Hemorrhage frequently accompanies abdominal injury, especially if the liver or spleen has been traumatized. Therefore, the patient is assessed continuously for signs and symptoms of external and internal bleeding. The front of the body, flanks, and back are inspected for bluish discoloration, asymmetry, abrasion, and contusion. Abdominal CT scans permit detailed evaluation of abdominal contents and retroperitoneal examination. Abdominal ultrasounds can be used to rapidly assess patients who are hemodynamically unstable to detect

intraperitoneal bleeding. This is referred to as the focused assessment with sonography for trauma (FAST) examination (ACS, 2013). During the resuscitation period, pain is managed using administration of small dosages of opioids (ACS, 2013).

Nursing Alert: The location of pain can indicate certain types of intra-abdominal injuries. Pain in the left shoulder is common in a patient with bleeding from a ruptured spleen, whereas pain in the right shoulder can result from laceration of the liver.

Intraperitoneal Injury

The abdomen is assessed for tenderness, rebound tenderness, guarding, rigidity, spasm, increasing distention, and pain. Referred pain is a significant finding because it suggests intraperitoneal injury. To determine if there is intraperitoneal injury and bleeding, the patient is usually prepared for diagnostic procedures, such as peritoneal lavage, abdominal ultrasonography, or abdominal CT scanning. Diagnostic peritoneal lavage (DPL), although no longer the standard diagnostic study used to evaluate a traumatized abdomen, remains a backup procedure that is easily performed and is very useful during mass casualty situations when CT scanners may not be readily available. DPL involves the instillation of 1 L of warmed lactated Ringer's or normal saline solution into the abdominal cavity. After a minimum of 400 mL has been returned, a fluid specimen is sent to the laboratory for analysis. Positive laboratory findings include a red blood cell count greater than 100,000/mm^3; a WBC count greater than 500/mm^3; or the presence of bile, feces, or food (ACS, 2013).

In patients with stab wounds, sinography may be performed to detect peritoneal penetration; a purse-string suture is placed around the wound and a small catheter is introduced through the wound. A contrast agent is then introduced through the catheter, and x-rays are taken to identify any peritoneal penetration.

Genitourinary Injury

A focused genitourinary examination, which typically includes a rectal and/or vaginal examination, is performed to determine any injury to the pelvis, bladder, urethra, vagina, or intestinal wall. In the male patient, a high-riding prostate gland (abnormal position) discovered during a rectal examination indicates a potential urethral injury. A digital vaginal examination is performed on female patients to determine if there is an open pelvic fracture that has torn the vagina.

Nursing Alert: To decompress the bladder and monitor urine output in a patient with a genitourinary injury, an indwelling catheter is inserted after a rectal examination has been completed, not before the examination. In addition, urethral catheter insertion when a possible urethral injury is present is contraindicated; a urology consultation and further evaluation of the urethra are required.

Management

As indicated by the patient's condition, resuscitation procedures (restoration of airway, breathing, and circulation) are initiated as described previously.

With blunt trauma, the patient is kept on a stretcher to immobilize the spine. If the patient has been placed on a backboard, it should be removed as early as possible to prevent skin breakdown. Cervical spine immobilization is maintained until cervical x-rays have been obtained and cervical spine injury has been ruled out. Likewise, once the backboard is removed, logrolling can be used to protect the spine until x-rays are obtained and confirm that there is no evidence of injuries.

Knowing the mechanism of injury (e.g., penetrating force from a gunshot or knife, blunt force from a blow) is essential to determining the type of management needed. All wounds are located, counted, and documented. If abdominal viscera protrude, the area is covered with sterile, moist saline dressings to keep the viscera from drying.

Typically, oral fluids are withheld in anticipation of surgery, and the stomach contents are aspirated with an orogastric tube to reduce the risk of aspiration and to decompress the stomach in preparation for diagnostic procedures.

Trauma predisposes the patient to infection by disruption of mechanical barriers, exposure to exogenous bacteria from the environment at the time of injury, aspiration of vomitus, and diagnostic and therapeutic procedures (hospital-acquired infection). Tetanus prophylaxis and broad-spectrum antibiotics are given as prescribed.

Throughout the stay in the ED, the patient's condition is continuously monitored for changes. If there is continuing evidence of shock, blood loss, free air under the diaphragm, evisceration, hematuria, severe head injury, musculoskeletal injury, or suspected or known abdominal injury, the patient is rapidly transported to surgery. In most cases, blunt liver and spleen injuries are managed nonsurgically. The goal for the management of all patients who have experienced trauma is to minimize the length of stay in the ED. The patient should be moved to the definitive destination quickly so that care and rehabilitation can continue.

Crush Injuries

Crush injuries occur when a person is caught between opposing forces (e.g., run over by a moving vehicle, crushed between two cars, crushed under a collapsed building).

Assessment and Diagnostic Findings

The patient is observed for the following:

- Hypovolemic shock resulting from extravasation of blood and plasma into injured tissues after compression has been released (see Chapter 8)
- Spinal cord injury (see Chapter 51)
- Erythema and blistering of skin
- Fractures (usually an extremity) (see Chapter 38)
- Acute kidney injury (acute tubular necrosis [ATN]) (see Chapter 44)

Management

In conjunction with maintaining the airway, breathing, and circulation, the patient is observed for acute kidney injury (AKI). Injury to the back can cause renal trauma (see Chapter 44). Severe muscular damage may cause rhabdomyolysis, a toxic syndrome caused by a release of myoglobin from ischemic skeletal muscle, resulting in ATN. See Chapter 44 for the treatment of AKI and ATN. Rhabdomyolysis may also result from major burns (see Chapter 47), heat stroke, and abuse of illicit drugs, in addition to crush injuries (see later discussions). The classic triad of clinical manifestations suggestive of rhabdomyolysis includes myalgias (muscle cramps), generalized muscle weakness, and

darkened urine. The serum creatine kinase (CK) is monitored as the most sensitive indicator of rhabdomyolysis; levels in excess of 6000 IU/L are considered diagnostic (Muscal & DeGuzman, 2016). In addition to treatment aimed at preventing or treating ATN, major soft tissue injuries are splinted promptly to control bleeding and pain. The serum lactic acid level is monitored; a decrease to less than 2.5 mmol/L is an indication of successful resuscitation (Blow, Magliore, Claridge, et al., 1999).

If an extremity is injured, it is elevated to relieve swelling and pressure. If compartment syndrome develops, the physician may perform a fasciotomy (i.e., surgical incision to the level of the fascia) to restore neurovascular function (see Chapter 38). Medications for pain and anxiety are then given as prescribed, and the patient is quickly transported to the operating suite for wound débridement and fracture repair. A hyperbaric oxygen chamber (if available) may be used to hyperoxygenate crushed tissue, if indicated.

Fractures

Immediate appropriate management of a fracture may determine the patient's eventual outcome and may mean the difference between recovery and disability. When the patient is being examined for fracture, the body part is handled gently and as little as possible. Clothing is cut off to visualize the affected body part. Assessment is conducted for pain over or near a bone, swelling (from blood, lymph, and exudate infiltrating the tissue), and circulatory disturbance. The patient is assessed for ecchymosis, tenderness, and crepitation (see Chapter 38). The nurse must remember that the patient may have multiple fractures accompanied by head, chest, spine, or abdominal injuries.

Management

Immediate attention is given to the patient's general condition. Assessment of airway, breathing, and circulation (which includes pulses in the extremities) is conducted. The patient is also evaluated for neurologic or abdominal injuries before the extremity is treated, unless a pulseless extremity is detected.

If a pulseless extremity is identified, repositioning of the extremity to proper alignment is required. If the pulseless extremity involves a fractured femur, Hare traction (a portable in-line traction device) may be applied to assist with alignment. If repositioning is ineffective in restoring the pulse, a rapid total-body assessment must be completed, followed by transfer of the patient to the operating room for arteriography and possible arterial repair versus amputation.

After the initial evaluation has been completed, all injuries identified are evaluated and treated. The fractured body part is inspected. Using a systematic head-to-toe approach, the nurse inspects the entire body, observing for lacerations, swelling, and deformities, including angulation (bending), shortening, rotation, and asymmetry. All peripheral pulses, especially those distal to the fractured extremity, are palpated. The extremity is also assessed for coolness, blanching, and decreased sensation and motor function, which are indicative of injury to the extremity's neurovascular supply.

A splint is applied before the patient is moved. Splinting immobilizes the joint at a site distal and proximal to the fracture, relieves pain, restores or improves circulation, prevents further tissue injury, and prevents a closed fracture from becoming an open one. To splint an extremity, one hand is placed distal to the fracture and some traction is applied while the other hand is placed beneath the fracture for support. The splints should extend beyond the joints adjacent to the fracture. Upper extremities must be splinted in a functional position. If the fracture is open, a moist, sterile dressing is applied.

After splinting, the vascular status of the extremity is checked by assessing color, temperature, pulse, and blanching of the nail bed. In addition, the patient is assessed for neurovascular compromise if pain or pressure is reported. See Chapter 38 for a complete description of fracture management.

ENVIRONMENTAL EMERGENCIES

Heat-Induced Illnesses

Heat-induced illnesses may range in severity from mild and self-limiting to life-threatening emergencies. The most serious of these—heat stroke—is an acute medical emergency caused by failure of the heat-regulating mechanisms of the body. It is the inability to maintain cardiac output in the face of moderately high body temperatures and is associated with dehydration. The most common cause of heat stroke is nonexertional, prolonged exposure to an environmental temperature of greater than 39.2°C (102.5°F), although a heat index of greater than 35°C (95°F) is associated with increased mortality (Auerbach, 2017). It usually occurs during extended heat waves, especially when they are accompanied by high humidity. Exertional heat stroke is caused by strenuous physical activity that occurs in a hot environment (Auerbach, 2017); (ENA, 2013).

People at risk for nonexertional heat stroke are those not acclimatized to heat, those who are older or very young, those unable to care for themselves, those with chronic and debilitating diseases, and those taking certain medications (e.g., major tranquilizers, anticholinergics, diuretics, beta blockers) (Tintinalli, Stapcyznski, Ma, et al., 2016); (ENA, 2013). In a study of heat-induced injury from 2006 to 2010, mortality was greater among older adults, men, and patients with pre-existing chronic illnesses. Heat-related events occurred most often in rural areas (Hess, Saha, & Luber, 2014). Exertional heat stroke occurs in healthy individuals during sports or work activities (e.g., exercising in extreme heat and humidity). Hyperthermia results because of inadequate heat loss. Strategies used to prevent heat stroke are reviewed in Chart 60-5.

Less severe forms of heat-induced illnesses include heat exhaustion and heat cramps or heat illness. The causes of heat exhaustion are the same as for heat stroke. Heat illness is caused by a loss of electrolytes, typically during strenuous physical activity in a hot environment (ENA, 2013).

Gerontologic Considerations

Most heat-related deaths occur in older adults because their circulatory systems are unable to compensate for stress imposed by heat. Older adults have a decreased ability to perspire as well as a decreased ability to vasodilate and vasoconstrict. They have less subcutaneous tissue, a decreased thirst mechanism, and a diminished ability to concentrate urine to compensate for heat. Many older adults do not drink adequate amounts of fluid, partly because of fear of incontinence, and thus have a greater risk of heat stroke. In addition, many older adults fear being victims of crime, so even if their residence lacks air conditioning, they tend to keep windows closed despite high temperatures and humidity levels (ENA, 2013).

Chart 60-5 HEALTH PROMOTION

Preventing Heat-Induced Illnesses

The nurse provides the following advice for the patient treated for heat-induced illness:

- Avoid immediate re-exposure to high temperatures; hypersensitivity to high temperatures may remain for a considerable time.
- Maintain adequate fluid intake, wear loose clothing, and reduce activity in hot weather.
- Monitor fluid losses and weight loss during workout activities or exercise and replace fluids and electrolytes.
- Use a gradual approach to physical conditioning, allowing sufficient time for return to baseline temperature.
- Plan outdoor activities to avoid the hottest part of the day (between 10 AM and 2 PM).

For older patients living in urban settings with high environmental temperatures:

- The nurse directs these patients to places where air conditioning is available (e.g., shopping mall, library, church) and advises them that fans alone are not adequate to prevent heat-induced illness.

Assessment and Diagnostic Findings

Heat stroke, whether the cause is exertional or nonexertional, causes thermal injury at the cellular level, resulting in coagulopathies and widespread damage to the heart, liver, and kidneys. Recent patient history reveals exposure to elevated ambient temperature or excessive exercise during extreme heat. When assessing the patient, the nurse notes the following symptoms: profound central nervous system (CNS) dysfunction (manifested by confusion, delirium, bizarre behavior, coma, seizures); elevated body temperature (40.6°C [105°F] or higher); hot, dry skin; and usually anhidrosis (absence of sweating), tachypnea, hypotension, and tachycardia. The patient with heat exhaustion, on the other hand, may exhibit similarly high body temperatures accompanied by headaches, anxiety, syncope, profuse diaphoresis, gooseflesh, and orthostasis. The cardinal manifestations of heat cramps include muscle cramps, particularly in the shoulders, abdomen, and lower extremities; profound diaphoresis; and profound thirst (ENA, 2013).

Management

The main goal is to reduce the high body temperature as quickly as possible, because mortality in heat stroke or morbid progression to heat stroke with less serious forms of heat-induced illnesses is directly related to the duration of hyperthermia. For the patient with heat stroke, simultaneous treatment focuses on stabilizing oxygenation using the CABs (*c*irculation, *a*irway, and *b*reathing) (formerly referred to as the ABCs) of basic life support. This includes establishing IV access for fluid administration.

After the patient's clothing is removed, the core (internal) temperature is reduced to 39°C (102°F) as rapidly as possible, preferably within 1 hour (Auerbach, 2017). One or more of the following methods may be used as prescribed (Auerbach, 2017):

- Cool sheets and towels or continuous sponging with cool water
- Ice applied to the neck, groin, chest, and axillae while spraying with tepid water
- Cooling blankets
- Immersion of the patient in a cold water bath is the optimal method for cooling (if available)

During cooling procedures, an electric fan is positioned so that it blows on the patient to augment heat dissipation by convection and evaporation. The patient's temperature is constantly monitored with a thermistor placed in the rectum, bladder, or esophagus to evaluate core temperature. Caution is used to avoid hypothermia and to prevent hyperthermia, which may recur spontaneously within 3 to 4 hours. The cooling process should stop at 38°C (100.4°F) in order to avoid iatrogenic hypothermia (ENA, 2013).

Throughout treatment, the patient's status is monitored carefully, including vital signs, ECG findings (for possible myocardial ischemia, myocardial infarction, and dysrhythmias), central venous pressure (CVP), and level of responsiveness, all of which may change with rapid alterations in body temperature. A seizure may be followed by recurrence of hyperthermia. To meet tissue needs exaggerated by the hypermetabolic condition, 100% oxygen is given. Endotracheal intubation and mechanical ventilation to support failing cardiopulmonary systems may be required.

IV infusion therapy of normal saline or lactated Ringer solution is initiated as directed to replace fluid losses and maintain adequate circulation. Fluids are given carefully because of the dangers of myocardial injury from high body temperature and poor kidney function. Cooling redistributes fluid volume from the periphery to the core.

Urine output is also measured frequently, because ATN may occur as a complication of heat stroke from rhabdomyolysis (see previous discussion). Blood specimens are obtained for serial testing to detect bleeding disorders, such as disseminated intravascular coagulation, and for serial enzyme studies to estimate thermal hypoxic injury to the liver, heart, and muscle tissue. Permanent liver, cardiac, and CNS damage may occur.

Additional supportive care may include dialysis for AKI, anticonvulsant medications to control seizures, potassium for hypokalemia, and sodium bicarbonate to correct metabolic acidosis. Benzodiazepines such as diazepam (Valium) may be prescribed to suppress seizure activity, while a phenothiazine such as chlorpromazine (Thorazine) may be prescribed to suppress shivering (Auerbach 2017); (Tintinalli et al., 2016).

Patients with heat exhaustion or heat cramps may be managed less aggressively. These patients should lie supine in a cool environment. Patients with heat exhaustion may require IV fluids but may also take oral fluids, if they are tolerated. Patients with heat cramps are given oral sodium supplements and oral electrolyte solutions (ENA, 2013). Patients who have experienced a heat-induced illness should receive education to prevent another heat-related illness (see Chart 60-5).

