-soluble gel or lubricant is used on the transducer (Fischbach & Dunning, 2015). Either of these two low-risk tests can be performed at the patient's bedside.

Electroencephalography

An electroencephalogram (EEG) represents a record of the electrical activity generated in the brain (Hickey, 2014). It is obtained through electrodes applied on the scalp or through microelectrodes placed within the brain tissue. It provides an assessment of cerebral electrical activity. It is useful for diagnosing and evaluating seizure disorders, coma, or organic brain syndrome. Tumors, brain abscesses, blood clots, and infection may cause abnormal patterns in electrical activity. The EEG is also used in making a determination of brain death.

Electrodes are applied to the scalp to record the electrical activity in various regions of the brain. The amplified activity of the neurons between any two of these electrodes is recorded on continuously moving paper; this record is called the *encephalogram*.

For a baseline recording, the patient lies quietly with both eyes closed. The patient may be asked to hyperventilate for 3 to 4 minutes or to look at a bright, flashing light for photic stimulation. These activation procedures are performed to evoke abnormal electrical discharges, such as seizure potentials. A sleep EEG may be recorded after sedation because some abnormal brain waves are seen only when the patient is asleep. If the epileptogenic area is inaccessible to conventional scalp electrodes, nasopharyngeal electrodes may be used.

Depth recording of EEG is performed by introducing electrodes stereotactically (radiologically placed using instrumentation) into a target area of the brain, as indicated by the patient's seizure pattern and scalp EEG. It is used to identify patients who may benefit from surgical excision of epileptogenic foci. Special transsphenoidal, mandibular, and nasopharyngeal electrodes can be used, and video recording combined with EEG monitoring and telemetry is used in hospital settings to capture epileptiform abnormalities and their sequelae. Some epilepsy centers provide long-term ambulatory EEG monitoring with portable recording devices (Bader et al., 2016).

Nursing Interventions

To increase the chances of recording seizure activity, it is sometimes recommended that the patient be deprived of sleep the night before the EEG. Anticonvulsant agents, tranquilizers, stimulants, and depressants should be withheld 24 to 48 hours before an EEG, because these medications can alter the EEG wave patterns or mask the abnormal wave patterns of seizure disorders (Pagana & Pagana, 2013). Coffee, tea, chocolate, and cola drinks are omitted from the meal before the test because of their stimulating effect. However, the meal itself is not omitted, because an altered blood glucose level can cause changes in brain wave patterns.

The patient is informed that the standard EEG takes 45 to 60 minutes; a sleep EEG requires 12 hours. The patient is assured that the procedure does not cause an electric shock and that the EEG is a diagnostic test, not a form of treatment. An EEG requires the patient to lie quietly during the test. Sedation is not advisable, because it may lower the seizure threshold in patients with a seizure disorder and it alters brain wave activity in all patients. The nurse needs to check the prescription regarding the administration of anticonvulsant medication prior to testing.

Routine EEGs use a water-soluble lubricant for electrode contact, which can be wiped off and removed by shampooing later. Sleep EEGs involve the use of collodion glue for electrode contact, which requires acetone for removal.

Electromyography

An electromyogram (EMG) is obtained by inserting needle electrodes into the skeletal muscles to measure changes in the electrical potential of the muscles (Pagana & Pagana, 2013). The electrical potentials are shown on an oscilloscope and amplified so that both the sound and appearance of the waves can be analyzed and compared simultaneously.

An EMG is useful in determining the presence of neuromuscular disorders and myopathies. It helps distinguish weakness due to neuropathy (functional or pathologic changes in the peripheral nervous system) from weakness resulting from other causes.

Nursing Interventions

The procedure is explained, and the patient is warned to expect a sensation similar to that of an intramuscular injection as the needle is inserted into the muscle. The muscles examined may ache for a short time after the procedure.

Nerve Conduction Studies

Nerve conduction studies are performed by stimulating a peripheral nerve at several points along its course and recording the muscle action potential or the sensory action potential that results. Surface or needle electrodes are placed on the skin over the nerve to stimulate the nerve fibers. This test is useful in the study of peripheral neuropathies and is often included as part of the EMG.

Evoked Potential Studies

Evoked potential studies involve application of an external stimulus to specific peripheral sensory receptors with subsequent measurement of the electrical potential generated. Electrical changes are detected with the aid of computerized devices that extract the signal, display it on an oscilloscope, and store the data on magnetic tape or disc. In neurologic diagnosis, they reflect nerve conduction times in the peripheral nervous system. In clinical practice, the visual, auditory, and somatosensory systems are most often tested.

In visual evoked responses, the patient looks at a visual stimulus (flashing lights, a checkerboard pattern on a screen). The average of several hundred stimuli is recorded by EEG leads placed over the occipital lobe. The transit time from the retina to the occipital area is measured using computer-averaging methods.

Brainstem auditory evoked responses (BAERs) are measured by applying an auditory stimulus (repetitive auditory click) and measuring the transit time via the brain stem into the cortex. Specific lesions in the auditory pathway modify or delay the response. BAERs may be used in the diagnosis of brain stem abnormalities and in determination of brain death.

In somatosensory evoked responses (SERs), the peripheral nerves are stimulated (electrical stimulation through skin electrodes) and the transit time along the spinal cord to the cortex is measured and recorded from scalp electrodes. SERs are used to detect deficits in spinal cord or peripheral nerve conduction and to monitor spinal cord function during surgical procedures. It is also useful in the diagnosis of demyelinating diseases, such as multiple sclerosis and polyneuropathies, where nerve conduction is slowed.

Nursing Interventions

The nurse explains the procedure and reassures the patient and encourages him or her to relax. The patient is advised to remain perfectly still throughout the recording to prevent artifacts (signals not generated by the brain) that interfere with the recording and interpretation of the test.

Lumbar Puncture and Examination of Cerebrospinal Fluid

A lumbar puncture (spinal tap) is carried out by inserting a needle into the lumbar subarachnoid space to withdraw CSF. The test may be performed to obtain CSF for examination, to measure and reduce CSF pressure, to determine the presence or absence of blood in the CSF, and to administer medications intrathecally (into the spinal canal).

The needle is usually inserted into the subarachnoid space between the third and fourth or fourth and fifth lumbar vertebrae. Because the spinal cord ends at the first lumbar vertebra, insertion of the needle below the level of the third lumbar vertebra prevents puncture of the spinal cord.

A successful lumbar puncture requires that the patient be relaxed; a patient who is anxious is tense, and this may increase the pressure reading. CSF pressure with the patient in a lateral recumbent position is normally 80 to 100 mm H_2O or 8 to 14 mm Hg (Hickey, 2014).

A lumbar puncture may be risky in the presence of an intracranial mass lesion because intraspinal pressure is decreased by removal of CSF, and the brain may herniate downward through the foramen magnum. Chart 48-4 provides instructions for assisting with a lumbar puncture.

Cerebrospinal Fluid Analysis

The CSF should be clear and colorless. Pink, blood-tinged, or grossly bloody CSF may indicate a subarachnoid hemorrhage. The CSF may be bloody initially because of local trauma but becomes clearer as more fluid is drained. Specimens are obtained for cell count, culture, glucose, protein, and other tests as indicated. The specimens should be sent to the laboratory immediately because changes will take place and alter the result if the specimens are allowed to stand. See Table A-5 in Appendix A on for the normal values of CSF.

Post–Lumbar Puncture Headache

A post–lumbar puncture headache, ranging from mild to severe, may occur a few hours to several days after the procedure. It is a throbbing bifrontal or occipital headache that is dull and deep in character. It is particularly severe on sitting or standing but lessens or disappears when the patient lies down.

The headache is caused by CSF leakage at the puncture site. The fluid continues to escape into the tissues by way of the needle track from the spinal canal. As a result of a leak, the supply of CSF in the cranium is depleted to a point at which it is insufficient to maintain proper mechanical stabilization of the brain. When the patient assumes an upright position, tension and stretching of the venous sinuses and pain-sensitive structures occur.

Post–lumbar puncture headache may be avoided if a small-gauge needle is used and if the patient remains prone after the procedure. The patient is positioned supine for 4 to 8 hours (Hickey, 2014). A postpuncture headache is usually managed by bed rest, analgesic agents, and hydration.

Other Complications of Lumbar Puncture

Herniation of the intracranial contents, spinal epidural abscess, spinal epidural hematoma, and meningitis are rare but serious complications of lumbar puncture. Other complications include temporary voiding problems, slight elevation of temperature, backache or spasms, and stiffness of the neck.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care

Many diagnostic tests that were once performed as part of a hospital stay are now carried out in short-procedure units or outpatient testing settings or units. As a result, family members often provide the postprocedure care. Therefore, the patient and family must receive adequate education about precautions to take after the procedure, complications to watch for, and steps to take if complications occur. Because many patients undergoing neurologic diagnostic studies are older adults or have neurologic deficits, provisions must be made to ensure that transportation, postprocedure care, and appropriate monitoring are available.

Continuing and Transitional Care

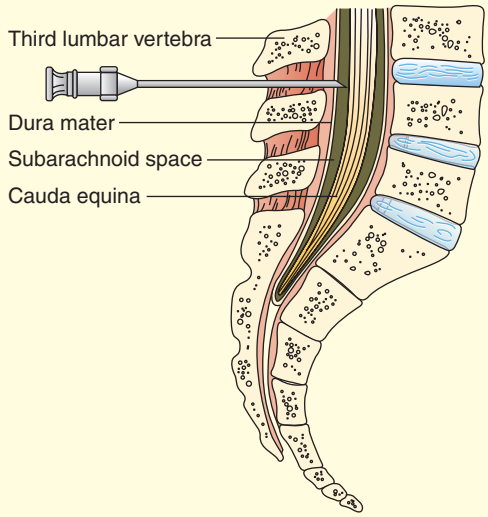
Contacting the patient and family after diagnostic testing enables the nurse to determine whether they have any questions about the procedure or whether the patient had any untoward results. Education is reinforced and the patient and family are reminded to make and keep follow-up appointments. Patients, family members, and health care providers are focused on the immediate needs, issues, or deficits that necessitated the diagnostic testing.

Chart 48-4

Assisting with a Lumbar Puncture

A needle is inserted into the subarachnoid space through the third and fourth or fourth and fifth lumbar interface to withdraw spinal fluid.

Preprocedure



1. Determine whether written consent for the procedure has been obtained.
2. Explain the procedure to the patient, and describe sensations that are likely during the procedure (i.e., a sensation of cold as the site is cleansed with solution, a needle prick when local anesthetic agent is injected).
3. Determine whether the patient has any questions or misconceptions about the procedure; reassure the patient that the needle will not enter the spinal cord or cause paralysis.
4. Instruct the patient to void before the procedure.

Procedure

1. The patient is positioned on one side at the edge of the bed or examining table with the back toward the physician; the thighs and legs are flexed as much as possible to increase the space between the spinous processes of the vertebrae, for easier entry into the subarachnoid space.

2. A small pillow may be placed under the patient's head to maintain the spine in a horizontal position; a pillow may be placed between the legs to prevent the upper leg from rolling forward.
3. The nurse assists the patient to maintain the position to avoid sudden movement, which can produce a traumatic (bloody) tap.
4. The patient is encouraged to relax and is instructed to breathe normally, because hyperventilation may lower an elevated pressure.
5. The nurse describes the procedure step by step to the patient as it proceeds.
6. The physician cleanses the puncture site with an antiseptic agent solution and drapes the site.
7. The physician injects local anesthetic agent to numb the puncture site and then inserts a spinal needle into the subarachnoid space through the third and fourth or fourth and fifth lumbar interspace. A pressure reading may be obtained.
8. A specimen of cerebrospinal fluid (CSF) is removed and usually collected in three test tubes, labeled in order of collection. The needle is withdrawn.
9. The physician applies a small dressing to the puncture site.
10. The tubes of CSF are sent to the laboratory immediately.

Postprocedure

1. Instruct the patient to lie prone to separate the alignment of the dural and arachnoid needle punctures in the meninges, to reduce leakage of CSF.
2. Monitor the patient for complications of lumbar puncture; notify primary provider if complications occur.
3. Encourage increased fluid intake to reduce the risk of postprocedure headache.

CRITICAL THINKING EXERCISES

1. Identify the priorities, approach, and techniques you would use to perform a neurologic assessment on a 82-year-old patient with confusion. How will your priorities, approach, and techniques differ if the patient has a visual impairment, is hard of hearing, or has lower extremity weakness?
2. A 40-year-old patient is scheduled for an electroencephalogram (EEG). What resources would you use to identify the current guidelines for EEG? What is the evidence base for these practices? Identify the criteria used to evaluate the strength of the evidence for these practices.
3. A 35-year-old female patient is having a lumbar puncture at the bedside. Identify the nursing interventions indicated before, during, and after the procedure. What patient education is indicated? How will your nursing interventions and patient education change if the patient is pregnant or lactating?

CHAPTER 49

Management of Patients with Neurologic Dysfunction

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the causes, clinical manifestations, and medical management of various neurologic dysfunctions.
2. Use the nursing process as a framework for care of the multiple needs of the patient with altered level of consciousness.
3. Identify the early and late clinical manifestations of increased intracranial pressure.
4. Apply the nursing process as a framework for care of the patient with increased intracranial pressure.
5. Compare and contrast the indications for intracranial or transsphenoidal surgery.
6. Use the nursing process as a framework for care of the patient undergoing intracranial or transsphenoidal surgery.
7. Explain the various types and causes of seizures and develop a plan of care for the patient experiencing seizures.
8. Recognize the causes, clinical manifestations, and medical and nursing management of the patient experiencing various types of headaches.

GLOSSARY

akinetic mutism: unresponsiveness to the environment; the patient makes no movement or sound but sometimes opens the eyes
altered level of consciousness (LOC): when a patient is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness
brain death: irreversible loss of all functions of the entire brain, including the brainstem
coma: prolonged state of unconsciousness
craniectomy: a surgical procedure that involves removal of a portion of the skull
craniotomy: a surgical procedure that involves entry into the cranial vault
Cushing's response: the brain's attempt to restore blood flow by increasing arterial pressure to overcome the increased intracranial pressure
decerebration: an abnormal body posture associated with a severe brain injury, characterized by extreme extension of the upper and lower extremities
decortication: an abnormal posture associated with severe brain injury, characterized by abnormal flexion of the upper extremities and extension of the lower extremities
epilepsy: at least two unprovoked seizures occurring more than 24 hours apart
herniation: abnormal protrusion of tissue through a defect or natural opening
intracranial pressure (ICP): pressure exerted by the volume of the intracranial contents within the cranial vault
locked-in syndrome: condition resulting from a lesion in the pons in which the patient lacks all distal motor activity (paralysis) but cognition is intact
migraine: a severe, unrelenting headache often accompanied by symptoms such as nausea, vomiting, and visual disturbances
minimally conscious state: a state in which the patient demonstrates awareness but cannot communicate thoughts or feelings
Monro–Kellie hypothesis: theory that states that due to limited space for expansion within the skull, an increase in any one of the cranial contents—brain tissue, blood, or cerebrospinal fluid (CSF)—causes a change in the volume of the others; also referred to as Monro–Kellie doctrine
persistent vegetative state: condition in which the patient is wakeful but devoid of conscious content, without cognitive or affective mental function
primary headache: a headache for which no specific organic cause can be found
secondary headache: headache identified as a symptom of another organic disorder (e.g., brain tumor, hypertension)
seizures: paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity
status epilepticus: episode in which the patient experiences multiple seizures with no recovery time in between
transsphenoidal: surgical approach to the pituitary via the sphenoid sinuses

Introduction

This chapter presents an overview of care of the patient with an altered level of consciousness (LOC); the patient with increased intracranial pressure (ICP); and the patient who is undergoing neurosurgical procedures, experiencing seizures, or experiencing headaches. Some of the disorders in this chapter, such as headaches and seizures, may be symptoms of dysfunction in another body system. Alternatively, headaches and seizures can be symptoms of a disruption of the neurologic system. These disorders can also be diagnosed at times as "idiopathic," or without an identifiable cause. The commonalities of these disorders are often the behaviors and needs of the patient and the approaches nurses use to support the patient.

The central nervous system (CNS) contains a vast network of neurons that control the body's vital functions. However, this system is vulnerable, and its optimal function depends on several key factors. First, the neurologic system relies on its structural integrity for support and homeostasis, but this integrity may be disrupted. Examples of structural disruption include head injury, brain tumor, intracranial hemorrhage, infection, and stroke. As brain tissue expands in the inflexible cranium, intracranial pressure (ICP) (pressure exerted by the volume of the intracranial contents within the cranial vault)

rises, and cerebral perfusion is impaired. Further expansion places pressure on vital centers, which can cause permanent neurologic deficits or lead to brain death.

Second, the neurologic system relies on the body's ability to maintain a homeostatic environment. It requires the delivery of the essential elements of oxygen and glucose, as well as filtration of substrates that are toxic to the neurons. The functions of the neurologic system may be decreased or absent because of the effect of toxic substrates or the body's inability to provide essential substrates. Sepsis, hypovolemia, myocardial infarction, cardiopulmonary arrest, hypoglycemia, electrolyte imbalance, drug and/or alcohol overdose, encephalopathy, and ketoacidosis are examples of such circumstances. Some conditions can be treated and reversed; others result in permanent neurologic deficits and disabilities.

Although the specialty of neuroscience nursing requires an understanding of neuroanatomy, neurophysiology, neurodiagnostic testing, critical care nursing, and rehabilitation nursing, nurses in all settings care for patients with neurologic disorders (Hickey, 2014). Ongoing assessment of the patient's neurologic function and health needs, identification of problems, mutual goal setting, development and implementation of care plans (including education, counseling, and coordinating activities), and evaluation of the outcomes of care are nursing actions integral to the recovery of the patient. The nurse also collaborates with other members of the health care team to provide essential care, offer a variety of solutions to problems, help the patient and family gain control of their lives, and explore the educational and supportive resources available in the community. The goals are to achieve as high a level of function as possible and to enhance the quality of life for the patient with neurologic impairment and their family.

ALTERED LEVEL OF CONSCIOUSNESS

An altered level of consciousness (LOC) is present when the patient is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness. LOC is gauged on a continuum, with a normal state of alertness and full cognition (consciousness) on one end and coma on the other end. Coma is a clinical state of unarousable unresponsiveness in which there are no purposeful responses to internal or external stimuli, although nonpurposeful responses to painful stimuli and brainstem reflexes may be present. The usual duration of coma is variable. Akinetic mutism is a state of unresponsiveness to the environment in which the patient makes no voluntary movement. Persistent vegetative state is a condition in which the unresponsive patient resumes sleep–wake cycles after coma but is devoid of cognitive or affective mental function. A minimally conscious state differs from persistent vegetative state in that the patient has inconsistent but reproducible signs of awareness (Bruno, Laureys, & Demertzi, 2013). Locked-in syndrome results from a lesion affecting the pons and results in paralysis and the inability to speak, but vertical eye movements and lid elevation remain intact and are used to indicate responsiveness (Bruno et al., 2013). The level of responsiveness and consciousness is the most important indicator of the patient's condition.

Pathophysiology

Altered LOC is not a disorder itself; rather, it is a result of multiple pathophysiologic phenomena. The cause may be neurologic (head injury, stroke), toxicologic (drug overdose, alcohol intoxication), or metabolic (hepatic or kidney injury, diabetic ketoacidosis).

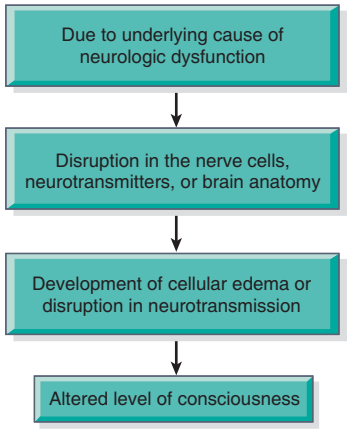

Figure 49-1 • Pathophysiology of altered level of consciousness.

The underlying cause of neurologic dysfunction is disruption in the cells of the nervous system, neurotransmitters, or brain anatomy (see Chapter 48). Disruptions result from cellular edema or other mechanisms, such as disruption of chemical transmission at receptor sites by antibodies.

Intact anatomic structures of the brain are needed for normal function. The two hemispheres of the cerebrum must communicate, via an intact corpus callosum, and the lobes of the brain (frontal, parietal, temporal, and occipital) must communicate and coordinate their specific functions (see Chapter 48). Other anatomic structures of importance are the cerebellum and the brainstem. The cerebellum has both excitatory and inhibitory actions and is largely responsible for coordination of movement. The brainstem contains areas that control the heart rate, respiration, and blood pressure. Disruptions in the anatomic structures result from trauma, edema, pressure from tumors, or other mechanisms, such as an increase or decrease in the circulation of blood or CSF. A flowchart for pathophysiology of altered level of consciousness is presented in Figure 49-1.

Clinical Manifestations

Alterations in LOC occur along a continuum, and the clinical manifestations depend on where the patient is on this continuum. As the patient's state of alertness and consciousness decreases, changes occur in the pupillary response, eye opening response, verbal response, and motor response. However, initial alterations in LOC may be reflected by subtle behavioral changes, such as restlessness or increased anxiety. The pupils, normally round and quickly reactive to light, become sluggish (response is slower); as the patient becomes comatose, the pupils become fixed (no response to light). The patient in a coma does not open the eyes to voice or command, respond verbally, or move the extremities in response to a request to do so.

Assessment and Diagnostic Findings

The patient with an altered LOC is at risk for alterations in every body system. A complete assessment is performed, with particular attention to the neurologic system. The neurologic examination should be as complete as the LOC allows. It

includes an evaluation of mental status, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. LOC, a sensitive indicator of neurologic function, is assessed based on the criteria in the Glasgow Coma Scale: eye opening, verbal response, and motor response (Hickey, 2014). The patient's responses are rated on a scale from 3 to 15. A score of 3 indicates severe impairment of neurologic function, brain death, or pharmacologic inhibition of the neurologic response. A score of 15 indicates that the patient is fully responsive (see Chapter 51).

If the patient is comatose and has localized signs such as abnormal pupillary and motor responses, it is assumed that neurologic disease is present until proven otherwise. If the patient is comatose but pupillary light reflexes are preserved, a toxic or metabolic disorder is suspected. Common diagnostic procedures used to identify the cause of unconsciousness include computed tomography (CT) scanning, perfusion CT (PCT), magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and electroencephalography (EEG). Additional procedures include positron emission tomography (PET) and single-photon emission computed tomography (SPECT) (see Chapter 48). Emerging research identifies EEG, MRI, and PET as important technologies in determining brain function through the evaluation of metabolic and electrical activity (Van Der Naalt, 2015). Laboratory tests include analysis of blood glucose, electrolytes, serum ammonia, and liver function tests; blood urea nitrogen (BUN) levels; serum osmolality; calcium level; and partial thromboplastin and prothrombin times. Other studies may be used to evaluate serum ketones, alcohol and drug concentrations, and arterial blood gases.

Medical Management

The first priority of treatment for the patient with altered LOC is to obtain and maintain a patent airway. The patient may be orally or nasally intubated, or a tracheostomy may be performed. Until the ability of the patient to breathe is determined, a mechanical ventilator is used to maintain adequate oxygenation and ventilation. The circulatory status (blood pressure, heart rate) is monitored to ensure adequate perfusion to the body and brain. An intravenous (IV) catheter is inserted to provide access for IV fluids and medications. Neurologic care focuses on the specific neurologic pathology, if known. Nutritional support, via a feeding tube or a gastrostomy tube, is initiated as soon as possible. In addition to measures designed to determine and treat the underlying causes of altered LOC, other medical interventions are aimed at pharmacologic management and prevention of complications.

NURSING PROCESS

The Patient with an Altered Level of Consciousness

Assessment

Assessment of the patient with an altered LOC often starts with assessing the verbal response through determining the patient's orientation to time, person, and place. Patients are asked to identify the day, date, or season of the year, as well as where they are or the clinicians, family members, or visitors present. Other questions such as "Who is the Prime Minister?" or "What is the next holiday?" may be helpful in determining the patient's processing of information. Verbal response cannot be evaluated if the patient is intubated or has a tracheostomy, and this should be clearly documented.

Alertness is measured by the patient's ability to open the eyes spontaneously or in response to a vocal or noxious stimulus (pressure or pain). Patients with severe neurologic dysfunction cannot do this. The nurse assesses for periorbital edema (swelling around the eyes) or trauma, which may prevent the patient from opening the eyes, and documents any such condition that interferes with eye opening.

Motor response includes spontaneous, purposeful movement (e.g., the awake patient can move all four extremities with equal strength on command), movement only in response to painful stimuli, or abnormal posturing. If the patient is not responding to commands, the motor response is tested by applying a painful stimulus (firm but gentle pressure) to the nail bed or by squeezing a muscle. If the patient attempts to push away or withdraw, the response is recorded as purposeful or appropriate ("Patient withdraws to painful stimulus"). This response is considered purposeful if the patient can cross the midline from one side of the body to the other in response to a painful stimulus. An inappropriate or nonpurposeful response is random and aimless. Posturing may be decorticate or decerebrate (see Fig. 49-2; see also Chapter 48). The most severe neurologic impairment results in flaccidity. The motor response cannot be elicited or assessed when the patient has been given pharmacologic paralyzing agents (i.e., neuromuscular blocking agents).

In addition to LOC, the nurse monitors parameters such as respiratory status, eye signs, and reflexes on an ongoing basis. Table 49-1 summarizes the assessment and the clinical significance of the findings. Body functions (circulation, respiration, elimination, fluid and electrolyte balance) are examined in a systematic and ongoing manner.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Ineffective airway clearance related to inability to maintain an airway due to altered LOC
- Risk for injury related to lack of adaptive and defensive resources due to decreased LOC
- Deficient fluid volume related to inability to take fluids by mouth
- Risk for imbalanced nutrition: less than body requirements related to inability to ingest nutrients to meet metabolic needs
- Impaired oral mucous membrane related to mouth breathing, absence of pharyngeal reflex, and altered fluid intake
- Risk for impaired skin integrity related to prolonged immobility
- Risk for impaired tissue integrity of cornea related to diminished or absent corneal reflex
- Ineffective thermoregulation related to damage to hypothalamic center
- Impaired urinary elimination (incontinence or retention) related to impairment in neurologic sensing and control
- Bowel incontinence related to impairment in neurologic sensing and control and also related to changes in nutritional delivery methods
- Ineffective health maintenance related to neurologic impairment
- Interrupted family processes related to health crisis

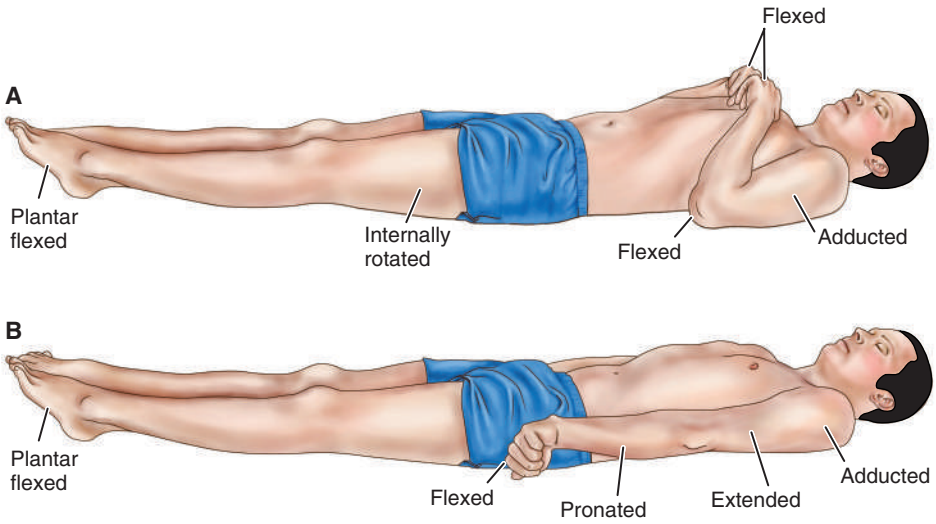

Figure 49-2 • Abnormal posture response to stimuli. **A.** Decorticate posturing and flexion of the upper extremities, internal rotation of the lower extremities, and plantar flexion of the feet. **B.** Decerebrate posturing, involving extension and outward rotation of upper extremities and plantar flexion of the feet. Adapted from Posner, J. B., Saper, C. B., Schiff, N. D., et al. (2007). Plum and Posner's diagnosis of stupor and coma (4th ed.). Oxford, UK: Oxford University Press.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Respiratory distress or failure
- Pneumonia
- Aspiration
- Pressure ulcer
- Venous thromboembolism (VTE)
- Contractures

Planning and Goals

The patient with altered LOC is subject to all of the complications associated with immobility. Therefore, the goals of care for the patient with altered LOC include maintenance of a clear airway, protection from injury, attainment of fluid volume balance, maintenance of nutritional needs, achievement of intact oral mucous membranes, maintenance of normal skin integrity, absence of corneal irritation, attainment of effective thermoregulation, and effective urinary elimination. Additional goals include bowel continence, restoration of health maintenance, maintenance of intact family or support system, and absence of complications.

Because the protective reflexes of the patient who is unconscious are impaired, the quality of nursing care provided may mean the difference between life and death. The nurse must assume responsibility for the patient until the basic reflexes (coughing, blinking, and swallowing) return and the patient becomes conscious and oriented. Therefore, the major nursing goal is to compensate for the absence of these protective reflexes.

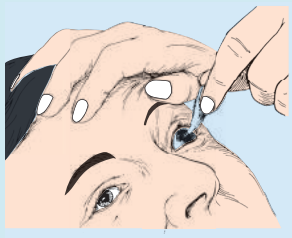
Nursing Interventions

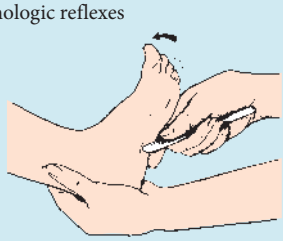
Maintaining the Airway

The most important consideration in managing the patient with altered LOC is to establish an adequate airway and ensure ventilation. Obstruction of the airway is a risk because the epiglottis and tongue may relax, occluding the oropharynx, or the patient may aspirate vomitus or nasopharyngeal secretions.

The accumulation of secretions in the pharynx presents a serious problem. Because the patient cannot swallow and lacks pharyngeal reflexes, these secretions must be removed to eliminate the danger of aspiration. Elevating the head of the bed to 30 degrees helps prevent aspiration. Positioning the patient in a lateral or semiprone position also helps because it allows the jaw and tongue to fall forward, thus promoting drainage of secretions.

Positioning alone is not always adequate, however. Suctioning and oral hygiene may be required. Suctioning is performed to remove secretions from the posterior pharynx and upper trachea. Before and after suctioning, the patient is adequately ventilated to prevent hypoxia (Hickey, 2014). Chest physiotherapy and postural drainage may be initiated to promote pulmonary hygiene, unless contraindicated by the patient's underlying condition. The chest should be auscultated at least every 8 hours to detect adventitious breath sounds or absence of breath sounds.





Despite these measures, or because of the severity of impairment, the patient with altered LOC often requires intubation and mechanical ventilation. Nursing actions for the patient who is mechanically ventilated include maintaining the patency of the endotracheal tube or tracheostomy, providing frequent oral care, monitoring arterial blood gas measurements, and maintaining ventilator settings (see Chapter 11).

Protecting the Patient

For the protection of the patient, side rails are padded. Two rails are kept in the raised position during the day and three at night; however, raising all four side rails is considered a restraint by the Joint Commission if the intent is to limit the patient's mobility. Care should be taken to prevent injury from invasive lines and equipment, and other potential sources of injury should be identified, such as restraints, tight dressings, environmental irritants, damp bedding or dressings, and tubes and drains.

Protection also includes ensuring the patient's dignity during altered LOC. Simple measures such as providing privacy and speaking to the patient during nursing care activities preserve the patient's dignity. Not speaking negatively about the patient's condition or prognosis is also important, because patients in a coma may be able to hear. The patient who is comatose has an increased need for advocacy, and the nurse is responsible for seeing that these advocacy needs are met.

TABLE 49-1 Nursing Assessment of the Patient who Is Unconscious

Examination	Clinical Assessment	Clinical Significance
Level of responsiveness or consciousness	Eye opening; verbal and motor responses; pupils (size, equality, reaction to light)	Obeying commands is a favorable response and demonstrates a return to consciousness
Pattern of respiration	Respiratory pattern Cheyne–Stokes respiration Hyperventilation Ataxic respiration with irregularity in depth/rate	Disturbances of respiratory center of brain may result in various respiratory patterns Suggests lesions deep in both hemispheres; area of basal ganglia and upper brainstem Suggests onset of metabolic problem or brainstem damage Ominous sign of damage to medullary center
Eyes Pupils (size, equality, reaction to light) 	Equal, normally reactive pupils Equal or unequal diameter Progressive dilation Fixed dilated pupils	Suggests that coma is toxic or metabolic in origin Helps determine location of lesion Indicates increasing intracranial pressure Indicates injury at level of midbrain
Eye movements	Normally, eyes should move from side to side	Functional and structural integrity of brainstem is assessed by inspection of extraocular movements; usually absent in deep coma
Corneal reflex 	When cornea is touched with a wisp of clean cotton, blink response is normal	Tests cranial nerves V and VII; helps determine location of lesion if unilateral; absent in deep coma
Facial symmetry	Asymmetry (sagging, decrease in wrinkles)	Sign of paralysis
Swallowing reflex	Drooling vs. spontaneous swallowing	Absent in coma Paralysis of cranial nerves X and XII
Neck	Stiff neck Absence of spontaneous neck movement	Subarachnoid hemorrhage, meningitis Fracture or dislocation of cervical spine
Response of extremity to noxious stimuli	Firm pressure on a joint of the upper and lower extremity Observe spontaneous movements	Asymmetric response in paralysis Absent in deep coma
Deep tendon reflexes	Tap patellar and biceps tendons	Brisk response may have localizing value. Asymmetric response in paralysis Absent in deep coma
Pathologic reflexes 	Firm pressure with blunt object on sole of foot, moving along lateral margin and crossing to the ball of foot	Flexion of the toes, especially the great toe, is normal except in newborn Dorsiflexion of toes (especially great toe) indicates contralateral pathology of corticospinal tract (Babinski reflex) Helps determine location of lesion in brain
Abnormal posture	Observation for posturing (spontaneous or in response to noxious stimuli) Flaccidity with absence of motor response Decorticate posture (flexion and internal rotation of forearms and hands) Decerebrate posture (extension and external rotation)	Deep extensive brain lesion Seen with cerebral hemisphere pathology and metabolic depression of brain function Decerebrate posturing indicates deeper and more severe dysfunction than does decorticate posturing; implies brain pathology; poor prognostic sign

Nursing Alert: If the patient begins to emerge from unconsciousness, every measure that is available and appropriate for calming and quieting the patient should be used. Any form of restraint is likely to be countered with resistance, leading to self-injury or to a dangerous increase in ICP. Therefore, physical restraints are avoided, if possible; a written prescription must be obtained if their use is essential for the patient's well-being.

Maintaining Fluid Balance and Managing Nutritional Needs

Hydration status is assessed by examining tissue turgor and mucous membranes, assessing intake and output trends, and analyzing laboratory data. Fluid needs are met initially by administering the required IV fluids. However, IV solutions (and blood component therapy) for patients with intracranial conditions must be given slowly. If they are given too rapidly, they can increase ICP. The quantity of fluids given may be restricted to minimize the possibility of cerebral edema.

If the patient does not recover quickly and sufficiently enough to take adequate fluids and calories by mouth, a feeding or gastrostomy tube will be inserted for the administration of fluids and enteral feedings. Research suggests that patients fed within 48 hours of injury have improved outcomes over those in whom nutrition is delayed (Wang, Dong, Han, et al., 2013).