Frostbite

Frostbite is trauma from exposure to freezing temperatures and freezing of the intracellular fluid and fluids in the intercellular spaces. It results in cellular and vascular damage. Frostbite can result in venous stasis and thrombosis. Body parts most frequently affected by frostbite include the feet, hands, nose, and ears. Frostbite ranges from first degree (redness and erythema) to fourth degree (full-depth tissue destruction).

Assessment and Diagnostic Findings

A frozen extremity may be hard, cold, and insensitive to touch and may appear white or mottled blue-white. The extent of injury from exposure to cold is not always initially known. The patient history should include environmental temperature, duration

of exposure, clothing worn, humidity, and the presence of wet conditions. Protective clothing may partially prevent exposure to cold environments; however, wearing wet socks and exercise/movement may diminish the protective effects of insulation by 45% (Auerbach 2017); (Zafren, 2013).

Management

The goal of management is to restore normal body temperature. Constrictive clothing and jewelry that could impair circulation are removed. Wet clothing is removed as rapidly as possible. If the lower extremities are involved, the patient should not be allowed to ambulate.

Controlled yet rapid rewarming is instituted. Frozen extremities are usually placed in a 37°C to 40°C (98.6°F to 104°F) circulating bath for 30- to 40-minute spans. This treatment is repeated until circulation is effectively restored. Early rewarming appears to decrease the amount of ultimate tissue loss. During rewarming, an analgesic for pain is given as prescribed, because the rewarming process may be very painful. To avoid further mechanical injury, the body part is not handled. Massage is contraindicated.

Once rewarmed, the part is protected from further injury and is elevated to help control swelling. Sterile gauze or cotton is placed between affected fingers or toes to prevent maceration, and a bulky dressing is placed on the extremity. A foot cradle may be used to prevent contact with bedclothes if the feet are involved. Hemorrhagic blebs, which may develop 1 hour to a few days after rewarming, are left intact and not ruptured. Nonhemorrhagic blisters are débrided to decrease the inflammatory mediators found in the blister fluid.

A physical assessment is conducted with rewarming to observe for concomitant injury, such as soft tissue injury, dehydration, alcohol intoxication, or fat embolism. Problems such as hyperkalemia (e.g., from release of potassium in the damaged cells) and hypovolemia, which occur frequently in people with frostbite, are corrected. Risk of infection is also great; therefore, aseptic technique is used during dressing changes, and tetanus prophylaxis is given as indicated. Nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed for their anti-inflammatory effects and to control pain.

Additional measures that may be carried out when appropriate after emergency stabilization measures have been instituted include the following:

- Whirlpool bath for the affected body parts to aid circulation and débridement of necrotic tissue to help prevent infection
- Escharotomy (incision through the eschar) to prevent further tissue damage, to allow for normal circulation, and to permit joint motion
- Fasciotomy to treat compartment syndrome

After rewarming, hourly active motion of any affected digits is encouraged to promote maximal restoration of function and to prevent contractures. Discharge instructions also include encouraging the patient to avoid tobacco, alcohol, and caffeine because of their vasoconstrictive effects, which further reduce the already deficient blood supply to injured tissues.

Hypothermia

Hypothermia is a condition in which the core (internal) temperature is 35°C (95°F) or less as a result of exposure to cold or an inability to maintain body temperature in the absence of low ambient temperatures. Urban hypothermia (extreme exposure to cold in an urban setting) is associated with a high mortality rate; older adults, infants, people with concurrent illnesses, and those who are homeless are particularly susceptible. Alcohol ingestion increases susceptibility because it causes systemic vasodilation. Some medications (e.g., phenothiazines) or medical conditions (e.g., hypothyroidism, spinal cord injury) decrease the ability to shiver, hampering the body's innate ability to generate body heat. Fatigue and sleep deprivation are also associated with the development of hypothermia. Heat loss of 2% is normal but increases with exposure. Wet clothing accelerates heat loss, and immersion in cold water increases heat loss by 25% (ENA, 2013). Victims of trauma are also at risk for hypothermia resulting from treatment with cold fluids, unwarmed oxygen, and exposure during examination. The patient may also have frostbite, but hypothermia takes precedence in treatment.

Assessment and Diagnostic Findings

Hypothermia leads to physiologic changes in all organ systems. There is progressive deterioration, with apathy, poor judgment, ataxia, dysarthria, drowsiness, pulmonary edema, acid–base abnormalities, coagulopathy, and eventual coma. Shivering may be suppressed at a temperature of less than 32.2°C (90°F), because the body's self-warming mechanisms become ineffective. The heartbeat and blood pressure may be so weak that peripheral pulses become undetectable. Cardiac dysrhythmias may also occur. Other physiologic abnormalities include hypoxemia and acidosis.

Management

Management consists of removal of wet clothing, continuous monitoring, rewarming, and supportive care.

Monitoring

The CABs of basic life support are a priority. The patient's vital signs, CVP, urine output, arterial blood gas levels, blood chemistry determinations (blood urea nitrogen, creatinine, glucose, electrolytes), and chest x-rays are evaluated frequently. Core body temperature is monitored with an esophageal, bladder, or rectal thermistor. Continuous ECG monitoring is performed, because cold-induced myocardial irritability leads to conduction disturbances, especially ventricular fibrillation. An arterial line is inserted and maintained to record blood pressure and to facilitate blood sampling.

Rewarming

Rewarming methods include active internal (core) rewarming and passive (spontaneous) or active external rewarming.

Active internal (core) rewarming methods are used for moderate to severe hypothermia (less than 28°C to 32.2°C [82.5°F to 90°F]) and include cardiopulmonary bypass, warm fluid administration, warmed humidified oxygen by ventilator, and warmed peritoneal lavage. Monitoring for ventricular fibrillation as the patient's temperature increases from 31°C to 32°C (88°F to 90°F) is essential.

Passive or active external rewarming is used for mild hypothermia (32.2°C to 35°C [90°F to 95°F]). Passive external rewarming uses over-the-bed heaters to the extremities and increases blood flow to the acidotic, anaerobic extremities. The cold blood from peripheral tissues has high lactic acid levels. As this blood returns to the core, it causes a significant drop in the core temperature (i.e., core temperature afterdrop) and can potentially cause cardiac dysrhythmias and electrolyte

disturbances. Active external rewarming uses forced-air warming blankets. Care must be taken to prevent extremity burn from these devices, because the patient may not have effective sensation to feel the burn.

Supportive Care

Supportive care during rewarming includes the following as directed:

- External cardiac compression (typically performed only as directed in patients with temperatures higher than 31°C [88°F])
- Defibrillation of ventricular fibrillation. A patient whose temperature is less than 32°C [90°F] experiences spontaneous ventricular fibrillation if moved or touched. Defibrillation is ineffective in patients with temperatures lower than 31°C (88°F); therefore, the patient must be rewarmed first.
- Mechanical ventilation with positive end-expiratory pressure (PEEP) and heated humidified oxygen to maintain tissue oxygenation
- Administration of warmed IV fluids to correct hypotension and to maintain urine output and core rewarming, as described previously
- Administration of sodium bicarbonate to correct metabolic acidosis if necessary
- Administration of antiarrhythmic medications
- Insertion of an indwelling urinary catheter to monitor urinary output and kidney function

Nonfatal Drowning

Nonfatal drowning is defined as survival for at least 24 hours after submersion that caused a respiratory arrest. The most common consequence is hypoxemia. Children under 5 years of age and those over the age of 85 have the highest risk of drowning (CDC 2014). An estimated 372,000 drownings occur throughout the world annually, accounting for 7% of global mortality from unintentional injury (World Health Organization [WHO], 2016). Drowning and nonfatal drowning can be prevented by avoiding rip currents offshore; approximately 85% of shore drownings involve a rip current. Pool drownings can be prevented by surrounding the pool with fencing, a self-latching/closing gate, and providing swimming lessons. Supervision near water is still the best prevention measure. When boating, a personal flotation device (PFD), even for swimmers, prevents drowning events. Approximately 50% of nonfatal drownings require hospital admission for management (WHO, 2016).

Factors associated with drowning and nonfatal drowning include alcohol ingestion, inability to swim, diving injuries, hypothermia, and exhaustion. The majority of drowning events occur in pools, lakes, and bathtubs. Suicide by drowning rarely occurs in pools and rarely involves alcohol (Auerbach, 2017).

Efforts to save the patient should not be abandoned prematurely. Successful resuscitation with full neurologic recovery has occurred in patients who have experienced nonfatal drowning after prolonged submersion in cold water. This is possible because of a decrease in metabolic demands and/or the diving reflex. The nonfatal drowning process involves the onset of hypoxia, hypercapnia, bradycardia, and dysrhythmias. If there is a violent struggle associated with the nonfatal drowning episode, exercise-induced acidosis and tachypnea can result in aspiration. Hypoxia and acidosis cause eventual apnea and loss of consciousness. When the victim loses consciousness and makes a final effort to breathe, the terminal gasp occurs. Water then moves passively into the airways prior to death.

After resuscitation, hypoxia and acidosis are the major complications experienced by a person who has experienced nonfatal drowning; immediate intervention in the ED is essential. Resultant pathophysiologic changes and pulmonary injury depend on the type of fluid (fresh or salt water) and the volume aspirated. Freshwater aspiration results in a loss of surfactant and, therefore, an inability to expand the lungs. Salt-water aspiration leads to pulmonary edema from the osmotic effects of the salt within the lungs. If a person survives submersion, acute respiratory distress syndrome (ARDS), resulting in hypoxia, hypercarbia, and respiratory or metabolic acidosis, can occur.

Management

Therapeutic goals include maintaining cerebral perfusion and adequate oxygenation to prevent further damage to vital organs. Cardiopulmonary resuscitation is the factor with the greatest influence on survival. The most important priority in resuscitation is to manage the hypoxia, acidosis, and hypothermia. Prevention and management of hypoxia are accomplished by ensuring an adequate airway and respiration, thus improving ventilation (which helps correct respiratory acidosis) and oxygenation. Arterial blood gases are monitored to evaluate oxygen, carbon dioxide, bicarbonate levels, and pH. These parameters determine the type of ventilatory support needed. The use of endotracheal intubation with PEEP improves oxygenation, prevents aspiration, and corrects intrapulmonary shunting and ventilation–perfusion abnormalities (caused by aspiration of water). If the patient is breathing spontaneously, supplemental oxygen may be given by mask. However, an endotracheal tube is necessary if the patient does not breathe spontaneously.

Because of submersion, the patient is usually hypothermic. A rectal probe or other core measurement device is used to determine the degree of hypothermia. Prescribed rewarming procedures (e.g., extracorporeal warming, warmed peritoneal dialysis, inhalation of warm aerosolized oxygen, torso warming) are started during resuscitation. The choice of warming method is determined by the severity and duration of hypothermia and available resources. Intravascular volume expansion and inotropic agents are used to treat hypotension and impaired tissue perfusion. ECG monitoring is initiated, because dysrhythmias frequently occur. An indwelling urinary catheter is inserted to measure urine output. Hypothermia and accompanying metabolic acidosis may compromise kidney function. Nasogastric intubation is used to decompress the stomach and to prevent the patient from aspirating gastric contents.

Even if the patient appears healthy, close monitoring continues with serial vital signs, serial arterial blood gas values, ECG monitoring, intracranial pressure assessments, serum electrolyte levels, intake and output, and serial chest x-rays. After a nonfatal drowning, the patient is at risk for complications such as hypoxic or ischemic cerebral injury, ARDS, and life-threatening cardiac arrest. The patient is also at heightened risk for aspiration; vomiting frequently occurs in patients requiring rescue breathing and in up to 86% of patients requiring CPR (Auerbach, 2017).

Decompression Sickness

Decompression sickness, also known as "the bends," occurs in patients who have engaged in diving (lake/ocean diving),

high-altitude flying, or flying in commercial aircraft within 24 hours after diving. Its effects can be hazardous. Being aware of decompression sickness and assessing the patient properly ensures appropriate management and results in decreased morbidity.

Decompression sickness results from formation of nitrogen bubbles that occur with rapid changes in atmospheric pressure. They may occur in joint or muscle spaces, resulting in musculoskeletal pain, numbness, or hypesthesia. More significantly, nitrogen bubbles can become air emboli in the bloodstream and thereby produce stroke, paralysis, or death. Taking a rapid history about the events preceding the symptoms is essential.

Assessment and Diagnostic Findings

To identify decompression sickness, a detailed history is obtained from the patient or diving partner. Evidence of rapid ascent, loss of air in the tank, buddy breathing, recent alcohol intake or lack of sleep, or a flight within 24 hours after diving suggests possible decompression sickness. Some patients describe a perfect dive yet still have the signs and symptoms of decompression sickness, in which case they must receive treatment for the condition.

Signs and symptoms include joint or extremity pain, numbness, hypesthesia, and loss of range of motion. Neurologic symptoms mimicking those of a stroke or spinal cord injury can indicate an air embolus. Cardiopulmonary arrest can also occur in severe cases and is usually fatal. Any neurologic symptoms should be rapidly assessed. All patients with decompression sickness need rapid transfer to a hyperbaric chamber.

Management

A patent airway and adequate ventilation are established, as described previously, and 100% oxygen is given throughout treatment and transport. A chest x-ray is obtained to identify aspiration, and at least one IV line is started with lactated Ringer's or normal saline solution. Research findings suggest that among patients requiring air transport (e.g., helicopter), oxygen saturations and symptoms improve when both oxygen and IV fluids are given and the transport flight remains at low altitude (i.e., below 300 m [approximately 1000 feet]) (Oode, Yanagawa, Omori, et al., 2015).

The cardiopulmonary and neurologic systems are supported as needed. If an air embolus is suspected, the head of the bed should be lowered. If the patient's wet clothing is still present, it is removed. The patient is kept warm. Transfer to the closest hyperbaric chamber for treatment is initiated. If air transport is necessary, low-altitude flight (below 300 m) is required (Oode et al., 2015). However, the patient who is awake and alert without central neurologic deficits may be able to travel by ground ambulance or by automobile, depending on the severity of symptoms. Throughout treatment, the patient is continually assessed, and changes are documented. If aspiration is suspected, antibiotic agents and other treatment may be prescribed.

Animal and Human Bites

Bites are a common reason for visits to the ED. Dog bites constitute 80% to 90% of these bites and are responsible for the majority of deaths from bites by a nonvenomous animal (Tintinalli et al., 2016). Cat bites have a high risk of infection because of the presence of *Pasteurella* in their saliva. All animal bites must be reported to public health authorities, which must provide follow-up screening of the offending animal for rabies. If the animal cannot be located and rabies vaccination verified, rabies prophylaxis for the person who has been bitten must be instituted (ENA, 2013). As per WHO, every year nearly 23,000–25,000 people die owing to rabies in Southeast Asian countries. Around 19,000 deaths were reported in India due to rabies annually. Bangladesh reported 2000 deaths per annum due to rabies (Marathe & Kumar, 2016). Although all animal bites can cause rabies, dog bite is a major cause of rabies in India. Dog bite contributes to 91.5% animal bites and out of which 60% are stray dog bites. The incidence rate of dog bite in India is 17.4 per 1000 population (Menezes, 2008).

The Govt. of India has launched the National Rabies Control Program from the 12th five-year plan period (2012–2017). The National Institute of Disease Control, Delhi, has given out guidelines for the management of bite victims. Dog bite or animal bite which causes rabies is 100% preventable, but if not managed properly it can become 100% fatal. The guidelines insist on postexposure prophylaxis for those bitten by animals and preexposure prophylaxis for those who handle human being with fully evolved rabies or animal handlers, veterinarians, world life wardens, animal catchers, and travelers from rabies free area to rabies endemic area such as India.

Classification and Management of Bite Wound

Based on the extent and exposure the management differs. The bite wound is classified into three as follows (National Center for Disease Control (NCDC) Guidelines, 2015):

Category I: Touching or licking of intact skin by rabid animals or rabies-infected person—No need of any treatment.

Category II: Nibbling of skin or minor abrasions—Wound cleansing with copious water immediately and antirabies vaccination: 0 day, 3rd day, 7th day, 14th day, and 28th day.

Category III: Wound may be only one or numerous skin bites or scratches, licks on broken skin or mucous membrane, contamination with saliva. Wild animal bite of any extent needs to be considered as a Category III wound.

Treatment of Category III Wound:

1. Cleansing with soap and water/normal saline
2. Antirabies serum or antirabies immunoglobulin: Usually antirabies serum containing immunoglobulins should be given as close as to the bite wound. Antirabies serum should not be given after 14 days of dog bite with vaccination schedule going on as it interferes with antibody production
3. Administration of antirabies vaccination on 0, 3rd, 7th, 14th, and 28th day. Both intramuscular and intradermal vaccines are available in India. As per the preparatory guidelines, vaccines should be preserved and administered.

Human bites are frequently associated with rapes, sexual assaults, or other forms of battery. The human mouth contains more bacteria than that of most other animals, so a high risk of bite-related infection exists. Depending on the circumstances surrounding the event, the victim may delay seeking treatment. The ED nurse should inspect any bitten tissue for pus, erythema, or necrosis. A health care provider should take photographs, which can be used as evidence in criminal and legal proceedings. Guidelines for collecting forensic evidence for photographing with and without a measuring device should be followed. Cleansing with soap and water is then necessary, followed by the administration of antibiotics and tetanus toxoid as prescribed (Tintinalli et al., 2016).

Snakebites

Across the globe, more than 400,000 snakebites occur each year with a 5% mortality rate (Smith, Sammons, Carr, et al. 2014). Children between 1 and 9 years of age are the most likely victims. Dry bites are bites by poisonous snakes but without venom deposition (Tintinalli et al., 2016). In the Southeast Asian countries, cobras, Russell viper, pit viper, and kraits are common poisonous snakes. The estimated deaths owing to snakebite in India are 50,000 per year, which is definitely an underestimate because of the lack of proper registration of snakebite. The population at risk of snakebite in India is around 50 million people (Ghosh, Mukhopadhyay, & Chatterjee, 2016). Similarly, in all the South Asian countries, the mortality rate due to snakebite is higher. It occurs mostly during the monsoon seasons and at night or in dim light. The Indian states of Uttar Pradesh, Andhra Pradesh, Bihar, West Bengal, Maharashtra, and Tamil Nadu report snakebites commonly (Ghosh et al., 2016). Venomous snakebites are medical emergencies.

Pathophysiology

Snake venom consists primarily of proteins and has a broad range of physiologic effects. It may affect multiple organ systems, especially the neurologic, cardiovascular, and respiratory systems.

The envenomation effect depends on the type of snake and the amount of toxins. The cobra bites are primarily cardiotoxic and neurotoxic in nature whereas the Russell viper and Pit viper produce nephrotoxic effects and lead to acute kidney injury. Even if the antivenom is injected within 1 hour, it cannot prevent acute kidney insult. Procoagulase and hyaluronidase produce massive hemorrhage and disseminated intravascular coagulation. The local effect at the site of injury is due to the direct release of cytotoxin and myotoxin that lead to necrosis and endothelial injury and persistent bleeding (Warrell, 2016; Ghosh, et al., 2016). The pathophysiology of snake envenomation is presented in Figure 60-4.

Clinical Manifestations

Classic clinical signs of envenomation are edema, ecchymosis, and hemorrhagic bullae, leading to necrosis at the site of envenomation. Symptoms include lymph node tenderness, nausea, vomiting, numbness, and a metallic taste in the mouth. Without decisive treatment, these clinical manifestations may progress to include fasciculations, hypotension, paresthesias, seizures, and coma (Smith et al., 2014). Systemic effects manifest as profound hypotension, tachycardia, ECG changes, respiratory difficulty, ptosis, ophthalmoplegia, dark colored urine or anuria, bleeding disturbances, bilateral parotid edema, facial edema, hemoglobinuria, and myoglobinuria, which is responsible for dark-colored urine (Warrell, 2016; Ghosh et al., 2016).

Management

Initial first aid at the site of the snakebite includes having the person lie down, removing constrictive items such as rings, providing warmth, cleansing the wound, covering the wound with a light sterile dressing, and immobilizing the injured body part below the level of the heart. Airway, breathing, and circulation are the priorities of care. Ice, incision and suction, or a tourniquet is *not* applied. Tetanus and analgesia should be given as necessary. Initial evaluation in the ED is performed quickly and includes information about the following:

- Whether the snake was venomous or nonvenomous; discourage bringing the snake for identification—even a dead snake's venom is poisonous. Do *not* handle any snake brought to the ED. If the snake is transported to the ED, caution should be taken because the snake is frequently in a stunned, not dead, state. The bite reflex can remain intact for up to 90 minutes after the death of the snake (Auerbach, 2017).
- Where and when the bite occurred and the circumstances of the bite.
- Sequence of events, signs, and symptoms (fang punctures, pain, edema, and erythema of the bite and nearby tissues).
- Vital signs.
- Circumference of the bitten extremity or area at several points. The circumference of the extremity that was bitten is compared with the circumference of the opposite extremity.
- Laboratory data (complete blood count, urinalysis, and coagulation studies).

The course and prognosis of snakebite injuries depend on the kind and amount of venom injected; where on the body the bite occurred; and the general health, age, and size of the patient. There is no one specific protocol for treatment of snakebites. In general, ice, tourniquets, heparin, and corticosteroids are not used during the acute stage. Corticosteroids are contraindicated

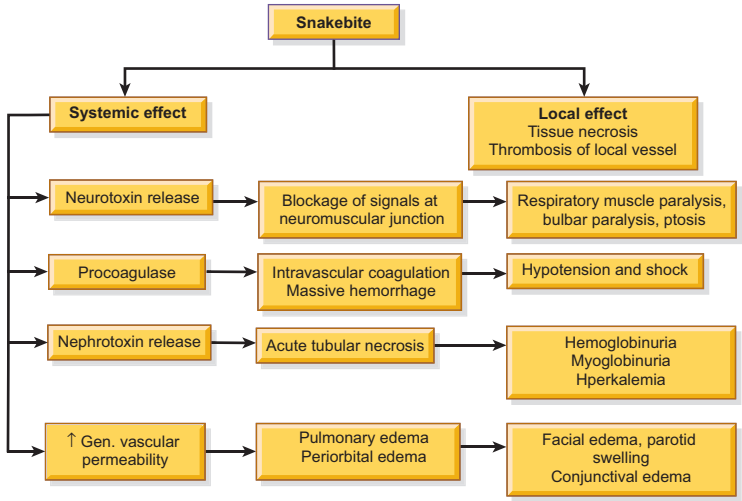

Figure 60-4 • Pathophysiology of snake envenomation.

in the first 6 to 8 hours after the bite because they may depress antibody production and hinder the action of antivenin (antitoxin manufactured from the snake venom and used to treat snakebites).

Parenteral fluids may be used to treat hypotension. If vasopressors are used to treat hypotension, their use should be short term. Surgical exploration of the bite is rarely indicated. Typically, the patient is observed closely for at least 6 hours. The patient is *never* left unattended.

Administration of Antivenin (Antitoxin)

Although envenomation does not always occur, it should always be suspected with snakebites. An assessment of progressive signs and symptoms is essential before considering administration of antivenin, which is most effective if given within 4 hours and no greater than 12 hours after the snakebite. The decision to administer antivenin depends on worsening tissue injury and evidence of systemic and coagulopathic symptoms. Rattlesnakes are more likely to cause coagulation abnormalities as well as more systemic effects. Coagulation abnormalities are not restricted to severe envenomation (Auerbach, 2017).

The most readily available antivenin in the United States is Crotalidae polyvalent immune Fab antivenom (FabAV or CroFab) (Auerbach, 2017). In India, the polyvalent antivenom serum available is effective against the four common poisonous snake species namely the cobra (Naja naja), Russel viper (*Daboia russelii*), common krait (*Bungarus caeruleus*), and saw-scaled viper (*Echis carinatus*). The dose depends on the type of snake and the estimated severity of the bite. Indications for antivenin depend on the progression of symptoms, including coagulopathy and systemic reaction.

Before administering antivenin and every 15 minutes thereafter, the circumference of the affected part is measured. Premedication with diphenhydramine (Benadryl) or cimetidine (Tagamet) may be indicated, because these antihistamines may decrease the allergic response to antivenin. Antivenin is given as an IV infusion whenever possible, although intramuscular administration can be used.

Depending on the severity of the snakebite, the antivenin is diluted in 500 to 1000 mL of normal saline solution. The infusion is started slowly, and the rate is increased after 10 minutes if there is no reaction. The total dose should be infused during the first 4 to 6 hours after the bite. The initial dose is repeated until symptoms decrease, after which time the circumference of the affected part should be measured every 30 to 60 minutes for the next 48 hours to detect symptoms of compartment syndrome (swelling, loss of pulse, increased pain, and paresthesias).

There is no limit to the number of antivenin vials that can be given. The decision to continue to administer vials is based upon patient symptoms. The most common cause of allergic reaction to the antivenin is too-rapid infusion. Reactions may consist of a feeling of fullness in the face, urticaria, pruritus, malaise, and apprehension. These symptoms may be followed by tachycardia, shortness of breath, hypotension, and shock. In this situation, the infusion should be stopped immediately and IV diphenhydramine given. Vasopressors (Inj. Adrenaline) are used for patients in shock, and resuscitation equipment must be on standby while antivenin is infusing. It is important to note that serum sickness (hypersensitivity) can occur within the first few weeks after discharge. The patient and the patient's family members should be educated about the clinical manifestations of serum sickness (i.e., fever; rash starting on the chest and spreading to the back; arthralgia; GI disturbances [e.g., nausea, vomiting, diarrhea, abdominal pain], and headache) and return to the ED if they occur (Auerbach, 2017); (Tintinalli et al., 2016).

In case of neurotoxic envenomation as in cobra bite, Inj. Neostigmine in the dose of 0.04 mg/kg IV, Inj. Atropine, Inj. Glycopyrrolate may be prescribed as continuous infusion to prolong the effect of acetylcholine and thereby reverse the respiratory failure and neurotoxic symptoms (Ghosh, et al., 2016).

Tick Bites

Tick bites are common in, and they usually occur in grassy or wooded areas. It is important to learn the place where the bite occurred as well as the location of the bite on the body. The tick bite itself is not usually the problem; rather, it is the pathogen transmitted by the tick that can cause serious disease. Ticks can carry diseases such and Lyme disease.

Ticks transmit pathogens through their saliva; therefore, the earlier the tick is removed, the better the prognosis. The tick should be removed with tweezers using a straight upward pull (see Fig. 60-5), and the patient should be informed of the signs and symptoms of diseases carried by ticks, especially if the patient lives in or has visited an area endemic for tick-related diseases (e.g., Lyme disease) (Auerbach 2017); (ENA, 2013).

Lyme disease has three stages. Stage I may present with a classic "bull's-eye" rash (i.e., erythema migrans) that typically can be found in the axilla, groin, or thigh area and that appears within 4 weeks after the tick bite, with a peak manifestation time of 7 days after the bite. Classically, this rash is at least 5 cm in diameter with bright red borders. It is accompanied by flulike signs and symptoms that may include chills, fever, myalgia, fatigue, and headache. Without treatment, the rash subsides within 3 to 4 weeks. However, the rash and flulike manifestations can be significantly reduced within days if prompt treatment with antibiotic agents (e.g., doxycycline [Vibramycin]) is initiated. If antibiotics are not given, stage II Lyme disease may present within 4 to 10 weeks following the tick bite and may manifest with joint pain, memory loss, poor motor coordination, adenopathy, and cardiac abnormalities. Facial nerve palsy is the most common manifestation of stage II Lyme disease (Tintinalli et al., 2016). Stage III can begin anywhere from weeks to more than a year after the bite and has serious long-term chronic sequelae, including arthritis, neuropathy, myalgia, and myocarditis. Even after appropriate treatment with antibiotics, 10% to 20% of patients may experience long-term effects including fatigue and arthralgias; some experience neurologic symptoms that may persist for over 10 years (Tintinalli et al., 2016).

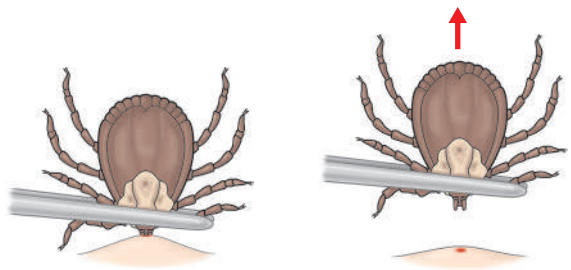

Figure 60-5 • Removal of tick with tweezers using a straight upward pull.

POISONING

- A poison is any substance that, when ingested, inhaled, absorbed, applied to the skin, or produced within the body in relatively small amounts, injures the body by its chemical action. Poisoning from inhalation and ingestion of toxic materials, both intentional and unintentional, constitutes a major health hazard and an emergency situation. Removal or inactivation of the poison before it is absorbed
- Provision of supportive care in maintaining vital organ function
- Administration of a specific antidote to neutralize a specific poison
- Implementation of treatment that hastens the elimination of the absorbed poison

Ingested (Swallowed) Poisons

Swallowed poisons may be corrosive. Corrosive poisons include alkaline and acid agents that can cause tissue destruction after coming in contact with mucous membranes. Alkaline products include lye, drain cleaners, toilet bowl cleaners, bleach, nonphosphate detergents, oven cleaners, and button batteries (batteries used to power watches, calculators, hearing aids, or cameras). Acid products include toilet bowl cleaners, pool cleaners, metal cleaners, rust removers, and battery acid.

Control of the airway, ventilation, and oxygenation are essential. In the absence of cerebral or renal damage, the patient's prognosis depends largely on successful management of respiration and circulation. Measures are instituted to stabilize cardiovascular and other body functions. ECG, vital signs, and neurologic status are monitored closely for changes. Shock may result from the cardiodepressant action of the substance ingested, from venous pooling in the lower extremities, or from reduced circulating blood volume resulting from increased capillary permeability (see Chapter 8). An indwelling urinary catheter is inserted to monitor kidney function. Blood specimens are obtained to determine the concentration of drug or poison.

Efforts are made to determine what substance was ingested; the amount; the time since ingestion; signs and symptoms, such as pain or burning sensations, any evidence of redness or burn in the mouth or throat, pain on swallowing or an inability to swallow, vomiting, or drooling; age and weight of the patient; and pertinent health history.

Measures are instituted to remove the toxin or decrease its absorption. If there is a specific chemical or physiologic antagonist (antidote), it is given as early as possible to reverse or diminish the effects of the toxin. If this measure is ineffective, procedures may be initiated to remove or dilute the ingested substance. These procedures include administration of multiple doses of activated charcoal, dialysis, or hemoperfusion. Hemoperfusion involves detoxification of the blood by processing it through an extracorporeal circuit and an adsorbent cartridge containing charcoal or resin, after which the cleansed blood is returned to the patient.

The patient who has ingested a corrosive poison, which can be a strong acid or alkaline substance, is given water or milk to drink for dilution. However, dilution is not attempted if the patient has acute airway edema or obstruction; potential for vomiting; or if there is clinical evidence of esophageal, gastric, or intestinal burn or perforation. The following gastric emptying procedures may be used as prescribed:

- Gastric lavage for the patient who is obtunded is only useful within 1 hour of ingestion, for sustained-release substances, or massive life-threatening amounts of a substance; however, complications of aspiration and stomach or esophageal perforation outweigh its usefulness. If performed, gastric aspirate is saved and sent to the laboratory for testing (toxicology screens).
- Activated charcoal administration if the poison is one that is absorbed by charcoal; given orally or by nasogastric tube, it is effective in small intermittent doses to decrease vomiting. It should be diluted as a slurry so that it is easier to drink or pass through the nasogastric tube. Activated charcoal absorbs most commonly ingested poisons except corrosives, heavy metals and hydrocarbons, iron, and lithium.

Cathartics, which had traditionally accompanied the use of activated charcoal, are now rarely indicated because they can result in severe electrolyte imbalances, diarrhea, and hypovolemia (ENA, 2013). Furthermore, syrup of ipecac to induce vomiting in the patient who is alert is not recommended due to the risk of aspiration and should *never* be used with corrosive poisons or with petroleum distillates (e.g., lubricating oil, fuel oil) or further corrosive damage to the upper airway and pharyngeal structures may occur.