Providing Mouth Care

The mouth is inspected for dryness, inflammation, and crusting. The patient who is unconscious requires careful oral care, because there is a risk of parotitis if the mouth is not kept scrupulously clean. The mouth is cleansed and rinsed carefully to remove secretions and crusts and to keep the mucous membranes moist. A thin coating of petrolatum on the lips prevents drying, cracking, and encrustations. If the patient has an endotracheal tube, the tube should be moved to the opposite side of the mouth daily to prevent ulceration of the mouth and lips. If the patient is intubated and mechanically ventilated, good oral care is also necessary. Research suggests that comprehensive mouth care with antiseptic such as chlorhexidine and head of bed elevation decreases ventilator-associated pneumonia and improves the oral health in patients who are intubated (Munro & Ruggiero, 2014).

Maintaining Skin and Joint Integrity

Preventing skin breakdown requires continuing nursing assessment and intervention. Special attention is given to patients who are unconscious, because they cannot respond to external stimuli. Assessment includes a regular schedule of turning to avoid pressure, which can cause breakdown and necrosis of the skin. Turning also provides kinesthetic (sensation of movement), proprioceptive (awareness of position), and vestibular (equilibrium) stimulation. After turning, the patient is carefully repositioned to prevent ischemic necrosis over pressure areas. Dragging or pulling the patient up in bed must be avoided, because this creates a shearing force and friction on the skin surface.

Maintaining correct body position is important; equally important is passive exercise of the extremities to prevent contractures. The use of splints or foam boots aids in the prevention of footdrop and eliminates the pressure of bedding on the toes. The use of trochanter rolls to support the hip joints keeps the legs in proper alignment. The arms are in abduction, the fingers lightly flexed, and the hands in slight supination. The heels of the feet are assessed for pressure areas. Specialty beds, such as fluidized or low-air-loss beds, may be used to decrease pressure on bony prominences (Hickey, 2014).

Preserving Corneal Integrity

Some patients who are unconscious have their eyes open and have inadequate or absent corneal reflexes. The cornea may become irritated, dry, or scratched, leading to ulceration. The eyes may be cleansed with cotton balls moistened with sterile normal saline to remove debris and discharge. If artificial tears are prescribed, they may be instilled every 2 hours. Periorbital edema often occurs after cranial surgery. If cold compresses are prescribed, care must be exerted to avoid contact with the cornea. Eye patches should be used cautiously because of the potential for corneal abrasion from contact with the patch.

Maintaining Body Temperature

High fever in the patient who is unconscious may be caused by infection of the respiratory or urinary tract, drug reactions, or damage to the hypothalamic temperature-regulating center. A slight elevation of temperature may be caused by dehydration. The environment can be adjusted, depending on the patient's condition, to promote a normal body temperature. If body temperature is elevated, a minimum amount of bedding is used. The room may be cooled to 18.3°C (65°F). However, if the patient is an older adult and does not have an elevated temperature, a warmer environment is needed.

Because of damage to the temperature-regulating center in the brain or severe intracranial infection, patients who are unconscious often develop very high temperatures. Such temperature elevations must be controlled, because the increased metabolic demands of the brain can exceed cerebral circulation and oxygen delivery, potentially resulting in cerebral deterioration (Hickey, 2014). Studies suggest that hyperthermia may contribute to poor outcome after brain injury but not through a decreased brain oxygen level (Madden & DeVon, 2015). Persistent hyperthermia with no identified clinical source of infection indicates brainstem damage and a poor prognosis.

Nursing Alert: The body temperature of a patient who is unconscious is never taken by mouth. Rectal, tympanic (if not contraindicated), or core temperature measurement is preferred to the less accurate axillary temperature.

Strategies for reducing fever include:

- Removing all bedding over the patient (with the possible exception of a light sheet, towel, or small drape)
- Administering acetaminophen/paracetamol or ibuprofen as prescribed
- Giving cool sponge baths
- Using a hypothermia blanket
- Monitoring temperature frequently to assess the patient's response to the therapy and to prevent an excessive decrease in temperature and shivering

Preventing Urinary Retention

The patient with an altered LOC is often incontinent or has urinary retention. The bladder is palpated or scanned at intervals to determine whether urinary retention is present, because a full bladder may be an overlooked cause of overflow incontinence. A portable bladder ultrasound instrument is a useful tool in bladder management and retraining programs.

If the patient is not voiding, a program of intermittent catheterization should be devised in order to reduce the patient's

risk of urinary tract infection. A catheter may be inserted during the acute phase of illness to monitor urinary output. Because catheters are a major cause of urinary tract infection, the patient is observed for fever and cloudy urine. The area around the urethral orifice is inspected for drainage and cleansed routinely. The urinary catheter is usually removed if the patient has a stable cardiovascular system and if no diuresis, sepsis, or voiding dysfunction existed before the onset of coma. Although many patients who are unconscious urinate spontaneously after catheter removal, the bladder should be palpated or scanned with a portable ultrasound device periodically for urinary retention (see Chapter 43, Fig. 43-8).

An external catheter (condom catheter) for the male patient and absorbent pads for the female patient can be used for patients who are unconscious and can urinate spontaneously, although involuntarily. As soon as consciousness is regained, a bladder training program is initiated (Hickey, 2014). The patient who is incontinent is monitored frequently for skin irritation and skin breakdown. Appropriate skin care is implemented to prevent these complications.

Promoting Bowel Function

The abdomen is assessed for distention by listening for bowel sounds and measuring the girth of the abdomen with a tape measure. There is a risk of diarrhea from infection, antibiotic agents, and hyperosmolar fluids. Frequent loose stools may also occur with fecal impaction. Commercial fecal collection bags are available for patients with fecal incontinence (see Chapter 18, Fig. 18-1).

Immobility and lack of dietary fiber can cause constipation. The nurse monitors the number and consistency of bowel movements and performs a rectal examination for signs of fecal impaction. Stool softeners may be prescribed and can be given with tube feedings. To facilitate bowel emptying, a glycerin suppository may be indicated. The patient may require an enema every other day to empty the lower colon.

Restoring Health Maintenance

Once increased ICP is not a problem, the nurse assists the patient and family to restore the health of the patient who is unconscious. This involves using auditory, visual, olfactory, gustatory, tactile, and kinesthetic activities to stimulate the patient emerging from coma (Megha, Harpreet, & Nayeem, 2013). Efforts are made to restore the sense of daily rhythm by maintaining usual day and night patterns for activity and sleep. The nurse touches and talks to the patient and encourages family members and friends to do so. Communication is extremely important and includes touching the patient and spending enough time with the patient to become sensitive to their needs. It is also important to avoid making any negative comments about the patient's status or prognosis in the patient's presence.

The nurse orients the patient to time and place at least once every 8 hours. Sounds from the patient's usual environment may be introduced using a tape recorder. Family members can read to the patient from a favorite book and may suggest radio and television programs that the patient previously enjoyed as a means of enriching the environment and providing familiar input.

When arousing from coma, many patients experience a period of agitation, indicating that they are becoming more aware of their surroundings but still cannot react or communicate in an appropriate fashion. Although this is disturbing for many family members, it is actually a positive clinical sign. At this time, it is necessary to minimize stimulation by limiting background noises, having only one person speak to the patient at a time, giving the patient a longer period of time to respond, and allowing for frequent rest or quiet times. After the patient has regained consciousness, videotaped family or social events may assist the patient in recognizing family and friends and allow him or her to experience missed events.

Programs of sensory stimulation for patients with brain injury have been developed in an effort to improve outcomes. Although these are controversial programs with inconsistent results, some research supports the concept of providing structured stimulation (Megha et al., 2013).

Meeting the Family's Needs

The family of the patient with altered LOC may be thrown into a sudden state of crisis and go through the process of severe anxiety, denial, anger, remorse, grief, and reconciliation. Depending on the disorder that caused the altered LOC and the extent of the patient's recovery, the family may be unprepared for the changes in the cognitive and physical status of their loved one. If the patient has significant residual deficits, the family may require considerable time, assistance, and support to come to terms with these changes. To help family members mobilize resources and coping skills, the nurse reinforces and clarifies information about the patient's condition, encourages the family to be involved in care, and listens to and encourages ventilation of feelings and concerns while supporting decision making about management and placement after hospitalization. Families may benefit from participation in support groups offered through the hospital, rehabilitation facility, or community organizations.

The family may need to face the death of their loved one. The patient with a neurologic disorder is often pronounced brain dead before the heart stops beating. The term brain death describes irreversible loss of all functions of the entire brain and absence of brainstem reflexes (Wijdicks, 2013). The term may be misleading to the family because, although brain function has ceased, the patient appears to be alive, with the heart rate and blood pressure sustained by vasoactive medications and breathing continued by mechanical ventilation. When discussing a patient who is brain dead with family members, it is important to provide accurate, timely, understandable, and consistent information. See Chapter 59 for discussion of end-of-life care.

Monitoring and Managing Potential Complications

Pneumonia, aspiration, and respiratory failure are potential complications in any patient who has a depressed LOC and who cannot protect the airway or turn, cough, and take deep breaths. The longer the period of unconsciousness, the greater the risk of pulmonary complications.

Vital signs and respiratory function are monitored closely to detect any signs of respiratory failure or distress. Complete blood count and arterial blood gas measurements are assessed to determine whether there are adequate red blood cells to carry oxygen and whether ventilation is effective. Chest physiotherapy and suctioning are initiated to prevent respiratory complications such as pneumonia. Oral care interventions are performed for patients receiving mechanical ventilation to maintain oral health and decrease the incidence of pneumonia (Kiyoshi-Teo & Blegen, 2015). If pneumonia develops, cultures are obtained to identify the organism so that appropriate antibiotic agents can be given.

The patient with altered LOC is monitored closely for evidence of impaired skin integrity, and strategies to prevent skin breakdown and pressure ulcers are continued through all phases of care, including hospitalization, rehabilitation, and home care. Factors that contribute to impaired skin integrity (e.g., incontinence, inadequate dietary intake, pressure on bony prominences, edema) are addressed. If pressure ulcers develop, strategies to promote healing are undertaken. Care is taken to prevent bacterial contamination of pressure ulcers, which may lead to sepsis and septic shock.

The patient should also be monitored for signs and symptoms of VTE, which may manifest as a deep vein thrombosis (DVT) or pulmonary embolism (PE). Prophylaxis with subcutaneous heparin or low–molecular-weight heparin (dalteparin [Fragmin], danaparoid [Orgaran]) as well as antiembolism stockings or pneumatic compression devices are prescribed according to the patient's risk factors for thrombosis and bleeding (Foreman, Schmalz, & Griessenauer, 2014). The nurse observes for signs and symptoms of DVT or PE.

Patients with a prolonged decrease in LOC are at risk for developing contractures. During acute care, the patient is turned every 2 hours and passive range of motion performed at least twice a day. Splints, provided by occupational therapy, are applied to the hands and feet in a rotating manner to maintain functional joint alignment. Hand splints have been reported to be safe and beneficial for patients in decreasing spasticity and improving hand opening (Thibault, Deltombe, Wannez, et al., 2015). See Chapter 38 for further information on prevention of contractures.

Evaluation

Expected patient outcomes may include:

1. Maintains clear airway and demonstrates appropriate breath sounds
2. Experiences no injuries
3. Attains or maintains adequate fluid balance and nutritional status
   a. Has no clinical signs or symptoms of dehydration
   b. Demonstrates normal range of serum electrolytes
   c. Has no clinical signs or symptoms of overhydration or malnutrition
4. Achieves healthy oral mucous membranes
5. Maintains normal skin integrity
6. Has no corneal irritation
7. Attains or maintains thermoregulation
8. Has no urinary retention
9. Has no diarrhea or fecal impaction
10. Receives appropriate sensory stimulation
11. Has family members who cope with crisis
    a. Verbalize fears and concerns
    b. Participate in patient's care and provide sensory stimulation by talking and touching
12. Is free of complications
    a. Has arterial blood gas values or oxygen saturation levels within normal range
    b. Displays no signs or symptoms of pneumonia
    c. Exhibits intact skin over pressure areas
    d. Does not develop VTE such as DVT or PE

INCREASED INTRACRANIAL PRESSURE

The rigid cranial vault contains brain tissue (1400 g), blood (75 mL), and CSF (75 mL). The volume and pressure of these three components are usually in a state of equilibrium and produce the ICP. ICP is usually measured in the lateral ventricles, with the normal pressure being 0 to 10 mm Hg, and 15 mm Hg being the upper limit of normal (Hickey, 2014).

The Monro–Kellie hypothesis, also known as the Monro–Kellie doctrine, explains the dynamic equilibrium of cranial contents. The hypothesis states that because of the limited space for expansion within the skull, an increase in any one of the components causes a change in the volume of the others. Because brain tissue has limited space to expand, compensation typically is accomplished by displacing or shifting CSF, increasing the absorption or diminishing the production of CSF, or decreasing cerebral blood volume. Without such changes, ICP begins to rise. Under normal circumstances, minor changes in blood volume and CSF volume occur constantly as a result of alterations in intrathoracic pressure (coughing, sneezing, straining), posture, blood pressure, and systemic oxygen and carbon dioxide levels (Hickey, 2014).

Pathophysiology

Increased ICP affects many patients with acute neurologic conditions because pathologic conditions alter the relationship between intracranial volume and ICP. Although elevated ICP is most commonly associated with head injury, it also may be seen as a secondary effect in other conditions, such as brain tumors, subarachnoid hemorrhage, and toxic and viral encephalopathies. Increased ICP from any cause decreases cerebral perfusion, stimulates further swelling (edema), and may shift brain tissue, resulting in herniation—a dire and frequently fatal event. A flowchart for pathophysiology of increased ICP is presented in Figure 49-3.

Decreased Cerebral Blood Flow

Increased ICP may reduce cerebral blood flow, resulting in ischemia and cell death. In the early stages of cerebral ischemia, the vasomotor centers are stimulated and the systemic pressure rises to maintain cerebral blood flow. Usually, this is accompanied by a slow bounding pulse and respiratory irregularities. These changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP.

The concentration of carbon dioxide in the blood and in the brain tissue also plays a role in the regulation of cerebral blood flow. An increase in the partial pressure of arterial carbon dioxide ($PaCO_2$) causes cerebral vasodilation, leading to increased cerebral blood flow and increased ICP. A decrease in $PaCO_2$ has a vasoconstrictive effect, limiting blood flow to the brain. Decreased venous outflow may also increase cerebral blood volume, thus raising ICP.

Cerebral Edema

Cerebral edema or swelling is defined as an abnormal accumulation of water or fluid in the intracellular space, extracellular space, or both, associated with an increase in the volume of brain tissue. Edema can occur in the gray, white, or interstitial matter. As brain tissue swells within the rigid skull, several mechanisms

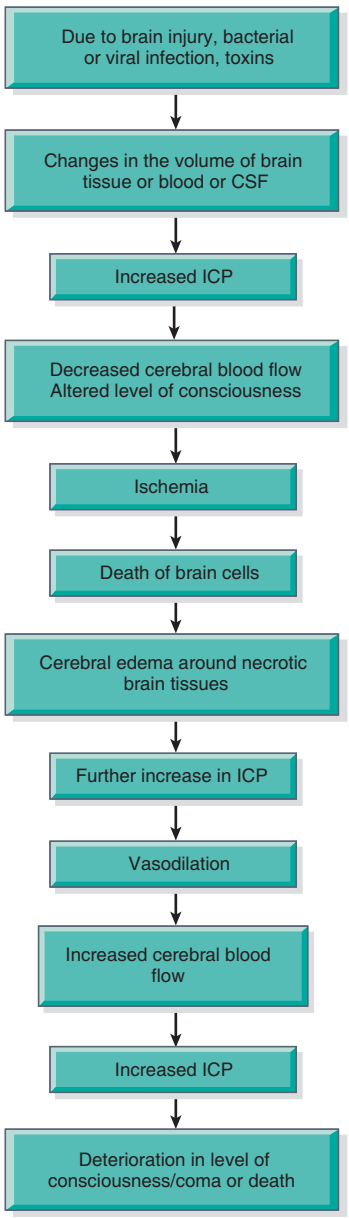


Figure. 49-3 • Pathophysiology of increased intracranial pressure.

attempt to compensate for the increasing ICP. These compensatory mechanisms include autoregulation as well as decreased production and flow of CSF. **Autoregulation** refers to the brain's ability to change the diameter of its blood vessels to maintain a constant cerebral blood flow during alterations in systemic blood pressure. This mechanism can be impaired in patients who are experiencing a pathologic and sustained increase in ICP.

Cerebral Response to Increased Intracranial Pressure

As ICP rises, compensatory mechanisms in the brain work to maintain blood flow and prevent tissue damage. The brain can maintain a steady perfusion pressure if the arterial systolic blood pressure is 50 to 150 mm Hg and the ICP is less than 40 mm Hg. Changes in ICP are closely linked with cerebral perfusion pressure (CPP). The CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP). For example, if the MAP is 100 mm Hg and the ICP is 15 mm Hg, then the CPP is 85 mm Hg. The normal CPP is 70 to 100 mm Hg (Hickey, 2014). As ICP rises and the autoregulatory mechanism of the brain is overwhelmed, the CPP can increase to greater than 100 mm Hg or decrease to less than 50 mm Hg. Patients with a CPP of less than 50 mm Hg experience irreversible neurologic damage. Therefore, the CPP must be maintained at 70 to 80 mm Hg to ensure adequate blood flow to the brain. If ICP is equal to MAP, cerebral circulation ceases.

A clinical phenomenon known as the Cushing's response (or Cushing's reflex) is seen when cerebral blood flow decreases significantly. When ischemic, the vasomotor center triggers an increase in arterial pressure in an effort to overcome the increased ICP. A sympathetically mediated response causes an increase in the systolic blood pressure with a widening of the pulse pressure and cardiac slowing. This response is seen clinically as an increase in systolic blood pressure, widening of the pulse pressure, and reflex slowing of the heart rate. It is a late sign requiring immediate intervention; however, perfusion may be recoverable if the Cushing's response is treated rapidly.

At a certain point, the brain's ability to autoregulate becomes ineffective and decompensation (ischemia and infarction) begins. When this occurs, the patient exhibits significant changes in mental status and vital signs. The bradycardia, hypertension, and bradypnea associated with this deterioration are known as Cushing's triad, which is a grave sign. At this point, herniation of the brainstem and occlusion of the cerebral blood flow occur if therapeutic intervention is not initiated. Herniation refers to the shifting of brain tissue from an area of high pressure to an area of lower pressure (see Fig. 49-4). The herniated tissue exerts pressure on the brain area into which it has shifted, which interferes with the blood supply in that area.

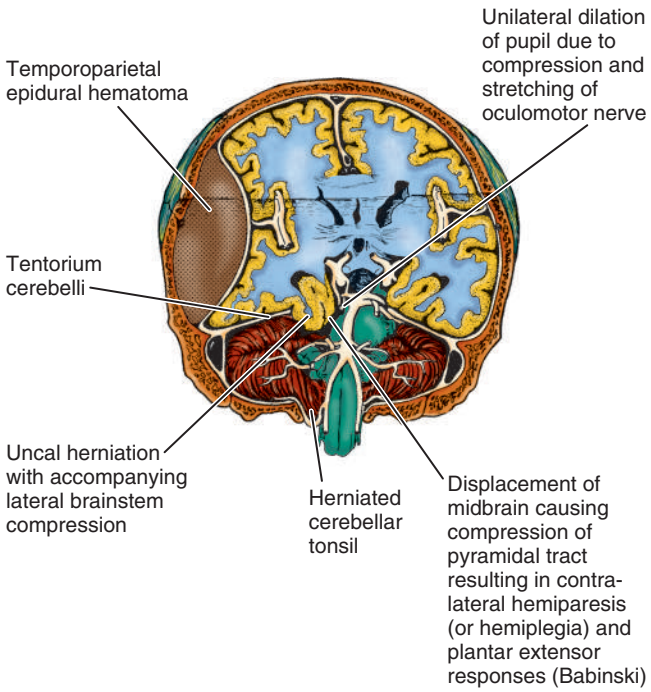

Figure 49-4 • Cross-section of the brain showing herniation of part of the temporal lobe through the tentorium as a result of a temporoparietal epidural hematoma. Reprinted with permission from Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Cessation of cerebral blood flow results in cerebral ischemia, infarction, and brain death.

Clinical Manifestations

If ICP increases to the point at which the brain's ability to adjust has reached its limits, neural function is impaired; this may be manifested at first by clinical changes in LOC and later by abnormal respiratory and vasomotor responses.

Nursing Alert: The earliest sign of increasing ICP is a change in LOC. Agitation, slowing of speech, and delay in response to verbal suggestions may be early indicators.

Any sudden change in the patient's condition, such as restlessness (without apparent cause), confusion, or increasing drowsiness, has neurologic significance. These signs may result from compression of the brain due to swelling from hemorrhage or edema, an expanding intracranial lesion (hematoma or tumor), or a combination of both.

As ICP increases, the patient becomes stuporous, reacting only to loud or painful stimuli. At this stage, serious impairment of brain circulation is probably taking place, and immediate intervention is required. As neurologic function deteriorates further, the patient becomes comatose and exhibits abnormal motor responses in the form of decortication (abnormal flexion of the upper extremities and extension of the lower extremities), decerebration (extreme extension of the upper and lower extremities), or flaccidity (see Fig. 49-2). If the coma is profound and irreversible with no known confounding factors, brainstem reflexes are absent, and respirations are impaired or absent, the patient may be evaluated for brain death (Wijdicks, 2013).

Assessment and Diagnostic Findings

The diagnostic studies used to determine the underlying cause of increased ICP are discussed in detail in Chapter 48. The most common diagnostic tests are CT scanning and MRI. The patient may also undergo cerebral angiography, PET, or SPECT. Transcranial Doppler studies provide information about cerebral blood flow. The patient with increased ICP may also undergo electrophysiologic monitoring to observe cerebral blood flow indirectly. Evoked potential monitoring measures the electrical potentials produced by nerve tissue in response to external stimulation (auditory, visual, or sensory). Lumbar puncture is avoided in patients with increased ICP, because the sudden release of pressure in the lumbar area can cause the brain to herniate (Hickey, 2014). See Chapter 48 for further discussion of lumbar puncture and other diagnostic tests.

Complications

Complications of increased ICP include brainstem herniation, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH).

Brainstem herniation results from an excessive increase in ICP in which the pressure builds in the cranial vault and the brain tissue presses down on the brainstem. This increasing pressure on the brainstem results in cessation of blood flow to the brain, leading to irreversible brain anoxia and brain death.

Neurogenic diabetes insipidus is the result of decreased secretion of antidiuretic hormone (ADH). The patient has excessive urine output, decreased urine osmolality, and serum hyperosmolarity (Grossman & Porth, 2014). Therapy consists of administration of fluids, electrolyte replacement, and administration of a synthetic vasopressin (desmopressin [DDAVP]). See Chapters 7 and 32 for a discussion of diabetes insipidus.

SIADH is the result of increased secretion of ADH. The patient becomes volume overloaded, urine output diminishes, and serum sodium concentration becomes dilute. Treatment of SIADH includes fluid restriction (less than 800 mL/day with no free water), which is usually sufficient to correct the hyponatremia. In severe cases, careful administration of a 3% hypertonic saline solution may be therapeutic (Aylwin, Burst, Peri, et al., 2015). The change in serum sodium concentration should not exceed a correction rate of approximately 1.3 mEq/L/hr. See Chapters 7 and 32 for further discussion of SIADH.

Medical Management

Increased ICP is a true emergency and must be treated promptly. Invasive monitoring of ICP is an important component of management. Immediate management to relieve increased ICP requires decreasing cerebral edema, lowering the volume of CSF, or decreasing cerebral blood volume while maintaining cerebral perfusion. These goals are accomplished by administering osmotic diuretics, restricting fluids, draining CSF, controlling fever, maintaining systemic blood pressure and oxygenation, and reducing cellular metabolic demands. See Chapter 51 for a discussion of the management of increased ICP.

Monitoring Intracranial Pressure and Cerebral Oxygenation

The purposes of ICP monitoring are to identify increased pressure early in its course (before cerebral damage occurs), to quantify the degree of elevation, to initiate appropriate treatment, to provide access to CSF for sampling and drainage, and to evaluate the effectiveness of treatment. ICP can be monitored with the use of an intraventricular catheter (ventriculostomy), a subarachnoid bolt, an epidural or subdural catheter, or a fiberoptic transducer-tipped catheter placed in the subdural space or in the ventricle (see Fig. 49-5).

When a ventriculostomy or intraventricular catheter monitoring device is used for monitoring ICP, a fine-bore catheter is inserted into a lateral ventricle, preferably in the nondominant hemisphere of the brain (American Association of Neuroscience Nurses [AANN], 2012). The catheter is connected by a fluid-filled system to a transducer, which records the pressure in the form of an electrical impulse. In addition to obtaining continuous ICP recordings, the ventricular catheter allows CSF to drain, particularly during acute increases in pressure. The ventriculostomy can also be used to drain blood from the ventricle. Continuous drainage of CSF under pressure control is an effective method of treating intracranial hypertension. Another advantage of a ventricular catheter is access for the intraventricular administration of medications and the occasional instillation of air or a contrast agent for ventriculography. Complications associated with its use include infection, meningitis, ventricular collapse, occlusion of the catheter by brain tissue or blood, and problems with the monitoring system.

The subarachnoid screw or bolt is a hollow device that is inserted through the skull and dura mater into the cranial

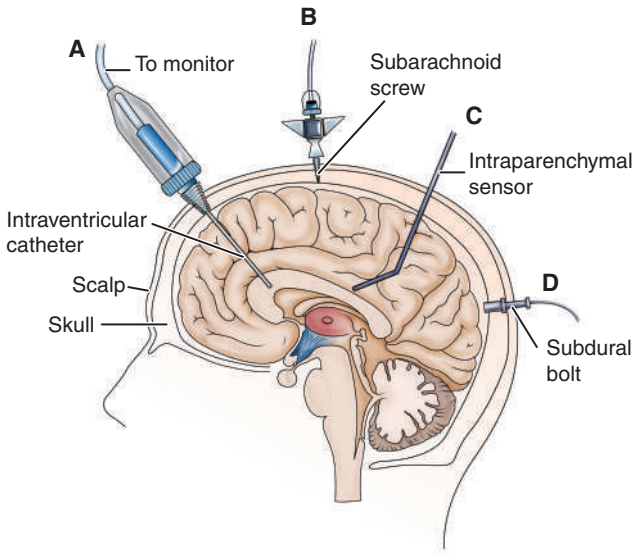

Figure 49-5 • Intracranial pressure monitoring. A device may be placed in the ventricle (**A**), the subarachnoid space (**B**), the intraparenchymal space (**C**), or the subdural space (**D**).

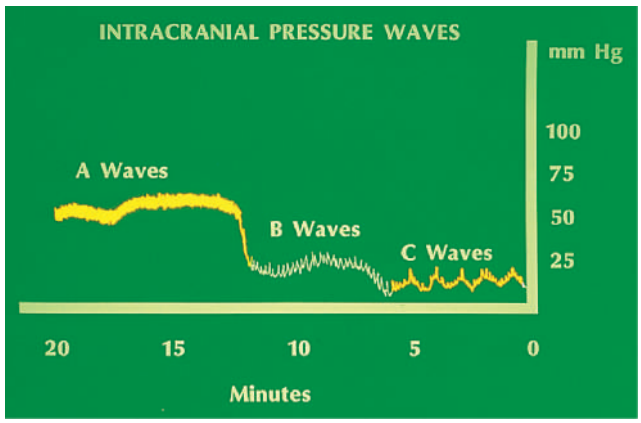

Figure 49-6 • Intracranial pressure waves. Composite diagram of A (plateau) waves, which indicate cerebral ischemia; B waves, which indicate intracranial hypertension and variations in the respiratory cycle; and C waves, which relate to variations in systemic arterial pressure and respirations.

subarachnoid space (Hickey, 2014). It has the advantage of not requiring a ventricular puncture. The subarachnoid screw is attached to a pressure transducer, and the output is recorded on an oscilloscope. The hollow screw technique also has the advantage of avoiding complications from brain shift and small ventricle size. Complications include infection and blockage of the screw by clot or brain tissue, which leads to a loss of pressure tracing and a decrease in accuracy at high ICP readings.

An epidural monitor uses a pneumatic flow sensor to detect ICP. The epidural ICP monitoring system has a low incidence of infection and complications and appears to read pressures accurately. Calibration of the system is maintained automatically, and abnormal pressure waves trigger an alarm system. One disadvantage of the epidural catheter is the inability to withdraw CSF for analysis.

A fiberoptic monitor, or transducer-tipped catheter, is an alternative to other intraventricular, subarachnoid, and subdural systems (Sandsmark, Kumar, Park, et al., 2012). The miniature transducer reflects pressure changes, which are converted to electrical signals in an amplifier and displayed on a digital monitor. The catheter can be inserted into the ventricle, subarachnoid space, subdural space, or brain parenchyma or under a bone flap. If inserted into the ventricle, it can also be used in conjunction with a CSF drainage device.

Interpreting Intracranial Pressure Waveforms

Waves of high pressure and troughs of relatively normal pressure indicate changes in ICP. Waveforms are captured and recorded on an oscilloscope. These waves have been classified as A waves (plateau waves), B waves, and C waves (see Fig. 49-6). The plateau waves (A waves) are transient, paroxysmal, recurring elevations of ICP that may last 5 to 20 minutes and range in amplitude from 40 to 100 mm Hg (Dias, Maia, Cerejo, et al., 2014). Plateau waves have clinical significance and indicate changes in vascular volume within the intracranial compartment that are beginning to compromise cerebral perfusion. The A waves may increase in amplitude and frequency, reflecting cerebral ischemia and brain damage that can occur before overt signs and symptoms of raised ICP are seen clinically. B waves are shorter (30 seconds to 2 minutes) and have smaller amplitude (up to 50 mm Hg). They have less clinical significance, but if seen in a series in a patient with depressed consciousness, they may precede the appearance of A waves. B waves may be seen in patients with intracranial hypertension and decreased intracranial compliance. C waves are small, rhythmic oscillations with frequencies of 4 to 8 per minute and appear to be related to rhythmic variations of the systemic arterial blood pressure and respirations (Hickey, 2014).

Other Neurologic Monitoring Systems

Another trend in neurologic monitoring is microdialysis of the patient with a brain injury (de Lima Oliveira, Kairalla, Fonoff, et al., 2014). Cortical probes are placed near the injured area and are used to measure levels of glutamate, lactate, pyruvate, and glucose, substances that reflect the metabolic function of the brain. Some researchers theorize that direct measurements of glucose and energy by-products in the brain will lead to better management of these patients. Although cerebral microdialysis has reduced the mortality of patients who are brain injured, more study is needed to link it to improved outcomes (de Lima Oliveira et al., 2014).

An additional trend is monitoring of cerebral oxygenation through monitoring of the oxygen saturation in the jugular venous bulb ($SjvO_2$) or via a catheter in the brain. Cerebral oxygenation is thought to be important because changes in cerebral perfusion may reflect an increase in ICP. Readings taken from a catheter residing in the jugular outflow tract allow for a comparison of arterial and venous oxygen saturation, and the balance of cerebral oxygen supply and demand is demonstrated. Venous jugular desaturations can reflect early cerebral ischemia, alerting the clinician before an increase in ICP occurs. Minimizing cerebral desaturations can potentially improve outcomes (Sandsmark et al., 2012). This type of monitoring is now widely available and has been successfully used to identify secondary brain insults. A limiting factor is that this saturation reflects overall perfusion of the brain rather than that of a specific injured area (Oddo, Bosel, & Participants in the International Multidisciplinary Consensus Conference on Multimodality Monitoring, 2014).

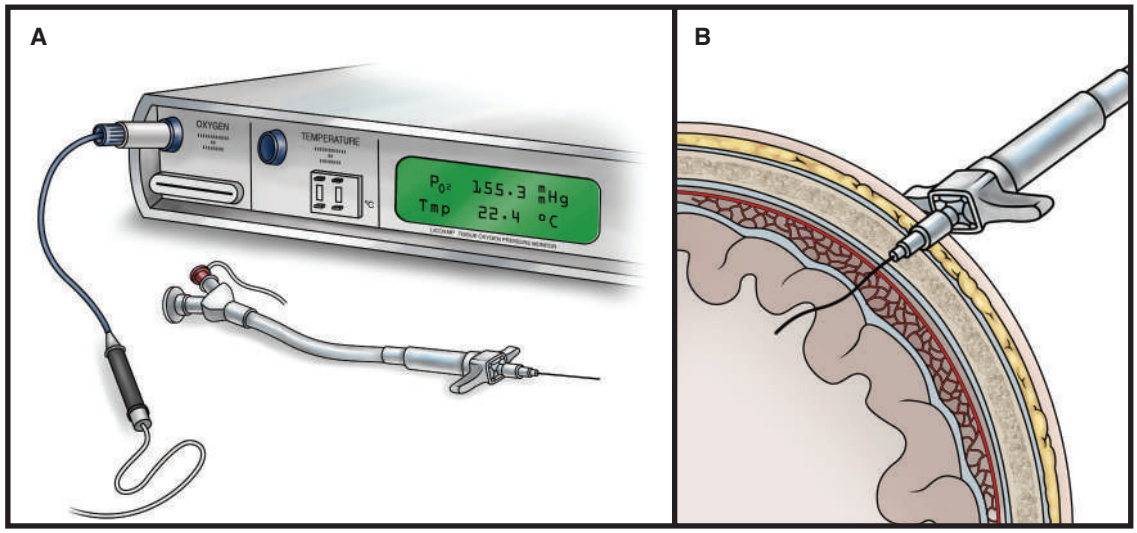

Figure 49-7 • Licox catheter system. **A.** The brain tissue oxygen catheter and monitor. **B.** Placement of the catheter in brain white matter. Redrawn with permission of Integra NeuroSciences, Plainsboro, NJ.

Another method of measuring cerebral oxygenation and temperature is by inserting a fiberoptic catheter into the brain matter (Oddo et al., 2014). The most common system is Licox (see Fig. 49-7). The system includes a monitor with a screen for the display of oxygen and temperature values and cables that connect to the monitoring probes in the brain (Hickey, 2014).

Decreasing Cerebral Edema

Osmotic diuretics such as mannitol and hypertonic saline (3%) may be given to dehydrate the brain tissue and reduce cerebral edema (Ong, Keyrouz, & Diringer, 2015). They act by drawing water across intact membranes, thereby reducing the volume of the brain and extracellular fluid. An indwelling urinary catheter is usually inserted to monitor urinary output and to manage the resulting diuresis. If the patient is receiving osmotic diuretics, serum osmolality and electrolytes should be determined to assess hydration status. If a brain tumor is the cause of the increased ICP, corticosteroids (e.g., dexamethasone) help reduce the edema surrounding the tumor.

Another method for decreasing cerebral edema is fluid restriction (Hickey, 2014). Limiting overall fluid intake leads to dehydration and hemoconcentration, which draws fluid across the osmotic gradient and decreases cerebral edema. Conversely, overhydration of the patient with increased ICP is avoided, because it increases cerebral edema.

Researchers have long hypothesized that lowering body temperature would decrease cerebral edema by reducing the oxygen and metabolic requirements of the brain, thus protecting the brain from continued ischemia. If body metabolism can be reduced by lowering the body temperature, the collateral circulation in the brain may be able to provide an adequate blood supply to the brain. The effect of hypothermia on ICP requires more study; thus far, induced hypothermia has not consistently been shown to be beneficial for patients with brain injury. Inducing and maintaining hypothermia is a major clinical treatment and requires knowledge and skilled nursing observation and management. The type and length of rewarming techniques after hypothermia may also be factors in the outcome of patients with neurologic injuries (Andrews, Sinclair, Rodriguez, et al., 2015); (Madden & DeVon, 2015).

Maintaining Cerebral Perfusion

Cardiac output may be manipulated to provide adequate perfusion to the brain. Improvements in cardiac output are made using fluid volume and inotropic agents such as dobutamine (Dobutrex) and norepinephrine (Levophed). The effectiveness of the cardiac output is reflected in the CPP, which is maintained at greater than 70 mm Hg (Oddo et al., 2014). A lower CPP indicates that the cardiac output is insufficient to maintain adequate cerebral perfusion. $SjvO_2$ and Licox, described earlier, assist in monitoring cerebral perfusion.

Decompressive hemicraniectomy may also be considered as a surgical strategy to assist in the management of refractory intracranial hypertension. The removal of a part of the skull allows the brain to expand without the pressure constraints exerted by the cranial vault. Complications of this procedure include infection and increased potential for injury to the unprotected underlying brain structures. Once the patient is no longer at risk for increased ICP, the bone flap may be surgically replaced (Alali, Naimark, Wilson, et al., 2014).

Reducing Cerebrospinal Fluid and Intracranial Blood Volume

CSF drainage is frequently performed, because the removal of CSF with a ventriculostomy drain can dramatically reduce ICP and restore CPP. Caution should be used in draining CSF, however, because excessive drainage may result in collapse of the ventricles and herniation. The reduction in $PaCO_2$ may result in hypoxia, ischemia, and an increase in cerebral lactate levels. Maintaining the $PaCO_2$ at greater than 30 mm Hg may prove beneficial (Hickey, 2014).

Controlling Fever

Preventing a temperature elevation is critical, because fever increases cerebral metabolism and the rate at which cerebral edema forms. Strategies to reduce body temperature include administration of antipyretic medications, as prescribed, and the use of a hypothermia blanket. Additional strategies for reducing fever were discussed previously in the Nursing Process section on altered LOC. The patient's temperature is monitored

closely, and the patient is observed for shivering, which should be avoided because it is associated with increased oxygen consumption, increased levels of circulating catecholamines, and increased vasoconstriction. Shivering is associated with decreased levels of brain oxygenation; however, the association between shivering and neurologic outcome is unknown.

Maintaining Oxygenation and Reducing Metabolic Demands

Arterial blood gases and pulse oximetry are monitored to ensure that systemic oxygenation remains optimal. Metabolic demands may be reduced through the administration of high doses of barbiturates if the patient is unresponsive to conventional treatment. The mechanism by which barbiturates decrease ICP and protect the brain is uncertain, but the resultant comatose state is thought to reduce the metabolic requirements of the brain, thus providing cerebral protection (Alali et al., 2014).

Another method of reducing cellular metabolic demand and improving oxygenation is the administration of medications causing sedation. The patient who receives these agents cannot move; this decreases the metabolic demands and results in a decrease in cerebral oxygen demand. The patient cannot respond to or report pain either. The most common agents used for sedation are pentobarbital (Nembutal), thiopental (Pentothal), propofol (Diprivan), and dexmedetomidine (Precedex) (Majdan, Mauritz, Wilbacher, et al., 2013); (Wang, Ji, Fen, et al., 2013).

If sedative agents are used, the ability to perform serial neurologic assessments is lost. Therefore, other monitoring tools are needed to assess the patient's status and response to therapy. Important parameters that must be assessed include ICP, blood pressure, heart rate, respiratory rate, and the patient's response to ventilator therapy (e.g., "fighting or bucking the ventilator"). The level of pharmacologic paralysis is adjusted based on serum levels of the medications given and the assessed parameters. Potential complications of these medications include hypotension caused by decreased sympathetic tone and myocardial depression.

Patients receiving high doses of barbiturates or pharmacologic sedatives require continuous cardiac monitoring, endotracheal intubation, mechanical ventilation, and arterial pressure monitoring, as well as ICP monitoring.

NURSING PROCESS

The Patient with Increased Intracranial Pressure

Assessment

Initial assessment of the patient with increased ICP includes obtaining a history of events leading to the present illness and the pertinent past medical history. It is usually necessary to obtain this information from family or friends. The neurologic examination should be as complete as the patient's condition allows. It includes an evaluation of mental status, LOC, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. Because the patient is critically ill, ongoing assessment is more focused, including pupil checks, (see Table 49-1) assessment of selected cranial nerves, frequent measurements of vital signs and ICP, and the use of the Glasgow Coma Scale.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses include the following:

- Ineffective airway clearance related to diminished protective reflexes (cough, gag)
- Ineffective breathing patterns related to neurologic dysfunction (brainstem compression, structural displacement)
- Risk for ineffective cerebral tissue perfusion related to the effects of increased ICP
- Deficient fluid volume related to fluid restriction
- Risk for infection related to ICP monitoring system (fiberoptic or intraventricular catheter)

Other relevant nursing diagnoses are included in the earlier section on altered LOC.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Brainstem herniation
- Diabetes insipidus
- SIADH

Planning and Goals

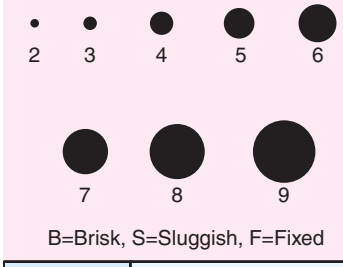
The goals for the patient include maintenance of a patent airway, normalization of respiration, adequate cerebral tissue perfusion through reduction in ICP, restoration of fluid balance, absence of infection, and absence of complications.

Nursing Interventions

Maintaining a Patent Airway

The patency of the airway is assessed. Secretions that are obstructing the airway must be suctioned with care, because transient elevations of ICP occur with suctioning (Hickey, 2014). Hypoxia caused by poor oxygenation leads to cerebral ischemia and edema. Coughing is discouraged because it increases ICP. The lung fields are auscultated at least every 8 hours to determine the presence of adventitious sounds or any areas of congestion. Elevating the head of the bed may aid in clearing secretions and improve venous drainage of the brain.

Achieving an Adequate Breathing Pattern



The patient must be monitored constantly for respiratory irregularities. Increased pressure on the frontal lobes or deep midline structures may result in Cheyne–Stokes respirations, whereas pressure in the midbrain can cause hyperventilation. If the lower portion of the brainstem (the pons and medulla) is involved, respirations become irregular and eventually cease.

Hyperventilation therapy is a controversial therapy in traumatic brain injury used in some centers to reduce ICP by causing cerebral vasoconstriction and a decrease in cerebral blood volume. The nurse collaborates with the respiratory therapist in monitoring the $PaCO_2$, which is usually maintained at less than 30 mm Hg. Patients undergoing hyperventilation therapy also benefit from multimodality monitoring to determine the overall effect of this therapy on brain perfusion (de Lima Oliveira et al., 2014).

A neurologic observation record (see Fig. 49-8) is maintained, and all observations are made in relation to the patient's baseline condition. Repeated assessments of the patient are made (sometimes minute by minute) so that improvement or deterioration may be noted immediately. If the patient's condition deteriorates, the primary provider is notified emergently and preparations are made for surgical intervention.

TABLE 49-2 Increased Intracranial Pressure and Interventions

Factor	Physiology	Interventions	Rationale
Cerebral edema	Can be caused by contusion, tumor, or abscess; water intoxication (hypo-osmolality); alteration in the blood–brain barrier (protein leaks into the tissue, causing water to follow)	Administer osmotic diuretics as prescribed (monitor serum osmolality). Maintain head of bed elevation at 30 degrees. Maintain alignment of the head.	Promotes venous return Prevents impairment of venous return through the jugular veins
Hypoxia	A decrease in PaO_2 to <60 mm Hg causes cerebral vasodilation.	Maintain PaO_2 >60 mm Hg. Maintain oxygen therapy. Monitor arterial blood gas values. Suction when needed. Maintain a patent airway.	Prevents hypoxia and vasodilation
Hypercapnia (elevated $PaCO_2$)	Causes vasodilation	Maintain $PaCO_2$ (normally 35–45 mm Hg) by establishing ventilation.	Normalizing $PaCO_2$ minimizes vasodilation and thus reduces the cerebral blood volume.
Impaired venous return	Increases the cerebral blood volume	Maintain head alignment. Elevate head of bed 30 degrees.	Hyperextension, rotation, or hyperflexion of the neck causes decreased venous return.
Increase in intrathoracic or abdominal pressure	An increase in these pressures due to coughing, PEEP, or Valsalva maneuver causes a decrease in venous return.	Monitor arterial blood gas values, and keep PEEP as low as possible. Provide humidified oxygen. Administer stool softeners as prescribed.	To keep secretions loose and easy to suction or expectorate Soft bowel movements will prevent straining or Valsalva maneuver.

$PaCO_2$, partial pressure of arterial carbon dioxide; PaO_2, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure.

Care of the patient undergoing intracranial pressure monitoring/external ventricular drainage or lumbar drainage: AANN Clinical Practice Guideline Series. Glenview, IL: Author; Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Optimizing Cerebral Tissue Perfusion

In addition to ongoing nursing assessment, strategies are initiated to reduce factors contributing to the elevation of ICP (see Table 49-2).

Proper positioning helps reduce ICP. The patient's head is kept in a neutral (midline) position, maintained with the use of a cervical collar if necessary, to promote venous drainage. Elevation of the head is maintained at 30 to 45 degrees unless contraindicated. Extreme rotation of the neck and flexion of the neck are avoided, because compression or distortion of the jugular veins increases ICP. Extreme hip flexion is also avoided, because this position causes an increase in intra-abdominal and intrathoracic pressures, which can produce an increase in ICP. Relatively minor changes in position can significantly affect ICP. If monitoring reveals that turning the patient raises ICP, rotating beds, turning sheets, and holding the patient's head during turning may minimize the stimuli that increase ICP. Research suggests that patient response to position change is highly variable and requires close hemodynamic monitoring and individualized care (Mitchell, Kirkness, & Blissitt, 2015).

The Valsalva maneuver, which can be produced by straining at defecation or even moving in bed, raises ICP and is to be avoided. Stool softeners may be prescribed. If the patient is alert and able to eat, a diet high in fiber may be indicated. Abdominal distention, which increases intra-abdominal and intrathoracic pressure and ICP, should be noted. Enemas and cathartics are avoided if possible. When moving or being turned in bed, the patient can be instructed to exhale (which opens the glottis) to avoid the Valsalva maneuver.

Mechanical ventilation presents unique problems for the patient with increased ICP. Before suctioning, the patient should be preoxygenated and briefly hyperventilated using 100% oxygen on the ventilator. Suctioning should not last longer than 15 seconds. High levels of positive end-expiratory pressure (PEEP) must be utilized cautiously, because they may decrease venous return to the heart and decrease venous drainage from the brain through increased intrathoracic pressure (Nemer, Caldeira, Santos, et al., 2015).

Activities that increase ICP, as indicated by changes in waveforms, should be avoided if possible. Spacing of nursing interventions may prevent transient increases in ICP. During nursing interventions, the ICP should not increase above 25 mm Hg, and it should return to baseline levels within 5 minutes. Patients with increased ICP should not demonstrate a significant increase in pressure or change in the ICP waveform. Patients with the potential for a significant increase in ICP may need sedation before initiation of nursing activities (Bader, Littlejohns, & Olson, 2016).

Emotional stress and frequent arousal from sleep are avoided. A calm atmosphere is maintained. Environmental stimuli (e.g., noise, conversation) should be minimal.

Maintaining Negative Fluid Balance

The administration of osmotic and loop diuretics is part of the treatment protocol to reduce ICP. Corticosteroids may be used to reduce cerebral edema (except when it results from trauma), and fluids may be restricted. All of these treatment modalities promote dehydration.

Skin turgor, mucous membranes, urine output, and serum and urine osmolality are monitored to assess fluid status. If IV fluids are prescribed, the nurse ensures that they are given at a slow to moderate rate with an IV infusion pump, to prevent too-rapid administration and avoid overhydration. For the patient receiving mannitol, the nurse observes for the possible

development of heart failure and pulmonary edema. The intent of treatment is to promote a shift of fluid from the intracellular to the intravascular compartment and to control cerebral edema. However, this shift of fluid volume to the intravascular compartment may overwhelm the ability of the myocardium to increase workload sufficient to meet these demands, which may cause failure and pulmonary edema.

For patients undergoing dehydrating procedures, vital signs, including blood pressure, must be monitored to assess fluid volume status. An indwelling urinary catheter is inserted to permit assessment of renal function and fluid status. During the acute phase, urine output is monitored hourly. An output greater than 200 mL per hour for 2 consecutive hours may indicate the onset of diabetes insipidus (Hickey, 2014). These patients need careful oral hygiene, because mouth dryness occurs with dehydration. Frequently rinsing the mouth with nondrying solutions, lubricating the lips, and removing encrustations relieve dryness and promote comfort.

Preventing Infection

The risk of infection is greatest when ICP is monitored with an intraventricular catheter and increases with the duration of the monitoring. Most health care facilities have written protocols for managing these systems and maintaining their sterility; strict adherence to the protocols is essential.

Aseptic technique must be used when managing the system and changing the ventricular drainage bag. The drainage system is also checked for loose connections, because they can cause leakage and contamination of the CSF as well as inaccurate readings of ICP. The nurse observes the character of the CSF drainage and reports increasing cloudiness or blood. The patient is monitored for signs and symptoms of meningitis: fever, chills, nuchal (neck) rigidity, and increasing or persistent headache. See Chapter 52 for a discussion of meningitis.

Monitoring and Managing Potential Complications

The primary complication of increased ICP is brain herniation resulting in death (see Fig. 49-4). Nursing management focuses on detecting early signs of increasing ICP, because medical interventions are usually ineffective once later signs develop (Bader et al., 2016). Frequent neurologic assessments and documentation and analysis of trends will reveal the subtle changes that may indicate increasing ICP.

Detecting Indications of Increasing Intracranial Pressure. The nurse assesses for and immediately reports any signs or symptoms of increasing ICP (see Chart 49-1). The focus is on detecting early signs of increasing ICP.

Monitoring Intracranial Pressure. Because clinical assessment is not always a reliable guide in recognizing increased ICP, especially in patients who are comatose, monitoring of ICP and cerebral oxygenation is an essential part of management. ICP is monitored closely for continuous elevation or significant increase over baseline. The trend of ICP measurements over time is an important indication of the patient's underlying status. Vital signs are assessed when an increase in ICP is noted (Bader et al., 2016).

Careful attention to aseptic technique is needed when handling any part of the monitoring system. The insertion site is inspected for signs of infection. Temperature, pulse, and respirations are closely monitored for systemic signs of infection. All connections and stopcocks are checked for leaks, because even small leaks can distort pressure readings and lead to infection (AANN, 2012).

Chart 49-1

Detecting Increasing Intracranial Pressure (ICP)

Early Signs and Symptoms of Increasing ICP

- *Disorientation, restlessness, increased respiratory effort, purposeless movements, and mental confusion.* These are early clinical indications of increasing ICP because the brain cells responsible for cognition are extremely sensitive to decreased oxygenation.
- *Pupillary changes and impaired extraocular movements.* These occur as the increasing pressure displaces the brain against the oculomotor and optic nerves (cranial nerves II, III, IV, and VI), which arise from the midbrain and brainstem (see Chapter 48).
- *Weakness in one extremity or on one side of the body.* This occurs as increasing ICP compresses the pyramidal tracts.
- *Headache that is constant, increasing in intensity, and aggravated by movement or straining.* This occurs as increasing ICP causes pressure and stretching of venous and arterial vessels in the base of the brain.

Later Signs and Symptoms of Increasing ICP

- The level of consciousness continues to deteriorate until the patient is comatose (Glasgow Coma Scale score ≤8).
- The pulse rate and respiratory rate decrease or become erratic, and the blood pressure and temperature increase. The pulse pressure (the difference between the systolic and diastolic pressures) widens. The pulse fluctuates rapidly, varying from bradycardia to tachycardia.
- Altered respiratory patterns develop, including Cheyne–Stokes breathing (rhythmic waxing and waning of rate and depth of respirations alternating with brief periods of apnea) and ataxic breathing (irregular breathing with a random sequence of deep and shallow breaths).
- Projectile vomiting may occur with increased pressure on the reflex center in the medulla.
- Hemiplegia or decorticate or decerebrate posturing may develop as pressure on the brainstem increases; bilateral flaccidity occurs before death.
- Loss of brainstem reflexes, including pupillary, corneal, gag, and swallowing reflexes, is an ominous sign of approaching death.

Adapted from Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

When ICP is monitored with a fluid system, the transducer is calibrated at a particular reference point, usually 2.5 cm (1 inch) above the ear with the patient in the supine position; this point corresponds to the level of the foramen of Monro (see Fig. 49-9). CSF pressure readings depend on the patient's position. For subsequent pressure readings, the head should be in the same position relative to the transducer. Fiberoptic catheters are calibrated before insertion and do not require further referencing; they do not require the head of the bed to be at a specific position to obtain an accurate reading.

When technology is associated with patient management, the nurse must be certain that the technologic equipment is functioning properly. The most important concern must be the patient to whom equipment is attached. The patient and family must be informed about the technology and the goals of its use. The patient's response is monitored, and appropriate comfort measures are implemented to ensure that the patient's stress is minimized.

ICP measurement is only one parameter; repeated neurologic checks and clinical examinations remain important measures. Astute observation, comparison of findings with

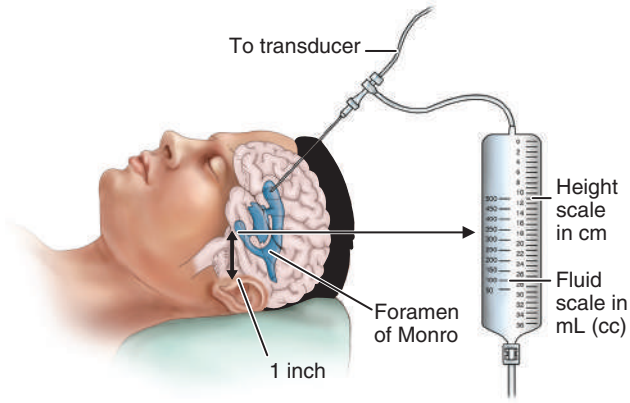

Figure 49-9 • Location of the foramen of Monro for calibration of the intracranial pressure monitoring system.

previous observations, and interventions can assist in preventing life-threatening ICP elevations.

Monitoring for Secondary Complications. The nurse also assesses for complications of increased ICP, including diabetes insipidus and SIADH (see Chapters 7 and 32). Urine output should be monitored closely. Diabetes insipidus requires fluid and electrolyte replacement, along with the administration of vasopressin, to replace and slow the urine output. Serum electrolyte levels are monitored for imbalances. SIADH requires fluid restriction and monitoring of serum electrolyte levels.

Evaluation

Expected patient outcomes may include:

1. Maintains patent airway
2. Attains optimal breathing pattern
   a. Breathes in a regular pattern
   b. Attains or maintains arterial blood gas values within acceptable range
3. Demonstrates optimal cerebral tissue perfusion
   a. Increasingly oriented to time, place, and person
   b. Follows verbal commands; answers questions correctly
4. Attains desired fluid balance
   a. Maintains fluid restriction
   b. Demonstrates serum and urine osmolality values within acceptable range
5. Has no signs or symptoms of infection
   a. Has no fever
   b. Shows no redness, swelling, or drainage at arterial, IV, and urinary catheter sites
   c. Has no redness, swelling, or purulent drainage from invasive intracranial monitoring device
6. Absence of complications
   a. Has ICP values that remain within normal limits
   b. Demonstrates urine output and serum electrolyte levels within acceptable limits

INTRACRANIAL SURGERY

A craniotomy involves opening the skull surgically to gain access to intracranial structures. This procedure is performed to remove a tumor, relieve elevated ICP, evacuate a blood clot, or control hemorrhage. The surgeon cuts the skull to create a bony flap, which can be repositioned after surgery and held in place by periosteal or wire sutures. One of two approaches through the skull is used: (1) above the tentorium (supratentorial craniotomy) into the supratentorial compartment, or (2) below the tentorium into the infratentorial (posterior fossa) compartment. A third approach, the transsphenoidal approach (through the mouth and nasal sinuses) is often used to gain access to the pituitary gland (Bader et al., 2016). Table 49-3 compares these three different surgical approaches.

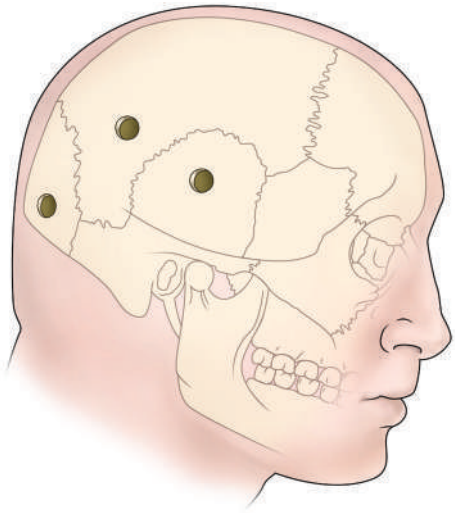

Figure 49-10 • Burr holes may be used in neurosurgical procedures to make a bone flap in the skull, to aspirate a brain abscess, or to evacuate a hematoma.

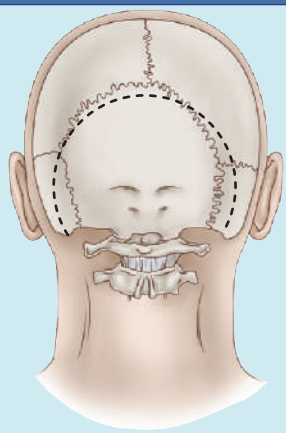
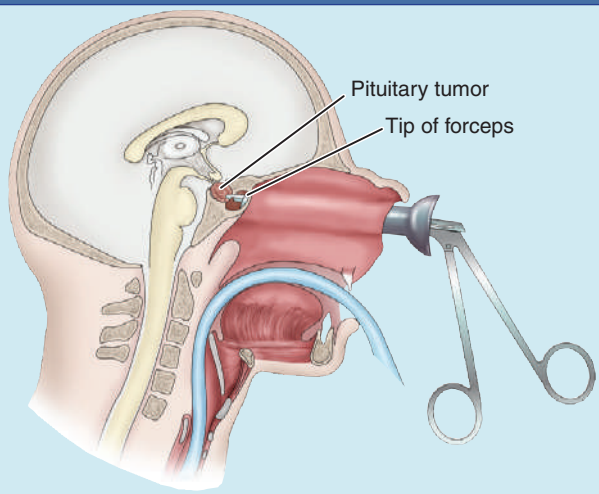
Alternatively, intracranial structures may be approached through burr holes (see Fig. 49-10), which are circular openings made in the skull by either a hand drill or an automatic craniotome (which has a self-controlled system to stop the drill when the bone is penetrated). Burr holes may be used to determine the presence of cerebral swelling and injury and the size and position of the ventricles. They are also a means of evacuating an intracranial hematoma or abscess and for making a bone flap in the skull that allows access to the ventricles for decompression, ventriculography, or shunting procedures. Other cranial procedures include craniectomy (excision of a portion of the skull) and cranioplasty (repair of a cranial defect using a plastic or metal plate).





Supratentorial and Infratentorial Approaches

Preoperative Management

Medical Management

Preoperative diagnostic procedures may include a CT scan to demonstrate the lesion and show the degree of surrounding brain edema, the ventricular size, and the displacement. An MRI scan provides information similar to that of a CT scan with improved tissue contrast, resolution, and anatomic definition. Cerebral angiography may be used to study a tumor's blood supply or obtain information about vascular lesions. Transcranial Doppler flow studies are used to evaluate the blood flow within intracranial blood vessels.

TABLE 49-3 Comparison of Cranial Surgical Approaches

Supratentorial	Infratentorial	Transsphenoidal
		
Site of Surgery		
Above the tentorium	Below the tentorium, brainstem	Sella turcica and pituitary region
Incision Location		
Incision is made above the area to be operated on; usually located behind the hairline.	Incision is made at the nape of the neck, around the occipital lobe.	Incision is made beneath the upper lip to gain access into the nasal cavity.
Selected Nursing Interventions		
Maintain head of bed elevated at 30 degrees, with neck in neutral alignment.	Maintain neck in straight alignment. Avoid flexion of the neck to prevent possible tearing of the suture line.	Maintain nasal packing in place and reinforce as needed. Instruct patient to avoid blowing the nose. Provide oral care according to institutional procedure.
Position patient on either side or back. (Avoid positioning patient on operative side if a large tumor has been removed.)	Position the patient on either side. (Check surgeon's preference for positioning of patient.)	Keep head of bed elevated to promote venous drainage and drainage from the surgical site.

Most patients are prescribed an anticonvulsant medication such as phenytoin (Dilantin), levetiracetam (Keppra), or a phenytoin metabolite fosphenytoin sodium (Cerebyx) before surgery to reduce the risk of postoperative seizures (paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity) (Karch, 2015). Before surgery, corticosteroids such as dexamethasone may be given to reduce cerebral edema if the patient has a brain tumor. Fluids may be restricted. A hyperosmotic agent (mannitol) and a diuretic agent such as furosemide (Lasix) may be administered IV immediately before and sometimes during surgery if the patient tends to retain fluid, as do many who have intracranial zdysfunction. Antibiotic agents may be given if there is a chance of cerebral contamination; diazepam (Valium) or lorazepam (Ativan) may be prescribed before surgery to allay anxiety.

Nursing Management

The preoperative assessment serves as a baseline against which postoperative status and recovery are compared (Bauman & McCourt, 2014). This assessment includes evaluating the LOC and responsiveness to stimuli and identifying any neurologic deficits, such as paralysis, visual dysfunction, alterations in personality or speech, and bladder and bowel disorders. Baseline distal and proximal motor strength in both upper and lower extremities is tested and recorded. See Chapter 48 for a discussion of the testing of motor function.

The patient's and family's understanding of and reactions to the anticipated surgical procedure and its possible sequelae are assessed, as is the availability of support systems for the patient and family. Adequate preparation for surgery, with attention to the patient's physical and emotional status, can reduce the risk of anxiety, fear, and postoperative complications. The patient is assessed for neurologic deficits and their potential impact after surgery. For motor deficits or weakness or paralysis of the arms or legs, trochanter rolls are applied to the extremities, and the feet are positioned against a footboard or the ankles are supported in a neutral position with orthotic boots. A patient who can ambulate is encouraged to do so. If the patient is aphasic, writing materials or picture and word cards showing the bedpan, glass of water, blanket, and other frequently used items may help improve communication.

Preparation of the patient and family includes providing education about what to expect during and after surgery. The patient should plan to shower and wash their hair prior to surgery using the preferred cleansing solution. Hair is removed with the use of clippers and the surgical site prepared immediately before surgery (usually in the operating room), and intravenous antibiotics are given 1 hour prior to the incision to decrease the chance of infection (AANN, 2016b).

An indwelling urinary catheter is inserted in the operating room to drain the bladder during the administration of diuretic agents and to permit monitoring of urinary output. The patient may have a central and an arterial line placed for fluid administration and monitoring of pressures after surgery. The large head dressing applied after surgery may impair hearing temporarily. Vision may be limited if the eyes are swollen shut. If a tracheostomy or endotracheal tube is in place, the patient will be unable to speak until the tube is removed, so an alternative method of communication must be established.

An altered cognitive state may make the patient unaware of the impending surgery. Even so, encouragement and attention to the patient's needs are necessary. Whatever the state of awareness of the patient, the family need reassurance and support, because they usually recognize the seriousness of brain surgery.

Postoperative Management

Postoperatively, an arterial line and a central venous pressure line may be in place to monitor and manage blood pressure and central venous pressure. The patient may be intubated and may receive supplemental oxygen therapy. Ongoing postoperative management is aimed at detecting and reducing cerebral edema, relieving pain and preventing seizures, and monitoring ICP and neurologic status.

Reducing Cerebral Edema

Medications to reduce cerebral edema include mannitol, which increases serum osmolality and draws free water from areas of the brain (with an intact blood–brain barrier). The fluid is then excreted by osmotic diuresis. Dexamethasone may be administered IV every 6 hours for 24 to 72 hours; the route is changed to oral as soon as possible, and the dosage is tapered over 5 to 7 days (Karch, 2015).

Relieving Pain and Preventing Seizures

Acetaminophen is usually prescribed for temperatures exceeding 37.5°C (99.6°F) and for mild pain. The patient usually has a headache after a craniotomy as a result of stretching and irritation of nerves in the scalp during surgery. Codeine, administered IV or orally, is often sufficient to relieve headache. Morphine sulfate may also be used in the management of postoperative pain in patients who have undergone a craniotomy with the goal of a patient reporting acceptable pain level (AANN, 2016b).

Anticonvulsant medication (phenytoin, levetiracetam) is often prescribed prophylactically for patients who have undergone supratentorial craniotomy because of the high risk of seizures after these procedures (Hickey, 2014). Serum levels are monitored to check that the medication levels are within the therapeutic range.

Monitoring Intracranial Pressure

A patient undergoing intracranial surgery may have an ICP or cerebral oxygenation monitor inserted during surgery. Strict adherence to written protocols for managing these systems is essential, as discussed earlier, for preventing infection and managing ICP. The system is removed after the ICP or cerebral oxygenation is normal and stable. The neurosurgeon must be notified immediately if the system is not functioning.

NURSING PROCESS

The Patient who has Undergone Intracranial Surgery

Assessment

After surgery, the frequency of postoperative monitoring is based on the patient's clinical status. Assessing respiratory function is essential, because even a small degree of hypoxia can increase cerebral ischemia. The respiratory rate and pattern are monitored, and arterial blood gas values are assessed frequently. Fluctuations in vital signs are carefully monitored and documented, because they may indicate increased ICP. The patient's temperature is measured to assess for hyperthermia secondary to infection or damage to the hypothalamus. Neurologic checks are made frequently to detect increased ICP resulting from cerebral edema or bleeding. A change in LOC or response to stimuli may be the first sign of increasing ICP.

The surgical dressing is inspected for evidence of bleeding and CSF drainage. The incision is monitored for redness, tenderness, bulging, separation, or foul odor. Sodium retention may occur in the immediate postoperative period. Serum and urine electrolytes, BUN, blood glucose, weight, and clinical status are monitored. Intake and output are measured in view of losses associated with fever, respiration, and CSF drainage. The nurse must be alert to the development of complications; all assessments are carried out with these problems in mind. Seizures are a potential complication, and any seizure activity is carefully recorded and reported. Restlessness may occur as the patient becomes more responsive, or restlessness may be caused by pain, confusion, hypoxia, or other stimuli.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective cerebral tissue perfusion related to cerebral edema
- Risk for imbalanced body temperature related to damage to the hypothalamus, dehydration, and infection
- Potential for impaired gas exchange related to hypoventilation, aspiration, and immobility
- Ineffective coping related to sensory perception changes due to periorbital edema, head dressing, endotracheal tube, and effects of ICP
- Disturbed body image related to change in appearance or physical disabilities

Other nursing diagnoses may include impaired communication (aphasia) related to insult to brain tissue and high risk for impaired skin integrity related to immobility, pressure, and incontinence; impaired physical mobility related to a neurologic deficit secondary to the neurosurgical procedure or to the underlying disorder may also occur.

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Increased ICP
- Bleeding and hypovolemic shock
- Fluid and electrolyte disturbances
- Infection
- CSF leak
- Seizures

Planning and Goals

The major goals for the patient include maintaining or restoring neurologic homeostasis to improve cerebral tissue perfusion, adequate thermoregulation, normal ventilation and gas exchange, ability to cope with sensory deprivation, adaptation to changes in body image, and absence of complications.

Nursing Interventions

Maintaining Cerebral Tissue Perfusion

Attention to the patient's respiratory status is essential, because even slight decreases in the oxygen level (hypoxia) or slight increases in the carbon dioxide level (hypercarbia) can affect cerebral perfusion, the clinical course, and the patient's outcome. The endotracheal tube is left in place until the patient shows signs of awakening and has adequate spontaneous ventilation, as evaluated clinically and by arterial blood gas analysis. Secondary brain damage can result from impaired cerebral oxygenation.

Some degree of cerebral edema occurs after brain surgery; it tends to peak 24 to 36 hours after surgery, potentially producing decreased responsiveness on the second postoperative day. The control of cerebral edema was discussed earlier. Nursing strategies used to control factors that may raise ICP were presented in the previous Nursing Process section on increased ICP. Intraventricular drainage is carefully monitored, using strict asepsis when any part of the system is handled.

Vital signs and neurologic status (LOC and responsiveness, pupillary and motor responses) are assessed every 15 to 60 minutes. Extreme head rotation is avoided, because this raises ICP. After supratentorial surgery, the patient is placed on their back or side (on the unoperated side if a large lesion was removed) with one pillow under the head. The head of the bed may be elevated 30 degrees, depending on the level of the ICP and the neurosurgeon's preference. After posterior fossa (infratentorial) surgery, the patient is kept flat on one side (off the back) with the head on a small, firm pillow. The patient may be turned on either side, keeping the neck in a neutral position. When the patient is being turned, the body should be turned as a unit to prevent placing strain on the incision and possibly tearing the sutures. The head of the bed may be elevated slowly as tolerated by the patient.

The patient's position is changed every 2 hours, and skin care is given frequently. During position changes, care is taken to prevent disruption of the ICP monitoring system. A turning sheet or lift sling placed under the patient's head to midthigh makes it easier to move and turn the patient safely.

Regulating Temperature

Moderate temperature elevation can be expected after intracranial surgery because of the reaction to blood at the operative site or in the subarachnoid space. Injury to the hypothalamic centers that regulate body temperature can occur during surgery. Fever is treated vigorously to combat the effect of an elevated temperature on brain metabolism and function.

Nursing interventions include monitoring the patient's temperature and using the following measures to reduce body temperature: removing blankets, placing ice packs, and administering prescribed antipyretics to reduce fever (Rockett, Thompson, & Blissitt, 2015).

Conversely, hypothermia may be seen after lengthy neurosurgical procedures. Therefore, frequent measurements of rectal temperatures are necessary. Rewarming should occur slowly to prevent shivering, which increases cellular oxygen demands.

Improving Gas Exchange

The patient undergoing neurosurgery is at risk for impaired gas exchange and pulmonary infections due to immobility, immunosuppression, decreased LOC, and fluid restriction. Immobility compromises the respiratory system by causing pooling and stasis of secretions in dependent areas and the development of atelectasis. The patient whose fluid intake is restricted may be more vulnerable to atelectasis as a result of inability to expectorate thickened secretions. Pneumonia can develop due to aspiration and restricted mobility.

Repositioning the patient every 2 hours helps to mobilize pulmonary secretions and prevent stasis. After the patient regains consciousness, additional measures to expand collapsed alveoli can be instituted, such as yawning, sighing, deep breathing, incentive spirometry, and coughing (unless contraindicated). If necessary, the oropharynx and trachea are suctioned to remove secretions that cannot be raised by coughing; however, coughing and suctioning increase ICP. Therefore, suctioning should be used cautiously. Increasing the humidity in the oxygen delivery system may help to loosen secretions. The nurse and the respiratory therapist work together to monitor the effects of chest physiotherapy.

Coping with Sensory Deprivation

Periorbital edema is a common consequence of intracranial surgery, because fluid drains into the dependent periorbital areas when the patient has been positioned in a prone position during surgery. A hematoma may form under the scalp and spread down to the orbit, producing an area of ecchymosis (black eye).

Before surgery, the patient and family should be informed that one or both eyes may be edematous temporarily after surgery. After surgery, elevating the head of the bed (if not contraindicated) and applying cold compresses over the eyes will help reduce the edema. The surgeon is notified if periorbital edema increases significantly, because this may indicate that a postoperative clot is developing or that there is increasing ICP and poor venous drainage. Health care personnel should announce their presence when entering the room to avoid startling the patient whose vision is impaired due to periorbital edema or neurologic deficits.

Additional factors that can affect sensation include a bulky head dressing, the presence of an endotracheal tube, and effects of increased ICP. The first postoperative dressing change is usually performed by the neurosurgeon. In the absence of bleeding or a CSF leak, every effort is made to minimize the size of the head dressing. If the patient requires an endotracheal tube for mechanical ventilation, every effort is made to extubate the patient as soon as clinical signs indicate it is possible. The patient is monitored closely for the effects of elevated ICP.

Enhancing Self-Image

The patient is encouraged to verbalize feelings and frustrations about any change in appearance. Nursing support is based on the patient's reactions and feelings. Factual information may need to be provided if the patient has misconceptions about puffiness about the face, periorbital bruising, and hair loss. Attention to grooming, the use of the patient's own clothing, and covering the head with a turban (and later a wig until hair growth occurs) are encouraged. Social interaction with close friends, family, and hospital personnel may increase the patient's sense of self-worth.