Nursing Alert: Vomiting is never induced after ingestion of caustic substances (acid or alkaline) or petroleum distillates.

Throughout detoxification, the patient's vital signs, CVP, and fluid and electrolyte balance are monitored closely. Hypotension and cardiac dysrhythmias are possible. Seizures are also possible because of CNS stimulation from the poison or from oxygen deprivation. If the patient complains of pain, analgesic agents are given cautiously. Severe pain causes vasomotor collapse and reflex inhibition of normal physiologic functions.

After the patient's condition has stabilized and discharge is imminent, written material should be given to the patient indicating the signs and symptoms of potential problems related to the poison ingested and signs or symptoms requiring evaluation by a health care provider. If poisoning was determined to be a suicide or self-harm attempt, a psychiatric consultation should be requested before the patient is discharged. In cases of inadvertent poison ingestion, poison prevention and home poison-proofing instructions should be provided to the patient and family.

Legal Implications while Caring for Poisoning Patients

All types of poisoning is considered as medicolegal case and emergency medical officer or medical director has to intimate it to the nearby police station on admission of such patients. All records and evidences pertaining to the patient also have to be preserved safely. In case of death of the patient owing to poison, the same police officers need to be informed. The deceased body will be handed over to police for further investigation and autopsy. Emergency treatment is initiated with the following goals.

- Removal or inactivation of the poison before it is absorbed
- Provision of supportive care in maintaining vital organ function
- Administration of a specific antidote to neutralize a specific poison
- Implementation of treatment that hastens the elimination of the absorbed poison

Carbon Monoxide Poisoning

Carbon monoxide poisoning may occur as a result of industrial or household incidents or attempted suicide. It is the most common cause of fatality from poisoning and is frequently under-reported to poison control centers or misdiagnosed (Tintinalli et al., 2016). Carbon monoxide exerts its toxic effect by binding to circulating hemoglobin and thereby reducing the oxygen-carrying capacity of the blood. Hemoglobin absorbs carbon monoxide 200 times more readily than it absorbs oxygen. Carbon monoxide–bound hemoglobin, called carboxyhemoglobin, does not transport oxygen.

Clinical Manifestations

Because the CNS has a critical need for oxygen, CNS symptoms predominate with carbon monoxide toxicity. A person with carbon monoxide poisoning may appear intoxicated (from cerebral hypoxia). Other signs and symptoms include headache, muscular weakness, palpitation, dizziness, and confusion, which can progress rapidly to coma. Skin color, which can range from pink or cherry-red to cyanotic and pale, is not a reliable sign. Pulse oximetry may reveal a high hemoglobin saturation, which may be deceiving, since the hemoglobin molecule is saturated with carbon monoxide rather than oxygen (ENA, 2013).

Management

Exposure to carbon monoxide requires immediate treatment. Goals of management are to reverse cerebral and myocardial hypoxia and to hasten elimination of carbon monoxide. Whenever a patient inhales a poison, the following general measures apply:

- Carry the patient to fresh air immediately; open all doors and windows.
- Loosen all tight clothing.
- Initiate traditional cardiopulmonary resuscitation.
- Prevent chilling; wrap the patient in blankets.
- Keep the patient as quiet as possible.
- Do not give alcohol in any form or permit the patient to smoke.

In addition, for the patient with carbon monoxide poisoning, carboxyhemoglobin levels are analyzed on arrival at the ED and before treatment with oxygen if possible. To reverse hypoxia and accelerate the elimination of carbon monoxide, 100% oxygen is given at atmospheric or preferably hyperbaric pressures. Oxygen is given until the carboxyhemoglobin level is less than 5%. The patient is monitored continuously. Psychoses, spastic paralysis, ataxia, visual disturbances, and deterioration of mental status and behavior may persist after resuscitation and may be symptoms of permanent brain damage (Tintinalli et al., 2016).

A psychiatric consultation is warranted if it has been determined that the poisoning was a suicide attempt.

Skin Contamination Poisoning (Chemical Burns)

Skin contamination injuries from exposure to chemicals are challenging because of the large number of possible offending agents with diverse actions and metabolic effects. The severity of a chemical burn is determined by the mechanism of action, the penetrating strength and concentration, and the amount and duration of exposure of the skin to the chemical.

The skin should be drenched immediately with running water from a shower, hose, or faucet, except in the case of lye and white phosphorus, which should be brushed off the skin dry (Moore, 2015).

Nursing Alert: Water should not be applied to burns from lye or white phosphorus because of the potential for an explosion or for deepening of the burn. All evidence of these chemicals should be brushed off the patient before any flushing occurs.

The skin should be flushed with a constant stream of water as the patient's clothing is removed. The skin of health care personnel assisting the patient should be appropriately protected if the burn is extensive or if the agent is significantly toxic or still present. Prolonged lavage with generous amounts of tepid water is important. The decontamination shower (deluge) in the ED is the optimal place for total body flushing. The staff attending the patient should wear proper personal protective equipment (PPE) to prevent cross-contamination (Moore, 2015).

Attempts to determine the identity and characteristics of the chemical agent are necessary in order to specify future treatment. The standard burn treatment appropriate for the size and location of the wound (antimicrobial treatment, débridement, tetanus prophylaxis, antidote administration as prescribed) is instituted (Moore, 2015) (see Chapter 47). The patient may require plastic surgery for further wound management. The patient is instructed to have the affected area reexamined at 24 and 72 hours and in 7 days because of the risk of underestimating the extent and depth of these types of injuries.

Food Poisoning

Food poisoning is a sudden illness that occurs after ingestion of contaminated food or drink. Botulism is a serious form of food poisoning that requires continual surveillance (see Chapter 61, Table 61-5). Assessment questions for patients with food poisoning are discussed in Chart 60-6.

The key to treatment is determining the source and type of food poisoning. If possible, the suspected food should be brought to the medical facility and a history obtained from the patient or family.

Food, gastric contents, vomitus, serum, and feces are collected for examination. The patient's respirations, blood pressure, level of consciousness (LOC), CVP (if indicated), and muscular activity are monitored closely. Measures are instituted

Chart 60-6 ASSESSMENT

Food Poisoning

Use the following questions to elicit information about the circumstances surrounding the possibility of food poisoning:

- How soon after eating did the symptoms occur? (Immediate onset suggests chemical, plant, or animal poisoning.)
- What was eaten in the previous meal? Did the food have an unusual odor or taste? (Most foods causing bacterial poisoning *do not* have unusual odor or taste.)
- Did anyone else become ill from eating the same food?
- Did vomiting occur? What was the appearance of the vomitus?
- Did diarrhea occur? (Diarrhea is usually absent with botulism and with shellfish or other fish poisoning.)
- Are any neurologic symptoms present? (These occur in botulism and in chemical, plant, and animal poisoning.)
- Does the patient have a fever? (Fever is characteristic in salmonella, ingestion of fava beans, and some fish poisoning.)

to support the respiratory system. Death from respiratory paralysis can occur with botulism, fish poisoning, and some other food poisonings.

Because large volumes of electrolytes and water are lost by vomiting and diarrhea, fluid and electrolyte status should be assessed. Severe vomiting produces alkalosis, and severe diarrhea produces acidosis. Hypovolemic shock may also occur from severe fluid and electrolyte losses. The patient is assessed for signs and symptoms of fluid and electrolyte imbalances, including lethargy, rapid pulse rate, fever, oliguria, anuria, hypotension, and delirium. Baseline weight and serum electrolyte levels are obtained for future comparisons.

Measures to control nausea are also important to prevent vomiting, which could exacerbate fluid and electrolyte imbalances. An antiemetic medication is given parenterally as prescribed if the patient cannot tolerate fluids or medications by mouth (Tintinalli et al., 2016). For mild nausea, the patient is encouraged to take sips of weak tea, carbonated drinks, or tap water. After nausea and vomiting subside, clear liquids are usually prescribed for 12 to 24 hours, and the diet is gradually progressed to a low-residue, bland diet.

SUBSTANCE ABUSE

Substance abuse is the misuse of specific substances, such as drugs or alcohol, to alter mood or behavior. Drug abuse is the use of drugs for other than legitimate medical purposes. People who abuse drugs often take a variety of drugs simultaneously (such as alcohol, barbiturates, opioids, and tranquilizers), and the combination may have additive and addictive effects.

One of the most commonly used drugs is 3,4-methylenedioxymethamphetamine (MDMA), or Ecstasy, a methamphetamine-based drug that users believe produces a "harmless high."

Spice is a synthetic cannabinoid sold commercially as a smoking mixture under the names "spice," "incense," or "K2." Its chemical structure and effects are similar to marijuana, targeting the same receptor sites in the brain. Spice is sold with variable concentrations and unregulated potency (National Institute on Drug Abuse, 2015b).

Bath salts are synthetic stimulants similar to Ecstasy known as "mephedrone," "drone," or "MCAT." Their effects are similar to amphetamines, MDMA, and cocaine. Although bath salts are most commonly swallowed or snorted, they may also be smoked or injected; the method of intake affects the severity and duration of effects (Table 60-1). The structural formula 3,4-methylenedioxypyrovalerone (MDPV) is the most common type of bath salt abused (Baumann, Partilla, Lehner, et al., 2013).

Abuse of various inhalants (see Table 60-1) has also increased in popularity; these products generally result more often in cravings than withdrawal when their use is stopped. The method of inhalation varies with the product chosen and requires several deep inhalations to reach euphoria. Methods include sniffing or snorting by directly inhaling the fumes. "Bagging" (from a bag) or "huffing" (from a rag or cloth) provide the greatest concentration; "dusting" is another method that delivers the inhalant by directly spraying it into the nostrils. Long-term use results in cortical atrophy and brainstem dysfunction, in addition to cardiomyopathy and emphysema-like abnormalities of the lung. Significant others or parents may report that the patient has had poor school or work performance or attendance, weight loss, poor hygiene, fatigue, nosebleeds, and decreased appetite (ENA 2013).

Clinical manifestations vary with the substance used, but the underlying principles of management are essentially the same. Table 60-1 identifies commonly abused drugs, listing their clinical manifestations and therapeutic management. Treatment goals for a patient with a drug overdose are to support the respiratory and cardiovascular functions, to enhance clearance of the agent, and to provide for safety of the patient and staff. People who abuse IV/injection drugs are at increased risk for HIV infection, acquired immune deficiency syndrome, hepatitis B and C, and tetanus.

Acute Alcohol Intoxication

Alcohol is a psychotropic drug that affects mood, judgment, behavior, concentration, and consciousness. Many people who drink heavily are young adults or those older than 60 years. There is a high prevalence of alcoholism among patients presenting to the ED for management; up to 31% have histories of alcohol abuse. Among patients who present to the ED with various injuries, up to 50% may have histories of alcohol abuse (ENA 2013). Because patients who abuse alcohol return frequently to the ED, they present a challenge to the health professionals who care for them. The CDC advocates routine screening for alcohol abuse in all outpatient settings, including EDs. Therefore, screenings, brief interventions, and referral to treatment (SBIRT) for patients presenting with suspected alcohol abuse are recommended. SBIRT is considered cost-effective in saving quality of life-years lost and preventing the morbid consequences of continued alcohol abuse (Kane, Mitchell, Aiello, et al., 2016); (Slain, Rickard-Aasen, Pringle, et al., 2014).

Alcohol, or ethanol, is a multisystem toxin and CNS depressant that causes drowsiness, impaired coordination, slurring of speech, sudden mood changes, aggression, belligerence, grandiosity, and uninhibited behavior. In excess, it can also cause stupor and eventually coma and death (i.e., alcohol poisoning). Increasingly, underage minors and college students arrive at the ED with alcohol poisoning from binge drinking.

In the ED, the patient who is intoxicated with alcohol or who presents with alcohol poisoning is assessed for head injury, hypoglycemia (which mimics intoxication), and other health problems. Possible nursing diagnoses include ineffective breathing pattern related to CNS depression and ineffective impulse control related to severe intoxication from alcohol.

Treatment involves detoxification of the acute poisoning, recovery, and rehabilitation. Commonly, the patient uses mechanisms of denial and defensiveness. The nurse should approach the patient in a nonjudgmental manner, using a firm, consistent, accepting, and reasonable attitude. Speaking in a calm and slow manner is helpful because alcohol interferes with thought processes. If the patient appears intoxicated, hypoxia, hypovolemia, and neurologic impairment must be ruled out before it is assumed that the patient is intoxicated. Typically, a blood specimen is obtained for analysis of the blood alcohol level.

If drowsy, the patient should be allowed to sleep off the state of alcoholic intoxication. During this time, maintenance of a patent airway and observation for symptoms of CNS depression are essential. The patient should be undressed and kept warm with blankets. On the other hand, if the patient is noisy or belligerent, sedation may be necessary. If sedation is used, the

TABLE 60-1 Emergency Management of Patients with Drug Overdose

Drug	Clinical Manifestations	Therapeutic Management
Cocaine		
Routes may include: • Intranasally ("snorting")—inhaled into nostrils through straws • By smoking ("freebasing")—cocaine hydrochloride dissolved in ether to yield a pure cocaine alkaloid base ("crack," "rocks"); smoking in a small pipe delivers large quantities of cocaine to lungs. • IV • Polysubstance (cocaine and heroin)	Cocaine is a CNS stimulant that can cause: • Increased heart rate and blood pressure • Hyperpyrexia • Seizures • Sluggish, dilated pupillary response • Muscle rigidity • Increased energy, agitation, aggression • Ventricular dysrhythmias • Intense euphoria, then anxiety, sadness, insomnia, and sexual indifference • Cocaine hallucinations with delusions • Psychosis with extreme paranoia and ideas of persecution • Hypervigilance Chronic psychotic symptoms may persist. Overall psychotic symptoms are short-lived compared to methamphetamines	1. Maintain airway and provide respiratory support. 2. Control seizures. 3. Monitor cardiovascular effects; have antiarrhythmic drugs and defibrillator available. 4. Treat for hyperthermia. 5. If cocaine was ingested, evacuate stomach contents and use activated charcoal to treat. Whole bowel irrigation may be necessary to treat body packers ("mules"). 6. Refer for psychiatric evaluation and treatment in an inpatient unit that eliminates access to the drug. Include drug rehabilitation counseling.
Opioids		
Heroin Opium or paregoric Morphine, codeine, semisynthetic derivatives: oxycodone (OxyContin), methadone, meperidine (Demerol), tramadol (Ultram), fentanyl (Sublimaze)	Acute intoxication (overdose) can result in: • Pinpoint pupils (may be dilated with severe hypoxia) • Decreased blood pressure • Marked respiratory depression/arrest • Pulmonary edema • Stupor → coma • Seizures Fresh needle marks along course of any superficial vein Skin abscesses (from "popping")	1. Support respiratory and cardiovascular functions. 2. Establish IV lines; obtain blood for chemical and toxicologic analysis. Patient may be given bolus of glucose to eliminate possibility of hypoglycemia. 3. Administer narcotic antagonist (naloxone hydrochloride IV, IM [Narcan]) as prescribed to reverse severe respiratory depression and coma. 4. Continue to monitor level of responsiveness and respirations, pulse, and blood pressure. Duration of action of naloxone hydrochloride is shorter than that of heroin; repeated dosages may be necessary. 5. Send urine for analysis; opioids can be detected in urine. 6. Obtain an ECG. 7. Do not leave patient unattended; he or she may lapse back into coma rapidly. Clinical status may change from minute to minute. Hemodialysis may be indicated for severe drug intoxication. Activated charcoal may be considered if opioids were taken orally and if the patient is alert. 8. Monitor for pulmonary edema, which is frequently seen in patients who abuse/overdose on narcotics. 9. Refer patient for psychiatric and drug rehabilitation evaluation before discharge.
Barbiturates		
Pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), gamma-hydroxybutyrate (GHB, "liquid Ecstasy")	*Acute intoxication (may mimic alcohol intoxication):* • Respiratory depression • Flushed face • Decreased pulse rate; decreased blood pressure • Increasing nystagmus (to vertical and horizontal gaze) • Sluggish pupils • Lack of convergence of eyes • Depressed deep tendon reflexes • Decreasing mental alertness • Difficulty in speaking • Poor motor coordination and flaccid muscles • Coma, death	1. Maintain airway and provide respiratory support. 2. Endotracheal intubation or tracheostomy is considered if there is any doubt about the adequacy of airway exchange. a. Check airway frequently. b. Perform suctioning as necessary. 3. Support cardiovascular and respiratory functions; most deaths result from respiratory depression or shock. 4. Start infusion through large-gauge needle or IV catheter to support blood pressure; coma and dehydration result in hypotension and respond to infusion of IV fluids with elevation of blood pressure. 5. Evacuate stomach contents or lavage if within 1 hour of ingestion to prevent absorption; repeated doses of activated charcoal may be given. 6. Assist with hemodialysis for patient with severe overdose.