The family and social support system can be of assistance while the patient recovers from surgery.

Monitoring and Managing Potential Complications

The nurse must be vigilant for complications that may develop within hours of surgery and require close collaboration with the neurosurgeon. These include increased ICP, bleeding and hypovolemic shock, altered fluid and electrolyte balance (e.g., water intoxication and diabetes insipidus), infection, identification of a CSF leak, and seizures.

Monitoring for Increased Intracranial Pressure and Bleeding. Increased ICP and bleeding are life threatening to the patient who has undergone intracranial surgery. The following points must be kept in mind when caring for any patient who has undergone such surgery:

- An increase in blood pressure and decrease in pulse with respiratory failure may indicate increased ICP.
- An accumulation of blood under the bone flap (extradural, subdural, or intracerebral hematoma) may pose a threat to life. A clot must be suspected in any patient who does not awaken as expected or whose condition deteriorates. An intracranial hematoma is suspected if the patient has any new postoperative neurologic deficits (especially a dilated pupil on the operative side). In these circumstances, the patient is returned to the operating room immediately for evacuation of the clot, if indicated.
- Cerebral edema, infarction, metabolic disturbances, and hydrocephalus are conditions that may mimic the clinical manifestations of a clot.

The patient is monitored closely for indicators of complications, and early signs and trends in clinical status are reported to the surgeon. Treatments are initiated promptly, and the nurse assists in evaluating the patient's response to treatment. The nurse also provides support to the patient and family.

Nursing Alert: If signs and symptoms of increased ICP occur, efforts to decrease the ICP are initiated: alignment of the head in a neutral position without flexion to promote venous drainage, elevation of the head of the bed to 30 degrees (when prescribed), administration of mannitol (an osmotic diuretic), and possible administration of pharmacologic paralyzing agents.

Managing Fluid and Electrolyte Disturbances. Fluid and electrolyte imbalances may occur because of the patient's underlying condition and its management or as complications of surgery. These disturbances can contribute to the development of cerebral edema.

The postoperative fluid regimen depends on the type of neurosurgical procedure and is determined on an individual basis. The volume and composition of fluids are adjusted based on daily serum electrolyte values, along with fluid intake and output. Fluids may have to be restricted in patients with cerebral edema.

Oral fluids are usually resumed after the first 24 hours. The presence of gag and swallowing reflexes must be checked before initiation of oral fluids. Some patients with posterior fossa tumors have impaired swallowing, so fluids may need to be given by alternative routes. The patient should be observed for signs and symptoms of nausea and vomiting as the diet is progressed (AANN, 2016b).

Patients undergoing surgery for brain tumors often receive large doses of corticosteroids and are at risk for hyperglycemia. Serum glucose levels are measured every 4 to 6 hours, and sliding scale insulin is prescribed as needed. These patients are prone to stress ulcers, so histamine-2 receptor antagonists (H_2 blockers) are prescribed to suppress the secretion of gastric acid. Patients also are monitored for bleeding and assessed for gastric pain.

If the surgical site is near to (or causes edema to) the pituitary gland and hypothalamus, the patient may develop symptoms of diabetes insipidus, which is characterized by excessive urinary output, elevated serum osmolality, decreased urine osmolality, hypernatremia, and a low urine-specific gravity. The urine-specific gravity is measured hourly, and fluid intake and output are monitored. Fluid replacement must compensate for urine output, and serum potassium levels must be monitored.

SIADH, which results in water retention with hyponatremia and serum hypo-osmolality, occurs in a wide variety of CNS disorders (e.g., brain tumor, head trauma) causing fluid disturbances. Nursing management includes careful intake and output measurements, specific gravity determinations of urine, and monitoring of serum and urine electrolyte levels while following directives for fluid restriction. SIADH is usually self-limited.

Preventing Infection. The patient undergoing neurosurgery is at risk for infection related to the neurosurgical procedure (brain exposure, bone exposure, wound hematomas) and the presence of IV and arterial lines for fluid administration and monitoring. Risk for infection is increased in patients who undergo lengthy intracranial operations and in those who have external ventricular drains in place.

The dressing is often stained with blood in the immediate postoperative period. Because blood is an excellent culture medium for bacteria, the dressing is reinforced with sterile pads so that contamination and infection are avoided. A heavily stained or displaced dressing should be reported immediately. A drain is sometimes placed in the craniotomy incision to facilitate drainage.

After suboccipital surgical procedures, CSF may leak through the incision. This complication is dangerous because of the possibility of meningitis. After a craniotomy, the patient is instructed to avoid coughing, sneezing, or nose blowing, which can cause CSF leakage by creating pressure on the operative site.

Nursing Alert: Any sudden discharge of fluid from a cranial incision is reported at once, because a large leak requires surgical repair. Attention should be paid to the patient who complains of a salty taste or "postnasal drip," because this can be caused by CSF trickling down the throat.

Aseptic technique is used when handling dressings, drainage systems, and IV and arterial lines. The patient is monitored carefully for signs and symptoms of infection, and cultures are obtained if infection is suspected. Appropriate antibiotic agents are given as prescribed. Other causes of infection in the patient undergoing intracranial surgery, such as pneumonia and urinary tract infections, are similar to those in other patients postoperatively.

Monitoring for Seizure Activity. Seizures may occur as complications after any intracranial neurosurgical procedure. Preventing seizures is essential to avoid further cerebral edema. Administering the prescribed anticonvulsant medication before and after surgery may prevent the development of seizures in subsequent months and years. Status epilepticus (prolonged seizures without recovery of consciousness in the intervals between seizures) may occur after craniotomy and also may be related to the development of complications

(hematoma, ischemia). The management of status epilepticus is described later in this chapter.

Monitoring and Managing Other Complications. Other complications may occur during the first 2 weeks or later and may compromise the patient's recovery. The most important of these are VTE (DVT, PE), pulmonary and urinary tract infection, and pressure ulcers. Most of these complications may be avoided with frequent changes of position, adequate suctioning of secretions, thrombosis prophylaxis, early removal of indwelling urinary catheter, early ambulation, and skin care.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The recovery at home of a patient who has had neurosurgery depends on the extent of the surgical procedure and its success. The patient's strengths as well as limitations are assessed and explained to the family, along with the family's part in promoting recovery. Because administration of anticonvulsant medication is a priority, the patient and family are educated to use a check-off system, pill boxes, and alarms to ensure that the medication is taken as prescribed.

The patient and family are educated about what to expect after intracranial surgery (see Chart 49-2). Dietary restrictions usually are not required unless another health problem necessitates a special diet. Although showering or tub bathing is permitted, the scalp should be kept dry until all sutures have been removed. A clean scarf or cap may be worn until a wig or hairpiece is purchased. If skull bone has been removed, a protective helmet may be prescribed. The patient may require rehabilitation, depending on the postoperative level of function. The patient may require physical therapy for residual weakness and mobility issues. An occupational therapist is consulted to assist with self-care issues. If the patient has aphasia, speech therapy may be necessary.

Continuing and Transitional Care. The patient is discharged from the hospital as soon as possible. Patients with severe motor deficits require extensive physical therapy and rehabilitation. Those with postoperative cognitive and speech impairments require psychological evaluation, speech therapy, and rehabilitation. The nurse collaborates with the physician and other health care professionals during hospitalization and home or transitional care to achieve as complete a rehabilitation as possible and to assist the patient in living with residual disability.

If tumor, injury, or disease makes the prognosis poor, care is directed toward making the patient as comfortable as possible. With return of the tumor or cerebral compression, the patient becomes less alert and aware. Other possible consequences include paralysis, blindness, and seizures. The home care nurse, hospice nurse, and social worker collaborate with the family to plan for additional services or placement of the patient in an extended care facility (see the Cerebral Metastases section in Chapter 53). The patient and family are encouraged to discuss end-of-life preferences for care; the patient's end-of-life preferences must be respected (see Chapter 59). The nurse involved in home and continuing care of patients after cranial surgery also should remind patients and family members of the need for health promotion activities and recommended health screening.

Evaluation

Expected patient outcomes may include:

1. Achieves optimal cerebral tissue perfusion
   a. Opens eyes on request; uses recognizable words, progressing to normal speech
   b. Obeys commands with appropriate motor responses
2. Maintains normal body temperature
   a. Registers normal body temperature
3. Has normal gas exchange
   a. Has arterial blood gas values within normal ranges
   b. Breathes easily; lung sounds clear without adventitious sounds
   c. Takes deep breaths and changes position as directed
4. Copes with sensory deprivation
5. Demonstrates improving self-concept
   a. Pays attention to grooming
   b. Visits and interacts with others
6. Exhibits absence of complications
   a. Exhibits ICP within normal range
   b. Has minimal bleeding at surgical site; surgical incision healing without evidence of infection
   c. Shows fluid balance and electrolyte levels within desired ranges
   d. Exhibits no evidence of seizures

Chart 49-2 HOME CARE CHECKLIST

Discharge after Intracranial Surgery

At the completion of education, the patient and/or caregiver will be able to:

- Name the procedure that was performed, any complications that occurred, and identify any permanent changes in anatomic structure or function as well as changes in ADLs, IADLs, roles, relationships, and spirituality.
- Identify interventions and strategies (e.g., durable medical equipment, adaptive equipment) used in recovery period.
- Describe ongoing postoperative therapeutic regimen, including diet and activities to perform (e.g., walking and breathing exercises) and to limit or avoid (e.g., lifting weights, driving a car, contact sports).
- State the name, dose, side effects, frequency, and schedule for all medications.
- State how to obtain medical supplies and carry out dressing changes, wound care, and other prescribed regimens.
- Identify durable medical equipment needs, proper usage, and maintenance necessary for safe utilization.
- Describe signs and symptoms of complications.
- State time and date of follow-up appointments.
- Relate how to reach primary provider with questions or complications.
- Identify community resources for peer and caregiver/family support:
  - Identify sources of support (e.g., friends, relatives, faith community).
  - Identify phone numbers, meeting locations/times of community resources for patients and their caregivers/families.
- Identify the need for health promotion (e.g., weight reduction, smoking cessation, stress management), disease prevention and screening activities.

ADL, activities of daily living; IADL, independent activities of daily living.

Transsphenoidal Approach

Tumors within the sella turcica and small adenomas of the pituitary can be removed through a transsphenoidal approach (see Table 49-3). Although an otorhinolaryngologist may make the initial opening, the neurosurgeon completes the opening into the sphenoidal sinus and exposes the floor of the sella. Microsurgical techniques provide improved illumination, magnification, and visualization so that nearby vital structures can be avoided.

The transsphenoidal approach offers direct access to the sella turcica with minimal risk of trauma and hemorrhage (Bader et al., 2016). It avoids many of the risks of craniotomy, and the postoperative discomfort is similar to that of other transnasal surgical procedures. It may also be used for pituitary ablation (destruction) in patients with metastatic breast or prostatic cancer.

Complications

Manipulation of the posterior pituitary gland during surgery may produce transient diabetes insipidus of several days' duration (Hickey, 2014). It is treated with vasopressin but occasionally persists. Other complications include CSF leakage, visual disturbances, postoperative meningitis, pneumocephalus (air in the intracranial cavity), and SIADH (see Chapter 32).

Preoperative Management

Medical Management

The preoperative evaluation includes a series of endocrine tests, rhinologic evaluation (to assess the status of the sinuses and nasal cavity), and neuroradiologic studies. Funduscopic examination and visual field determinations are performed, because the most serious effect of pituitary tumor is localized pressure on the optic nerve or chiasm. In addition, the nasopharyngeal secretions are cultured, because a sinus infection is a contraindication to an intracranial procedure using this approach. Corticosteroids may be given before and after surgery, because the surgery involves removal of the pituitary, which is the source of adrenocorticotropic hormone (ACTH). Antibiotic agents may or may not be given prophylactically.

Nursing Management

The patient is educated in deep breathing techniques before surgery. In addition, the patient is instructed that after the surgery, they will need to avoid vigorous coughing, blowing the nose, sucking through a straw, or sneezing, because these actions may place increased pressure at the surgical site and cause a CSF leak (Hickey, 2014).

Postoperative Management

Medical Management

Because the procedure disrupts the oral and nasal mucous membranes, management focuses on preventing infection and promoting healing. Medications include antimicrobial agents (which are continued until the nasal packing inserted at the time of surgery is removed), corticosteroids, analgesic agents for discomfort, and agents for the control of diabetes insipidus, if necessary (Hickey, 2014).

Nursing Management

Vital signs are measured to monitor hemodynamic, cardiac, and ventilatory status. Because of the anatomic proximity of the pituitary gland to the optic chiasm, visual acuity and visual fields are assessed at regular intervals. One method is to ask the patient to count the number of fingers held up by the nurse. Evidence of decreasing visual acuity suggests an expanding hematoma.

The head of the bed is raised to decrease pressure on the sella turcica and to promote normal drainage. The patient is cautioned against blowing the nose or engaging in any activity that raises ICP, such as bending over or straining during urination or defecation.

Intake and output are measured as a guide to fluid and electrolyte replacement and to assess for diabetes insipidus. The urine-specific gravity is measured after each voiding. Daily weight is monitored. Fluids are usually given after nausea ceases, and the patient then progresses to a regular diet.

The nasal packing inserted during surgery is checked frequently for blood or CSF drainage. The major discomfort is related to the nasal packing and to mouth dryness and thirst caused by mouth breathing. Oral care is provided every 4 hours or more frequently. Usually, the teeth are not brushed until the incision above the teeth has healed. Warm saline mouth rinses and the use of a cool mist vaporizer are helpful. Petrolatum is soothing when applied to the lips. A room humidifier assists in keeping the mucous membranes moist. The packing is removed in 3 to 4 days, and only then can the area around the nares be cleaned with the prescribed solution to remove crusted blood and moisten the mucous membranes (Hickey, 2014).

Home care considerations include advising the patient to use a room humidifier to keep the mucous membranes moist and to soothe irritation. The head of the bed is elevated at 30 degrees for at least 2 weeks after surgery. The patient is cautioned against blowing the nose or sneezing for at least 1 month (Hickey, 2014).

SEIZURE DISORDERS

Seizures are episodes of abnormal motor, sensory, autonomic, or psychic activity (or a combination of these) that result from sudden excessive discharge from cerebral neurons (Hickey, 2014). A localized area or all of the brain may be involved. The International League Against Epilepsy (ILAE) has defined epilepsy as at least two unprovoked seizures occurring more than 24 hours apart (Fisher, Acevedo, Arzimanoglou, et al., 2014). The ILAE differentiates between three main seizure types: focal, generalized, and unknown seizures (see Chart 49-3). Generalized seizures occur in and rapidly engage bilaterally distributed networks. Focal seizures are thought to originate within one hemisphere in the brain. The unknown type includes epileptic spasms. Unclassified seizures are so termed because of incomplete data but are not considered a classification (Fisher et al., 2014) Seizures may also be characterized as "provoked," or related to acute, reversible conditions such as structural, metabolic, immune, infectious or unknown etiologies (Scheffer, French, Hirsch, et al., 2016).

Pathophysiology

The underlying cause is an electrical disturbance (dysrhythmia) in the nerve cells in one section of the brain; these cells emit abnormal, recurring, uncontrolled electrical discharges. The characteristic seizure is a manifestation of this excessive neuronal discharge. Associated loss of consciousness, excess movement or loss of muscle tone or movement, and disturbances of behavior, mood, sensation, and perception may also occur (Fig. 49-11).

Chart 49-3

Classification of Seizures: 2016 Basic Scheme

Focal

- Motor
- Nonmotor
- Awareness
  - Aware
  - Impaired awareness
  - Unknown awareness

Generalized

- Motor

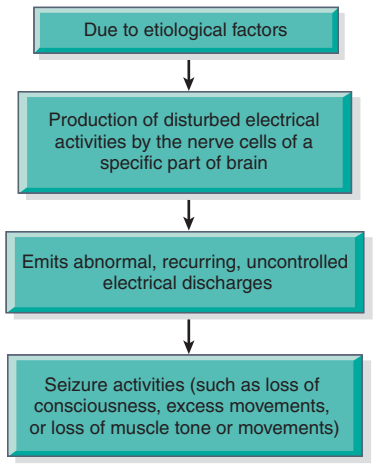

Figure 49-11 • Pathophysiology of seizure disorders.

The specific causes of seizures are varied and can be categorized as genetic, due to a structural or metabolic condition, or the cause may be yet unknown etiologies (Scheffer et al., 2016).
Causes of seizures include:

- Cerebrovascular disease
- Hypoxemia of any cause, including vascular insufficiency
- Fever (childhood)
- Head injury
- Hypertension
- CNS infections
- Metabolic and toxic conditions (e.g., kidney injury, hyponatremia, hypocalcemia, hypoglycemia, pesticide exposure)
- Brain tumor
- Drug and alcohol withdrawal
- Allergies

Clinical Manifestations

Depending on the location of the discharging neurons, seizures may range from a simple staring episode (generalized absence seizure) to prolonged convulsive movements with loss of consciousness.

The initial pattern of the seizures indicates the region of the brain in which the seizure originates (see Chart 49-3). Only a finger or hand may shake, or the mouth may jerk uncontrollably. The person may talk unintelligibly; may be dizzy; and may experience unusual or unpleasant sights, sounds, odors, or tastes, but without loss of consciousness (Hickey, 2014).

Generalized seizures often involve both hemispheres of the brain, causing both sides of the body to react. Intense rigidity of the entire body may occur, followed by alternating muscle relaxation and contraction (generalized tonic–clonic contraction). The simultaneous contractions of the diaphragm and chest muscles may produce a characteristic epileptic cry. The tongue is often chewed, and the patient is incontinent of urine and feces. After 1 or 2 minutes, the convulsive movements begin to subside; the patient relaxes and lies in deep coma, breathing noisily. The respirations at this point are chiefly abdominal. In the postictal state (after the seizure), the patient is often confused and hard to arouse and may sleep for hours. Many patients report headache, sore muscles, fatigue, and depression (AANN, 2016a). Other generalized seizures may be absence types of seizures (Fisher, Cross, French et al., 2016).

Focal seizures are subdivided into events characterized by both motor and non-motor symptoms. There may be an impairment of consciousness or awareness or other dyscognitive features, localization, and progression of symptoms (Fisher et al., 2016).

Assessment and Diagnostic Findings

The diagnostic assessment is aimed at determining the type of seizures, their frequency and severity, and the factors that precipitate them. A developmental history is taken, including events of pregnancy and childbirth, to seek evidence of pre-existing injury. The patient is also questioned about illnesses or head injuries that may have affected the brain. In addition to physical and neurologic evaluations, diagnostic examinations include biochemical, hematologic, and serologic studies. MRI is used to detect structural lesions such as focal abnormalities, cerebrovascular abnormalities, and cerebral degenerative changes (AANN, 2016a).

The EEG furnishes diagnostic evidence for a substantial proportion of patients with epilepsy and assists in classifying the type of seizure. Abnormalities in the EEG usually continue between seizures or, if not apparent, may be elicited by hyperventilation or during sleep (AANN, 2016a). Microelectrodes (depth electrodes) can be inserted deep in the brain to probe the action of single brain cells. Some people with clinical seizures have normal EEGs, whereas others who have never had seizures have abnormal EEGs. Telemetry and computerized equipment are used to monitor electrical brain activity while the patient pursues their normal activities and to store the readings on computer tapes for analysis. Video recording of seizures taken simultaneously with EEG telemetry is useful in determining the type of seizure as well as its duration and magnitude (Updyke & Duryea, 2013).

SPECT is an additional tool that is sometimes used in the diagnostic workup. It is useful for identifying the epileptogenic zone so that the area in the brain giving rise to seizures can be removed surgically (AANN, 2016a).

Nursing Management

During a Seizure

A major responsibility of the nurse is to observe and record the sequence of signs. The nature of the seizure usually indicates the type of treatment required (AANN, 2016a). Before and during a seizure, the patient is assessed and the following items are documented:

- Circumstances before the seizure (visual, auditory, or olfactory stimuli; tactile stimuli; emotional or psychological disturbances; sleep; hyperventilation)
- Occurrence of an aura (a premonitory or warning sensation, which can be visual, auditory, or olfactory)
- First thing the patient does in the seizure—where the movements or the stiffness begins, conjugate gaze position, and the position of the head at the beginning of the seizure. This information gives clues to the location of the seizure origin in the brain. (In recording, it is important to state whether the beginning of the seizure was observed.)
- Type of movements in the part of the body involved
- Areas of the body involved (turn back bedding to expose patient)
- Size of both pupils and whether the eyes are open
- Whether the eyes or head are turned to one side
- Presence or absence of automatisms (involuntary motor activity, such as lip smacking or repeated swallowing)
- Incontinence of urine or stool
- Duration of each phase of the seizure
- Unconsciousness, if present, and its duration
- Any obvious paralysis or weakness of arms or legs after the seizure
- Inability to speak after the seizure
- Movements at the end of the seizure
- Whether or not the patient sleeps afterward
- Cognitive status (confused or not confused) after the seizure

In addition to providing data about the seizure, nursing care is directed at preventing injury and supporting the patient, not only physically but also psychologically. Consequences such as anxiety, embarrassment, fatigue, and depression can be devastating to the patient.

After a Seizure

After a patient has a seizure, the nurse's role is to document the events leading to and occurring during and after the seizure and to prevent complications (e.g., aspiration, injury). The patient is at risk for hypoxia, vomiting, and pulmonary aspiration. To prevent complications, the patient is placed in the side-lying position to facilitate drainage of oral secretions, and suctioning is performed, if needed, to maintain a patent airway and prevent aspiration (see Chart 49-4). Seizure precautions are maintained, including having available functioning suction equipment with a suction catheter and oral airway. The bed is placed in a low position with two to three side rails up and padded, if necessary, to prevent injury to the patient. The patient may be drowsy and may wish to sleep after the seizure; they may not remember events leading up to the seizure and for a short time thereafter.

The Epilepsies

Epilepsy is a group of syndromes characterized by unprovoked, recurring seizures (AANN, 2016a). Epileptic syndromes are classified by specific patterns of clinical features, including age at onset, family history, and seizure type. The epilepsies include electroclinical syndromes (a complex of clinical features, signs, and symptoms) and other epilepsies (Institute of Medicine [IOM], 2012). Epilepsy can be primary (idiopathic) or secondary (when the cause is known and the epilepsy is a symptom of another underlying condition, such as a brain tumor).

Epilepsy affects an estimated 3% of people during their lifetime, and most forms of epilepsy occur in children and older adults (England, Liverman, Schultz, et al., 2012). It is estimated that around 70 million people live with epilepsy globally and the prevalence rate is 5–9/1,000 population (Sander, 2004; Amudhan et al.,2015;). In India, more than 12 million people are suffering with epilepsy, which contributes to nearly one-sixth of the global burden (Amudhan et al., 2015). The prevalence rate of epilepsy in South East Asia ranges from 2–10/1,000 population and more than half of the total disability-adjusted life years (DALYs) due to epilepsy in India.

The improved treatment for cerebrovascular disorders, head injuries, brain tumors, meningitis, and encephalitis has increased the number of patients at risk for seizures after recovery from these conditions. In addition, advances in EEG have aided in the diagnosis of epilepsy. The general public has been educated about epilepsy, which has reduced the stigma associated with it; as a result, more people are willing to acknowledge that they have epilepsy.

Although some evidence suggests that susceptibility to some types of epilepsy may be inherited, the cause of seizures in many people is idiopathic (unknown). Epilepsy can follow birth trauma, asphyxia neonatorum, head injuries, some infectious diseases (bacterial, viral, parasitic), toxicity (carbon monoxide and lead poisoning), circulatory problems, fever, metabolic and nutritional disorders, or drug or alcohol intoxication. It is also associated with brain tumors, abscesses, and congenital malformations.

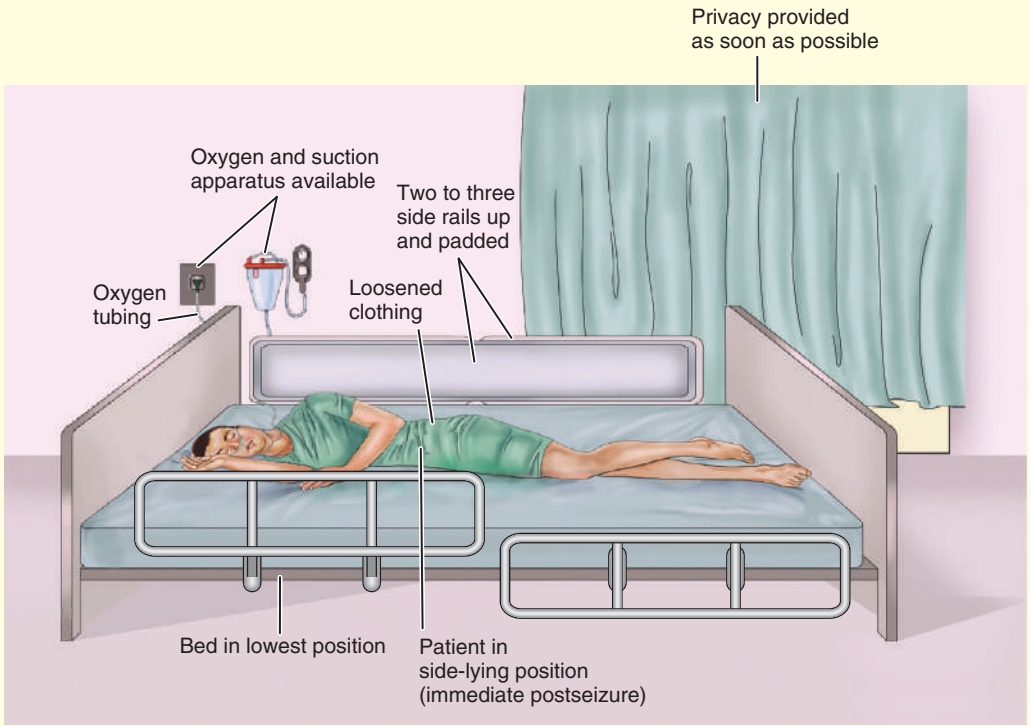
Pathophysiology

Messages from the body are carried by the neurons (nerve cells) of the brain by discharges of electrochemical energy that sweep along them. These impulses occur in bursts whenever a nerve cell has a task to perform. Sometimes, these cells or groups of cells continue firing after a task is finished. During the period of unwanted discharges, parts of the body controlled by the errant cells may perform erratically. Resultant dysfunction ranges from mild to incapacitating and often causes loss of consciousness (Hickey, 2014). If these uncontrolled, abnormal discharges occur repeatedly, a person is said to have an epileptic syndrome. Epilepsy is not associated with intellectual level. People who have epilepsy without other brain or nervous system disabilities fall within the same intelligence ranges as the overall population. Epilepsy is not synonymous with intellectual or developmental disabilities, but many people who have these types of disabilities, because of serious neurologic damage, also have epilepsy (Fig. 49-12).

Epilepsy in Women

More than 1 million American women have epilepsy, and they face particular needs associated with the syndrome. Women with epilepsy often note an increase in seizure frequency during menses; this has been linked to the increase in sex hormones that alter the excitability of neurons in the cerebral cortex. The

Chart 49-4



Care of the Patient During and After a Seizure

Nursing Care during a Seizure

- Provide privacy, and protect the patient from curious onlookers. (The patient who has an aura may have time to seek a safe, private place.)
- Ease the patient to the floor, if possible.
- Protect the head with a pad to prevent injury (from striking a hard surface).
- Loosen constrictive clothing and remove eyeglasses.
- Push aside any furniture that may injure the patient during the seizure.
- If the patient is in bed, remove pillows and raise side rails.
- *Do not attempt to pry open jaws that are clenched in a spasm or attempt to insert anything in the mouth during a seizure.* Broken teeth and injury to the lips and tongue may result from such an action.
- Do not attempt to restrain the patient during the seizure, because muscular contractions are strong and restraint can produce injury.
- If possible, place the patient on one side with head flexed forward, which allows the tongue to fall forward and facilitates drainage of saliva and mucus. If suction is available, use it if necessary to clear secretions.

Nursing Care after the Seizure

- Keep the patient on one side to prevent aspiration. Make sure the airway is patent.
- On awakening, reorient the patient to the environment.
- If the patient is confused or wandering, guide the patient gently to a bed or chair.
- If the patient becomes agitated after a seizure (postictal), stay a distance away, but close enough to prevent injury until the patient is fully aware.

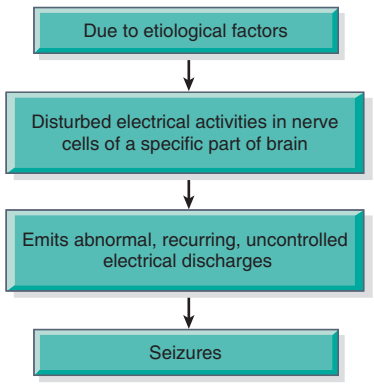

Figure 49-12 • Pathophysiology of epilepsy.

effectiveness of contraceptives is decreased by anticonvulsant medications. Therefore, patients should be encouraged to discuss family planning with their primary provider and to obtain preconception counseling if they are considering childbearing (Lagana, Triolo, D'Amico, et al., 2016).

Women of childbearing age who have epilepsy require special care and guidance before, during, and after pregnancy. Many women note a change in the pattern of seizure activity during pregnancy. The risk of congenital fetal anomaly is two to three times higher in women with epilepsy. Maternal seizures, anticonvulsant medications, and genetic predisposition all contribute to possible malformations. Women who take certain anticonvulsant medications for epilepsy are at risk and need careful monitoring, including blood studies to detect the level

of anticonvulsant medications taken throughout pregnancy. Mothers who are at high risk (teenagers, women with histories of difficult deliveries, women who use illicit drugs [e.g., "crack" cocaine, heroin], and women with diabetes or hypertension) should be identified and monitored closely during pregnancy, because damage to the fetus during pregnancy and delivery can increase the risk of epilepsy. All of these issues need further study (Lagana et al., 2016).

Because of bone loss associated with the long-term use of anticonvulsant medications, patients receiving anticonvulsant agents should be assessed for low bone mass and osteoporosis. They should be instructed about strategies to reduce their risks of osteoporosis (AANN, 2016a).

Gerontologic Considerations

Older adults have a high incidence of new-onset epilepsy (see Chart 49-5) (Hickey, 2014); (Miller, Buelow, & Bakas, 2014). Cerebrovascular disease is the leading cause of seizures in the older adult. The increased incidence is also associated with head injury, dementia, infection, alcoholism, and aging. Treatment depends on the underlying cause. Because many older adults have chronic health problems, they may be taking other medications that can interact with medications prescribed for seizure control. In addition, the absorption, distribution, metabolism, and excretion of medications are altered in the older adult as a result of age-related changes in renal and liver function. Therefore, older adult patients must be monitored closely for adverse and toxic effects of anticonvulsant medications and for osteoporosis. The cost of anticonvulsant medications can lead to poor adherence to the prescribed regimen in older adult patients on fixed incomes.

Prevention

Society-wide efforts are the key to prevention of epilepsy. Head injury is one of the main causes of epilepsy that can be prevented. Through highway safety programs and occupational safety precautions, lives can be saved and epilepsy due to head injury prevented; these programs are discussed in Chapter 51.

Medical Management

The management of epilepsy is individualized to meet the needs of each patient and not just to manage and prevent seizures. Management differs from patient to patient, because some forms of epilepsy arise from brain damage and others result from altered brain chemistry.

Pharmacologic Therapy

Many medications are available to control seizures, although the exact mechanisms of action are unknown. The objective is to achieve seizure control with minimal side effects. Medication therapy controls—rather than cures—seizures. Medications are selected on the basis of the type of seizure being treated and the effectiveness and safety of the medications. If properly prescribed and taken, medications control seizures in 70% to 80% of patients with seizures. However, 20% of patients with generalized seizures and 30% of those with focal seizures do not demonstrate improvement with any prescribed medication or may be unable to tolerate the side effects of medications (AANN, 2016a). Table 49-4 lists select anticonvulsant medications.

Treatment usually starts with a single medication. The starting dose and the rate at which the dosage is increased depend on the occurrence of side effects. The medication levels in the blood are monitored, because the rate of drug absorption varies among patients. Changing to another medication may be necessary if seizure control is not achieved or if toxicity makes it impossible to increase the dosage. The medication may need to be adjusted because of concurrent illness, weight changes, or increases in stress. Side effects of anticonvulsant medications may be divided into three groups: (1) idiosyncratic or allergic disorders, which manifest primarily as skin reactions; (2) acute toxicity, which may occur when the medication is initially

Chart 49-5 NURSING RESEARCH PROFILE

Experiences with a New Diagnosis of Epilepsy in Older Adults

Miller, W., Buelow, J., & Bakas, T. (2014). Older adults and new onset epilepsy: Experiences with diagnosis. Journal of Neuroscience Nursing, 46(1), 2–10.

Purpose

Older adults in the United States have a high rate of new-onset epilepsy; however, most research focuses on children and young adults. Older adults may exhibit a different clinical presentation, display age-related cognitive and metabolic changes, and have comorbidities that increase the likelihood of polypharmacy, creating unique challenges. This research was undertaken to identify the experience and characteristics of the older adult with new-onset epilepsy.

Design

A qualitative descriptive approach was undertaken to describe the experiences of 20 community dwelling older adults with new-onset epilepsy living in both urban and rural settings. Eligible participants were diagnosed at or after the age of 60 years, diagnosed within the previous 3 months, took at least one anticonvulsant medication, and spoke and read English. Semi-structured interviews were conducted by one researcher and analyzed and coded using conventional content analysis that identified clusters and themes.

Findings

The mean age of the participants was 70 years; 12 were women and 8 were men. Length of time until diagnosis was the most prominent theme during the interviews and split into two main themes: delayed diagnosis and nondelayed diagnosis. Participants with delayed diagnosis (epilepsy not diagnosed within 3 months of symptoms) attributed the delay to their primary providers not recognizing atypical symptoms or attributing symptoms to another neurologic process, or to their own delay in seeking care. The nondelayed participants reported typical seizure characteristics and rapid referral to a neurologic provider. The seizure events were obvious and interfered with daily life. Participants living in rural areas and women more often experienced delays in diagnosis.

Nursing Implications

Nurses need to be aware that older adults are the group at highest risk for developing new-onset epilepsy, and what might be identified as symptoms of aging may in fact be seizure-related events. Nurses can educate older adults regarding their risk of developing epilepsy and should describe both typical and atypical seizure presentations. Patients should be encouraged to seek specialized care for symptoms such as unexplained changes in mental status, syncopy, and dizziness.

TABLE 49-4 Select Anticonvulsant Medications

Medication	Dose-Related Side Effects	Toxic Effects
Carbamazepine (Tegretol)	Dizziness, drowsiness, unsteadiness, nausea and vomiting, diplopia, mild leukopenia	Severe skin rash, blood dyscrasias, hepatitis
Clonazepam (Klonopin)	Drowsiness, behavior changes, headache, hirsutism, alopecia, palpitations	Hepatotoxicity, thrombocytopenia, bone marrow failure, ataxia
Ethosuximide (Zarontin)	Nausea and vomiting, headache, gastric distress	Skin rash, blood dyscrasias, hepatitis, systemic lupus erythematosus
Felbamate (Felbatol)	Cognitive impairments, insomnia, nausea, headache, fatigue	Aplastic anemia, hepatotoxicity
Gabapentin (Neurontin)	Dizziness, drowsiness, somnolence, fatigue, ataxia, weight gain, nausea	Leukopenia, hepatotoxicity
Lamotrigine (Lamictal)	Drowsiness, tremor, nausea, ataxia, dizziness, headache, weight gain	Severe rash (Stevens–Johnson syndrome)
Levetiracetam (Keppra)	Somnolence, dizziness, fatigue	Unknown
Oxcarbazepine (Trileptal)	Dizziness, somnolence, double vision, fatigue, nausea, vomiting, loss of coordination, abnormal vision, abdominal pain, tremor, abnormal gait	Hepatotoxicity
Phenobarbital (Luminal)	Sedation, irritability, diplopia, ataxia	Skin rash, anemia
Phenytoin (Dilantin)	Visual problems, hirsutism, gingival hyperplasia, dysrhythmias, dysarthria, nystagmus	Severe skin reaction, peripheral neuropathy, ataxia, drowsiness, blood dyscrasias
Primidone (Mysoline)	Lethargy, irritability, diplopia, ataxia, impotence	Skin rash
Tiagabine (Gabitril)	Dizziness, fatigue, nervousness, tremor, difficulty concentrating, dysarthria, weak or buckling knees, abdominal pain	Unknown
Topiramate (Topamax)	Fatigue, somnolence, confusion, ataxia, anorexia, depression, weight loss	Nephrolithiasis
Valproate (Depakote, Depakene)	Nausea and vomiting, weight gain, hair loss, tremor, menstrual irregularities	Hepatotoxicity, skin rash, blood dyscrasias, nephritis
Zonisamide (Zonegran, Excegran)	Somnolence, dizziness, anorexia, headache, nausea, agitation, rash	Leukopenia, hepatotoxicity

Adapted from Karch, A. (2015). 2015 Lippincott's nursing drug guide. Philadelphia, PA: Lippincott Williams & Wilkins.

prescribed; and (3) chronic toxicity, which occurs late in the course of therapy.

The manifestations of drug toxicity are variable, and any organ system may be involved. For example, gingival hyperplasia (swollen and tender gums) can be associated with long-term use of phenytoin (Karch, 2015). Periodic physical and dental examinations and laboratory tests are performed for patients receiving medications that are known to have hematopoietic, genitourinary, or hepatic effects.

Surgical Management

Surgery is indicated for patients whose epilepsy results from intracranial tumors, abscesses, cysts, or vascular anomalies. Some patients have intractable seizure disorders that do not respond to medication. A focal atrophic process may occur secondary to trauma, inflammation, stroke, or anoxia. If the seizures originate in a reasonably well-circumscribed area of the brain that can be excised without producing significant neurologic deficits, the removal of the area generating the seizures may produce long-term control and improvement (AANN, 2016a).

This type of neurosurgery has been aided by several advances, including microsurgical techniques, EEGs with depth electrodes, improved illumination and hemostasis, and the introduction of neuroleptanalgesic agents (droperidol and fentanyl). These techniques, combined with the use of local anesthetic agents, enable the neurosurgeon to perform surgery on an alert and cooperative patient. Using special testing devices, electrocortical mapping, and the patient's responses to stimulation, the boundaries of the epileptogenic focus (i.e., abnormal area of the brain) are determined. Any abnormal epileptogenic focus is then excised (AANN, 2016a). Resection surgery significantly reduces the incidence of seizures in patients with refractory epilepsy.

When seizures are refractory to medication in adolescents and adults with focal seizures, a vagal nerve stimulator (VNS) may be implanted under the clavicle. The device is connected to the vagus nerve in the cervical area, where it delivers electrical signals to the brain to control and reduce seizure activity. An external programming system is used by the physician to change stimulator settings (Wheless, 2013). Patients can activate the stimulator with a magnet at the time of a seizure or aura. Some patients report that use of the vagal nerve stimulator diminishes the severity or duration of the seizure. Complications such as infection, cardiac dysrhythmias, hoarseness, cough, and laryngeal spasm can occur with the use of this device (AANN, 2016a); (Wheless, 2013).

Another surgical option for patients with refractory seizure activity is the responsive neurostimulation system (RNS) (U.S. Food and Drug Administration, 2014). This is a surgically implanted device with electrodes that sense and record brain electrical activity. Electrodes deliver an electrical stimulation to the location of seizure origination within the brain. The

RNS works by interrupting brainwave activity before a clinical seizure can occur (AANN, 2016a).

More research is needed to determine the effects of the various surgical approaches on complication rates, quality of life, anxiety, and depression, all of which are issues for patients with epilepsy.

NURSING PROCESS

The Patient with Epilepsy

Assessment

The nurse elicits information about the patient's seizure history. The patient is asked about the factors or events that may precipitate the seizures. Alcohol intake is documented. The nurse determines whether the patient has an aura before an epileptic seizure, which may indicate the origin of the seizure (e.g., seeing a flashing light may indicate that the seizure originated in the occipital lobe). Observation and assessment during and after a seizure assist in identifying the type of seizure and its management.

The effects of epilepsy on the patient's lifestyle are assessed (AANN, 2016a). What limitations are imposed by the seizure disorder? Does the patient participate in any recreational activities? Have any social contacts? Is the patient working, and is it a positive or stressful experience? What coping mechanisms are used?

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for injury related to seizure activity
- Fear related to the possibility of seizures
- Ineffective individual coping related to stresses imposed by epilepsy
- Deficient knowledge related to epilepsy and anticonvulsant medications

Collaborative Problems/Potential Complications

The major potential complications for patients with epilepsy are status epilepticus and medication side effects (toxicity).

Planning and Goals

The major goals for the patient may include prevention of injury, control of seizures, achievement of a satisfactory psychosocial adjustment, acquisition of knowledge and understanding about the condition, and absence of complications.

Nursing Interventions

Preventing Injury

Injury prevention for the patient with seizures is a priority. Patients for whom seizure precautions are instituted should have pads applied to the side rails while in bed. Steps to prevent or minimize injury are presented in Chart 49-4.

Reducing Fear of Seizures

Fear that a seizure may occur unexpectedly can be reduced by the patient's adherence to the prescribed treatment regimen. Cooperation of the patient and family and their trust in the prescribed regimen are essential for control of seizures. The nurse emphasizes that the prescribed anticonvulsant medication must be taken on a continuing basis and that drug dependence or addiction does not occur. Periodic monitoring is necessary to ensure the adequacy of the treatment regimen, to prevent side effects, and to monitor for drug resistance (Hickey, 2014).

In an effort to control seizures, factors that may precipitate them are identified, such as emotional disturbances, new environmental stressors, onset of menstruation in female patients, or fever (AANN, 2016a). The patient is encouraged to follow a regular and moderate routine in lifestyle, diet (avoiding excessive stimulants), exercise, and rest (sleep deprivation may lower the seizure threshold). Moderate activity is therapeutic, but excessive exercise should be avoided. An additional dietary intervention, referred to as the ketogenic diet, may be helpful for control of seizures in some patients. This high-protein, low-carbohydrate, high-fat diet is most effective in children whose seizures have not been controlled with two anticonvulsant medications, but it is sometimes used for adults who have had poor seizure control (Nei, Ngo, Sirven, et al., 2014).

Photic stimulation (e.g., bright flickering lights, television viewing) may precipitate seizures; wearing dark glasses or covering one eye may be preventive. Tension states (anxiety, frustration) induce seizures in some patients. Classes in stress management may be of value. Because seizures are known to occur with alcohol intake, alcoholic beverages should be avoided.

Improving Coping Mechanisms

The social, psychological, and behavioral problems that frequently accompany epilepsy can be more of a disability than the actual seizures. Epilepsy may be accompanied by feelings of stigmatization, alienation, depression, and uncertainty (IOM, 2012). The patient must cope with the constant fear of a seizure and the psychological consequences (AANN, 2016a). Children with epilepsy may be ostracized and excluded from school and peer activities. These problems are compounded during adolescence and add to the challenges of dating, not being able to drive, and feeling different from other people. Adults face these problems in addition to the burden of finding employment, concerns about relationships and childbearing, insurance problems, and legal barriers. Alcohol abuse may complicate matters. Family reactions may vary from outright rejection of the person with epilepsy to overprotection.

Counseling assists the patient and family to understand the condition and the limitations it imposes. Social and recreational opportunities are necessary for good mental health. Nurses can improve the quality of life for patients with epilepsy by educating them and their families about symptoms and their management (AANN, 2016a).

Providing Patient and Family Education

Perhaps the most valuable facets of care contributed by the nurse to the person with epilepsy are education and efforts to modify the attitudes of the patient and family toward the disorder. The person who experiences seizures may consider every seizure a potential source of humiliation and shame. This may result in anxiety, depression, hostility, and secrecy on the part of the patient and family. Ongoing education and encouragement should be given to patients to enable them to overcome these reactions. The patient with epilepsy should carry an emergency medical identification card or wear a medical information bracelet. The patient and family need to be educated about medications as well as care during a seizure.

Monitoring and Managing Potential Complications

Status epilepticus is the major potential complication and is described later in this chapter. Another complication is the toxicity of medications. The patient and family are instructed about side effects and are given specific guidelines to assess and report signs and symptoms that indicate medication overdose.

Anticonvulsant medications require careful monitoring for therapeutic levels. The patient should plan to have serum drug levels assessed at regular intervals. Many known drug interactions occur with anticonvulsant medications. A complete pharmacologic profile should be reviewed with the patient to avoid interactions that either potentiate or inhibit the effectiveness of the medications.

Nursing Alert: Patients with epilepsy are at risk for status epilepticus from having their medication regimen interrupted.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Thorough oral hygiene after each meal, gum massage, daily flossing, and regular dental care are essential to prevent or control gingival hyperplasia in patients receiving phenytoin. The patient is also educated to inform all health care providers of the medication being taken, because of the possibility of drug interactions. An individualized comprehensive education plan is needed to assist the patient and family to adjust to this chronic disorder. Written patient education materials must be appropriate for the patient's reading level and must be provided in alternative formats if warranted.

Continuing and Transitional Care. Because epilepsy can be lifelong, health promotion is important. See Chart 49-6 for health promotion strategies for the patient with epilepsy.

Patients who have uncontrollable seizures accompanied by psychological and social difficulties should be referred as early as possible to a comprehensive epilepsy center where continuous audio-video and EEG monitoring, specialized treatment, and rehabilitation services are available (AANN, 2016a). Patients and their families need to be reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Genetic and preconception counseling is advised.

Chart 49-6 HEALTH PROMOTION

Strategies for the Patient with Epilepsy

- Take anticonvulsant medications daily as prescribed to keep the drug level constant to prevent seizures. Never discontinue medications, even if there is no seizure activity.
- Keep a medication and seizure record (in electronic or paper format), noting when medications are taken and any seizure activity.
- Notify the primary provider if unable to take medications due to illness.
- Have anticonvulsant medication serum levels checked regularly. When testing is prescribed, report to the laboratory for blood sampling before taking morning medication.
- Avoid activities that require alertness and coordination (driving, operating machinery) until after the effects of the medication have been evaluated.
- Report signs of toxicity so that dosage can be adjusted. Common signs include drowsiness, lethargy, dizziness, difficulty walking, hyperactivity, confusion, inappropriate sleep, and visual disturbances.
- Avoid over-the-counter medications unless approved by the primary provider.
- Carry a medical alert bracelet or identification card specifying the name of the anticonvulsant medication and primary provider.
- Avoid seizure triggers, such as alcoholic beverages, electrical shocks, stress, caffeine, constipation, fever, hyperventilation, and hypoglycemia.
- Take showers rather than tub baths to avoid drowning if seizure occurs; never swim alone.
- Exercise in moderation in a temperature-controlled environment to avoid excessive heat.
- Develop regular sleep patterns to minimize fatigue and insomnia.

Evaluation

Expected patient outcomes may include:

1. Sustains no injury during seizure activity
   a. Adheres to treatment regimen and identifies the hazards of stopping the medication
   b. Can identify appropriate care during seizure; caregivers can do so as well
2. Indicates a decrease in fear
3. Displays effective individual coping
4. Exhibits knowledge and understanding of epilepsy
   a. Identifies the side effects of medications
   b. Avoids factors or situations that may precipitate seizures (e.g., flickering lights, hyperventilation, alcohol)
   c. Follows a healthy lifestyle by getting adequate sleep and eating meals at regular times to avoid hypoglycemia
5. Absence of complications

Status Epilepticus

Status epilepticus (acute prolonged seizure activity) is a series of generalized seizures that occur without full recovery of consciousness between attacks (Trinka, Cock, Hesdorffer, et al., 2015). The term has been broadened to include continuous clinical or electrical seizures (on EEG) lasting at least 30 minutes, even without impairment of consciousness. It is considered a medical emergency. Status epilepticus produces cumulative effects. Vigorous muscular contractions impose a heavy metabolic demand and can interfere with respirations. Some respiratory arrest at the height of each seizure produces venous congestion and hypoxia of the brain. Repeated episodes of cerebral anoxia and edema may lead to irreversible and fatal brain damage. Factors that precipitate status epilepticus include interruption of anticonvulsant medication, fever, concurrent infection, or other illness.

Medical Management

The goals of treatment are to stop the seizures as quickly as possible, to ensure adequate cerebral oxygenation, and to maintain the patient in a seizure-free state. An airway and adequate oxygenation are established. If the patient remains unconscious and unresponsive, an endotracheal tube is inserted. IV diazepam (Valium), lorazepam (Ativan), or fosphenytoin is given slowly in an attempt to halt seizures immediately. Other medications (phenytoin, phenobarbital) are given later to maintain a seizure-free state.

An IV line is established, and blood samples are obtained to monitor serum electrolytes, glucose, and phenytoin levels. EEG monitoring may be useful in determining the nature of the seizure activity. Vital signs and neurologic signs are monitored on a continuing basis. An IV infusion of dextrose is given if the seizure is caused by hypoglycemia. If initial treatment is unsuccessful, general anesthesia with a short-acting barbiturate

may be used. The serum concentration of the anticonvulsant medication is measured, because a low level suggests that the patient was not taking the medication or that the dosage was too low. Cardiac involvement or respiratory depression may be life threatening. The potential for postictal cerebral edema also exists.

Nursing Management

The nurse initiates ongoing assessment and monitoring of respiratory and cardiac function because of the risk for delayed depression of respiration and blood pressure secondary to administration of anticonvulsant medications and sedatives to halt the seizures. Nursing assessment also includes monitoring and documenting the seizure activity and the patient's responsiveness.

The patient is turned to a side-lying position, if possible, to assist in draining pharyngeal secretions. Suction equipment must be available because of the risk of aspiration. The IV line is closely monitored, because it may become dislodged during seizures.

A person who has received long-term anticonvulsant therapy has a significant risk for fractures resulting from bone disease (osteoporosis, osteomalacia, and hyperparathyroidism), which is a side effect of therapy (Karch, 2015). Therefore, during seizures, the patient is protected from injury with the use of seizure precautions and is monitored closely. The patient having seizures can inadvertently injure nearby people, so nurses should protect themselves. Additional nursing interventions for the person having seizures are presented in Chart 49-4.

HEADACHE

Headache, or cephalalgia, is one of the most common of all human physical complaints. Headache is a symptom rather than a disease entity; it may indicate organic disease (neurologic or other disease), a stress response, vasodilation (migraine), skeletal muscle tension (tension headache), or a combination of factors. A primary headache is one for which no organic cause can be identified. This type of headache includes migraine, tension-type, and cluster headaches (Hickey, 2014). Cranial arteritis is another common cause of headache. A classification of headaches was issued first by the Headache Classification Committee of the International Headache Society in 1988. The International Headache Society revised the headache classification in (2013); an abbreviated list is shown in Chart 49-7.

Migraine is a complex of symptoms characterized by periodic and recurrent attacks of severe headache lasting from hours to days in adults. The cause of migraine has not been clearly demonstrated, but it is primarily a vascular disturbance that has a strong familial tendency. The typical time of onset is at puberty, and the incidence is higher in women than men (D'Arcy, 2014).

There are many subtypes of migraine headache, including migraine with and without aura. Most patients have migraine without an aura. *Tension-type headaches* tend to be chronic and less severe and are probably the most common type of headache. *Trigeminal autonomic cephalalgias* include cluster headaches and paroxysmal hemicrania. Cluster headaches are relatively uncommon and seen more frequently in men than in women (Grossman & Porth, 2014). Types of headaches not subsumed under these categories fall into the *other primary headache* group and include headaches triggered by cough, exertion, and sexual activity.

Chart 49-7

International Headache Society Classification of Headache

1. Migraine
2. Tension-type headache
3. Trigeminal autonomic cephalalgias
4. Other primary disorders
5. Headache attributed to trauma or injury to the head and/or neck
6. Headache attributed to cranial or cervical vascular disorder
7. Headache attributed to nonvascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache attributed to psychiatric disorder
13. Painful cranial neuropathies and other facial pains
14. Other headache disorders

Adapted from Headache Classification Subcommittee of the International Headache Society. (2013). The International Classification of Headache Disorders, 3rd edition (beta version). Cephalalgia, 33(9), 629–808.

Cranial arteritis is a cause of headache in the older population, reaching its greatest incidence in those older than 70 years of age. Inflammation of the cranial arteries is characterized by a severe headache localized in the region of the temporal arteries. The inflammation may be generalized (in which case cranial arteritis is part of a vascular disease) or focal (in which case only the cranial arteries are involved).

A secondary headache is a symptom associated with other causes, such as a brain tumor, an aneurysm, or lumbar puncture (Destrebecq, Terzoni, & Sala, 2014). Although most headaches do not indicate serious disease, persistent headaches require further investigation. Serious disorders related to headache include brain tumors, subarachnoid hemorrhage, stroke, severe hypertension, meningitis, and head injuries.

Pathophysiology

The cerebral signs and symptoms of migraine result from a hyperexcitable brain that is susceptible to a phenomenon known as cortical spreading depression, a wave of depolarization over the cerebral cortex, cerebellum, and hippocampus. This depolarization activates inflammatory neuropeptides and other neurotransmitters (including serotonin), resulting in the stimulation of meningeal nociceptors. Vascular changes, inflammation, and a continuation of pain signal stimulation occur (Charles, 2015). The initial phase of this process is known as the premonitory phase and may include light, sound, and smell sensitivity. If treatment is initiated at this point, the migraine may be fully terminated. As the attack progresses, central sensitization occurs, and the migraine becomes much harder to treat.

Attacks can be triggered by hormonal changes associated with menstrual cycles, bright lights, stress, depression, sleep deprivation, fatigue, or odors. Certain foods containing tyramine (especially aged cheese), monosodium glutamate, and chocolate may be food triggers (Grossman & Porth, 2014). The use of oral contraceptives may be associated with increased frequency and severity of attacks in some women.

Emotional or physical stress may cause contraction of the muscles in the neck and scalp, resulting in tension headache.

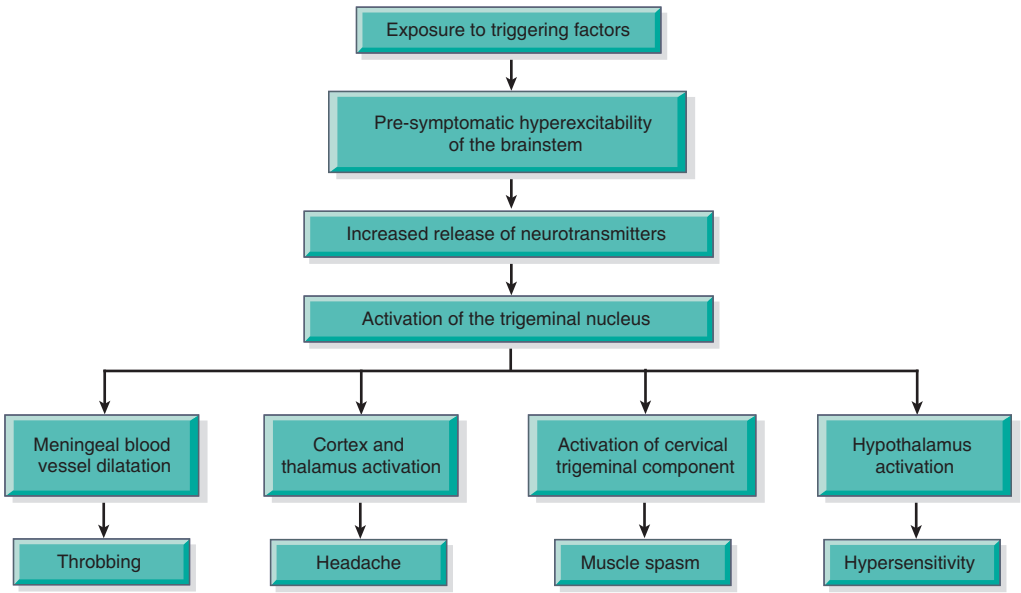

Figure 49-13 • Pathophysiology of headache.

The pathophysiology of cluster headache is not fully understood. One theory is that it is caused by dilation of orbital and nearby extracranial arteries. Cranial arteritis is thought to represent an immune vasculitis in which immune complexes are deposited within the walls of affected blood vessels, producing vascular injury and inflammation. A biopsy may be performed on the involved artery to make the diagnosis. A flowchart for pathophysiology of headache is presented in Figure 49-13.

Clinical Manifestations

Migraine

The migraine with aura can be divided into four phases: premonitory, aura, the headache, and recovery (headache termination and postdrome).

Premonitory Phase

The premonitory phase is experienced by more than 80% of adult migraine sufferers, with symptoms that occur hours to days before a migraine headache (Charles, 2013). Symptoms may include depression, irritability, feeling cold, food cravings, anorexia, change in activity level, increased urination, diarrhea, or constipation. Patients may experience the same prodrome with each migraine headache. A current theory regarding premonitory symptoms is that they involve the neurotransmitter dopamine.

Aura Phase

An aura may be a variable feature for patients who experience migraines (Charles & Hansen, 2015). An aura is characterized by focal neurologic symptoms. Visual disturbances (i.e., light flashes and bright spots) are most common and may be hemianopic (affecting only half of the visual field). Other symptoms that may follow include numbness and tingling of the lips, face, or hands; mild confusion; slight weakness of an extremity; drowsiness; and dizziness.

This period of aura was thought to correspond to the phenomenon of cortical spreading depression that is associated with reduced metabolic demand in abnormally functioning neurons. This can be associated with decreased blood flow; however, cerebral blood flow studies performed during migraine headaches demonstrate that although changes in blood vessels occur during phases of migraine, cerebral blood flow is not the main abnormality. In fact, some studies suggest that the aura and headache phases may occur simultaneously (Charles, 2013).

Headache Phase

Migraine headache is severe and incapacitating and is often associated with photophobia (light sensitivity), phonophobia (sound sensitivity), or allodynia (abnormal perception of innocuous stimuli) (Charles, 2013). Research differs in the role of vascular changes (either vasodilatory or vasoconstrictive) with respect to migraine pathophysiology and the experience of migraine headache. Symptoms of migraine can also include nausea and vomiting.

Postdrome Phase

In the postdrome phase, the pain gradually subsides, but patients may experience tiredness, weakness, cognitive difficulties, and mood changes for hours to days. Muscle contraction in the neck and scalp is common, with associated muscle ache and localized tenderness. Physical exertion may exacerbate the headache pain. During this postheadache phase, patients may sleep for extended periods.

Other Headache Types

The tension-type headache is characterized by a steady, constant feeling of pressure that usually begins in the forehead, temple, or back of the neck. It is often bandlike or may be described as "a weight on top of my head."

Cluster headaches are unilateral and come in clusters of one to eight daily, with excruciating pain localized to the eye and orbit and radiating to the facial and temporal regions. The pain is accompanied by watering of the eye and nasal congestion. Each attack lasts 15 minutes to 3 hours and may have a crescendo–decrescendo pattern (Hickey, 2014). The headache is often described as penetrating.

Cranial arteritis often begins with general manifestations, such as fatigue, malaise, weight loss, and fever. Clinical

manifestations associated with inflammation (heat, redness, swelling, tenderness, or pain over the involved artery) usually are present. Sometimes a tender, swollen, or nodular temporal artery is visible. Visual problems are caused by ischemia of the involved structures.

Assessment and Diagnostic Findings

The diagnostic evaluation includes a detailed history, a physical assessment of the head and neck, and a complete neurologic examination. Headaches may manifest differently in the same person over the course of a lifetime, and the same type of headache may manifest differently from patient to patient. The health history focuses on assessing the headache itself, with emphasis on the factors that precipitate or provoke it. The patient is asked to describe the headache in their own words.

Because headache is often the presenting symptom of a wider variety of physiologic and psychological disturbances, a general health history is an essential component of the patient database. Therefore, questions addressed in the health history should cover major medical and surgical illness as well as a body systems review.

The medication history can provide insight into the patient's overall health status and indicate medications that may be provoking headaches. Antihypertensive agents, diuretic medications, anti-inflammatory agents, and monoamine oxidase (MAO) inhibitors are a few of the categories of medications that can provoke headaches. Daily use of over-the-counter or prescribed pain medications for 8 to 10 days out of a month can lead to a chronic headache due to medication overuse (Becker, Findlay, Moga, et al., 2015). Emotional factors can play a role in precipitating headaches. Stress is thought to be a major initiating factor in migraine headaches; therefore, sleep patterns, level of stress, recreational interests, appetite, emotional problems, and family stressors are relevant. There is a strong familial tendency for headache disorders, and a positive family history may help in making a diagnosis.

A direct relationship may exist between exposure to toxic substances and headache. Careful questioning may uncover chemicals to which a worker has been exposed. Under the Right-to-Know Law, employees have access to the material safety data sheets (commonly referred to as MSDS) for all substances with which they come in contact in the workplace (see Chapter 64). The occupational history also includes assessment of the workplace as a possible source of stress and for a possible ergonomic basis of muscle strain and headache.

A complete description of the headache itself is crucial. The nurse reviews the age at onset of headaches; this particular headache's frequency, location, and duration; the type of pain; factors that relieve and precipitate the event; and associated symptoms. The data obtained should include the patient's own words about the headache in response to the following questions:

- What is the location? Is it unilateral or bilateral? Does it radiate?
- What is the quality—dull, aching, steady, boring, burning, intermittent, continuous, paroxysmal?
- How many headaches occur during a given period of time?
- What are the precipitating factors, if any—environmental (e.g., sunlight, weather change), foods, exertion, other?
- What makes the headache worse (e.g., coughing, straining)?
- What time (day or night) does it occur?
- How long does a typical headache last?
- Are there any associated symptoms, such as facial pain, lacrimation (excessive tearing), or scotomas (blind spots in the field of vision)?
- What usually relieves the headache (aspirin, nonsteroidal anti-inflammatory drugs, ergot preparation, food, heat, rest, neck massage)?
- Does nausea, vomiting, weakness, or numbness in the extremities accompany the headache?
- Does the headache interfere with daily activities?
- Do you have any allergies?
- Do you have insomnia, poor appetite, loss of energy?
- Is there a family history of headache?
- What is the relationship of the headache to your lifestyle or physical or emotional stress?
- What medications are you taking?

Diagnostic testing often is not helpful in the investigation of headache, because usually there are few objective findings. In patients who demonstrate abnormalities on the neurologic examination, CT scan, cerebral angiography, or MRI scan may be used to detect underlying causes, such as tumor or aneurysm. Electromyography (EMG) may reveal a sustained contraction of the neck, scalp, or facial muscles. Laboratory tests may include complete blood count, erythrocyte sedimentation rate, electrolytes, glucose, creatinine, and thyroid hormone levels.

Prevention

Prevention begins by having the patient avoid specific triggers that are known to initiate the headache syndrome. Preventive medical management of migraine involves the daily use of one or more agents that are thought to block the physiologic events leading to an attack. Treatment regimens vary greatly, as do patient responses; therefore, close monitoring is indicated.

Alcohol, nitrites, vasodilators, and histamines may precipitate cluster headaches. Elimination of these factors helps prevent the headaches.

Medical Management

Therapy for migraine headache is divided into abortive (symptomatic) and preventive approaches. The abortive approach, best used in those patients who have less frequent attacks, is aimed at relieving or limiting a headache at the onset or while it is in progress. The preventive approach is used in patients who experience more frequent attacks at regular or predictable intervals and may have a medical condition that precludes the use of abortive therapies (Becker et al., 2015). Medical management of migraine during pregnancy and lactation includes nonpharmacologic strategies in addition to safe medication practices (Wells, Turner, Lee, et al., 2016). Nonpharmacologic treatments include mainly avoidance of triggers (Grossman & Porth, 2014) (see Chart 49-8).

The triptans, which are serotonin receptor agonists, are the most specific antimigraine agents available. These agents cause vasoconstriction, reduce inflammation, and may reduce pain transmission. The five triptans in routine clinical use include sumatriptan (Imitrex), naratriptan (Amerge), rizatriptan (Maxalt), zolmitriptan (Zomig), and almotriptan (Axert) (D'Arcy, 2014). Numerous serotonin receptor agonists are under study. Many of the triptan medications are available in a variety of formulations, such as nasal sprays, inhalers, conventional tablet, disintegrating tablet, suppositories, or injections. The nasal sprays are useful

Chart 49-8 PATIENT EDUCATION

Migraine Headaches

The nurse instructs the patient to:

- Be aware of the definition of migraine headaches along with the characteristics and manifestations.
- Recognize triggers of migraine headaches and how to avoid such triggers as:
  - Foods that contain tyramine, such as chocolate, cheese, coffee, dairy products
  - Dietary habits that result in long periods between meals
  - Menstruation and ovulation (caused by hormone fluctuation)
  - Alcohol (causes vasodilation of blood vessels)
  - Fatigue and fluctuations in sleep patterns
- Develop and use a paper or electronic headache diary.
- Implement stress management and lifestyle changes to minimize the frequency of headaches.
- Ensure correct pharmacologic management: acute therapy and prophylaxis to include medication regimen and side effects.
- Use comfort measures during headache attacks, such as resting in a quiet and dark environment, applying cold compresses to the painful area, and elevating the head.

for patients experiencing nausea and vomiting (Dahlöf & Van Den Brink, 2012).

The triptans are considered first-line treatment of the management of moderate to severe migraine pain. Best results are achieved with early use of triptans; oral dosing takes effect within 20 to 60 minutes of taking the drug and if needed may be repeated in 2 to 4 hours. Triptans are contraindicated in patients with ischemic heart disease. Careful administration and dosing instructions to patients are important to prevent adverse reactions such as increased blood pressure, drowsiness, muscle pain, sweating, and anxiety. Interactions are possible if the medication is taken in conjunction with St. John wort (Karch, 2015).

Ergotamine preparations (taken orally, sublingually, subcutaneously, intramuscularly, by rectum, or by inhalation) may be effective in aborting the headache if taken early in the migraine process. They are low in cost. Ergotamine tartrate acts on smooth muscle, causing prolonged constriction of the cranial blood vessels. Each patient's dosage is based on individual needs. Side effects include aching muscles, paresthesias (numbness and tingling), nausea, and vomiting. Pretreatment with antiemetic agents may be required. None of the triptan medications should be taken concurrently with medications containing ergotamine because of the potential for a prolonged vasoactive reaction (Karch, 2015).

Many widely used medications for the prevention of migraine are available. An analysis of research in the last decade reported the most effective medications for migraine treatment include anticonvulsant agents (divalproex sodium [Depakote], valproate [Depacon], topiramate [Topamax]), beta-blockers (metoprolol [Lopressor], propranolol [Inderal], timolol [Blocadren]), and triptans (frovatriptan [Frova]). Other medications prescribed for migraine prevention include antidepressant agents (amitriptyline [Elavil], venlafaxine [Effexor]) and additional beta-blockers (atenolol [Tenormin], nadolol [Corgard]) and triptans (naratriptan [Amerge], zolmitriptan [Zomig]) (D'Arcy, 2014).

The medical management of an acute attack of cluster headaches may include 100% oxygen by facemask for 15 minutes, subcutaneous sumatriptan, or intranasal zolmitriptan (Becker et al., 2015).

The medical management of cranial arteritis consists of early administration of a corticosteroid to prevent the possibility of loss of vision due to vascular occlusion or rupture of the involved artery. The patient is instructed not to stop the medication abruptly, because this can lead to relapse. Analgesic agents are prescribed for comfort.

Nursing Management

When migraine or the other types of headaches have been diagnosed, the goal of nursing management is pain relief. It is reasonable to try nonpharmacologic interventions first, but the use of medications should not be delayed. The first priority is to treat the acute event of the headache and the second is to prevent recurrent episodes. Prevention involves patient education regarding precipitating factors, possible lifestyle or habit changes that may be helpful, and pharmacologic measures.

Relieving Pain

Individualized treatment depends on the type of headache and differs for migraine, cluster headaches, cranial arteritis, and tension headache. Nursing care is directed toward treatment of the acute episode. A migraine or a cluster headache in the early phase requires abortive medication therapy instituted as soon as possible. Some headaches can be prevented if the appropriate medications are taken before the onset of pain. Nursing care during an attack includes comfort measures such as a quiet, dark environment; elevation of the head of the bed to 30 degrees; and symptomatic treatment (i.e., administration of antiemetic medication) (Hickey, 2014).

Symptomatic pain relief for tension headache may be obtained by application of local heat or massage. Additional strategies may include administration of analgesic agents, antidepressant medications, and muscle relaxants.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care

Headaches, especially migraines, are more likely to occur when the patient is ill, overly tired, or stressed. Nonpharmacologic therapies are important and include patient education about the type of headache, its mechanism (if known), and appropriate changes in lifestyle to avoid triggers. Regular sleep, meals, exercise, relaxation, and avoidance of dietary triggers may be helpful in avoiding headaches (Becker et al., 2015).

The patient with tension headaches needs education and reassurance that the headache is not the result of a brain tumor or other intracranial disorder. Stress reduction techniques, such as biofeedback, exercise programs, and meditation, are examples of nonpharmacologic therapies that may prove helpful. The patient and family need to be educated about the importance of following the prescribed treatment regimen for headache and keeping follow-up appointments. In addition, the patient is reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Chart 49-8 presents educational topics for the patient with migraine headaches.

CRITICAL THINKING EXERCISES

1. A patient is admitted to your unit for a transsphenoidal cranial procedure. Identify the nursing interventions indicated before, during, and after the procedure. What patient and caregiver education is indicated in preparation for discharge? How will your nursing interventions and patient education change if a supratentorial surgical approach is used?

2. As a member of Hospital Quality Improvement Committee, you are working on updating interventions to manage increased intracranial pressure. Using your knowledge of evidence-based practice guidelines, list the most important interventions for nurses to implement. Compare and contrast the options supported by the guidelines.
3. Identify the priorities, approach, and techniques you would use to provide care to a 25-year-old female patient with migraine headaches. How will your priorities, approach, and techniques differ if the patient is male, if the patient has tension-type or cluster headaches?

CHAPTER 50

Management of Patients with Cerebrovascular Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the incidence and impact of cerebrovascular disorders.
2. Identify the risk factors for cerebrovascular disorders and related measures for prevention.
3. Compare the various types of cerebrovascular disorders: their causes, clinical manifestations, and medical management.
4. Explain the principles of nursing management as they relate to the care of a patient in the acute stage of an ischemic stroke.
5. Use the nursing process as a framework for care of a patient recovering from an ischemic stroke.
6. Apply the nursing process as a framework for care of a patient with a hemorrhagic stroke.
7. Discuss essential elements for family education and preparation for home care of the patient who has had a stroke.

GLOSSARY

agnosia: loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile
aneurysm: a weakening or bulge in an arterial wall
aphasia: inability to express oneself or to understand language
apraxia: inability to perform previously learned purposeful motor acts on a voluntary basis
dysarthria: defects of articulation due to neurologic causes
dysphagia: difficulty swallowing
expressive aphasia: inability to express oneself; often associated with damage to the left frontal lobe area
hemianopsia: blindness of half of the field of vision in one or both eyes
hemiparesis: weakness of one side of the body, or part of it, due to an injury in the motor area of the brain
hemiplegia: paralysis of one side of the body, or part of it, due to an injury in the motor area of the brain
infarction: tissue necrosis in an area deprived of blood supply
penumbra region: area of low cerebral blood flow
receptive aphasia: inability to understand what someone else is saying; often associated with damage to the temporal lobe area

Introduction

Cerebrovascular disorders is an umbrella term that refers to a functional abnormality of the central nervous system (CNS) that occurs when the blood supply to the brain is disrupted. Stroke is the primary cerebrovascular disorder in the United States, and while it dropped from the fourth to the fifth leading cause of death, it is still a leading cause of serious, long-term disability. Approximately 795,000 people experience a stroke each year in the United States. Approximately 610,000 of these are new strokes, and 185,000 are recurrent strokes (Mozaffarian, Benjamin, Go, et al., 2016). About 7 million people who have survived a stroke are alive today. The financial impact of stroke is profound, with estimated direct and indirect costs of $33 billion from 2011 to 2012 (Mozaffarian et al., 2016).