(Continued)

(Continued)

	GHB: • Sexual disinhibition • Amnesia, myoclonus, agitation • Overdoses when mixed with alcohol	7. Maintain neurologic and vital sign flow sheet. 8. Patient awakening from overdose may demonstrate combative behavior. 9. Refer for psychiatric and drug rehabilitation consultation to evaluate suicide potential and drug abuse.
Inhalants		
Amyl nitrate Freon Propane Trichloroethylene Gasoline Perchloroethylene Toluene (metallic paint spray) Helium Canned air Hand sanitizer *Routes may include:* • Sniffing/snorting—direct inhalation of fumes • "Bagging"—sniff from a bag • "Huffing"—sniff from a rag/cloth • "Dusting"—direct spray into the nostrils	Effects mimic those of alcohol, with dizziness and imbalance: • Euphoria, headache, disinhibition, altered level of consciousness to coma • Renal, hepatic, and cardiac toxicity • Aplastic anemia • Fetal growth retardation • Respiratory depression, arrest from CNS depression • Vasodilation • Nosebleeding • Vertical and horizontal nystagmus • Lack of convergence of eyes • Sluggish pupils • Temperature fluctuations • Circumoral red spots/rash • Air embolus	1. Provide airway support, ventilation, and oxygen. 2. Treat cardiac dysrhythmias and hypotension. 3. Provide advanced cardiac life support as needed. 4. Monitor for profound hypotension when amyl nitrate is combined with MDMA and sildenafil or with anesthetic agents. 5. Monitor for hypertension when volatile solvents used.
Amphetamine-Type Drugs (pep pills, "uppers," "speed," "crystal meth")		
Amphetamine (Benzedrine) Dextroamphetamine (Dexedrine) Methamphetamine (Desoxyn, "speed") 3,4-methylenedioxymethamphetamine (MDMA) ("Ecstasy," "Adam")[a] 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA) ("Eve") 3,4-methylenedioxyamphetamine (MDA); methylphenidate (Ritalin) "ice," "rocks," "crystal meth" 3,4-methylenedioxypyrovalerone (MDPV) or 4-methylmethcathinone (mephedrone); "Bath salts" (synthetic stimulant)	• Nausea, vomiting, anorexia • Palpitations, tachycardia • Increased blood pressure • Tachypnea, anxiety • Nervousness • Diaphoresis, mydriasis • Repetitive or stereotyped behavior • Irritability, insomnia, agitation • Visual misperceptions, auditory hallucinations • Fearfulness, anxiety, depression, hostility, paranoia • Hyperactivity, rapid speech, euphoria, hyperalertness • Decreased inhibition • Seizures, coma, hyperthermia • Cardiovascular collapse • Rhabdomyolysis • MDMA is both a hallucinogenic and stimulant. • MDPV and mephedrone effects last >24 hours.	1. Provide airway support, ventilation, cardiac monitoring; insert IV line. 2. Use GI evacuation in cases of oral overdose; activated charcoal, gastric lavage if within 1 hour of ingestion. 3. Keep in calm, cool, quiet environment; elevated temperature potentiates amphetamine toxicity. Maintain normothermia, cooling the patient as necessary. 4. Administer small doses of diazepam (Valium) (IV) or haloperidol (Haldol) as prescribed for CNS and muscular hyperactivity. 5. Administer appropriate pharmacologic therapy as prescribed for severe hypertension and ventricular dysrhythmias. 6. Treat seizures with benzodiazepines (e.g., diazepam) as prescribed. 7. Treat sympathetic stimulation with beta-blocker agents as prescribed. 8. Try to communicate with patient if delusions or hallucinations are present. 9. Place in a protective environment (preferably psychiatric security room with video monitoring) to observe for suicide attempt. 10. Refer for psychiatric and drug rehabilitation evaluation.
Hallucinogens or Psychedelic-Type Drugs		
Lysergic acid diethylamide (LSD) Phencyclidine HCl (PCP, "angel dust") Mescaline, psilocybin Cannabinoids (marijuana) Ketamine ("special K") Synthetic cannabinoids ("spice," "incense," "K2")	• Nystagmus • Pupil dilation • *Psychedelics* a. Sluggish pupillary response b. Increased pulse and temperature c. Muscle rigidity	1. Evaluate and maintain patient's circulation, airway, and breathing. 2. Determine by urine or serum drug screen whether the patient has ingested hallucinogenic drug or has a toxic psychosis.

(Continued)

(Continued)

Butane honey oil (BHo)—"dabs," "shatter"	• Mild hypertension • Marked confusion bordering on panic • Incoherence, hyperactivity • Withdrawn • Combative behavior; delirium, mania, self-injury (lasts 6–12 hours) • Hallucinations, body image distortion • Hypertension, hyperthermia, acute kidney injury • Flashback—recurrence of LSD-like state without having taken the drug; may occur weeks or months after drug was taken • Ketamine—"out-of-body" experience; increased aggressiveness • Synthetic cannabinoids—euphoria, increased sensory experience, relaxation • Manufacturing can result in burns	3. Try to communicate with and reassure the patient. a. "Talking down" involves understanding the process through which the patient is proceeding and helping the patient overcome fears while establishing contact with reality. b. Remind the patient that fear is common with this problem. c. Reassure the patient that he is not losing his mind but is experiencing the effect of drugs and that this will wear off. d. Instruct the patient to keep the eyes open; this reduces the intensity of reaction. e. Reduce sensory stimuli by minimizing noise, lights, movement, tactile stimulation. 4. Sedate the patient as prescribed if hyperactivity cannot be controlled; diazepam or a barbiturate may be prescribed. 5. Search for evidence of trauma; patients who use hallucinogens have a tendency to "act out" their hallucinations. 6. Manage seizures with benzodiazepines (e.g., diazepam) as necessary. 7. Observe patient closely; patient's behavior may become hazardous. Have safety officers stationed near the patient's room. 8. Monitor for hypertensive crisis if patient has prolonged psychosis due to drug ingestion. 9. Place patient in a protected environment under proper medical supervision to prevent self-inflicted bodily harm. **Management for Phencyclidine Abuse** 1. Place patient in a calm, supportive environment to minimize stimuli; protect from self-injury. 2. Avoid talking down. 3. Do not leave patient unobserved. Treat symptoms as they occur. a. Drug effects are unpredictable and prolonged. b. Symptoms are likely to exacerbate; patient becomes out of control. 4. Refer all patients in this category for psychiatric and drug evaluation/rehabilitation.
Drugs Producing Sedation, Intoxication, or Psychological and Physical Dependence (nonbarbiturate sedatives)		
Diazepam (Valium) Chlordiazepoxide (Librium) Oxazepam (Serax) Lorazepam (Ativan) Midazolam (Versed) Flunitrazepam (Rohypnol, "roofies," "date rape drug")[a]	Seizures, coma, circulatory collapse, death *Acute intoxication:* • Respiratory depression • Decreasing mental alertness • Confusion • Slurred speech, decreased blood pressure • Ataxia • Pulmonary edema • Coma, death **Flunitrazepam:** • Disinhibition with anterograde amnesia • Weakness and unsteadiness with impaired judgment • Powerlessness	1. Endotracheal tube is inserted as a precaution; use assisted ventilation to stabilize and correct respiratory depression. Observe for sudden apnea and laryngeal spasm. 2. Assess for hypotension. a. Insert indwelling urinary catheter for patient who is comatose; decreased urinary volume is an index of reduced renal flow associated with reduced intravascular volume or vascular collapse. b. Start volume expansion with saline or dextrose as prescribed. 3. Evacuate stomach contents; lavage (if within 1 hour of ingestion); activated charcoal. 4. Start ECG monitoring. Observe for dysrhythmias. 5. Administer flumazenil (Romazicon), a benzodiazepine antagonist (reversal agent). 6. Refer patient for psychiatric evaluation (potential suicide intent).

(Continued)

(Continued)

Salicylate Poisoning		
Aspirin (present in compound analgesic tablets) • Toxic levels (150–200 mg/kg body weight) • Chronic toxicity (occurs in older adults due to decreased kidney function) • Long-term intoxication (>100 mg/kg/day for more than 2 days)	• Restlessness • Tinnitus, deafness • Blurring of vision • Hyperpnea • Hyperpyrexia • Sweating • Epigastric pain, vomiting • Dehydration • Respiratory alkalosis and metabolic acidosis • Disorientation, coma • Cardiovascular collapse • Coagulopathy	1. Treat respiratory depression. 2. Induce gastric emptying by lavage (if within 1 hour after ingestion). 3. Give activated charcoal to adsorb aspirin. 4. Support patient with IV infusions as prescribed to establish hydration and correct electrolyte imbalances, including administration of sodium bicarbonate. 5. Enhance elimination of salicylates as directed by forced diuresis, alkalinization of urine, peritoneal dialysis, or hemodialysis, according to severity of intoxication. 6. Monitor serum salicylate level for efficacy of treatment. 7. Administer specific prescribed pharmacologic agent for bleeding and other problems. 8. Recognize that concretions formed in the gut may result in prolonged exposure as they are digested. 9. Refer patient for psychiatric evaluation (potential suicide intent). 10. Monitor thromboelastography for platelet function.
Acetaminophen/paracetamol (present in prescription and nonprescription analgesics, antipyretics, and cold remedies)	Lethargy to encephalopathy and death GI upset, diaphoresis Right upper quadrant pain Abnormal liver function tests, prolonged prothrombin time, increased bilirubin, disseminated intravascular coagulation Hepatomegaly leading to liver failure Metabolic acidosis Hypoglycemia Stage I—within 24 hours; GI irritation, possible metabolic acidosis and coma if severe ingestion Stage II—24–48 hours; monitor liver and coagulation studies. Stage III—after 48 hours; hepatic encephalopathy/jaundice, vomiting, right upper quadrant pain, coagulopathy, hypoglycemia, acute kidney injury	1. Maintain airway. 2. Obtain acetaminophen / paracetamol level. Levels ≥140 mg/kg are toxic. 3. Laboratory studies—liver function tests, prothrombin time/partial thromboplastin time, complete blood count, blood urea nitrogen, creatinine. 4. Lavage (if within 1 hour after ingestion); activated charcoal. 5. Prepare for possible hemodialysis, which clears acetaminophen / paracetamol but does not halt liver damage. 6. Administer N-acetylcysteine (Mucomyst) as soon as possible. N-acetylcysteine replenishes essential liver enzymes and requires a total of 18 doses every 4 hours. Charcoal absorbs N-acetylcysteine; do not administer together. Repeat N-acetylcysteine dose if patient vomits. 7. Refer patient for psychiatric evaluation (potential suicide intent).
Tricyclic Antidepressants		
Amitriptyline (Elavil) Doxepin (Sinequan) Nortriptyline (Aventyl) Imipramine (Tofranil)	Dysrhythmia: ventricular fibrillation/tachycardia, sinus tachycardia Hypotension Pulmonary edema, hypoxemia, acidosis Confusion, agitation, coma Visual hallucinations Clonus, tremors, hyperactive reflexes, nystagmus, myoclonic jerking Seizures Blurred vision, flushing, hyperthermia	1. Provide airway support, ventilation, cardiac monitoring; insert IV line with normal saline solution. 2. If within 1–2 hours after overdose, insert a nasogastric tube and instill activated charcoal every 4 hours × 3. 3. Administer a sodium bicarbonate drip to decrease dysrhythmias; the alkaline environment increases the protein binding of the metabolite. Synchronized cardioversion may be indicated with some dysrhythmias refractory to sodium bicarbonate. Torsades de pointes should be treated with IV magnesium sulfate. 4. Administer vasopressors. 5. Manage seizure activity with benzodiazepines (e.g., diazepam) as necessary. 6. Refer patient for psychiatric evaluation for potential suicide intent and evaluation of medication regimen for effectiveness.

(Continued)

(Continued)

Selective Serotonin Reuptake Inhibitors and Other Antidepressants		
Trazodone (Desyrel) Fluoxetine (Prozac) Paroxetine (Paxil) Sertraline (Zoloft) Venlafaxine (Effexor) Escitalopram (Lexapro) Bupropion (Wellbutrin)	Decreased level of consciousness, confusion Respiratory depression Increased heart rate Serotonin syndrome may occur if the SSRI was taken in conjunction with dextromethorphan or meperidine Agitation, seizures Hyperthermia, diaphoresis Hypertension, headache, shivering, "goose flesh," cardiac dysrhythmias, loss of consciousness	1. Administer activated charcoal with possibly whole bowel irrigation if a sustained-release medication was taken. 2. Use seizure precautions and administer benzodiazepines (e.g., diazepam) as prescribed.
Anabolic Steroids "roids," "juice," methandrostenolone, stanozolol, nandrolone Synthetic testosterone	Increase in LDL, decrease in HDL Alter carbohydrate metabolism Hyponatremia, hypokalemia Hypocalcemia/osteoporosis Mood swings/violent behaviors Invincibility, depression, potential for suicide attempts Memory loss, cognitive disabilities Immunosuppression Used to bulk up muscles, so skeletal muscle hypertrophy is a common manifestation.	1. Provide supportive therapy appropriate to patient's emotional manifestations. 2. Protect the patient from self-harm/harming others. 3. Encourage the patient to stop use; refer patient for psychiatric evaluation.

→, precedes; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; HDL, high-density lipoprotein; IM, intramuscular; IV, intravenous; LDL, low-density lipoprotein; NAC, N-acetylcysteine; SSRI, selective serotonin reuptake inhibitor.

[a]Polydrug use at "rave clubs" frequently involves MDMA, alcohol, amphetamines, LSD, and sometimes dextromethorphan. Terms such as "Ecstasy" may refer to flunitrazepam (Rohypnol), GHB, ephedrine, and/or caffeine, in addition to MDMA.

New York: McGraw-Hill Medical.

patient should be monitored carefully for hypotension and decreased LOC.

In addition, the patient is examined for alcohol withdrawal delirium and for injuries and organic disease (such as head injury, seizures, pulmonary infections, hypoglycemia, and nutritional deficiencies) that may be masked by alcoholic intoxication. People with alcoholism suffer more injuries than the general population. Acute alcohol intoxication is the cause of trauma for many patients without alcoholism as well. Pulmonary infections are also more common in patients with alcoholism, resulting from respiratory depression, an impaired defense system, and a tendency toward aspiration of gastric contents. The patient may show little increase in temperature or WBC count. The patient may be hospitalized or admitted to a detoxification center in an effort to examine problems underlying the substance abuse (ENA, 2013).

Alcohol Withdrawal Syndrome/ Delirium Tremens

Alcohol withdrawal syndrome is an acute toxic state that occurs as a result of sudden cessation of alcohol intake after a bout of heavy drinking or, more typically, after prolonged intake of alcohol. Severity of symptoms depends on how much alcohol was ingested and for how long. Delirium tremens may be precipitated by acute injury or infection (pneumonia, pancreatitis, hepatitis) and is the most severe form of alcohol withdrawal syndrome (ENA, 2013). Delirium tremens is a life-threatening condition and carries a high mortality rate if untreated (ENA, 2013).

Patients with alcohol withdrawal syndrome show signs of anxiety, uncontrollable fear, tremor, irritability, agitation, insomnia, and incontinence. They are talkative and preoccupied and experience visual, tactile, olfactory, and auditory hallucinations that often are terrifying. Autonomic overactivity occurs and is evidenced by tachycardia, dilated pupils, and profuse perspiration. Usually, all vital signs are elevated in the alcoholic toxic state.