The incidence rate of stroke in Asia ranges between 116 and 483/100,000 per year and the prevalence of stroke among each country differs based on the age of studied population (Suwanwela & Poungvarin, 2016). In India, there is no exact data about the prevalence of stroke. The prevalence rate varies from 147 to 922/100,000 among different community-based studies (Bharucha, Bharucha, Bharucha, Bhise, & Schoenberg, 1988; Prasad, Vibha, & Meenakshi, 2012). The prevalence rate of stroke is higher in urban India (334–424/100,000) as compared to rural India (84–262/100,000). Furthermore, age-adjusted prevalence rate among women is higher (564/100,000) than men (196/100,000). Similarly, incidence rate of stroke in men is 36/100,000 and 204/100,000 in women (Pandian & Sudhan, 2013). Stroke contributed 41% of deaths and 72% of disability adjusted life years amongst the noncommunicable diseases in India (*Stroke. In: Assessment of the burden of non-communicable diseases: Final project report.*, 2004). Strokes can be divided into two major categories: ischemic (approximately 87%), in which vascular occlusion and significant hypoperfusion occur, and hemorrhagic (approximately 13%), in which there is extravasation of blood into the brain or subarachnoid space (Hickey, 2014). Although there are some similarities between the two types of stroke, differences exist in etiology, pathophysiology, medical management, surgical management, and nursing care. Table 50-1 compares ischemic and hemorrhagic strokes.

Ischemic Stroke

An ischemic stroke, formerly referred to as a cerebrovascular disease (stroke) or "brain attack," is a sudden loss of function resulting from disruption of the blood supply to a part of the brain. The term *brain attack* has been used to suggest to health care practitioners and the public that a stroke is an urgent health care issue similar to a heart attack. With the approval of thrombolytic therapy for the treatment of acute ischemic stroke in 1996 came a revolution in the care of patients after a stroke. Early treatment with thrombolytic therapy for ischemic stroke results in fewer stroke symptoms and less loss of function (National Institute of Neurological Disorders and Stroke [NINDS], 1995). The only U.S. Food and Drug Administration

TABLE 50-1 Comparison of Major Types of Stroke

Types of Stroke	Causes	Main Presenting Symptoms	Functional Recovery
Ischemic	• Large artery thrombosis • Small penetrating artery thrombosis • Cardiogenic embolic • Cryptogenic (no known cause) • Other	Numbness or weakness of the face, arm, or leg, especially on one side of the body	Usually plateaus at 6 months
Hemorrhagic	• Intracerebral hemorrhage • Subarachnoid hemorrhage • Cerebral aneurysm • Arteriovenous malformation	• "Exploding headache" • Decreased level of consciousness	Slower, usually plateaus at about 18 months

Adapted from Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

(FDA)-approved thrombolytic therapy has a treatment window of 3 hours after the onset of a stroke, and scientific statements have endorsed its expanded use for up to 4.5 hours (Del Zoppo, Saver, Jauch, et al., 2009); (Jauch, Saver, Adams, et al., 2013). Although the time frame for treatment has expanded in some centers, urgency is needed on the part of the public and health care practitioners for rapid transport of the patient to a hospital for assessment and administration of the medication.

Ischemic strokes are subdivided into five different types based on the cause: large artery thrombotic strokes (20%), small penetrating artery thrombotic strokes (25%), cardiogenic embolic strokes (20%), cryptogenic strokes (30%), and other (5%) (see Table 50-1). Large artery thrombotic strokes are caused by atherosclerotic plaques in the large blood vessels of the brain. Thrombus formation and occlusion at the site of the atherosclerosis result in ischemia and infarction (tissue necrosis in an area deprived of blood supply) (Hickey, 2014).

Small penetrating artery thrombotic strokes affect one or more vessels and are a common type of ischemic stroke. Small artery thrombotic strokes are also called *lacunar strokes* because of the cavity that is created after the death of infarcted brain tissue (Hickey, 2014).

Cardiogenic embolic strokes are associated with cardiac dysrhythmias, usually atrial fibrillation. Embolic strokes can also be associated with valvular heart disease and thrombi in the left ventricle. Emboli originate from the heart and circulate to the cerebral vasculature, most commonly the left middle cerebral artery, resulting in a stroke. Embolic strokes may be prevented by the use of anticoagulation therapy in patients with atrial fibrillation.

The last two classifications of ischemic strokes are cryptogenic strokes, which have no known cause, and strokes from other causes, such as illicit drug use (cocaine), coagulopathies, migraine/vasospasm, and spontaneous dissection of the carotid or vertebral arteries.

Pathophysiology

In an ischemic brain attack, there is disruption of the cerebral blood flow due to obstruction of a blood vessel. This disruption in blood flow initiates a complex series of cellular metabolic events referred to as the ischemic cascade (see Fig. 50-1).

The ischemic cascade begins when cerebral blood flow decreases to less than 25 mL per 100 g of blood per minute. At this point, neurons are no longer able to maintain aerobic respiration. The mitochondria must then switch to anaerobic respiration, which generates large amounts of lactic acid, causing a change in the pH. This switch to the less efficient anaerobic respiration also renders the neuron incapable of producing sufficient quantities of adenosine triphosphate (ATP) to fuel the depolarization processes. The membrane pumps that maintain electrolyte balances begin to fail, and the cells cease to function.

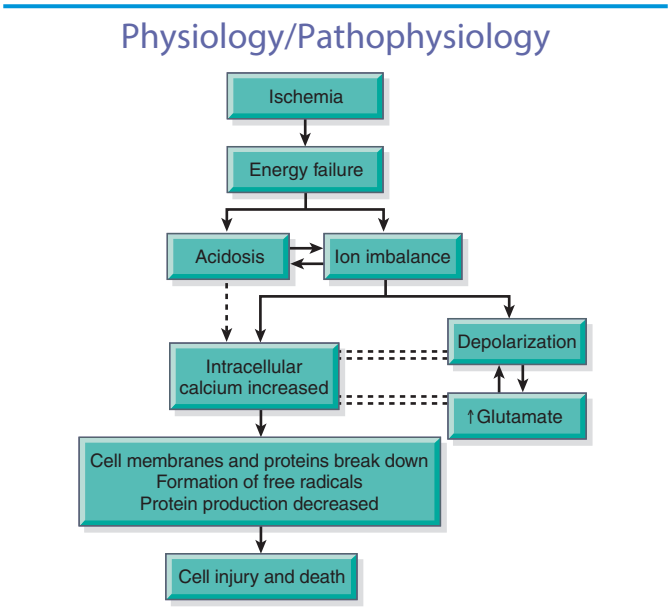

Figure 50-1 • Some of the processes contributing to ischemic brain cell injury.

Early in the cascade, an area of low cerebral blood flow, referred to as the penumbra region, exists around the area of infarction. The penumbra region is ischemic brain tissue that may be salvaged with timely intervention. The ischemic cascade threatens cells in the penumbra because membrane depolarization of the cell wall leads to an increase in intracellular calcium and the release of glutamate. The influx of calcium and the release of glutamate, if continued, activate a number of damaging pathways that result in the destruction of the cell membrane, the release of more calcium and glutamate, vasoconstriction, and the generation of free radicals. These processes enlarge the area of infarction into the penumbra, extending the stroke. A person experiencing a stroke typically loses 1.9 million neurons each minute that a stroke is not treated, and the ischemic brain ages 3.6 years each hour without treatment (Saver, 2006).

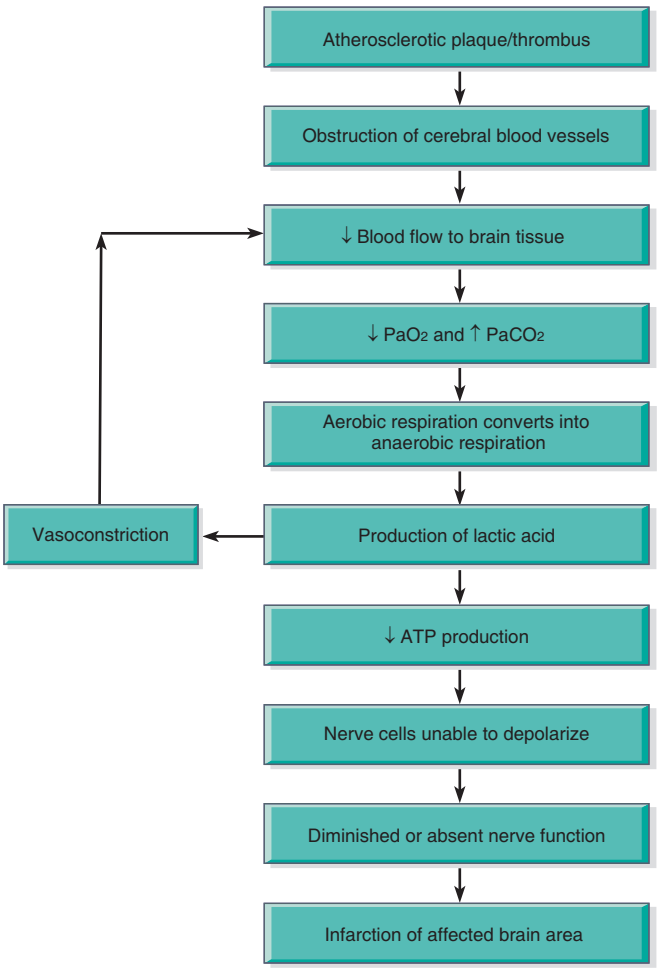

Figure 50-2 • Pathophysiology of ischemic stroke.

Each step in the ischemic cascade represents an opportunity for intervention to limit the extent of secondary brain damage caused by a stroke. The penumbra area may be revitalized by administration of tissue plasminogen activator (t-PA). Medications that protect the brain from secondary injury are called *neuroprotectants*. A number of ongoing clinical trials focus on neuroprotective medications and strategies to improve stroke recovery and survival (Jauch et al., 2013).

A flowchart for pathophysiology is presented in Figure 50.2.

Clinical Manifestations

An ischemic stroke can cause a wide variety of neurologic deficits, depending on the location of the lesion (which blood vessels are obstructed), the size of the area of inadequate perfusion, and the amount of collateral (secondary or accessory) blood flow. See Chapter 48 for discussion of anatomy and brain blood supply. The patient may present with any of the following signs or symptoms:

- Numbness or weakness of the face, arm, or leg, especially on one side of the body
- Confusion or change in mental status
- Trouble speaking or understanding speech
- Visual disturbances
- Difficulty walking, dizziness, or loss of balance or coordination
- Sudden severe headache

Motor, sensory, cranial nerve, cognitive, and other functions may be disrupted. Table 50-2 reviews the neurologic deficits frequently seen in patients with strokes. Table 50-3 compares the symptoms and behaviors seen in right hemispheric stroke with those seen in left hemispheric stroke.

Motor Loss

A stroke is an upper motor neuron lesion and results in loss of voluntary control over motor movements. Because the upper motor neurons decussate (cross), a disturbance of voluntary motor control on one side of the body may reflect damage to the upper motor neurons on the opposite side of the brain. The most common motor dysfunction is hemiplegia (paralysis of one side of the body, or part of it) caused by a lesion of the opposite side of the brain. Hemiparesis, or weakness of one side of the body, or part of it, is another sign. The concept of upper and lower motor neuron lesions is described in more detail in Chapter 48, Table 48-4.

In the early stage of stroke, the initial clinical features may be flaccid paralysis and loss of or decrease in the deep tendon reflexes. When these deep reflexes reappear (usually by 48 hours), increased tone is observed along with spasticity (abnormal increase in muscle tone) of the extremities on the affected side.

Communication Loss

Other brain functions affected by stroke are language and communication. In fact, stroke is the most common cause of aphasia (inability to express oneself or to understand language). The following are dysfunctions of language and communication:

- **Dysarthria** (difficulty in speaking) or dysphasia (impaired speech), caused by paralysis of the muscles responsible for producing speech
- **Aphasia**, which can be expressive aphasia (inability to express oneself), receptive aphasia (inability to understand language), or global (mixed) aphasia (see Chapter 48, Table 48-5)
- **Apraxia** (inability to perform a previously learned action), as may be seen when a patient makes verbal substitutions for desired syllables or words

Perceptual Disturbances

Perception is the ability to interpret sensation. Stroke can result in visual–perceptual dysfunctions, disturbances in visual–spatial relations, and sensory loss.

Visual–perceptual dysfunctions are caused by disturbances of the primary sensory pathways between the eye and visual cortex. Homonymous hemianopsia (blindness in half of the visual field in one or both eyes) may occur from stroke and may be temporary or permanent. The affected side of vision corresponds to the paralyzed side of the body.

Disturbances in visual–spatial relations (perceiving the relationship of two or more objects in spatial areas) are frequently seen in patients with right hemispheric damage.

Sensory Loss

Sensory losses from stroke may be mild, such as a slight impairment of touch, or more severe, with loss of proprioception (ability to perceive the position and motion of body parts) as well as difficulty in interpreting visual, tactile, and auditory stimuli. An agnosia is the loss of the ability to recognize objects through a particular sensory system; it may be visual, auditory, or tactile (see Chapter 48, Table 48-6).

TABLE 50-2 Neurologic Deficits of Stroke: Manifestations and Nursing Implications

Neurologic Deficit	Manifestation	Nursing Implications/Patient Education Applications
Visual Field Deficits		
Homonymous hemianopsia (loss of half of the visual field)	• Unaware of persons or objects on side of visual loss • Neglect of one side of the body • Difficulty judging distances	Place objects within intact field of vision. Approach the patient from side of intact field of vision. Instruct/remind the patient to turn head in the direction of visual loss to compensate for loss of visual field. Encourage the use of eyeglasses if available. When educating the patient, do so within patient's intact visual field.
Loss of peripheral vision	• Difficulty seeing at night • Unaware of objects or the borders of objects	Place objects in center of patient's intact visual field. Encourage the use of a cane or other object to identify objects in the periphery of the visual field. Ensure that the patient's driving ability is evaluated.
Diplopia	• Double vision	Explain to the patient the location of an object when placing it near the patient. Consistently place patient care items in the same location.
Motor Deficits		
Hemiparesis	• Weakness of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)	Place objects within the patient's reach on the nonaffected side. Instruct the patient to exercise and increase the strength on the unaffected side.
Hemiplegia	• Paralysis of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)	Encourage the patient to provide range-of-motion exercises to the affected side. Provide immobilization as needed to the affected side. Maintain body alignment in functional position. Exercise unaffected limb to increase mobility, strength, and use.
Ataxia	• Staggering, unsteady gait • Unable to keep feet together; needs a broad base to stand	Support patient during the initial ambulation phase. Provide supportive device for ambulation (walker, cane). Instruct the patient not to walk without assistance or supportive device.
Dysarthria	• Difficulty in forming words	Provide the patient with alternative methods of communicating. Allow the patient sufficient time to respond to verbal communication Support patient and family to alleviate frustration related to difficulty in communicating.
Dysphagia	• Difficulty in swallowing	Test the patient's pharyngeal reflexes before offering food or fluids. Assist the patient with meals. Place food on the unaffected side of the mouth. Allow ample time to eat.
Sensory Deficits		
Paresthesia (occurs on the side opposite the lesion)	• Sensation of numbness, tingling, or a "pins and needles" sensation • Difficulty with proprioception	Instruct patient that sensation may be altered. Provide range of motion to affected areas and apply corrective devices as needed.
Verbal Deficits		
Expressive aphasia	• Unable to form words that are understandable; may be able to speak in single-word responses	Encourage patient to repeat sounds of the alphabet. Explore the patient's ability to write as an alternative means of communication.
Receptive aphasia	• Unable to comprehend the spoken word; can speak but may not make sense	Speak clearly and in an unhurried manner to assist the patient in forming the sounds. Explore the patient's ability to read as an alternative means of communication.
Global (mixed) aphasia	• Combination of both receptive and expressive aphasia	Speak clearly and in simple sentences; use gestures or pictures when able Establish alternative means of communication.
Cognitive Deficits	• Short- and long-term memory loss • Decreased attention span • Impaired ability to concentrate • Poor abstract reasoning • Altered judgment	Reorient patient to time, place, and situation frequently. Use verbal and auditory cues to orient patient. Provide familiar objects (family photographs, favorite objects). Use noncomplicated language. Match visual tasks with a verbal cue; holding a toothbrush, simulate brushing of teeth while saying, "I would like you to brush your teeth now." Minimize distracting noises and views when providing education to the patient. Repeat and reinforce instructions frequently.

(Continued)

(Continued)

Emotional Deficits	• Loss of self-control • Emotional lability • Decreased tolerance to stressful situations • Depression • Withdrawal • Fear, hostility, and anger • Feelings of isolation	Support patient during uncontrollable outbursts. Discuss with the patient and family that the outbursts are due to the disease process. Encourage patient to participate in group activity. Provide stimulation for the patient. Control stressful situations, if possible. Provide a safe environment. Encourage patient to express feelings and frustrations related to disease process.

TABLE 50-3 Comparison of Left and Right Hemispheric Strokes

Left Hemispheric Stroke	Right Hemispheric Stroke
Paralysis or weakness on right side of body	Paralysis or weakness on left side of body
Right visual field deficit	Left visual field deficit
Aphasia (expressive, receptive, or global)	Spatial–perceptual deficits
Altered intellectual ability	Increased distractibility
Slow, cautious behavior	Impulsive behavior and poor judgment Lack of awareness of deficits

Adapted from Hickey, J. V. (2014). The clinical practice of neurological & neurosurgical nursing (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Cognitive Impairment and Psychological Effects

If damage has occurred to the frontal lobe, learning capacity, memory, or other higher cortical intellectual functions may be impaired. Such dysfunction may be reflected in a limited attention span, difficulties in comprehension, forgetfulness, and a lack of motivation. These changes can cause the patient to become easily frustrated during rehabilitation. Depression is common and may be exaggerated by the patient's natural response to this catastrophic event. Emotional lability, hostility, frustration, resentment, lack of cooperation, and other psychological problems may occur.

Assessment and Diagnostic Findings

Any patient with neurologic deficits needs a careful history eliciting the last time the patient was seen well (Zanichkowsky, Nascimento, McCune, et al., 2016) and a rapid focused physical and neurologic examination. Initial assessment focuses on airway patency, which may be compromised by loss of gag or cough reflexes and altered respiratory pattern; cardiovascular status (including blood pressure, cardiac rhythm and rate, carotid bruit); and gross neurologic deficits.

Patients may present to the acute care facility with temporary neurologic symptoms. A transient ischemic attack (TIA) is a neurologic deficit typically lasting 1 to 2 hours. A TIA is manifested by a sudden loss of motor, sensory, or visual function. The symptoms result from temporary ischemia (impairment of blood flow) to a specific region of the brain; however, when brain imaging is performed, there is no evidence of ischemia. A TIA may serve as a warning of impending stroke. Approximately 15% of all strokes are preceded by a TIA (Miller & Summers, 2014); (Mozaffarian et al., 2016). Lack of evaluation and treatment of a patient who has experienced previous TIAs may result in a stroke and irreversible deficits.

The initial diagnostic test for a stroke is usually a noncontrast computed tomography (CT) scan (Anderson, 2016). This should be performed within 25 minutes or less from the time the patient presents to the emergency department (ED) to determine if the event is ischemic or hemorrhagic as the type of stroke determines treatment (Anderson, 2016). Further diagnostic workup for ischemic stroke involves attempting to identify the source of the thrombi or emboli. A 12-lead electrocardiogram (ECG) and a carotid ultrasound are standard tests. Other studies may include CT angiography or CT perfusion; magnetic resonance imaging (MRI) and magnetic resonance angiography of the brain and neck vessels; transcranial Doppler flow studies; transthoracic or transesophageal echocardiography; xenon-enhanced CT scan; and single-photon emission CT scan (Summers, Leonard, Wentworth, et al., 2009); (Jauch et al., 2013); (Miller & Summers, 2014).

Prevention

Primary prevention of ischemic stroke remains the best approach. A healthy lifestyle including not smoking, engaging in physical activity (at least 40 minutes a day, 3 to 4 days a week), maintaining a healthy weight, and following a healthy diet (including modest alcohol consumption), can reduce the risk of having a stroke (Mozaffarian et al., 2016). Specific diets that have decreased risk of stroke include the Dietary Approaches to Stop Hypertension (DASH) diet (high in fruits and vegetables, moderate in low-fat dairy products, and low in animal protein), the Mediterranean diet (supplemented with nuts), and overall diets that are rich in fruits and vegetables. Research findings suggest that low-dose aspirin may lower the risk of a first stroke for those who are at risk (Meschia, Bushnell, Boden-Albala, et al., 2014).

Stroke risk screenings are an ideal opportunity to lower stroke risk by identifying people or groups of people who are at high risk for stroke and by educating patients and the community about recognition and prevention of stroke. Stroke screenings are usually coordinated and run by nurses. Age, gender, and race are well-known nonmodifiable risk factors for stroke. High-risk groups include people older than 55 years, and the incidence of stroke more than doubles in each successive decade. Men have a higher age-adjusted rate of stroke than that of women. However, the magnitude of strokes in women should not be underplayed; 1 in 6 women die of stroke as compared to 1 in 25 who die of breast cancer (Ennen, 2013), and each year 55,000 more women than men have a stroke (Mozaffarian et al., 2016). Compared to Caucasian Americans, African Americans and some Hispanic/Latino Americans have a higher incidence of stroke and higher mortality (Meschia et al., 2014); (Aycock & Clark, 2016). The Nursing Research Profile in Chart 50-1 examines the accuracy of perceived stroke risk in African Americans (Aycock & Clark, 2016).

There are many risk factors for ischemic stroke (see Chart 50-2). For people who are at high risk, interventions that alter modifiable factors, such as treating hypertension and stopping smoking, reduce stroke risk.

Chart 50-1 NURSING RESEARCH PROFILE

Awareness of Stroke Risk in Young African Americans

Aycock, D. M., & Clark, P. C. (2016). Incongruence between perceived long-term risk and actual risk of stroke in rural African Americans. Journal of Neuroscience Nursing, 48(1), 35–41.

Purpose

African Americans aged 20 to 44 years are twice as likely to have a stroke as Caucasians of the same age. African Americans aged 35 to 64 years also have a higher risk (three to four times) of dying from a stroke than Caucasians. When a stroke occurs in a younger adult, they live longer with disabilities with greater health care costs and loss of productivity. Because up to 80% of strokes can be prevented with recognition and elimination of risk factors, primary prevention is critically important. The purpose of this study was to examine the accuracy of perceived stroke risk of African Americans aged 19 to 54 years.

Design

This study used a descriptive-correlational design. Participants consisted of a nonrandom sample that was recruited from a mobile health clinic (traveling to four rural counties over 4 months). Participants self-identified as African American, were between 19 and 54 years of age, were current residents of a rural county, and could not have a physical impairment that could keep them from exercising. Sixty-six participants were enrolled in the study. Participants were asked to select the risk that represented their risk of having a stroke in the next 10 to 20 years (no risk, little risk, moderate risk, or high risk). This was compared to an individual actual risk assessment that was based on accepted risk factors for stroke. The form that was used included health, social and family histories, and biophysiologic health measures (blood pressure and glucose). A scoring system was used as a guide to obtain a risk factor score. Scores could range between 0 and 8 (zero would be no risk factors). The measures were compared and participants were placed into risk accuracy categories: accurate, underestimate, or overestimate.

Findings

The mean age of participants was 43.3 years. Most of the participants were female (71%). Comparisons of the scores showed that 44% underestimated their risk, 47% were accurate, and 9% overestimated their risk. 67% of participants with a family history of stroke and 69% with a history of hypertension did not identify these as risk factors. Eighty percent of those who smoked cigarettes, 93% of those with diabetes, and 88% of those who were either overweight or who had obesity did not identify these as risk factors. This sample had a high burden of risk factors for stroke. Of the 39 participants who had 3 or more risk factors, only 19 (49%) thought that they were moderate to high risk of stroke.

Nursing Implications

This study suggests that more public education about primary prevention and awareness of modifiable stroke risk factors is needed. Nurses are in an optimal position to provide this education. Nurses in all settings (hospital, community, rehabilitation, outpatient clinics, and industry) should be involved in prevention and wellness activities for the public. This study focused on a young to middle-aged African American sample. Awareness campaigns can be focused and individualized for a younger population, and this study indicates that this type of campaign is needed. More studies are needed to test educational materials and tools that can be of benefit to this young to middle-aged population.

Chart 50-2 MODIFIABLE RISK FACTORS

Ischemic Stroke

- Asymptomatic carotid stenosis
- Atrial fibrillation
- Diabetes (associated with accelerated atherogenesis)
- Dyslipidemia
- Excessive alcohol consumption
- Hypercoagulable states
- Hypertension (controlling hypertension, the major risk factor, is the key to preventing stroke)
- Migraine
- Obesity
- Sedentary lifestyle
- Sleep apnea
- Smoking

Adapted from Meschia, J. F., Bushnell, C., Boden-Albala, B., et al. (2014). Guidelines for the primary prevention of stroke: A statement for healthcare professionals from the American Heart Association/American Stroke Association. Stroke, 45(12), 3754–3832.

Additional treatable conditions that increase risk of stroke include sickle cell diseases, cardiomyopathy (ischemic and nonischemic), and valvular heart disease (e.g., endocarditis, prosthetic heart valves). Lesser known and potentially modifiable risk factors for stroke are migraine (especially migraine with aura), sleep apnea, and inherited and acquired hypercoagulable states. Chronic inflammatory conditions that have been associated with an increased risk of stroke are systemic lupus erythematosus and rheumatoid arthritis (Meschia et al., 2014).

Several methods of preventing recurrent stroke have been identified for patients with TIAs or ischemic stroke. Patients with moderate to severe carotid stenosis are treated with carotid endarterectomy (CEA) or carotid angioplasty and stenting. In patients with atrial fibrillation, which increases the risk of emboli, administration of an anticoagulant that inhibits clot formation may prevent both thrombotic and embolic strokes (Kernan, Ovbiagele, Black, et al., 2014).

Medical Management

Patients who have experienced a TIA or stroke should have medical management for secondary prevention. Those with atrial fibrillation (or cardioembolic strokes) are treated with dose-adjusted warfarin (Coumadin) with a target international normalized ratio (INR) of 2 to 3. Other newer anticoagulants that may be prescribed as alternative drugs include dabigatran (Pradaxa), apixaban (Eliquis), edoxaban (Savaysa), or rivaroxaban (Xarelto), unless they are contraindicated. These newer drugs are also known as new or novel oral anticoagulants (NOACs) (Bentz, 2015). If anticoagulants are contraindicated, aspirin alone is the best option, although the addition of clopidogrel (Plavix) to aspirin is also a reasonable therapy (Kernan et al., 2014).

Platelet-inhibiting medications, including aspirin, extended-release dipyridamole plus aspirin (Aggrenox), and clopidogrel decrease the incidence of cerebral infarction in patients who have experienced TIAs and stroke from suspected embolic or thrombotic causes. The specific medication that is used is based on the patient's health history.

Research suggests that medications known as statins reduce coronary events and ischemic strokes. The most current stroke prevention guideline now includes the recommendation of a statin even if the low-density lipoprotein (LDL) cholesterol is below 100 mg/dL and there is no evidence of atherosclerotic cardiovascular disease (coronary artery disease/myocardial infarction, hypertensive heart disease and peripheral arterial disease) (Kernan et al., 2014). The FDA has included indications for statin medications, such as simvastatin (Zocor), to include secondary stroke prevention.

After the acute stroke period, antihypertensive medications are also used, if indicated, for secondary stroke prevention. Preferred drugs include angiotensin-converting enzyme (ACE) inhibitors and diuretics, or a combination of both (Kernan et al., 2014).

Medical management of acute ischemic stroke needs to include consideration for endovascular treatment (Powers, Derdeyn, Biller, et al., 2015). The FDA has approved several devices that open the blocked artery and restore blood flow to the brain. These devices are used by specialists in the endovascular suite.

Thrombolytic Therapy

Thrombolytic agents are used to treat ischemic stroke by dissolving the blood clot that is blocking blood flow to the brain. Recombinant t-PA is a genetically engineered form of t-PA (a thrombolytic substance made naturally by the body) (Karch, 2014). It works by binding to fibrin and converting plasminogen to plasmin, which stimulates fibrinolysis of the clot. Rapid diagnosis of stroke and initiation of thrombolytic therapy (within 3 hours) in patients with ischemic stroke leads to a decrease in the size of the stroke and an overall improvement in functional outcome after 3 months (NINDS, 1995). The goal is for intravenous (IV) t-PA to be given within 60 minutes of the patient arriving to the ED (Jauch et al., 2013).

Intra-arterial delivery of t-PA is an alternative to IV administration. This type of administration can allow for higher concentrations of the drug to be given directly to the clot, and the time window for treatment may be extended up to 6 hours. Those not eligible for IV delivery may be eligible for intra-arterial delivery, and these methods may also be combined. Treatment using intra-arterial delivery must occur in specialized centers with access to emergent cerebral angiogram and interventional operating rooms/suites (Summers et al., 2009); (Jauch et al., 2013). Ongoing clinical trials continue to investigate the efficacy of other thrombolytic agents.

To realize the full potential of early intervention, community education directed at recognizing the symptoms of stroke and obtaining appropriate emergency care is necessary to ensure rapid transport to a hospital and initiation of therapy within the recommended 3-hour period (which may be extended up to 4.5 hours in some cases) (Del Zoppo et al., 2009). Delays make the patient ineligible for therapies, because revascularization of necrotic tissue (which develops after 3 hours) increases the risk of cerebral edema and hemorrhage.

Endovascular Therapy

It is now recommended that patients with acute ischemic stroke receive endovascular therapy and medical management with a stent retriever if they meet specific criteria (Powers et al., 2015). All of the following criteria need to be met:

- Prestroke status of no deficits
- Acute ischemic stroke receiving IV t-PA within 4.5 hours of onset according to guidelines from professional medical societies
- Causative occlusion of the internal carotid artery or proximal middle cerebral artery
- Age ≥18 years
- NIHSS score of ≥6
- ASPECT (a radiologic assessment of the CT scan) score of ≥6, and treatment can be initiated (groin puncture) within 6 hours of symptom onset

Patients eligible for t-PA should receive IV t-PA even if endovascular treatments are being considered (Powers et al., 2015). Thrombolytic therapy should not be delayed.

Enhancing Prompt Diagnosis

After being notified by emergency medical service personnel, the ED contacts the appropriate staff (neurologist, neuroradiologist, radiology department, nursing staff, ECG, and laboratory technicians) and informs them of the patient's imminent arrival at the hospital. Many institutions have acute stroke teams that respond rapidly, ensuring that treatment occurs within the allotted period. This may be called a Code Stroke.

Initial management requires the definitive diagnosis of an ischemic stroke by brain imaging and a careful history to determine whether the patient meets the criteria for t-PA therapy (see Chart 50-3). The goal is that diagnostic results from imaging are completed within 25 minutes of the patient's arrival to the ED (Middleton, Grimley, & Alexandrov, 2015). Some of the contraindications for thrombolytic therapy include symptom onset greater than 3 hours before admission (expanded to 4.5 hours in some cases), a patient who is anticoagulated (with an INR above 1.7), or a patient who has recently had any type of significant intracranial pathology (e.g., previous stroke, head injury, trauma) in the last 3 months.

Chart 50-3

Eligibility Criteria for Tissue Plasminogen Activator Administration

- Age ≥18 years
- Clinical diagnosis of ischemic stroke
- Time of onset of stroke known and is less than 3 hours before treatment
- Systolic blood pressure ≤185 mm Hg; diastolic ≤110 mm Hg
- No minor stroke or rapidly resolving stroke
- No seizure at onset of stroke
- Prothrombin time ≤15 seconds or international normalized ratio ≤1.7 (if taking an anticoagulant, the same guidance is used)
- Not received heparin during the past 48 hours with elevated partial thromboplastin time
- Platelet count ≥100,000/mm3
- Glucose >50 mg/dL
- No prior intracranial hemorrhage, neoplasm, arteriovenous malformation, or aneurysm
- No major surgical procedures or serious trauma within 14 days
- No stroke, serious head injury, or intracranial surgery within 3 months
- No gastrointestinal or urinary bleeding within 21 days
- No pregnancy

Some of these are relative contraindications (the provider administering the medication needs to weigh the risks and benefits of the therapy). There are more stringent criteria if t-PA is considered for those patients in the 3.0- to 4.5-hour time window.

Adapted from Jauch, E. C., Saver, J. L., Adams, H. P., et al. (2013). Guidelines for the early management of patients with ischemic stroke: A guideline from the American Heart Association/American Stroke Association. Stroke, 44(1), 870–947.

Before receiving t-PA, the patient is assessed using the National Institutes of Health Stroke Scale (NIHSS), a standardized assessment tool that helps evaluate stroke severity (see Table 50-4). Total NIHSS scores range from 0 (normal) to 42 (severe stroke). Certification in the administration of the scale is recommended and is available for nurses and other health care professionals.

Dosage and Administration

The patient is weighed to determine the dose of t-PA. Typically, two or more IV sites are established prior to administration of t-PA (one for the t-PA and the other for administration of IV fluids). The dosage for t-PA is 0.9 mg/kg, with a maximum dose of 90 mg. Ten percent of the calculated dose is given as an IV bolus over 1 minute. The remaining dose (90%) is given IV over 1 hour via an infusion pump (Jauch et al., 2013).

The patient is admitted to the intensive care unit or an acute stroke unit, where continuous cardiac monitoring and frequent neurologic assessments are conducted. Vital signs are obtained frequently, with particular attention to blood pressure (with the goal of lowering the risk of intracranial hemorrhage). An example of a standard protocol would be to obtain vital signs every 15 minutes for the first 2 hours, every 30 minutes for the next 6 hours, then

TABLE 50-4 Summary of National Institutes of Health Stroke Scale

Category	Description	Score
1a. LOC	Alert	0
	Arousable by minor stimulation	1
	Obtunded, strong stimulation to attend	2
	Unresponsive, or reflexive responses only	3
1b. LOC questions (month, age)	Answers both correctly	0
	Answers one correctly	1
	Both incorrect	2
1c. LOC commands (open, close eyes; make fist, let go)	Obeys both correctly	0
	Obeys one correctly	1
	Both incorrect	2
2. Best gaze (eyes open—patient follows examiner's finger or face)	Normal	0
	Partial gaze palsy	1
	Forced deviation	2
3. Visual (introduce visual stimulus/threat to patient's visual field quadrants)	No visual loss	0
	Partial hemianopsia	1
	Complete hemianopsia	2
	Bilateral hemianopsia	3
4. Facial palsy (show teeth, raise eyebrows, and squeeze eyes shut)	Normal	0
	Minor	1
	Partial	2
	Complete	3
5a. Motor; arm—left (elevate extremity to 90 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
5b. Motor; arm—right (elevate extremity to 90 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
6a. Motor; leg—left (elevate extremity to 30 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A

(Continued)

(Continued)

6b. Motor; leg—right (elevate extremity to 30 degrees and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
	Amputation, joint fusion (explain)	N/A
7. Limb ataxia (finger-to-nose and heel-to-shin testing)	Absent	0
	Present in one limb	1
	Present in two limbs	2
8. Sensory (pinprick to face, arm, trunk, and leg—compare side to side)	Normal	0
	Mild to moderate loss	1
	Severe to total loss	2
9. Best language (name items, describe a picture, and read sentences)	No aphasia	0
	Mild to moderate aphasia	1
	Severe aphasia	2
	Mute	3
10. Dysarthria (evaluate speech clarity by having patient repeat words)	Normal	0
	Mild to moderate dysarthria	1
	Severe dysarthria, mostly unintelligible or worse	2
	Intubated or other physical barrier	N/A
11. Extinction and inattention (use information from prior testing to score)	No abnormality	0
	Visual, tactile, auditory, or other extinction to bilateral simultaneous stimulation	1
	Profound hemiattention or extinction to more than one modality	2
Total score		___

LOC, level of consciousness; N/A, not applicable.

Retrieved on 4/23/17 at: www.ninds.nih.gov/sites/default/files/NIH_Stroke_Scale_Booklet.pdf. It is recommended that the full scale with all instructions be used.

every hour until 24 hours after treatment. Blood pressure should be maintained with the systolic pressure less than 180 mm Hg and the diastolic pressure less than 105 mm Hg (Jauch et al., 2013); (Middleton et al., 2015). Airway management is instituted based on the patient's clinical condition and arterial blood gas values.

Side Effects

Once it is determined that the patient is a candidate for t-PA therapy, no anticoagulant agents are given for the next 24 hours. Bleeding is the most common side effect of t-PA administration, and the patient is closely monitored for any bleeding (IV insertion sites, urinary catheter site, endotracheal tube, nasogastric tube, urine, stool, emesis, other secretions). A 24-hour delay in placement of nasogastric tubes, urinary catheters, and intra-arterial pressure catheters is recommended. Intracranial bleeding is a major complication that occurred in approximately 6.4% of patients in the initial t-PA study (NINDS, 1995). A number of factors are associated with the occurrence of symptomatic intracranial bleeding: age greater than 70 years, baseline NIHSS score greater than 20, serum glucose concentration 300 mg/dL or higher, and edema or mass effect observed on the patient's initial CT scan (NINDS, 1995).

Therapy for Patients With Ischemic Stroke Not Receiving Tissue Plasminogen Activator

Not all patients are candidates for t-PA therapy. In some centers, other treatments may include anticoagulant administration (IV heparin or low–molecular-weight heparin). Because of the risks associated with anticoagulation, their general use is no longer recommended for patients with acute ischemic stroke (Jauch et al., 2013).

Careful maintenance of cerebral hemodynamics to maintain cerebral perfusion is extremely important after a stroke. Increased intracranial pressure (ICP) from brain edema and associated complications may occur after a large ischemic stroke. Interventions during this period include measures to reduce ICP, such as administering an osmotic diuretic (e.g., mannitol) to those that are declining clinically (Wijdicks, Sheth, Carter, et al., 2014). Other treatment measures include the following:

- Providing supplemental oxygen if oxygen saturation is below 95%
- Elevation of the head of the bed to 30 degrees to assist the patient in handling oral secretions and decrease ICP
- Possible hemicraniectomy for increased ICP from brain edema in a very large stroke
- Intubation with an endotracheal tube to establish a patent airway, if necessary
- Continuous hemodynamic monitoring (the goals for blood pressure remain controversial for a patient who has not received thrombolytic therapy; antihypertensive treatment may be withheld unless the systolic blood pressure exceeds 220 mm Hg or the diastolic blood pressure exceeds 120 mm Hg.)
- Frequent neurologic assessments to determine if the stroke is evolving and if other acute complications are developing

(such complications may include seizures, bleeding from anticoagulation, or medication-induced bradycardia, which can result in hypotension and subsequent decreases in cardiac output and cerebral perfusion pressure).

Managing Potential Complications

Adequate cerebral blood flow is essential for cerebral oxygenation. If cerebral blood flow is inadequate, the amount of oxygen supplied to the brain will decrease, and tissue ischemia will result. Adequate oxygenation begins with pulmonary care, maintenance of a patent airway, and administration of supplemental oxygen as needed. The importance of adequate gas exchange in these patients cannot be overemphasized, because many patients are at risk for aspiration pneumonia.

Other potential complications after a stroke include urinary tract infections, cardiac dysrhythmias (ventricular ectopy, tachycardia, and heart blocks), and complications of immobility. Hyperglycemia has been associated with poor neurologic outcomes in acute stroke, therefore blood glucose should be in the range of 140 to 180 mg/dL, and hypoglycemia should be avoided (Jauch et al., 2013).

Surgical Prevention of Ischemic Stroke

The main surgical procedure for selected patients with TIAs and mild stroke is CEA, which currently is the most frequently performed noncardiac vascular procedure. A CEA is the removal of an atherosclerotic plaque or thrombus from the carotid artery to prevent stroke in patients with occlusive disease of the extracranial cerebral arteries (see Fig. 50-3). This surgery is indicated for patients with symptoms of TIA or mild stroke (or those without symptoms) that are found to have severe (70% to 99%) carotid artery stenosis or moderate (50% to 69%) stenosis with other significant risk factors.

Carotid artery stenting (CAS), with or without angioplasty, is a less invasive procedure that is used for treatment of carotid stenosis. This procedure has less discomfort for the patient and a shorter recovery time than CEA. Age can be considered when deciding which procedure will be best for the patient. For older patients (older than 70 years), CEA demonstrated improved outcomes in research studies; for those who were younger, outcomes between CAS and CEA were similar when comparing procedure complications (Kernan et al., 2014).

Nursing Management

The main complications of CEA are stroke, cranial nerve injuries, infection or hematoma at the incision, and carotid artery disruption. It is important to maintain adequate blood pressure levels in the immediate postoperative period. Hypotension is avoided to prevent cerebral ischemia and thrombosis. Uncontrolled hypertension may precipitate cerebral hemorrhage, edema, hemorrhage at the surgical incision, or disruption of the arterial reconstruction. Medications are used to reduce the blood pressure to previous levels. Close cardiac monitoring is necessary, because these patients frequently have concomitant coronary artery disease.

After CEA, a neurologic observation record (see Chapter 49, Fig. 49-8) is used to monitor and document assessment parameters for all body systems, with particular attention to neurologic status. The surgeon is notified immediately if a neurologic deficit develops. Formation of a thrombus at the site of the endarterectomy is suspected if there is a sudden new onset of neurologic deficits, such as weakness on one side of the body. The patient should be prepared for repeat endarterectomy.

Difficulty in swallowing, hoarseness, or other signs of cranial nerve dysfunction must be assessed. The nurse focuses on assessment of the following cranial nerves: facial (VII), vagus (X), spinal accessory (XI), and hypoglossal (XII). Some edema in the neck after surgery is expected; however, extensive edema and hematoma formation can obstruct the airway. Emergency airway supplies, including those needed for a tracheostomy, must be available. Table 50-5 provides more information about potential complications of carotid surgery.

Management after carotid stenting also requires monitoring of neurologic status and evaluation for hematoma formation (at the catheterization site). Cardiac monitoring is necessary with assessment for bilateral pulses distal to the catheterization site. Typically, patients are discharged the day after stenting if there are no complications (Treat-Jacobson, Rich, DeVeaux, et al., 2013).

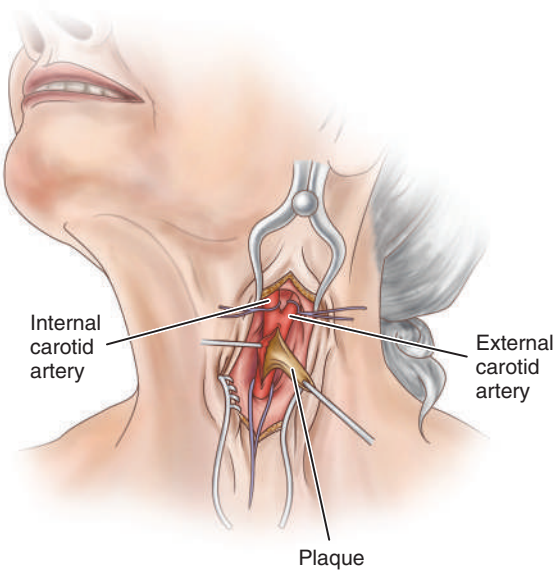

Figure 50-3 • Plaque, a potential source of emboli in transient ischemic attack and stroke, is surgically removed from the carotid artery.

TABLE 50-5 Selected Complications of Carotid Endarterectomy (CEA) and Nursing Interventions

Complication	Characteristics	Nursing Interventions
Incision hematoma	Occurs in 5.5% of patients. Large or rapidly expanding hematomas require emergency treatment. If the airway is obstructed by the hematoma, the incision may be opened at the bedside.	Monitor neck discomfort and wound expansion Report swelling, subjective feelings of pressure in the neck, difficulty breathing.
Hypertension	Poorly controlled hypertension increases the risk of postoperative complications, including hematoma and hyperperfusion syndrome. There is an increased incidence of neurologic impairment and death due to intracerebral hemorrhage. May be related to surgically induced abnormalities of carotid baroreceptor sensitivity.	Keep in mind that risk is highest in the first 48 hours after surgery. Check blood pressure frequently, and report deviations from baseline Administer medications, as prescribed, to reduce hypertension. Observe for and report new onset of neurologic deficits.
Postoperative hypotension	Occurs in approximately 5% of patients. Treated with fluids and low-dose phenylephrine infusion. Usually resolves in 24–48 hours. Patients with hypotension should have serial electrocardiograms to rule out myocardial infarction.	Monitor blood pressure, and observe for signs and symptoms of hypotension.
Hyperperfusion syndrome	Occurs when cerebral vessel autoregulation fails. Arteries accustomed to diminished blood flow may be permanently dilated; increased blood flow after endarterectomy coupled with insufficient vasoconstriction leads to capillary bed damage, edema, and hemorrhage.	Observe for severe unilateral headache improved by sitting upright or standing.
Intracerebral hemorrhage	Occurs infrequently but is often fatal (60%) or results in serious neurologic impairment. Can occur secondary to hyperperfusion syndrome. Increased risk with advanced age, hypertension, presence of high-grade stenosis, poor collateral flow, and slow flow in the region of the middle cerebral artery.	Monitor neurologic status, and report any changes in mental status or neurologic functioning immediately.

NURSING PROCESS

The Patient Recovering from an Ischemic Stroke

The acute phase of an ischemic stroke may last 1 to 3 days, but ongoing monitoring of all body systems is essential as long as the patient requires care. The patient who has had a stroke is at risk for multiple complications, including deconditioning and other musculoskeletal problems, swallowing difficulties, bowel and bladder dysfunction, inability to perform self-care, and skin breakdown. Nursing management focuses on the prompt initiation of rehabilitation for any deficits.

Assessment

During the acute phase, a neurologic flow sheet is maintained to provide data about the following important measures of the patient's clinical status:

- Change in level of consciousness or responsiveness as evidenced by movement, resistance to changes of position, and response to stimulation; orientation to time, place, and person
- Presence or absence of voluntary or involuntary movements of the extremities, muscle tone and strength, body posture, and position of the head
- Eye opening, comparative size of pupils and pupillary reactions to light, and ocular position
- Color of the face and extremities; temperature and moisture of the skin
- Quality and rates of pulse and respiration; arterial blood gas values as indicated, body temperature, and arterial pressure
- Ability to speak
- Volume of fluids ingested or given; volume of urine excreted each 24 hours
- Presence of bleeding
- Maintenance of blood pressure within the desired parameters
- Monitoring of continuous oxygen saturation

After the acute phase, the nurse assesses mental status (memory, attention span, perception, orientation, affect, speech/language), sensation/perception (the patient may have decreased awareness of pain and temperature), motor control (upper and lower extremity movement), swallowing ability, nutritional and hydration status, skin integrity, activity tolerance, and bowel and bladder function. Ongoing nursing assessment continues to focus on any impairment of function in the patient's daily activities, because the quality of life after stroke is closely related to the patient's functional status.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Impaired physical mobility related to hemiparesis, loss of balance and coordination, spasticity, and brain injury
- Acute pain (painful shoulder) related to hemiplegia and disuse
- Self-care deficits (bathing, hygiene, toileting, dressing, and feeding) related to stroke sequelae
- Impaired comfort related to altered sensory reception, transmission, and/or integration
- Impaired swallowing
- Impaired urinary elimination related to flaccid bladder, detrusor instability, confusion, or difficulty in communicating
- Constipation related to change in mental status or difficulty communicating
- Acute confusion related to brain infarction
- Impaired verbal communication related to brain damage
- Risk for impaired skin integrity related to hemiparesis, hemiplegia, or decreased mobility
- Interrupted family processes related to catastrophic illness and caregiving burdens
- Sexual dysfunction related to neurologic deficits or fear of failure

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Decreased cerebral blood flow due to increased ICP
- Inadequate oxygen delivery to the brain
- Pneumonia

Planning and Goals

Although rehabilitation begins on the day the patient has the stroke, the process is intensified during convalescence and requires a coordinated team effort. It is helpful for the team to know what the patient was like before the stroke: their illnesses, abilities, mental and emotional state, behavioral characteristics, and activities of daily living. It is also helpful for clinicians to be knowledgeable about the relative importance of predictors of stroke outcome (age, NIHSS score, and level of consciousness at the time of admission) in order to provide survivors of stroke and their families with realistic goals (Jauch et al., 2013).

The major goals for the patient (and family) may include improved mobility, avoidance of shoulder pain, achievement of self-care, relief of discomfort, prevention of aspiration, continence of bowel and bladder, decreasing confusion, achieving a form of communication, maintaining skin integrity, restored family functioning, improved sexual function, and absence of complications.

Nursing Interventions

Nursing care has a significant impact on the patient's recovery. Often, many body systems are impaired as a result of the stroke, and conscientious care and timely interventions can prevent debilitating complications. During and after the acute phase, nursing interventions focus on the whole person. In addition to providing physical care, the nurse encourages and fosters recovery by listening to the patient and asking questions to elicit the meaning of the stroke experience.

Improving Mobility and Preventing Joint Deformities

A patient with hemiplegia has unilateral paralysis (paralysis on one side). When control of the voluntary muscles is lost, the strong flexor muscles exert control over the extensors. The arm tends to adduct (adductor muscles are stronger than abductors) and to rotate internally. The elbow and the wrist tend to flex, the affected leg tends to rotate externally at the hip joint and flex at the knee, and the foot at the ankle joint supinates and tends toward plantar flexion.

Correct positioning is important to prevent contractures; measures are used to relieve pressure, assist in maintaining good body alignment, and prevent compressive neuropathies, especially of the ulnar and peroneal nerves. Because flexor muscles are stronger than extensor muscles, a splint applied at night to the affected extremity may prevent flexion and maintain correct positioning during sleep (see Chapter 38).

Preventing Shoulder Adduction. To prevent adduction of the affected shoulder while the patient is in bed, a pillow is placed in the axilla when there is limited external rotation; this keeps the arm away from the chest. A pillow is placed under the arm, and the arm is placed in a neutral (slightly flexed) position, with distal joints positioned higher than the more proximal joints (i.e., the elbow is positioned higher than the shoulder and the wrist higher than the elbow). This helps to prevent edema and the resultant joint fibrosis that will limit range of motion if the patient regains control of the arm (see Fig. 50-4).

Positioning the Hand and Fingers. The fingers are positioned so that they are barely flexed. The hand is placed in slight supination (palm faces upward), which is its most functional position. If the upper extremity is flaccid, a splint can be used to support the wrist and hand in a functional position. If the upper extremity is spastic, a hand roll is not used, because it stimulates the grasp reflex. In this instance, a dorsal wrist splint is useful in allowing the palm to be free of pressure. Every effort is made to prevent hand edema.

Figure 50-4 • Correct positioning to prevent shoulder adduction.

Spasticity, particularly in the hand, can be a disabling complication after stroke. Botulinum toxin type A injected intramuscularly into wrist and finger muscles has been shown to be effective in reducing this spasticity (although the effect is temporary, typically lasting 2 to 4 months) (Teasell, Foley, Pereira, et al., 2012). Other treatments for spasticity may include stretching, splinting, and oral medications such as baclofen (Lioresal), diazepam (Valium), dantrolene (Dantrium), and tizanidine (Zanaflex).

Changing Positions. The patient's position should be changed every 2 hours. To place a patient in a lateral (side-lying) position, a pillow is placed between the legs before the patient is turned. To promote venous return and prevent edema, the upper thigh should not be acutely flexed. The patient may be turned from side to side, but if sensation is impaired, the amount of time spent on the affected side should be limited.

If possible, the patient is placed in a prone position for 15 to 30 minutes several times a day. A small pillow or a support is placed under the pelvis, extending from the level of the umbilicus to the upper third of the thigh (see Fig. 50-5). This position helps promote hyperextension of the hip joints, which is essential for normal gait and helps prevent knee and hip flexion contractures. The prone position also helps drain bronchial secretions and prevents contractural deformities of the shoulders and knees. During positioning, it is important to reduce pressure and change position frequently to prevent pressure ulcers.

Establishing an Exercise Program. The affected extremities are exercised passively and put through a full range of motion four or five times a day to maintain joint mobility, regain motor control, prevent contractures in the paralyzed extremity, prevent further deterioration of the neuromuscular system,

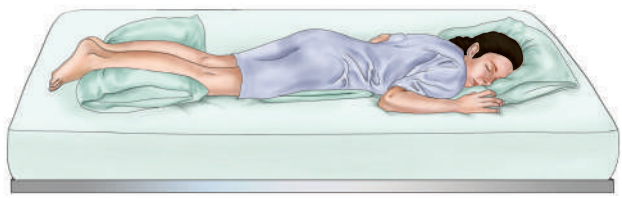

Figure 50-5 • Prone position with pillow support helps prevent hip flexion.

and enhance circulation. Exercise is helpful in preventing venous stasis, which may predispose the patient to venous thromboembolism (VTE). VTE includes deep vein thrombosis (DVT) and pulmonary embolus (PE).

Repetition of an activity forms new pathways in the CNS and therefore encourages new patterns of motion. At first, the extremities are usually flaccid. If tightness occurs in any area, the range-of-motion exercises should be performed more frequently (see Chapter 38).

The patient is observed for signs and symptoms that may indicate PE or excessive cardiac workload during exercise; these include shortness of breath, chest pain, cyanosis, and increasing pulse rate with exercise. Frequent short periods of exercise always are preferable to longer periods at infrequent intervals. Regularity in exercise is most important. Improvement in muscle strength and maintenance of range of motion can be achieved only through daily exercise.

The patient is encouraged and reminded to exercise the unaffected side at intervals throughout the day. It is helpful to develop a written schedule to remind the patient of the exercise activities. The nurse supervises and supports the patient during these activities. The patient can be instructed to put the unaffected leg under the affected one to assist in moving it when turning and exercising. Flexibility, strengthening, coordination, endurance, and balancing exercises prepare the patient for ambulation. Quadriceps muscle setting and gluteal setting exercises (see Chapter 36, Chart 36-1) are started early to improve the muscle strength needed for walking; these are performed at least five times daily for 10 minutes at a time.

Preparing for Ambulation. As soon as possible, the patient is assisted out of bed and an active rehabilitation program is started. The patient is first educated to maintain balance while sitting and then to learn to balance while standing. If the patient has difficulty in achieving standing balance, a tilt table, which slowly brings the patient to an upright position, can be used. Tilt tables are especially helpful for patients who have been on bed rest for prolonged periods and have orthostatic blood pressure changes.

If the patient needs a wheelchair, the folding type with hand brakes is the most practical because it allows the patient to manipulate the chair. The chair should be low enough to allow the patient to propel it with the uninvolved foot and narrow enough to permit it to be used at home. When the patient is transferred from the wheelchair, the brakes must be applied and locked on both sides of the chair.

The patient is usually ready to walk as soon as standing balance is achieved. Parallel bars are useful in these first efforts. A chair or wheelchair should be readily available in case the patient suddenly becomes fatigued or feels dizzy.

The training periods for ambulation should be short and frequent. As the patient gains strength and confidence, an adjustable cane can be used for support. In general, a three- or four-pronged cane provides a stable support in the early phases of rehabilitation.

Preventing Shoulder Pain

The incidence of shoulder pain after stroke can vary widely, but has been measured to be as high as 84% (Zheng & Alexander, 2015). That pain may prevent patients from learning new skills and affect their quality of life. Shoulder function is essential in achieving balance and performing transfers and self-care activities. Problems that can occur include rotator cuff disorders, spasticity of the shoulder muscles, painful shoulder, subluxation of the shoulder, and shoulder–hand syndrome. Development of a condition known as central pain syndrome may also contribute to the development of shoulder pain after a stroke.

A flaccid shoulder joint may be overstretched by the use of excessive force in turning the patient or from overstrenuous arm and shoulder movement. To prevent shoulder pain, the nurse should never lift the patient by the flaccid shoulder or pull on the affected arm or shoulder. Overhead pulleys should also be avoided. If the arm is paralyzed, subluxation (incomplete dislocation) at the shoulder can occur as a result of overstretching of the joint capsule and musculature by the force of gravity when the patient sits or stands in the early stages after a stroke. This results in severe pain. Shoulder–hand syndrome (painful shoulder and generalized swelling of the hand) can cause a frozen shoulder and ultimately atrophy of subcutaneous tissues. When a shoulder becomes stiff, it is usually painful.

Many shoulder problems can be prevented by proper patient movement and positioning. The flaccid arm is positioned on a table or with pillows while the patient is seated. Some clinicians advocate the use of a properly worn sling when the patient first becomes ambulatory, to prevent the paralyzed upper extremity from dangling without support. Range-of-motion exercises are important in preventing painful shoulder. Overstrenuous arm movements are avoided. The patient is instructed to interlace the fingers, place the palms together, and push the clasped hands slowly forward to bring the scapulae forward; he or she then raises both hands above the head. This is repeated throughout the day. The patient is instructed to flex the affected wrist at intervals and move all the joints of the affected fingers. The patient is encouraged to touch, stroke, rub, and look at both hands. Pushing the heel of the hand firmly down on a surface is useful. Elevation of the arm and hand is also important in preventing dependent edema of the hand. Patients with continuing pain after attempted movement and positioning may require the addition of analgesia to their treatment program. Other treatments may include injections to the shoulder joint with corticosteroid medications or botulinum toxin type A, shoulder strapping, acupuncture, electrical stimulation, heat or ice, and soft tissue massage (Zheng & Alexander, 2015).

Medications are often helpful in the management of poststroke pain. The medications that are used include: amitriptyline (Elavil), gabapentin (Neurontin), lamotrigine (Lamictal), and pregabalin (Lyrica) (Flaster, Meresh, Rao, et al., 2013).

Enhancing Self-Care

As soon as the patient can sit up, he or she is encouraged to participate in personal hygiene activities. The patient is helped to set realistic goals; if feasible, a new task is added daily. The first step is to carry out all self-care activities on the unaffected side. Such activities as combing the hair, brushing the teeth, shaving with an electric razor, bathing, and eating can be carried out with one hand and should be encouraged. Although the patient may feel awkward at first, these motor skills can be learned by repetition, and the unaffected side will become stronger with use. The nurse must be sure that the patient does not neglect the affected side. Assistive devices will help make up for some of the patient's deficits (see Chart 50-4). A small towel is easier to control while drying after bathing, and boxed paper tissues are easier to use than a roll of toilet tissue.

Return of functional ability is important to the patient recovering after a stroke. An early baseline assessment of functional ability with an instrument such as the Functional Independence Measure (FIM™) is important in team planning

Chart 50-4

Assistive Devices to Enhance Self-Care After Stroke

Bathing and Grooming Devices

- Electric razors with head at 90 degrees to handle
- Grab bars, nonskid mats, handheld shower heads
- Long-handled bath sponge
- Shower and tub seats, stationary or on wheels

Dressing Aids

- Elastic shoelaces
- Long-handled shoehorn
- Velcro closures

Eating Devices

- Nonskid mats to stabilize plates
- Plate guards to prevent food from being pushed off plate
- Wide-grip utensils to accommodate a weak grasp

Mobility Aids

- Canes, walkers, wheelchairs
- Transfer devices such as transfer boards and belts

Toileting Aids

- Grab bars next to toilet
- Raised toilet seat

and goal setting for the patient. The FIM™ is a widely used instrument in stroke rehabilitation and provides valuable information about motor, social, and cognitive function. The patient's morale may improve if ambulatory activities are carried out in street clothes. The family is instructed to bring in clothing that is preferably a size larger than that usually worn. Clothing fitted with front or side fasteners or Velcro closures is the most suitable. The patient has better balance if most of the dressing activities are carried out while seated.

Perceptual problems may make it difficult for the patient to dress without assistance because of an inability to match the clothing to the body parts. To assist the patient, the nurse can take steps to keep the environment organized and uncluttered, because the patient with a perceptual problem is easily distracted. The clothing is placed on the affected side in the order in which the garments are to be put on. The use of a large mirror while dressing promotes the patient's awareness of what he or she is putting on the affected side. The patient has to make many compensatory movements when dressing; these can produce fatigue and painful twisting of the intercostal muscles. Support and encouragement are provided to prevent the patient from becoming overly fatigued and discouraged. Even with intensive training, not all patients can achieve independence in dressing.

Adjusting to Physical Changes

Patients with a decreased field of vision should be approached on the side where visual perception is intact. All visual stimuli (e.g., clock, calendar, television) should be placed on this side. The patient can be educated to turn the head in the direction of the defective visual field to compensate for this loss. The nurse should make eye contact with the patient and draw their attention to the affected side by encouraging the patient to move the head. The nurse may also want to stand at a position that encourages the patient to move or turn to visualize who is in the room. Increasing the natural or artificial lighting in the room and providing eyeglasses are important aids to increasing vision.

The patient with homonymous hemianopsia turns away from the affected side of the body and tends to neglect that side and the space on that side; this is known as amorphosynthesis. In such instances, the patient cannot see food on half of the tray, and only half of the room is visible. It is important for the nurse to constantly remind the patient of the other side of the body; to maintain alignment of the extremities; and, if possible, to place the extremities where the patient can see them.

Assisting With Nutrition

Stroke can result in dysphagia (difficulty swallowing) due to impaired function of the mouth, tongue, palate, larynx, pharynx, or upper esophagus. Patients must be observed for paroxysms of coughing, food dribbling out of or pooling in one side of the mouth, food retained for long periods in the mouth, or nasal regurgitation when swallowing liquids. Swallowing difficulties place the patient at risk for aspiration, pneumonia, dehydration, and malnutrition.

A swallow assessment should be performed as soon as possible after the patient's arrival to the ED (preferably within 4 to 24 hours). This is done before allowing any oral intake. A speech therapist will evaluate the patient's swallowing ability, but an assessment may also be done by the nurse using a validated and reliable assessment tool (Middleton et al., 2015).

If swallowing function is partially impaired, it may return over time, or the patient may be educated in alternative swallowing techniques, advised to take smaller boluses of food, and educated about types of foods that are easier to swallow. The patient may be started on a thick liquid or pureed diet, because these foods are easier to swallow than thin liquids. Having the patient sit upright, preferably out of bed in a chair, and instructing him or her to tuck the chin toward the chest as he or she swallows will help prevent aspiration. The diet may be advanced as the patient becomes more proficient at swallowing. If the patient cannot resume oral intake, a gastrointestinal feeding tube is placed for ongoing tube feedings and medication administration.

Enteral tubes can be either nasogastric (placed in the stomach) or nasoenteral (placed in the duodenum) to reduce the risk of aspiration. Nursing responsibilities in feeding include elevating the head of the bed at least 30 degrees to prevent aspiration, checking the position of the tube before feeding, ensuring that the cuff of the tracheostomy tube (if in place) is inflated, and giving the tube feeding slowly. The feeding tube is aspirated periodically to ensure that the feedings are passing through the gastrointestinal tract. Retained or residual feedings increase the risk of aspiration. Patients with retained feedings may benefit from the placement of a gastrostomy tube or a percutaneous endoscopic gastrostomy tube. In a patient with a feeding tube, the tube should be placed in the duodenum to reduce the risk of aspiration. For long-term feedings, a gastrostomy tube is preferred (see Chapter 15).

Attaining Bladder and Bowel Control

After a stroke, the patient may have transient urinary incontinence due to confusion, inability to communicate needs, and inability to use the urinal or bedpan because of impaired motor and postural control. Occasionally after a stroke, the bladder becomes atonic, with impaired sensation in response to bladder filling. Sometimes, control of the external urinary sphincter is lost or diminished. During this period, intermittent catheterization with sterile technique is carried out. After muscle tone increases and deep tendon reflexes return, bladder tone increases and spasticity of the bladder may develop. Because the patient's sense of awareness is clouded, persistent

urinary incontinence or urinary retention may be symptomatic of bilateral brain damage. The voiding pattern is analyzed, and the urinal or bedpan is offered on this pattern or schedule. The upright posture and standing position are helpful for male patients during this aspect of rehabilitation.

Patients may have problems with bowel control, particularly constipation. Unless contraindicated, a high-fiber diet and adequate fluid intake (2 to 3 L/day) should be provided, and a regular time (usually after breakfast) should be established for toileting.

Improving Thought Processes

After a stroke, the patient may have problems with cognitive, behavioral, and emotional deficits related to brain damage. However, in many instances, a considerable degree of function can be recovered, because not all areas of the brain are equally damaged; some remain more intact and functional than others.

After assessment that delineates the patient's deficits, the neuropsychologist, in collaboration with the primary provider, psychiatrist, nurse, and other professionals, structures a training program using cognitive-perceptual retraining, visual imagery, reality orientation, and cueing procedures to compensate for losses.

The role of the nurse is supportive. The nurse reviews the results of neuropsychological testing; observes the patient's performance and progress; gives positive feedback; and, most importantly, conveys an attitude of confidence and hope. Interventions capitalize on the patient's strengths and remaining abilities while attempting to improve performance of affected functions. Other interventions are similar to those for improving cognitive functioning after a head injury (see Chapter 51).

Improving Communication

Aphasia, which impairs the patient's ability to express him- or herself and to understand what is being said, may become apparent in various ways. The cortical area that is responsible for integrating the myriad pathways required for the comprehension and formulation of language is called *Broca area*. It is located in a convolution adjoining the middle cerebral artery. This area is responsible for control of the combinations of muscular movements needed to speak each word. Broca area is so close to the left motor area that a disturbance in the motor area often affects the speech area. This is why so many patients who are paralyzed on the right side (due to damage or injury to the left side of the brain) cannot speak, whereas those paralyzed on the left side are less likely to have speech disturbances.

The speech therapist assesses the communication needs of the patient who has had a stroke, describes the precise deficit, and suggests the best overall method of communication. Most language intervention strategies can be tailored for the individual patient. The patient is expected to take an active part in establishing goals.

A person with aphasia may become depressed. The inability to talk on the telephone, answer a question, or participate in conversation often causes anger, frustration, fear of the future, and hopelessness. Nursing interventions include strategies to make the atmosphere conducive to communication. This includes being sensitive to the patient's reactions and needs and responding to them in an appropriate manner while always treating the patient as an adult. The nurse provides strong emotional support and understanding to allay anxiety and frustration.

A common pitfall is for the nurse or other health care team member to complete the thoughts or sentences of the patient. This should be avoided, because it causes the patient to become more frustrated at not being allowed to speak and may deter efforts to practice putting thoughts together and completing sentences. A consistent schedule, routines, and repetition help the patient to function despite significant deficits. A written copy of the daily schedule, a folder of personal information (birth date, address, names of relatives), checklists, and an audiotaped list help improve the patient's memory and concentration. The patient may also benefit from a communication board, which has pictures of common needs and phrases. The board may be translated into any language.

Chart 50-5

Communicating with the Patient with Aphasia

- Face the patient and establish eye contact.
- Speak in a clear, unhurried manner, and normal tone of voice.
- Use short phrases, and pause between phrases to allow the patient time to understand what is being said.
- Limit conversation to practical and concrete matters.
- Use gestures, pictures, objects, and writing.
- As the patient uses and handles an object, say what the object is. It helps to match the words with the object or action.
- Be consistent in using the same words and gestures each time you give instructions or ask a question.
- Keep extraneous noises and sounds to a minimum. Too much background noise can distract the patient or make it difficult to sort out the message being spoken.

When talking with the patient, it is important for the nurse to gain the patient's attention, speak slowly, and keep the language of instruction consistent. One instruction is given at a time, and time is allowed for the patient to process what has been said. The use of gestures may enhance comprehension. Speaking is thinking out loud, and the emphasis is on thinking. Listening and sorting out incoming messages requires mental effort; the patient must struggle against mental inertia and needs time to organize a response.

In working with the patient with aphasia, the nurse must remember to talk to the patient during care activities. This provides social contact for the patient. Chart 50-5 describes points to keep in mind when communicating with the patient with aphasia.

Maintaining Skin Integrity

The patient who has had a stroke may be at risk for skin and tissue breakdown because of altered sensation and inability to respond to pressure and discomfort by turning and moving. Preventing skin and tissue breakdown requires frequent assessment of the skin, with emphasis on bony areas and dependent parts of the body. During the acute phase, a specialty bed (e.g., low air-loss bed) may be used until the patient can move independently or assist in moving.

A regular turning schedule (e.g., every 2 hours) is adhered to, even if pressure-relieving devices are used to prevent tissue and skin breakdown. When the patient is positioned or turned, care must be used to minimize shear and friction forces, which cause damage to tissues and predispose the skin to breakdown.

The patient's skin must be kept clean and dry; gentle massage of healthy (nonreddened) skin and adequate nutrition are other factors that help to maintain skin and tissue integrity (see Chapter 51).

Improving Family Coping

Family members play an important role in the patient's recovery. Family members are encouraged to participate in counseling

and to use support systems that will help with the emotional and physical stress of caring for the patient. Involving others in the patient's care and providing education about stress management techniques and methods for maintaining personal health also facilitate family coping.

The family may have difficulty accepting the patient's disability and may be unrealistic in their expectations. They are given information about the expected outcomes and are counseled to avoid doing activities for the patient that he or she can do. They are assured that their love and interest are part of the patient's therapy.

The family needs to be informed that the rehabilitation of the patient with hemiplegia requires many months and that progress may be slow. The gains made by the patient in the hospital or rehabilitation unit must be maintained. All caregivers should approach the patient with a supportive and optimistic attitude, focusing on the patient's remaining abilities. The rehabilitation team, the medical and nursing team, the patient, and the family must all be involved in developing attainable goals for the patient at home.

Most relatives of patients with stroke handle the physical changes better than the emotional aspects of care. The family should be prepared to expect occasional episodes of emotional lability. The patient may laugh or cry easily and may be irritable and demanding or depressed and confused. The nurse can explain to the family that the patient's laughter does not necessarily connote happiness, nor does crying reflect sadness, and that emotional lability usually improves with time.

Family-centered care involves seeing patients and family caregivers as a one unit. Nurses can assess caregivers' strengths and ability to provide care. This assessment should be a continual process because needs change throughout the hospitalization period and rehabilitation stay. Providing information about community resources, respite care and adult day care, and mental health issues (for the patient who has had a stroke and for caregivers) will help with the transition to home (Creasy, Lutz, Young, et al., 2015).

Helping the Patient Cope with Sexual Dysfunction

Sexual functioning can be profoundly altered by stroke. Although research in this area of stroke management is limited, it appears that patients who have had a stroke consider sexual function important, and many have sexual dysfunction. Sexual dysfunction after stroke is multifactorial. There may be medical reasons for the dysfunction (neurologic and cognitive deficits, previous diseases, medications) as well as various psychosocial factors, including depression. A stroke is such a catastrophic illness that the patient experiences loss of self-esteem and value as a sexual being. These psychosocial factors play an important role in determining sexual drive, activity, and satisfaction after a stroke.

Nurses in the rehabilitation setting play a crucial role in beginning a dialogue between the patient and their partner about sexuality after a stroke. In-depth assessments to determine sexual history before and after the stroke should be followed by appropriate interventions. Interventions for the patient and partner focus on providing relevant information, education, reassurance, adjustment of medications, counseling regarding coping skills, suggestions for alternative sexual positions, and a means of sexual expression and satisfaction.

Monitoring and Managing Potential Complications

Decreased cerebral blood flow due to increased ICP, leading to inadequate oxygen delivery to the brain, and pneumonia are potential complications in any patient who has had an ischemic stroke. The more severe the stroke (i.e., the higher the NIHSS), the greater the risk of complications.

During the acute phase of care, a neurologic flow sheet (see Chapter 49, Fig. 49-8) is used to monitor and document assessment parameters. Changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP and are reported immediately. If signs and symptoms of pneumonia develop, cultures are obtained to identify the organism so that appropriate antibiotic agents can be given.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. Patient and family education is a fundamental component of stroke recovery. The nurse provides education about stroke, its causes and prevention, and the rehabilitation process. In both acute care and rehabilitation facilities, the focus is on educating the patient to resume as much self-care as possible. This may entail using assistive devices or modifying the home environment to help the patient live with a disability.