The goals of management are to give adequate sedation and support to allow the patient to rest and recover without danger of injury or peripheral vascular collapse. A physical examination is performed to identify pre-existing or contributing illnesses or injuries (e.g., head injury, pneumonia). A drug history is obtained to elicit information that may facilitate adjustment of any sedative requirements. Baseline blood pressure is determined, because the patient's subsequent treatment may depend on blood pressure changes.

Usually, the patient is sedated as directed with a sufficient dosage of benzodiazepines to establish and maintain sedation, which reduces agitation, prevents exhaustion, prevents seizures,

and promotes sleep. The patient should be calm, able to respond, and able to maintain an airway safely on their own. A variety of medications and combinations of medications are used (e.g., chlordiazepoxide [Librium], lorazepam [Ativan], and clonidine [Catapres]). Haloperidol (Haldol), esmolol (Brevibloc), or midazolam (Versed) may be given for severe acute alcohol withdrawal syndrome. Dosages are adjusted according to the patient's symptoms (agitation, anxiety) and blood pressure response (ENA, 2013).

The patient is placed in a calm, nonstressful environment (usually a private room) and observed closely. The room remains lighted to minimize the potential for illusions (visual misrepresentations) and hallucinations. Homicidal or suicidal responses may result from hallucinations. Closet and bathroom doors are closed to eliminate shadows. Someone is designated to stay with the patient as much as possible. The presence of another person has a reassuring and calming effect, which helps the patient maintain contact with reality. To orient the patient to reality, any illusions are explained.

Nursing Alert: Restraints are used as prescribed, if necessary, if the patient is aggressive or violent, but only when other alternatives have been unsuccessful. The least restrictive device that will prevent the patient from injuring him- or herself or others is used. Caution is taken to ensure that restraints are applied properly and that they are not impairing circulation to any part of the body or interfering with respirations. Restraints should be used in tandem with verbal intervention to calm the patient and promote adherence. Restraints must be released according to protocol. Physical observation (e.g., skin integrity, circulatory status, respiratory status) is ongoing, and the patient's response is documented.

Fluid losses may result from gastrointestinal losses (vomiting), profuse perspiration, and hyperventilation. In addition, the patient may be dehydrated as a result of alcohol's effect of decreasing antidiuretic hormone. The oral or IV route is used to restore fluid and electrolyte balance.

Temperature, pulse, respiration, and blood pressure are recorded frequently (every 30 minutes in severe forms of delirium) to monitor for peripheral circulatory collapse or hyperthermia (the two most serious complications).

Frequently seen complications include infections (e.g., pneumonia), trauma, hepatic failure, hypoglycemia, and cardiovascular problems. Hypoglycemia may accompany alcohol withdrawal, because alcohol depletes liver glycogen stores and impairs gluconeogenesis; many patients with alcoholism also are malnourished. Parenteral dextrose may be prescribed if the liver glycogen level is depleted. Orange juice, sports drinks, or other sources of carbohydrates are given to stabilize the blood glucose level and counteract tremulousness. Supplemental vitamin therapy and a high-protein diet are provided as prescribed to counteract nutritional deficits. The patient should be referred to an alcoholic treatment center for follow-up care and rehabilitation.

VIOLENCE, ABUSE, AND NEGLECT

Family Violence, Abuse, and Neglect

EDs are often the first place where victims of family violence, abuse, or neglect go to seek help.

Clinical Manifestations

When people who have been abused seek treatment, they may present with physical injuries or health problems such as anxiety, insomnia, or gastrointestinal symptoms related to stress. The possibility of abuse should be investigated whenever a person presents with multiple injuries that are in various stages of healing, when injuries are unexplained, and when the explanation does not fit the physical picture. The possibility of neglect should be investigated whenever a person who is dependent shows evidence of inattention to hygiene, to nutrition, or to know medical needs (e.g., unfilled medication prescriptions, missed appointments with health care providers). In the ED, the most common physical injuries seen are unexplained bruises, lacerations, abrasions, head injuries, or fractures. The most common clinical manifestations of neglect are malnutrition and dehydration.

Assessment and Diagnostic Findings

Nurses in EDs are in an ideal position to provide early detection and interventions for victims of Intimate Partner Violence (IPV). This requires an acute awareness of the signs of possible abuse, maltreatment, and neglect. Nurses must be skilled in interviewing techniques that are likely to elicit accurate information. A careful history is crucial in the screening process. Asking questions in private—away from others—may be helpful in eliciting information about abuse, maltreatment, and neglect. Nurses need to be aware that women may withhold directly answering questions regarding IPV in fear of retaliation, loss of children, and retribution against the children (Amerson, Whittington, & Duggan, 2014).

Whenever evidence leads the nurse to suspect abuse or neglect, an evaluation with careful documentation of descriptions of events and drawings or photographs of injuries is important, because the medical record may be used as part of a legal proceeding. Assessment of the patient's general appearance and interactions with significant others, an examination of the entire surface area of the body, and a mental status examination are crucial.

Management

The aims of IPV screening include earlier identification of patients who have been abused and prevention of continued abusive events, including homicide (Day, Fox, Majercik, et al., 2015). Whenever abuse, maltreatment, or neglect is suspected, the health care provider's main concern should be the safety and welfare of the patient. Treatment focuses on the consequences of the abuse, violence, or neglect and on prevention of further injury. Protocols of most EDs require that a multidisciplinary approach be used. Nurses, physicians, social workers, and community agencies work collaboratively to develop and implement a plan for meeting the patient's needs.

If the patient is in immediate danger, he or she should be separated from the person who is abusive or neglectful whenever possible. Referral to a shelter may be the most appropriate action, but many shelters are inaccessible to people with mobility limitations.

When abuse or neglect is the result of stress experienced by a caregiver who is no longer able to cope with the burden of caring for an older adult or a person with chronic disease or a disability, respite services may be necessary. Support groups may be helpful to these caregivers. When mental illness of the person who is abusive or neglectful is responsible for the situation, alternative living arrangements may be required.

Nurses must be mindful that competent adults are free to accept or refuse the help that is offered to them. Some patients insist on remaining in the home environment where the abuse or neglect is occurring. The wishes of patients who are competent and not cognitively impaired should be respected. However, all possible alternatives, available resources, and safety plans should be explored with the patient.

Health care workers are expected to report *suspected* child abuse or abuse of older adults to a local police station or Child Protective Services. All that is required for reporting is the suspicion of abuse; the health care worker is not required to prove abuse or neglect. Likewise, health care workers who report suspected abuse are immune from civil or criminal liability if the report is made in good faith. Subsequent home visits resulting from the report of suspected abuse are a part of gathering information about the patient in the home environment.

Sexual Assault

The definition of *rape* is forced sexual acts, especially if these acts involve vaginal or anal penetration. Attempted rape may include verbal threats of rape (ENA, 2013). Perpetrators and victims may be either male or female.

The manner in which the patient is received and treated in the ED is important to their future psychological well-being. Crisis intervention should begin when the patient enters the health care facility. The patient should be seen immediately. Most hospitals have a written protocol that addresses the patient's physical and emotional needs as well as collection of forensic evidence.

Assessment and Diagnostic Findings

The patient's reaction to rape has been termed *rape trauma syndrome* and is seen as an acute stress reaction to a life-threatening situation. The nurse performing the assessment is aware that the patient may go through several phases of psychological reactions, which have been described as follows:

- An acute disorganization phase, which may manifest as an expressed state in which shock, disbelief, fear, guilt, humiliation, anger, and other such emotions are encountered or as a controlled state in which feelings are masked or hidden and the victim appears composed
- A phase of denial and unwillingness to talk about the incident, followed by a phase of heightened anxiety, fear, flashbacks, sleep disturbances, hyperalertness, and psychosomatic reactions that is consistent with PTSD (see later discussion)
- A phase of reorganization, in which the incident is put into perspective. Some victims never fully recover and go on to develop chronic stress disorders and phobias.

Management

The goals of management are to provide support, to reduce the patient's emotional trauma, and to gather available evidence for possible legal proceedings. All of the interventions are aimed at encouraging the patient to gain a sense of control over their life.

Throughout the patient's stay in the ED, the patient's privacy and sensitivity must be respected. The patient may exhibit a wide range of emotional reactions, such as hysteria, stoicism, or feelings of being overwhelmed. Support and caring are crucial. The patient should be reassured. The patient should never be left alone.

Physical Examination

A written, witnessed informed consent must be obtained from the patient (or parent or guardian if the patient is a minor) for examination, for taking of photographs, and for release of findings to police. A history is obtained only if the patient has not already talked to a police officer, social worker, or crisis intervention worker. The patient should not be asked to repeat the history. Any history of the event that is obtained should be recorded in the patient's own words. The patient is asked whether he or she has bathed, douched, brushed his or her teeth, changed clothes, urinated, or defecated since the attack, because these actions may alter interpretation of subsequent findings. The time of admission, time of examination, date and time of the alleged rape, and the patient's emotional state and general appearance (including any evidence of trauma, such as discoloration, bruises, lacerations, secretions, or torn and bloody clothing) are documented. If the patient has no recollection of the event, drugs that induce retrograde amnesia may have been involved, such as alcohol, ketamine, gamma-hydroxybutyrate, benzodiazepines, or flunitrazepam (Rohypnol). Urine drug test must be completed within 96 hours of the event to capture the presence of these drugs. Emesis can also be collected for testing (ENA, 2013).

For the physical examination, the patient is helped to undress and is draped properly. Each item of clothing is placed in a separate paper bag. As noted earlier, plastic bags are not used in order to avoid possible destruction of evidence from mold or mildew formation. The bags are labeled and given to appropriate law enforcement authorities.

The patient is examined (from head to toe) for injuries, especially injuries to the head, neck, breasts, thighs, back, and buttocks. Body diagrams and photographs aid in documenting the evidence of trauma. The physical examination focuses on the following:

- External evidence of trauma (bruises, contusions, lacerations, stab wounds)
- Dried semen stains (appearing as crusted, flaking areas) on the patient's body or clothes
- Broken fingernails and body tissue and foreign materials under nails (if found, samples are taken)
- Oral examination, including a specimen of saliva and cultures of gum and tooth areas

Pelvic and rectal examinations are also performed. The perineum and other areas are examined with a Wood lamp or other filtered ultraviolet light. Areas that appear fluorescent may indicate semen stains. The color and consistency of any discharge present is noted. A water-moistened, rather than lubricated, vaginal speculum is used for the examination. Lubricant contains chemicals that may interfere with later forensic testing of specimens and acid phosphatase determinations. The rectum is examined for signs of trauma, blood, and semen. During the examination, the patient should be advised of the nature and necessity of each procedure and given the rationale for each (ENA, 2013).

Specimen Collection

During the physical examination, numerous laboratory specimens may be collected, including the following:

- Vaginal aspirate, examined for presence or absence of motile and nonmotile sperm.
- Secretions (obtained with a sterile swab) from the vaginal pool for acid phosphatase, blood group antigen of semen, and precipitin test against human sperm and blood.

- Separate smears from the oral, vaginal, and anal areas.
- Culture of body orifices for gonorrhea.
- Blood serum for syphilis and HIV testing and deoxyribonucleic acid (DNA) analysis. A sample of serum for syphilis may be frozen and saved for future testing.
- Pregnancy test if there is a possibility that the female patient may be pregnant.
- Any foreign material (leaves, grass, dirt), which is placed in a clean envelope.
- Pubic hair samples obtained by combing or trimming. Several pubic hairs with follicles are placed in separate containers and identified as the patient's hair.

To preserve the chain of evidence, each specimen is labeled with the name of the patient, the date and time of collection, the body area from which the specimen was obtained, and the names of personnel collecting specimens. The specimens are then given to a designated person (e.g., crime laboratory technician), and an itemized receipt is obtained (ENA, 2013).

Treating Potential Consequences of Rape

After the initial physical examination is completed and specimens have been obtained, any associated injuries are treated as indicated. The patient is given the option of prophylaxis against sexually transmitted infections (STIs) (also referred to as sexually transmitted disease [STDs]). Ceftriaxone (Rocephin), given intramuscularly with 1% lidocaine (Xylocaine), may be prescribed as prophylaxis for gonorrhea. In addition, a single oral dose of metronidazole (Flagyl) and either a single oral dose of azithromycin (Zithromax) or a 7-day oral regimen of doxycycline may be prescribed as prophylaxis for syphilis and chlamydia (ENA, 2013); (Solheim, 2016).

Antipregnancy measures may be considered if the patient is a female of childbearing age. A postcoital contraceptive medication, such as an oral contraceptive medication that contains levonorgestrel and ethinyl estradiol (Alesse, Seasonique), may be prescribed after a pregnancy test. To promote effectiveness, the contraceptive medication should be given within 12 to 24 hours and no later than 72 hours after intercourse. The 21-day package is prescribed so that the patient does not mistakenly take the inert tablets included in the 28-day package. An antiemetic agent may be given as prescribed to decrease discomfort from side effects. A cleansing douche, mouthwash, and fresh clothing are usually offered.

Follow-Up Care

The patient is informed of counseling services to prevent long-term psychological effects. Counseling services should be made available to both the patient and the family.

The patient is encouraged to return to their previous level of functioning as soon as possible. When leaving the ED, the patient should be accompanied by a family member or friend.

PSYCHIATRIC EMERGENCIES

A psychiatric emergency is an urgent, serious disturbance of behavior, affect, or thought that makes the patient unable to cope with life situations and interpersonal relationships. A patient presenting with a psychiatric emergency may display overactive or violent, underactive or depressed, or suicidal behaviors.

The most important concern of the ED personnel is determining whether the patient is at risk for injuring self or others. The aim is to try to maintain the patient's self-esteem (and life, if necessary) while providing care. Determining whether the patient is under psychiatric care is important so that contact can be made with the therapist or physician who works with the patient.

Patients who are Overactive

Patients who display disturbed, uncooperative, and paranoid behavior and those who feel anxious and panicky may be prone to assaultive and destructive impulses and abnormal social behavior. Intense nervousness, depression, and crying are evident in some patients. Disturbed and noisy behavior may be exacerbated or compounded by alcohol or drug intoxication.

A reliable source for obtaining an accurate history is needed to identify events leading to the crisis. Past mental illness, hospitalizations, injuries, serious illnesses, the use of alcohol or drugs, crises in interpersonal relationships, or intrapsychic conflicts are explored. Because abnormal thoughts and behavior may be manifestations of an underlying physical disorder, such as hypoglycemia, drug or alcohol toxicity, a stroke, a seizure disorder, or head injury, a physical assessment is also performed.

The immediate goal is to gain control of the situation. If the patient is potentially violent, security or police should be nearby. Restraints are used as a *last* resort and only as prescribed. Approaching the patient with a composed, confident, and firm manner is therapeutic and has a calming effect. Helpful interventions include the following:

- Introduce yourself by name.
- Tell the patient, "I am here to help you."
- Repeat the patient's name from time to time.
- Speak in one-thought sentences, and be consistent.
- Give the patient space and time to slow down.
- Show interest in, listen to, and encourage the patient to talk about personal thoughts and feelings.
- Offer appropriate and honest explanations.

A psychotropic agent (e.g., one that exerts an effect on the mind) may be prescribed for emergency management of functional psychosis. However, a patient with a personality disorder should not be treated with psychotropic medications, and psychotropic medications should not be used if the patient's behavior results from the use of hallucinogens (e.g., lysergic acid diethylamide [LSD]).

Agents such as chlorpromazine and haloperidol act specifically against psychotic symptoms of thought fragmentation and perceptual and behavioral aberrations. The initial dose depends on the patient's body weight and the severity of the symptoms. After administration of the initial dose, the patient is observed closely to determine the degree of change in psychotic behavior. Subsequent doses depend on the patient's response. Typically, after stabilization, the patient is transferred to an inpatient psychiatric unit, or psychiatric outpatient treatment is arranged.

Posttraumatic Stress Disorder

PTSD is the development of characteristic symptoms after a psychologically stressful event that is considered outside the range of normal human experience (e.g., rape, combat, motor vehicle crash, natural catastrophe, terrorist attack). Symptoms of this disorder include intrusive thoughts and dreams, phobic avoidance reaction (avoidance of activities that arouse recollection of the traumatic event), heightened vigilance,

exaggerated startle reaction, generalized anxiety, and societal withdrawal. PTSD may be acute, chronic, or delayed. PTSD often presents as multiple readmissions to the ED for minor or recurring complaints without evidence of injury.