An occupational therapist may be helpful in assessing the home environment and recommending modifications to help the patient become more independent. For example, a shower is more convenient than a tub for the patient with hemiplegia because most patients do not gain sufficient strength to get up and down from a tub. Sitting on a stool of medium height with rubber suction tips allows the patient to wash with greater ease. A long-handled bath brush with a soap container is helpful to the patient who has only one functional hand. If a shower is not available, a stool may be placed in the tub and a portable shower hose attached to the faucet. Handrails may be attached alongside the bathtub and the toilet. Other assistive devices include special utensils for eating, grooming, dressing, and writing (see Chart 50-4).

A program of physical therapy can be beneficial, whether it takes place in the home or in an outpatient program. Constraint-induced movement therapy has been used in stroke rehabilitation and involves constraint of the less affected upper limb with a mitt, and intensely training the more affected limb. Robotic-assisted therapy uses sensorimotor training of the upper limb. This method allows patients to train without the presence of a therapist. Recent research has focused on techniques using robotics, virtual reality and video game applications, transcranial magnetic stimulation, and ambulation with body weight support and treadmill training (Brainin & Zorowitz, 2013).

Continuing and Transitional Care. A variety of transitional care models are being used in patients with stroke (Puhr & Thompson, 2015). Some evidence supports positive outcomes using transitional care but more research and standardization of interventions is needed for confirmation (Puhr & Thompson, 2015). Depending on the specific neurologic deficits resulting from the stroke, the patient at home may require the services of a number of health care professionals. The nurse often coordinates the care of the patient at home and considers the many educational needs of caregivers and patients. The family (often the spouse) requires education as well as assistance in planning and providing care.

The family is advised that the patient may tire easily, may become irritable and upset by small events, and may be less interested in events than expected. Emotional problems

associated with stroke are often related to speech dysfunction and the frustrations of being unable to communicate. A speech therapist allows the family to be involved and gives the family practical instructions to help the patient between therapy sessions.

Depression is a common and serious problem in the patient who has had a stroke. The incidence of depression in patients who have had a stroke ranges from 25% to 79%. Risk factors include social isolation, gender (more prevalent in women), a history of depression, and cognitive or physical impairment (Miller, Murray, Richards, et al., 2010). Because the length of hospital stays has shortened, depression may not be identified in the acute setting. Nurses in all care settings should identify patients who may be at risk for depression or who show depressive symptoms (Miller et al., 2010). In the home or in the rehabilitation setting, nurses may be involved in coordinating care and referring patients and family to appropriate resources. The family can help by continuing to support the patient and by giving positive reinforcement for the progress that is being made. Antidepressant therapy may be prescribed, and may help with recovery from stroke (Flaster, Sharma, & Rao, 2013).

Community-based stroke support groups may allow the patient and family to learn from others with similar problems and to share their experiences. Support groups take the form of in-person meetings as well as Internet-based support programs. The patient is encouraged to continue hobbies and recreational and leisure interests and to maintain contact with friends to prevent social isolation. All nurses coming in contact with the patient should encourage the patient to keep active, adhere to the exercise program, and remain as self-sufficient as possible.

The nurse should recognize the potential effects of caregiving on the family. Not all families have the adaptive coping skills and adequate psychological functioning necessary for the long-term care of another person. The patient's spouse may be older, with their own health concerns; in some instances, the patient may have been the provider of care to the spouse. A spouse may have to take on new roles and responsibilities in the relationship and around the home. He or she may also feel a sense of loss (of freedom and leisure time as well as of the marital relationship). Caregivers may also experience social isolation and financial burdens. Depression is common in caregivers of patients who have survived a stroke, with rates as high as 30% to 52% (Miller et al., 2010). Nurses should assess caregivers for signs of depression.

Caregivers may require reminders to attend to their own health concerns and well-being. Even healthy caregivers may find it difficult to maintain a schedule that includes being available around the clock. The nurse encourages the family to arrange for respite care services (planned short-term care to relieve the family from having to provide continuous 24-hour care), which may be available from an adult day care center. Some hospitals also offer weekend respite care that can provide caregivers with needed time for themselves. The nurse involved in home and continuing care also needs to remind the patient and family of the need for respite care as well as continuing health promotion and screening practices.

Evaluation

Expected patient outcomes may include:

1. Achieves improved mobility
   a. Avoids deformities (contractures and foot drop)
   b. Participates in prescribed exercise program
   c. Achieves sitting balance
   d. Uses unaffected side to compensate for loss of function of hemiplegic side
2. Reports absence of shoulder pain
   a. Demonstrates shoulder mobility; exercises shoulder
   b. Elevates arm and hand at intervals
3. Achieves self-care; performs hygiene care; uses adaptive equipment
4. Demonstrates techniques to compensate for the discomfort of sensory deficits, such as turning the head to see people or objects
5. Demonstrates safe swallowing
6. Achieves usual pattern of bowel and bladder elimination
7. Participates in cognitive improvement program
8. Demonstrates improved communication
9. Maintains intact skin without breakdown
   a. Demonstrates skin turgor within normal limits
   b. Participates in turning and positioning activities
10. Family members demonstrate a positive attitude and coping mechanisms
    a. Encourage patient in exercise program
    b. Take an active part in rehabilitation process
    c. Contact respite care programs or arrange for other family members to assume some responsibilities for care
11. Develops alternative approaches to sexual expression
12. Absence of complications
    a. Has ICP values that remain within normal limits
    b. Has no signs and symptoms of pneumonia

Hemorrhagic Stroke

Hemorrhage accounts for approximately 13% of strokes and are primarily caused by intracranial (7%), subarachnoid hemorrhage (8%), and other causes. Hemorrhagic strokes are caused by bleeding into the brain tissue, the ventricles, or the subarachnoid space. Primary intracerebral hemorrhage from a spontaneous rupture of small vessels accounts for approximately 80% of hemorrhagic strokes and is caused chiefly by uncontrolled hypertension. Subarachnoid hemorrhage results from a ruptured intracranial aneurysm (discussed later in this chapter) in about half the cases (Hickey, 2014).

Another common cause of primary intracerebral hemorrhage in the older adult is cerebral amyloid angiopathy (CAA), which involves damage caused by the deposit of beta-amyloid protein in the small- and medium-sized blood vessels of the brain. CAA makes these blood vessels fragile and prone to bleeding. Secondary intracerebral hemorrhage is associated with arteriovenous malformations (AVMs), intracranial aneurysms, intracranial neoplasms, or certain medications (e.g., anticoagulants, amphetamines). The mortality rate has been reported to be as high as 50% after an intracranial hemorrhage (Hickey, 2014). Patients who survive the acute phase of care usually have more severe deficits and a longer recovery phase compared to those with ischemic stroke.

Pathophysiology

The pathophysiology of hemorrhagic stroke depends on the cause and type of cerebrovascular disorder. Symptoms are produced when a primary hemorrhage, aneurysm, or AVM presses on

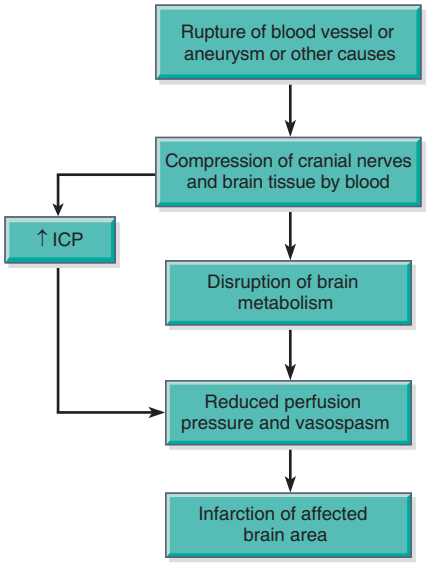

Figure 50-6 • Pathophysiology of hemorrhagic stroke.

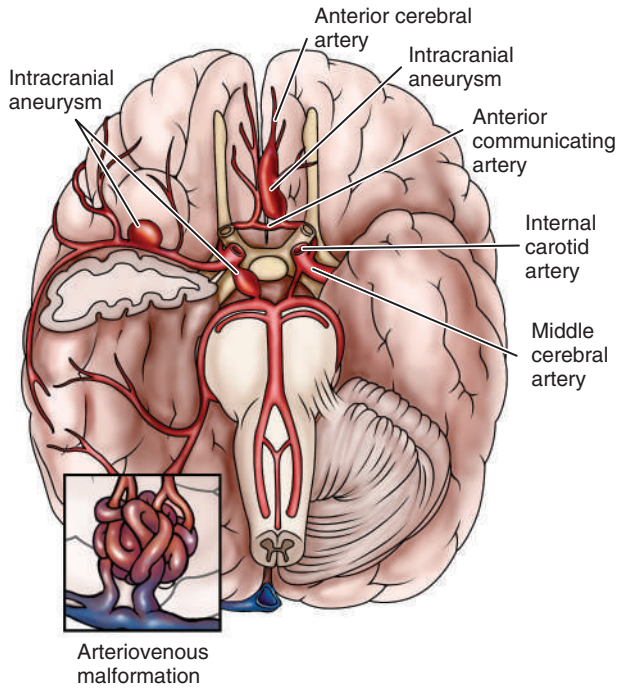

Figure 50-7 • Common sites of intracranial aneurysms and an arteriovenous malformation.

nearby cranial nerves or brain tissue or, more dramatically, when an aneurysm or AVM ruptures, causing subarachnoid hemorrhage (hemorrhage into the cranial subarachnoid space). Normal brain metabolism is disrupted by the brain's exposure to blood; by an increase in ICP resulting from the sudden entry of blood into the subarachnoid space, which compresses and injures brain tissue; or by secondary ischemia of the brain resulting from the reduced perfusion pressure and vasospasm that frequently accompany subarachnoid hemorrhage. A flowchart for pathophysiology of hemorrhagic stroke is presented in Figure 50.6.

Intracerebral Hemorrhage

An intracerebral hemorrhage, or bleeding into the brain tissue, is most common in patients with hypertension and cerebral atherosclerosis, because degenerative changes from these diseases cause rupture of the blood vessel. An intracerebral hemorrhage may also result from certain types of arterial pathology, brain tumors, and the use of medications (e.g., oral anticoagulants, amphetamines, and illicit drug use).

Bleeding related to hypertension occurs most commonly in the deeper structures of the brain (basal ganglia and thalamus); it occurs less frequently in the brainstem (mostly the pons) and cerebellum (Hickey, 2014). Bleeding in the outer cerebral lobes (lobar hemorrhages) in those 75 or older can be related to CAA. Bleeding from CAA frequently is in the frontal and parietal lobes. Occasionally, the bleeding ruptures the wall of the lateral ventricle and causes intraventricular hemorrhage, which is associated with poor outcomes and death (Hickey, 2014).

Intracranial (Cerebral) Aneurysm

An intracranial (cerebral) aneurysm is a dilation of the walls of a cerebral artery that develops as a result of weakness in the arterial wall. The cause of aneurysms is unknown, although research is ongoing. An aneurysm may be due to atherosclerosis, which results in a defect in the vessel wall with subsequent weakness of the wall; a congenital defect of the vessel wall; hypertensive vascular disease; head trauma; or advancing age.

Any artery within the brain can be the site of a cerebral aneurysm, but these lesions usually occur at the bifurcations of the large arteries at the circle of Willis (see Fig. 50-7). The cerebral arteries most commonly affected by an aneurysm are the internal carotid artery, anterior cerebral artery, anterior communicating artery, posterior communicating artery, posterior cerebral artery, and middle cerebral artery. Multiple cerebral aneurysms are not uncommon.

Arteriovenous Malformations

Most AVMs are caused by an abnormality in embryonal development that leads to a tangle of arteries and veins in the brain that lacks a capillary bed (see Fig. 50-7). The absence of a capillary bed leads to dilation of the arteries and veins and eventual rupture. AVM is a common cause of hemorrhagic stroke in young people (Bader, Littlejohns, & Olson, 2016).

Subarachnoid Hemorrhage

A subarachnoid hemorrhage (hemorrhage into the subarachnoid space) may occur as a result of an AVM, intracranial aneurysm, trauma, or hypertension. The most common causes are a leaking aneurysm in the area of the circle of Willis and a congenital AVM of the brain (Bader et al., 2016).

Clinical Manifestations

The patient with a hemorrhagic stroke can present with a wide variety of neurologic deficits, similar to the patient with ischemic stroke. The conscious patient most commonly reports a severe headache. A comprehensive assessment reveals the extent of the neurologic deficits. Many of the same motor, sensory, cranial nerve, cognitive, and other functions that are disrupted after ischemic stroke are also altered after a hemorrhagic stroke. Table 50-2 reviews the neurologic deficits frequently seen in patients who have had a stroke. Table 50-3 compares the symptoms seen in right hemispheric stroke with those seen in left hemispheric stroke. Other symptoms that may be observed more frequently in patients with acute intracerebral hemorrhage (compared with ischemic stroke) are nausea or vomiting, an early sudden change in level of consciousness, and possibly seizures.

In addition to the neurologic deficits (similar to those of ischemic stroke), the patient with an intracranial aneurysm or AVM may have some unique clinical manifestations. Rupture of an aneurysm or AVM usually produces a sudden, unusually severe headache and often loss of consciousness for a variable period of time. There may be pain and rigidity of the back of the neck (nuchal rigidity) and spine due to meningeal irritation. Visual disturbances (visual loss, diplopia, ptosis) occur if the aneurysm is adjacent to the oculomotor nerve. Tinnitus, dizziness, and hemiparesis may also occur.

At times, an aneurysm or AVM leaks blood, leading to the formation of a clot that seals the site of rupture. In this instance, the patient may show little neurologic deficit. In other cases, severe bleeding occurs, resulting in cerebral damage, followed rapidly by coma and death.

Prognosis depends on the neurologic condition of the patient, the patient's age, associated diseases, and the extent and location of the hemorrhage or intracranial aneurysm. Subarachnoid hemorrhage from an aneurysm is a catastrophic event with significant morbidity and mortality.

Assessment and Diagnostic Findings

Any patient with suspected stroke should undergo a CT scan or MRI scan to determine the type of stroke, the size and location of the hematoma, and the presence or absence of ventricular blood and hydrocephalus. Because hemorrhagic stroke is an emergency, CT scan is usually obtained first because it can be done rapidly. Cerebral angiography using the conventional method or CT (CTA) confirms the diagnosis of an intracranial aneurysm or AVM. These tests show the location and size of the lesion and provide information about the affected arteries, veins, adjoining vessels, and vascular branches. Lumbar puncture may be performed if there is no evidence of increased ICP, the CT scan results are negative, and subarachnoid hemorrhage must be confirmed. Lumbar puncture in the presence of increased ICP could result in brainstem herniation or rebleeding. When diagnosing a hemorrhagic stroke in a patient younger than 40 years, some clinicians obtain a toxicology screen for illicit drug use.

Prevention

Primary prevention of hemorrhagic stroke is the best approach and includes managing hypertension and ameliorating other significant risk factors. Control of hypertension can reduce the risk of hemorrhagic stroke. Additional risk factors are increased age, male gender, certain ethnicities (Latino, African American, and Japanese) and moderate or excessive alcohol intake (Hickey, 2014). Stroke risk screenings provide an ideal opportunity to lower hemorrhagic stroke risk by identifying individuals or groups at high risk and educating patients and the community about recognition and prevention.

Complications

Potential complications of hemorrhagic stroke include rebleeding or hematoma expansion; cerebral vasospasm resulting in cerebral ischemia; acute hydrocephalus, which results when free blood obstructs the reabsorption of cerebrospinal fluid (CSF) by the arachnoid villi; and seizures.

Cerebral Hypoxia and Decreased Blood Flow

Immediate complications of a hemorrhagic stroke include cerebral hypoxia, decreased cerebral blood flow, and extension of the area of injury. Providing adequate oxygenation of blood to the brain minimizes cerebral hypoxia. Brain function depends on delivery of oxygen to the tissues. Administering supplemental oxygen and maintaining the hemoglobin and hematocrit at acceptable levels will assist in maintaining tissue oxygenation.

Cerebral blood flow depends on the blood pressure, cardiac output, and integrity of cerebral blood vessels. Adequate hydration (IV fluids) must be ensured to reduce blood viscosity and improve cerebral blood flow. Extremes of hypertension or hypotension need to be avoided to prevent changes in cerebral blood flow and the potential for extending the area of injury.

A seizure can also compromise cerebral blood flow, resulting in further injury to the brain. Observing for seizure activity and initiating appropriate treatment are important components of care after a hemorrhagic stroke.

Vasospasm

The development of cerebral vasospasm (narrowing of the lumen of the involved cranial blood vessel) is a serious complication of subarachnoid hemorrhage and is a leading cause of morbidity and mortality in those who survive the initial subarachnoid hemorrhage. Of those with cerebral vasospasm, 15% to 20% die (Wuchner, Bakas, Adams, et al., 2012). The mechanism responsible for vasospasm is not clear, but it is associated with increasing amounts of blood in the subarachnoid cisterns and cerebral fissures, as visualized by CT scan. Monitoring for vasospasm may be performed through the use of bedside transcranial Doppler ultrasonography or follow-up cerebral angiography (Connolly, Rabinstein, Carhuapoma, et al., 2012).

Vasospasm most frequently occurs 7 to 10 days after initial hemorrhage (Connolly et al., 2012), when the clot undergoes lysis (dissolution), and the chance of rebleeding is increased. It leads to increased vascular resistance, which impedes cerebral blood flow and causes brain ischemia (delayed cerebral ischemia) and infarction. The signs and symptoms reflect the areas of the brain involved. Vasospasm is often heralded by a worsening headache, a decrease in level of consciousness (confusion, lethargy, and disorientation), or a new focal neurologic deficit (aphasia, hemiparesis).

Management of vasospasm remains difficult and controversial. It is believed that early surgery to clip the aneurysm prevents rebleeding and that removal of blood from the basal cisterns around the major cerebral arteries may prevent vasospasm.

Medication may be effective in the treatment and prevention of vasospasm. Based on the theory that vasospasm is caused by an increased influx of calcium into the cell, medication therapy may be used either to block or antagonize this action, or to prevent or reverse the action of vasospasm if already present. Nimodipine is the most studied calcium channel blocker for prevention of vasospasm in subarachnoid hemorrhage. An oral solution of nimodipine (Nymalize) was approved by the FDA in 2013; prior to this approval, the medication was only available in a liquid filled gel capsule (Nimotop). Current guidelines recommend that nimodipine be prescribed for all patients with subarachnoid hemorrhage (Connolly et al., 2012). This is currently the only drug approved by the FDA for the prevention and treatment of vasospasm in subarachnoid hemorrhage.

Another therapy for vasospasm and the resulting delayed cerebral ischemia, referred to as triple-H therapy, is aimed at minimizing the deleterious effects of the associated cerebral ischemia and includes (1) fluid volume expanders (hypervolemia), (2) induced arterial hypertension, and (3) hemodilution. However,

current research and guidelines now endorse euvolemia to prevent delayed cerebral ischemia and induced arterial hypertension for treatment of delayed cerebral ischemia (Connolly et al., 2012).

Increased Intracranial Pressure

An increase in ICP can occur after either an ischemic or a hemorrhagic stroke but almost always follows a subarachnoid hemorrhage, usually because of disturbed circulation of CSF caused by blood in the basal cisterns. Neurologic assessments are performed frequently, and if there is evidence of deterioration from increased ICP (due to cerebral edema, herniation, hydrocephalus, or vasospasm), CSF drainage may be instituted by ventricular catheter drainage (Hemphill, Greenberg, Anderson, et al., 2015). Mannitol may be given to reduce ICP. When mannitol is used as a long-term measure to control ICP, dehydration and disturbances in electrolyte balance (hyponatremia or hypernatremia; hypokalemia or hyperkalemia) may occur. Mannitol pulls water out of the brain tissue by osmosis and reduces total body water through diuresis. The patient's fluid balance is monitored continuously and is assessed for signs of dehydration and for rebound elevation of ICP. Other interventions may include elevating the head of the bed to 30 degrees, avoidance of hyperglycemia and hypoglycemia, sedation, and use of hypertonic saline in a variety of concentrations (e.g., 3%, 7.5%, or 23%) (Wijdicks et al., 2014).

Hypertension

Hypertension is the most common cause of intracerebral hemorrhage, and its treatment is critical. Specific goals for blood pressure management, which are individualized for each patient, remain controversial. Blood pressure goals may depend on the presence of increased ICP. Recently published guidelines for management of intracerebral hemorrhage recommend early blood pressure lowering (if the systolic blood pressure is between 150 and 220 mm Hg) to a goal systolic of 140 mm Hg, and report that lowering blood pressure can be effective for improving patient outcomes. If systolic blood pressure is above 220 mm Hg, IV continuous infusions of antihypertensives may be prescribed (Hemphill et al., 2015). Nicardipine (Cardene) is one agent that may be used as a continuous IV infusion. Labetalol (Trandate) and hydralazine (Apresoline) are other examples of medications that may be given as an IV bolus. During the administration of antihypertensive agents, hemodynamic monitoring is important to detect and avoid a precipitous drop in blood pressure, which can produce brain ischemia. Stool softeners are used to prevent straining, which can elevate the blood pressure.

Medical Management

The goals of medical treatment for hemorrhagic stroke are to allow the brain to recover from the initial insult (bleeding), to prevent or minimize the risk of rebleeding, and to prevent or treat complications. Management may consist of bed rest with sedation to prevent agitation and stress, management of vasospasm, and surgical or medical treatment to prevent rebleeding. If the bleeding is caused by anticoagulation with warfarin, the INR may be corrected with fresh-frozen plasma and vitamin K. Reversing the anticoagulation effect of the new oral anticoagulants is more complicated. Protocols may include hemodialysis, the use of oral activated charcoal, administration of prothrombin complex concentrates, or administration of recombinant activated factor VII (Kaatz, Kouides, Garcia, et al., 2012). Idarucizumab (Praxbind) is a medication that was recently approved for reversing dabigatran (Pradaxa). If seizures occur, they are treated with anticonvulsant drugs such as phenytoin (Dilantin). Hyperglycemia should also be treated, and hypoglycemia is avoided. Intermittent pneumatic compression devices should be used starting on the first day of the hospital admission to prevent DVT. If the patient is not mobile after 1 to 4 days from the onset of the hemorrhage and there is documentation of the bleeding ceasing, then DVT prevention medications (low–molecular-weight heparin or unfractionated heparin) may be prescribed (Hemphill et al., 2015). Analgesic agents may be prescribed for head and neck pain. Fever should be treated with acetaminophen/paracetamol (Tylenol), iced saline boluses, and devices such as cooling blankets (Bader et al., 2016). After discharge, most patients will require antihypertensive medications to decrease their risk of another intracerebral hemorrhage.

Surgical Management

In many cases, a primary intracerebral hemorrhage is not treated surgically. However, if the patient is showing signs of worsening neurologic examination, increased ICP, or signs of brainstem compression, then surgical evacuation is recommended for the patient with a cerebellar hemorrhage (Hemphill et al., 2015). Surgical evacuation is most frequently accomplished via a craniotomy (see Chapter 49).

The patient with an intracranial aneurysm is prepared for surgical intervention as soon as their condition is considered stable. Surgical treatment of the patient with an unruptured aneurysm is an option. The goal of surgery is to prevent bleeding in an unruptured aneurysm or further bleeding in an already ruptured aneurysm. This objective is accomplished by isolating the aneurysm from its circulation or by strengthening the arterial wall. An aneurysm may be excluded from the cerebral circulation by means of a ligature or a clip across its neck. If this is not anatomically possible, the aneurysm can be reinforced by wrapping it with some substance to provide support and induce scarring.

Advances in technology have led to the introduction of interventional neuroradiology for the treatment of aneurysms. These techniques are now being used more frequently. Endovascular techniques may be used in selected patients to occlude the blood flow from the artery that feeds the aneurysm with coils, liquid embolic agents, or other techniques to occlude the aneurysm itself. If the aneurysm is very large or very wide at its neck, a stent-like device made of a very fine mesh may be used to divert the blood flow away from the aneurysm. The determination of which technique should be used is based on many factors (characteristics of the patient and aneurysm) and is made by experienced endovascular specialists (Connolly et al., 2012); (Thompson, Brown, Amin-Hanjani, et al., 2015).

Postoperative complications are rare but can occur. Potential complications include psychological symptoms (disorientation, amnesia, Korsakoff syndrome [disorder characterized by psychosis, disorientation, delirium, insomnia, hallucinations, personality changes]), intraoperative embolization or artery rupture, postoperative artery occlusion, fluid and electrolyte disturbances (from dysfunction of the neurohypophyseal system), and gastrointestinal bleeding.

NURSING PROCESS

The Patient with a Hemorrhagic Stroke

Assessment

A complete neurologic assessment is performed initially and includes evaluation for the following:

- Altered level of consciousness
- Sluggish pupillary reaction
- Motor and sensory dysfunction
- Cranial nerve deficits (extraocular eye movements, facial droop, presence of ptosis)
- Speech difficulties and visual disturbance
- Headache and nuchal rigidity or other neurologic deficits

All patients should be monitored in the intensive care unit after an intracerebral or subarachnoid hemorrhage. Neurologic assessment findings are documented and reported as indicated. The frequency of these assessments varies depending on the patient's condition. Any changes in the patient's condition require reassessment and thorough documentation; changes should be reported immediately.

Nursing Alert: Alteration in level of consciousness often is the earliest sign of deterioration in a patient with a hemorrhagic stroke. Because nurses have the most frequent contact with patients, they are in the best position to detect subtle changes. Drowsiness and slight slurring of speech may be early signs that the level of consciousness is deteriorating.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective tissue perfusion (cerebral) related to bleeding or vasospasm
- Anxiety related to illness and/or medically imposed restrictions (aneurysm precautions)

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Vasospasm
- Seizures
- Hydrocephalus
- Rebleeding
- Hyponatremia

Planning and Goals

The goals for the patient may include improved cerebral tissue perfusion, relief of anxiety, and the absence of complications.

Nursing Interventions

Optimizing Cerebral Tissue Perfusion

The patient is closely monitored for neurologic deterioration resulting from recurrent bleeding, increasing ICP, or vasospasm. A neurologic flow record is maintained. The blood pressure, pulse, level of consciousness (an indicator of cerebral perfusion), pupillary responses, and motor function are checked hourly. Respiratory status is monitored, because a reduction in oxygen in areas of the brain with impaired autoregulation increases the chances of a cerebral infarction. Any changes are reported immediately.

Implementing Aneurysm Precautions. Cerebral aneurysm precautions are implemented for the patient with a diagnosis of aneurysm to provide a nonstimulating environment, prevent increases in ICP, and prevent further bleeding. The patient is placed on bed rest in a quiet, nonstressful environment, because activity, pain, and anxiety are thought to elevate the blood pressure, which may increase the risk for bleeding. Visitors may be restricted (American Association of Neuroscience Nurses [AANN], 2009); (Hickey, 2014).

The head of the bed is elevated 30 degrees to promote venous drainage and decrease ICP. Any activity that suddenly increases the blood pressure or obstructs venous return is avoided. This includes the Valsalva maneuver, straining, forceful sneezing, pushing oneself up in bed and acute flexion or rotation of the head and neck (which compromises the jugular veins). Stool softeners and mild laxatives are prescribed. Both prevent constipation, which can cause an increase in ICP. Dim lighting is helpful, because photophobia (visual intolerance of light) is common. The purpose of aneurysm precautions should be thoroughly explained to both the patient (if possible) and family. Intermittent pneumatic compression devices are prescribed to decrease the incidence of DVT resulting from immobility. The legs are observed for signs and symptoms of DVT (tenderness, redness, swelling, warmth, and edema), and abnormal findings are reported.

Relieving Anxiety

Sensory stimulation is kept to a minimum for patients on aneurysm precautions. For patients who are awake, alert, and oriented, an explanation of the restrictions helps reduce the patient's sense of isolation. Reality orientation is provided to help maintain orientation.

Keeping the patient well informed of the plan of care provides reassurance and helps minimize anxiety. Appropriate reassurance also helps relieve the patient's fears and anxiety. The family also requires information and support.

Monitoring and Managing Potential Complications

Vasospasm. The patient is assessed for signs of possible vasospasm: intensified headaches, a decrease in level of responsiveness (confusion, disorientation, lethargy), or evidence of aphasia or partial paralysis. These signs may develop several days after surgery or on the initiation of treatment and must be reported immediately. The calcium channel blocker nimodipine should be given for prevention of vasospasm, and fluid volume expanders in the form of triple-H therapy may be prescribed as well (Connolly et al., 2012).

Seizures. Seizure precautions are maintained for every patient who may be at risk for seizure activity. Should a seizure occur, maintaining the airway and preventing injury are the primary goals. Medication therapy is initiated at this time (see Chapter 51).

Hydrocephalus. Blood in the subarachnoid space or ventricles impedes the circulation of CSF, resulting in hydrocephalus. A CT scan that indicates dilated ventricles confirms the diagnosis. Hydrocephalus can occur within the first 24 hours (acute) after subarachnoid hemorrhage or several days (subacute) to several weeks (delayed) later. Symptoms vary according to the time of onset and may be nonspecific. Acute hydrocephalus is characterized by sudden onset of stupor or coma and is managed with a ventriculostomy drain to decrease ICP. Symptoms of subacute and delayed hydrocephalus include gradual onset of drowsiness, behavioral changes, and ataxic

gait. A ventriculoperitoneal shunt is surgically placed to treat chronic hydrocephalus. Changes in patient responsiveness are reported immediately.

Rebleeding. The rate of recurrent hemorrhage is approximately 1% to 5% per patient per year after intracerebral hemorrhage (Hemphill et al., 2015). Hypertension is the most serious and modifiable risk factor, which shows the importance of appropriate antihypertensive treatment.

Aneurysm rebleeding is the highest during the first 2 to 12 hours after the initial hemorrhage (Connolly et al., 2012) and is considered a major complication. Symptoms of rebleeding include sudden severe headache, nausea, vomiting, decreased level of consciousness, and neurologic deficit. Rebleeding is confirmed by CT scan. Blood pressure is carefully maintained with medications. The most effective preventive treatment is to secure the aneurysm if the patient is a candidate for surgery or endovascular treatment.

Hyponatremia. After subarachnoid hemorrhage, hyponatremia is found in 10% to 30% of patients. Hyponatremia has been found to be associated with the onset of vasospasm (Connolly et al., 2012). Laboratory data must be checked frequently, and hyponatremia (defined as a serum sodium concentration less than 135 mEq/L) must be identified as early as possible. The patient's primary provider needs to be notified of a low serum sodium level that has persisted for 24 hours or longer. The patient is then evaluated for syndrome of inappropriate antidiuretic hormone (SIADH) or cerebral salt-wasting syndrome. SIADH is described in Chapter 7. Cerebral salt-wasting syndrome occurs when the kidneys are unable to conserve sodium and volume depletion results. The treatment most often is the use of IV hypertonic 3% saline.

Promoting Home, Community-Based, and Transitional Care

Educating Patients about Self-Care. The patient and family are provided with education that will enable them to cooperate with the care and restrictions required during the acute phase of hemorrhagic stroke and to prepare them to return home. Patient and family education includes information about the causes of hemorrhagic stroke and its possible consequences. In addition, the patient and family are informed about the medical treatments that are implemented, including surgical intervention if warranted, and the importance of interventions taken to prevent and detect complications (i.e., aneurysm precautions, close monitoring of the patient). Depending on the presence and severity of neurologic impairment and other complications resulting from the stroke, the patient may be transferred to a rehabilitation unit or center for additional patient and family education about strategies to regain self-care ability. Education addresses the use of assistive devices or modification of the home environment to help the patient live with the disability. Modifications of the home may be required to provide a safe environment.

Continuing and Transitional Care. The acute and rehabilitation phase of care focuses on obvious needs, issues, and deficits for the patient with a hemorrhagic stroke. The patient and family are reminded of the importance of following recommendations to prevent further hemorrhagic stroke and keeping follow-up appointments with health care providers for monitoring of risk factors. Referral for home, community-based, or transitional care may be warranted to assess the home environment and the ability of the patient and to ensure that the patient and family are able to manage at home. Home visits provide opportunities to monitor the physical and psychological status of the patient and the ability of the family to cope with any alterations in the patient's status. In addition, the home care nurse reminds the patient and family of the importance of continuing health promotion and screening practices. Chart 50-6 lists education for the patient recovering from a stroke.

Chart 50-6 HOME CARE CHECKLIST

The Patient Recovering from a Stroke

At the completion of education, the patient and/or caregiver will be able to:

- State the impact of the stroke on physiologic functioning, ADLs, IADLs, roles, relationships, and spirituality.
- State names, dose, side effects, frequency and schedule for all medications.
- State how to contact all members of the treatment team (e.g., health care providers, home care professionals, rehabilitation team, and durable medical equipment and supply vendor).
- State changes in lifestyle (e.g., diet, ADLs, IADLs, activity) necessary for recovery and health maintenance as applicable.
  - Demonstrate environmental modifications and adaptive techniques for accomplishing activities of daily living.
  - Demonstrate home exercises, the use of splints or orthotics, proper positioning, and frequent repositioning.
  - Identify safety measures to prevent falls.
  - Identify holistic interventions for pain management (e.g., positioning, distraction).
  - Describe procedures for maintaining skin integrity.
  - Demonstrate indwelling catheter care, if applicable. Describe a bowel and bladder elimination program as appropriate.
  - Verbalize dietary adjustments (e.g., thickened liquids, pureed diet, small frequent meals) during recovery.
  - Demonstrate swallowing techniques or care of enteral feeding tube.
- Identify psychosocial consequences of stroke (e.g., depression, emotional lability, frustration, fatigue) and appropriate interventions.
- Discuss measures to prevent subsequent strokes.
- Identify potential complications and discuss measures to prevent them (blood clots, aspiration, pneumonia, urinary tract infection, fecal impaction, skin breakdown, contracture).
- Relate how to reach primary provider with questions or complications.
- State time and date of follow-up medical appointments, therapy, and testing.
- Identify resources and other sources of support (e.g., friends, relatives, faith community, stroke support groups, caregiver support).
- Identify the need for health promotion, disease prevention, and screening activities
- Identify appropriate recreational or diversional activities

ADL, activities of daily living; IADL, independent activities of daily living.

Evaluation

Expected patient outcomes may include:

1. Demonstrates stable neurologic status and vital signs and respiratory patterns within normal limits
   a. Is alert and oriented to time, place, and person
   b. Demonstrates understandable speech patterns and stable cognitive processes
   c. Demonstrates usual and equal strength, movement, and sensation of all four extremities
   d. Exhibits deep tendon reflexes and pupillary responses within normal limits

2. Exhibits reduced anxiety level
   a. States rationale for aneurysm precautions
   b. Exhibits clear thought processes
   c. Is less restless
   d. Exhibits absence of physiologic indicators of anxiety (e.g., has vital signs within normal limits; usual respiratory rate; absence of excessive, fast speech)
3. Is free of complications
   a. Exhibits absence of vasospasm
   b. Exhibits vital signs within normal limits and is without seizures
   c. Verbalizes understanding of seizure precautions
   d. Exhibits intact mental, motor, and sensory status
   e. Reports no visual changes

CRITICAL THINKING EXERCISES

1. A 72-year-old male is in the ED being evaluated for a suspected stroke. Identify the priorities, approach and techniques you would use to provide care for him. What are specific time goals for obtaining a head CT scan? If he is eligible for t-PA, how will your priorities change? If his stroke is a hemorrhagic stroke, how will your approach, techniques, and priorities change?
2. You are caring for a patient after a large ischemic stroke. The patient has hemiplegia and is beginning to experience shoulder pain on the side affected by the stroke. Identify the priority nursing interventions that can be implemented to prevent shoulder pain. What education can you provide to the patient for interventions that can be done at home once discharged?
3. A 69-year-old woman has experienced a brainstem stroke. She has just arrived to the nursing unit from the ED and you are her nurse. She has not had a swallow assessment yet. What is the time goal for obtaining an evaluation of her swallowing function? Evaluate the strength of the evidence to support nurses performing dysphagia screening.