Patients who are Underactive or Depressed

In the ED, depression may be seen as the main condition bringing the patient to the health care facility, or it may be masked by anxiety and somatic complaints. The person who is depressed has a mood disturbance.

Any patient who is depressed may be at risk for suicide. Attempts are made to find out whether the patient has thought about or attempted suicide. Questions such as "Have you ever thought about taking your own life?" may be helpful. In general, the patient is relieved to have an opportunity to discuss personal feelings. If the patient is seriously depressed, relatives should be notified. The patient should never be left alone, because suicide is usually committed in solitude.

Patients who are Suicidal

Attempted suicide is an act that stems from depression (e.g., loss of a loved one, loss of body integrity or status, poor self-image) and can be viewed as a cry for help and intervention. Males are at greater risk of successfully committing suicide than females, who attempt suicide more often (ENA, 2013). In 2016, the suicide rate among Indians was 15.7/100,000. Sri Lanka had the highest suicide-related mortality rate of 35.3/100,000. Pakistan and Bangladesh had lower suicide rate with 2.1 and 5.5 per 100,000 respectively. The suicidal death rate in Maldives was 11.7/100,000 while in Bhutan and in Nepal it was 6.0 per 100,000 (WHO, 2017).

Others at risk are older adults; young adults; people who are enduring unusual loss or stress; those who are unemployed, divorced, widowed, or living alone; those showing signs of significant depression (e.g., weight loss, sleep disturbances, somatic complaints, suicidal preoccupation); and those with a history of a previous suicide attempt, suicide in the family, or psychiatric illness.

Being aware of people at risk and assessing for specific factors that predispose a person to suicide are key management strategies. Specific signs and symptoms of potential suicide include the following:

- Communication of *suicidal intent,* such as preoccupation with death or speaking of someone else's suicide (e.g., "I'm tired of living. I've put my affairs in order. I'm better off dead. I'm a burden to my family.")
- History of a previous suicide attempt, with risk being much greater in these cases
- Family history of suicide
- Loss of a parent at an early age
- Specific plan for suicide
- A means to carry out the plan

Emergency management focuses on treating the consequences of the suicide attempt (e.g., gunshot wound, drug overdose) and preventing further self-injury. A patient who has made a suicidal attempt may do so again. Crisis intervention is used to determine suicidal potential, to discover areas of depression and conflict, to find out about the patient's support system, and to determine whether hospitalization or psychiatric referral is necessary. Depending on the patient's potential for suicide, the patient may be admitted to the intensive care unit, referred for follow-up care, or admitted to the psychiatric unit.

Legal and Ethical Issues in Emergency Nursing

Article 21 of the Constitution of India ensures the right to life and dignity, but there is no specific legal provision for the right for emergency care (Uttamdubey, 2021). During the COVID pandemic, patients who required medical services, O_2 therapy, and ventilator care were denied care due to lack of availability. In certain hospitals, emergency care was denied till patients could produce a COVID-19 negative certificate. India, with a vast population of 135 crores, has only 0.7 beds per 1000 people. Acute shortage of critical resources and lack of trained manpower leads to undue delay in provision of timely care to accident victims.

The trauma patients reaching emergency are denied care during golden period and they are subjected to travel far away hospitals for further treatment which puts life of the victims under jeopardy. Based on the litigation filed in supreme court of India, Pramand Katra vs. Union of India, the court directed that the emergency care should not be denied to accident victims. It mandates the duty doctors and other professionals in emergency room/casualty to attend and provide first aid to the victim irrespective of other legal formalities. The bystanders role is equally important for better patient outcome. As per the recent reports, three out of four bystanders at the accident scene do not help the injured victim for fear of police harassment, imprisonment, and legal hurdles (Chauhan, 2022). The recent amendment of the Motor Vehicle Act, 2019, based on the good Samaritan principle allows the bystanders/volunteers to help the accident victims without any legal impingements.

Nurses or Emergency room physician who handle victims of terror, road traffic accident, assault, or attempted suicide need to inform the nearest police station. The particular patient has to be considered as a medicolegal case. In the instances of the death of a patient registered under medicolegal case registry, the deceased victim's body should never be handed over to the family members; rather it has to be handed over to the police for autopsy. In case the victim is transferred or discharged, the same police station officials need to be intimated about the discharge/transfer.

Nurses' record become legal document and may be present to the court. Nurses need to record their observations neatly and legibly. All the evidence, articles, emesis, or discharge, etc., may be preserved for further forensic analysis. In some instances, the dying victim may explain the cause of her impending death to the health care team which may become the dying declaration.

Ethical Issues in Emergency Nursing

Ethics are the philosophical guidelines to guide nurses in decision making when the situation presents with an ethical dilemma. The guiding ethical principles are as follows:

- **Beneficence:** Doing things that help the patient to recover from illness or debility.
- **Nonmaleficence:** Doing no harm.
- **Justice:** Being fair to all in allocation of resources or time for care.
- **Autonomy:** Every individual patient has the right to determine what treatment they need to take or stop taking the treatment. Nurses need to ensure that the ethical principle of autonomy is adhered.
- **Confidentiality:** Keeping the confidential personal information secret. Divulging information only when the situation warrants to those involved in the personal care of the individual.
- **Veracity:** Telling the truth only.

There are many instances where more than one ethical principles lie contrary to each other and create a dilemma. According to the principle of beneficence, every patient needs to be treated and cared for in a timely manner to aid in recovery. During the process of triage some patients may be wrongly placed in low priority and eventually they may transcend to high priority. In a country like India with limited medical resources, a patient may not be provided with the most suitable treatment options all the time due to lack of valued resources.

In some situations, the injured patients or victims of terrorism may be brought to the hospital in unconscious state without any of their legal heir. Major health care decisions like surgery may get delayed or may be taken by the treating physician. In this case, the principle of autonomy and principle of beneficence may be the conflicting values. In case of poisoning, the confidentiality and autonomy is in question. Principle of Justice could not be adhered to at times. For example, the world witnessed the COVID pandemic and there was acute shortage of resources. Principles of Justice had been violated in this scenario

CRITICAL THINKING EXERCISES

1. After falling down the stairs, a 25-year-old woman arrives at the ED by car accompanied by an older male. Various parts of her body have bruises, some of which appear to be in various stages of healing. When asked to step to the waiting room, the male refuses; security is required to remove him from the room so that the patient examination can occur privately. The patient is particularly quiet and does not actively participate in her history or questions regarding her injuries. As the nurse interviewing and assessing this patient, what do you suspect? You also note that the patient jumps at a knock on the door and pulls away from touch. She states her occupation is a waitress. How do you evaluate the patient situation? What is expected of the nurse in terms of reporting the patient situation? What strategies should be used to provide sensitive care for this patient?
2. A 28-year-old male with a gunshot wound arrives to the hospital lobby after being dropped off by an unknown driver who has abandoned him. He is actively bleeding from multiple wounds in his chest and abdomen and is having difficulty breathing and speaking. The security guard in the lobby calls the ED. The patient is brought rapidly to the ED for assessment and disposition. What are the first measures of the primary survey that you will use to assess and stabilize the patient? Will you expect to administer blood products? What do you anticipate in terms of the ED disposition for this patient? What security measures need to be in place to maintain patient, staff, and visitor safety?
3. Two males in their thirties are transported by EMS to the ED after a house-fire. The EMS agency states suspicious evidence was found in the kitchen, which seemed to be the source of the fire. The patients are hesitant to discuss the events prior to the fire. Both suffered multiple full-thickness burns to their upper extremities, face, neck, and chest. EMS personnel expressed concern about contaminants at the scene, which may be on the patients' clothing. What decision must be made regarding decontamination versus immediate burn care? What is the possible source of the contaminants? As with all patients who have experienced trauma, what is the strength of the evidence that dictates first priorities? In addition to the contaminants, to what other chemical were the patients exposed that may result in inadequate ventilation?
4. It is midsummer and you work in an urban ED. The community includes a large low income and older adult population, and many local residents are concerned about the degree of crime in the area. An 80-year-old woman is brought to the ED unresponsive, skin very dry, pale, with low blood pressure, and with slight tachycardia. Her history includes that she takes a beta blocker and a diuretic for hypertension. Her family states that she lives alone without air conditioning. She rarely opens windows or uses a fan in a window due to fear of a break-in. What do you suspect is the primary problem for this patient? What would you expect her core temperature to be? What will be the immediate treatment for this disorder from which she is suffering? What do you expect her ED disposition to be?

CHAPTER 61

Terrorism, Mass Casualty, and Disaster Nursing

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Identify the necessary components of an emergency operations plan.
2. Discuss how triage in a disaster differs from triage in an emergency department.
3. Evaluate the different levels of personal protection and decontamination procedures that may be necessary during an event involving mass casualties or weapons of mass destruction.
4. Describe the physical injuries that may occur after blast events
5. Explain how to implement isolation precautions necessary for bioterrorism agents.
6. Compare and contrast the differences among various chemical agents used in terrorist events, their effects, and the decontamination and treatment procedures that are necessary.
7. Determine the injuries associated with varying levels of radiation or chemical exposure and the associated decontamination processes.

GLOSSARY

biologic weapon: a biologic agent that is used to spread disease among the general population or the military

chemical weapon: a chemical agent that is used to cause disability and mortality in the general population or the military

decontamination: process of removing, or rendering harmless, contaminants that have accumulated on personnel, patients, and equipment

disaster/mass casualty incident (MCI): a catastrophe or calamity which may be natural or manmade in which the number of casualties exceeds the number of available resources beyond the coping abilities of the affected community.

personal protective equipment (PPE): equipment beyond standard precautions; may include different levels of equipment to provide complete protection, depending on the nature of the suspected biologic, chemical or radiologic agent

radiologic weapon: by-products of radiation contamination that are used to cause morbidity and mortality in the general population or the military

terrorism: unlawful, systematic use of violence or threats of violence against people in order to coerce or intimidate

weapons of mass destruction (WMD): weapons used to cause widespread death and destruction

Introduction

The possibility and reality of mass casualties associated with disasters, terrorism, and biologic warfare are not new to human history, nor is the concept of using weapons of mass destruction (WMD) However, geopolitical forces and interests and the availability of destructive technology have brought the possibility of more terrorist events to our doorstep. Terrorism involves the systematic use of violence to create feelings of fear. Examples include the Mumbai terror attack on March 12, 1993, the destruction of the World Trade Center towers, and the damage to the Pentagon on September 11, 2001; the Delhi serial blast on October 29, 2005, the coordinated series of terrorist attacks in Mumbai for four days on November 26, 2008, and in Brussels on March 22, 2016. Since 2000, the number of deaths throughout the globe from terrorism equals the number of deaths from the bombing of Hiroshima in 1945 (Costa-Roberts, 2015). Terrorists have become increasingly sophisticated, organized, and therefore effective.

The U.S. Department of Homeland Security was created after the attacks of September 11, 2001, to coordinate federal and state efforts to combat terrorist activity. Similarly, in India, the disaster management act was passed in the parliament of India in 2005. This act enables coordinated, legally, and financially viable disaster management plan from center to peripheral community level. The preparation is based on the National disaster management guidelines which are effective in tackling both man terrorist events, as well as natural disasters.

Warfare, terrorism, and natural disasters are just some of the reasons nurses must plan for mass casualties. Airplane crashes, train crashes, toxic substance spills, and infectious disease outbreaks are other disasters that can result in mass casualties and tax the resources of health care facilities and their communities. Acute care facilities must be prepared for any and all of these disasters. This chapter focuses on disaster preparedness, including information about possible terrorist-related injuries and illnesses that can occur after, chemical, biologic and nuclear or radiation attacks. Information about the process that nurses should follow in order to respond to these emergencies is applicable to other types of mass disasters as well.

Central, State, and Local Responses to Emergencies

Many resources are available at the central, state, and local levels to assist in the disaster management and to provide emergency relief operations. A disaster is defined a catastrophe or calamity which may be natural or manmade in which the number of casualties exceeds the number of available resources to cope up (National Policy on Disaster Management, 2009). When resources to care for casualties become scarce, the greatest good for the greatest number of patients becomes the mode of operation (see Chart 61-1). Local communities must be prepared to act in isolation (i.e., called *sustainability planning*)

Chart 61-1 ETHICAL DILEMMA

Who Receives Care First During a Mass Casualty?

Case Scenario

You work as a staff nurse in the emergency department (ED) of a 75-bed community hospital. The unit is notified that an armed man entered the local social security office building and began shooting people in the lobby. There were numerous casualties, including the perpetrator, who was shot by a police officer. Within minutes of the notification, several patients are transported into the trauma bay area with gunshot wounds and other traumatic injuries. A young man appears to be hallucinating and attempts to assault a staff nurse. The perpetrator of the violent assault is transported into the trauma bay on a gurney, with an apparent gunshot wound to the head. An older woman grabs your arm and yells, "You have to take care of my husband first! He has a bad heart and may not be able to survive!" Another patient points at the perpetrator and yells, "He is the one who is responsible for this! How can you treat him?! He doesn't deserve to live!"

Discussion

One of the most difficult and morally distressing situations that nurses working in the ED may face is how to triage and treat patients when medical resources are scarce. Participating in disaster drills may prepare nurses working in the ED in how to respond if an emergency operations plan needs to be executed for a true mass casualty situation. These drills are intended to assist nurses in the ED to triage and prioritize care in a way that is unbiased. The key principle of triage in these situations is to do the greatest good for the greatest number of people. Medical resources must be distributed to patients in a fair and equitable manner.

Analysis

- Describe the ethical principles that are in conflict in this case (see Chapter 2, Chart 2-3). Which principle should have preeminence as you respond to the patient who feels the perpetrator does not have a right to receive medical care?
- Reflect upon your own desire to do good (i.e., practice beneficence) and how this desire to help an older couple may affect your triage decision. How would you respond to the wife? Should the age of her husband and his past medical history influence the triage process?
- How would you most appropriately triage the patient who has no visible physical injuries but is apparently experiencing a mental health crisis?

Resources

See Chapter 2, Chart 2-6 for ethics resources.

Abbasi, J. (2016). Expanding the health care response to mass violence. JAMA, 316(10), 1031–1033.

and provide competent care for up to 5 days before central or other state resources may become available (American College of Surgeons [ACS], 2010).

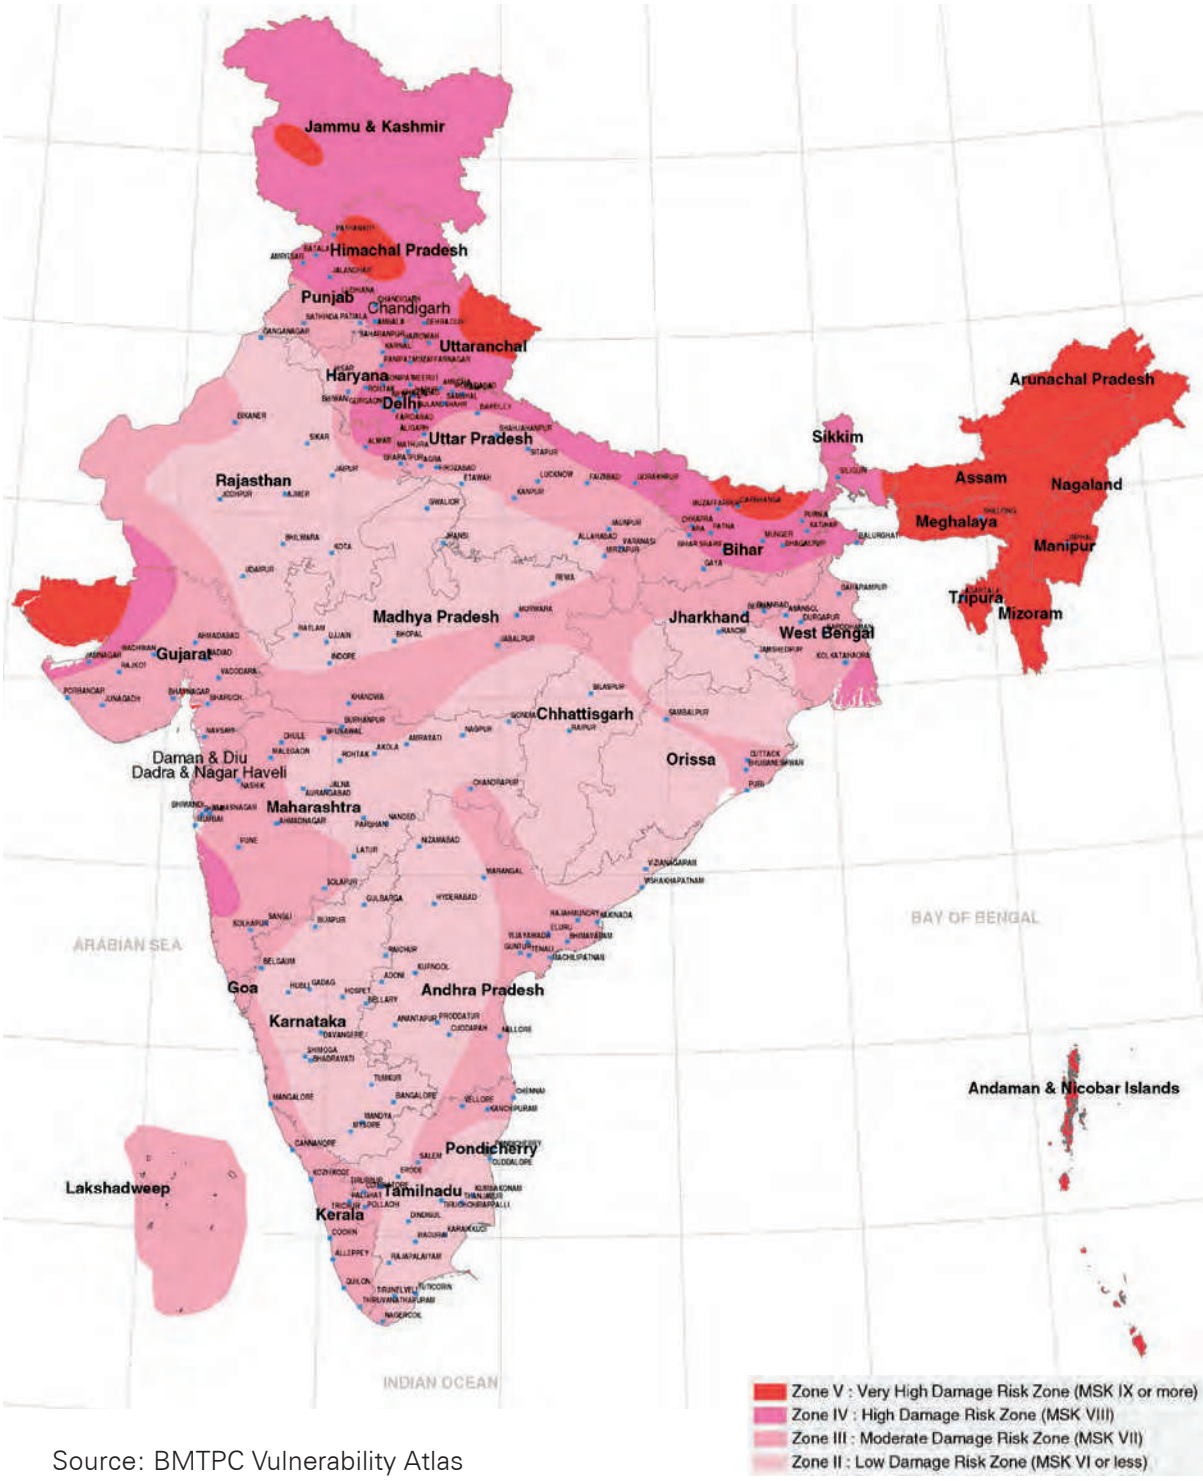
Disasters are categorized by type based upon anticipated use of resources and incident duration. A list of local resources with specific instructions about how and when to contact these agencies or organizations should be readily available to local disaster planning committees and frequently reviewed by those committees for necessary updates.

A disaster response strategy cannot succeed without appropriate physical assets and a staff trained and prepared to carry out the plan. Assets such as increased security; stockpiles of equipment and medications; and planning, drills, and training are essential (Veenema, 2013). Hazard vulnerability assessments should be performed to identify potential and actual threats that involve a particular facility and community. Mutual aid agreements among various communities must take these vulnerabilities into account. Successful execution of a response plan is based on knowledge, confidence, and readiness.

Disaster Management—Indian Perspective

India is susceptible to different types of natural and manmade disasters. 58.6% of the land area is prone to earthquakes of moderate to high degree. The states of Assam, West Bengal, parts of Odisha, Punjab are all flood prone. Figure 61-1A and B depicts high-risk areas for earthquake and cyclone of varying degrees respectively. The large hilly terrains have high risk of landslide and floods. States lying in the Himalayan ranges are at risk of avalanches. The country being in the tropical region is also prone to drought. India is also facing the threat of huge terrorist attacks and counter insurgency (National Policy on Disaster Management, 2009).

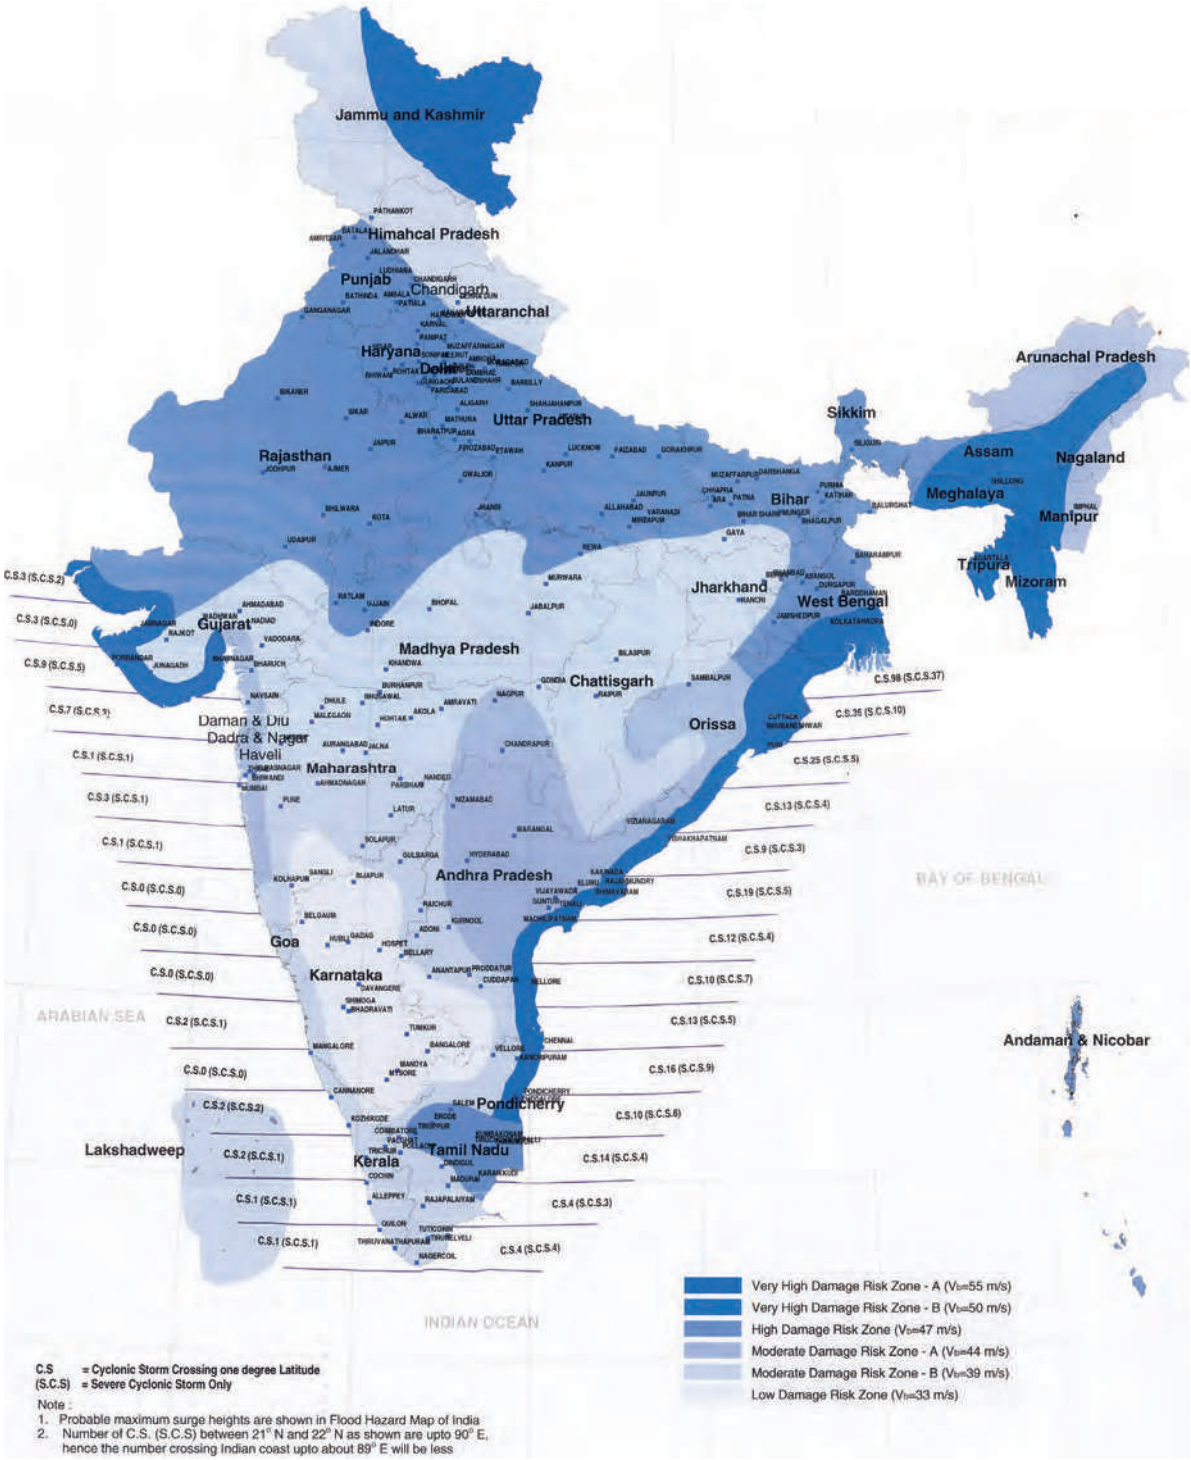
Disaster Management Cycle



Disaster management can be described as a cyclic phenomenon. The cycle consists of disaster preparedness, mitigation and prevention, and risk reduction which are all activities in the proactive phase of a crisis or pre-disaster phase activities. The disaster response and rehabilitation and recovery are post-disaster phase activities. If the pre-disaster phase activities are sound, the post-disaster phase response and recovery can be faster, quicker, and nearly complete one (Fig. 61-2). The new disaster management policy envisions a sound disaster resilient India. Capacity building forms the backbone of the pre-disaster phase activities.

Disaster Management at Central Level

The Government of India has passed a legislation in 2005 called Indian Disaster Management Act. This act enabled integrated financially and legally viable coordinated functioning from the central to state, district, and local levels. The National Disaster Management Authority (NDMA) is the apex body working under the leadership of the Prime Minister of India. The NDMA aims at effective disaster preparation, mitigation, and prevention so that the loss of life and property is minimized. The NDMA takes all policy decisions related to disaster management. It has the authority to deal with all types of disasters, including chemical, biological, radiation and nuclear attacks, and terror attacks. The direction and control of National Disaster Response Force (NDRF) comes under the purview of the NDMA. The National Institute of Disaster Management is the premier institute constituted with the objective of capacity building at the central level and region wise in collaboration with various ministries (National Disaster Management Plan, 2016).



Various types of disasters are coordinated by Ministry of Home Affairs. The specific ministries and the type of disaster handled are as follows.

- Flood: Ministry of Water Resources

- Chemical and industrial disaster: Ministry of Environment, Forest and Climate Change
- Radiation and nuclear disaster: Ministry of Atomic Energy

At the central level, the agencies handling disaster management are cabinet committee for security, national executive committee, and the national crisis management committee. The cabinet committee on security appraises periodically the disaster preparedness, the possible threats, and the national security implications. The national crisis management committee controls, directs, coordinates, and evaluates the disaster relief responses following specific disaster. The national executive committee under the chairmanship of Home secretary assists NDMA in its activities (National Disaster Management Plan, 2016).

Disaster Management at the State, District, and Local Level

The Home Ministry, other respective ministries, and NDMA coordinate with the state governments and union territories in disaster management activities. The state government has a similar pattern of organization with the chief minister heading the State Disaster Management Authority (SDMA). The respective home affairs minister coordinate the activities at the state level. The state executive committee provides assistance to SDMA. Under the Disaster Management Act, the state government is expected to be prepared with state disaster relief force and has its own mechanism to mitigate disaster.

At the district level, collector is the head of District Disaster Management Authority (DDMA). At times of crisis, relief activities are carried out by the collector and the DDMA with the direction and assistance of central and state government. The central and state relief forces are deployed (National Disaster Management Plan, 2016).

In the case of a disaster, the district level hospital or a medical college hospital is set up as the nodal center. Nodal medical relief team has to be set up under the direction of district medical officer. There should be networking to mobilize the needed resources, men, and material. The collector has to work in coordination with private and corporate health care agencies, blood banks, and voluntary agencies. Police may involve in appropriate traffic control for quick mobilization of needed resources, control of rumors, law and order problems. Fire fighters, home guards, and civil defense volunteers have to be involved in rescue, salvage, and transportation of casualties (Guidelines for Hospital Emergency Preparedness Plan, 2008).

Hospital Emergency Preparedness Plans

Health care facilities are required by the Joint Commission to create a plan for emergency preparedness and to practice this plan at least twice a year (ACS Committee on Trauma [ACS-COT], 2014). In general, these plans are developed by the facility's safety/disaster management committee and are overseen by an administrative liaison.

Before the basic emergency operations plan (EOP) can be developed, the planning committee of the health care facility first evaluates characteristics of the community to identify the likely types of natural and manmade disasters that might occur. This hazard vulnerability analysis process is the responsibility of the local health care facility and its safety committee, safety officer, or emergency department (ED) manager. This information can be gathered by questioning local law enforcement, fire departments, and emergency medical systems and assessing the patterns of local train traffic, automobile traffic, and flood, earthquake, tornado, or hurricane activity. Consideration is also given to possible mass casualties that could arise because of the community's proximity to chemical plants, nuclear facilities, or military bases. Government, judicial, or financial buildings, schools, and any places where large groups of people gather can be considered high-risk areas.

The emergency preparedness planning committee must have a realistic understanding of its resources. It must determine, for example, whether the facility has or needs a pharmaceutical stockpile (e.g., vaccinations, antibiotics) available to treat specific chemical or biologic agents (ACS, 2010). Another scenario that might be anticipated may include the dispersal of a pulmonary intoxicant or choking agent, which would require that emergency operations planners determine how many ventilators are available within the facility and throughout the greater community. The committee might also outline how staff would triage and assign priority to patients when the number of ventilators is limited. Multiple factors influence a facility's ability to respond effectively to a sudden influx of injured patients, and the committee must anticipate various scenarios to improve its preparedness.

Components of the Emergency Operations Plan

The principles of emergency management must be a part of the EOP design and include a comprehensive plan for tackling all potential and actual hazards. The main goal is protection of the community. The EOP should be integrated with local, state, and central government plans and coordinated with the private sector and volunteers. It must be coordinated in advance to achieve a single common purpose, yet the plan must be flexible enough to adapt to any likely situation at hand. Predetermined organization is essential to minimize confusion, ensure that all key operations are directed, identify and correct flaws in the plan, and promote a well-coordinated response. Essential components of the EOP include the following (ACS, 2010):

- **Activation response:** The EOP activation response of a health care facility defines where, how, and when the response is initiated.

- **Internal/external communication plan:** Communication is critical for all parties involved, including communication to and from the prehospital arena.
- **Plan for coordinated patient care:** A response is planned for organized patient care into and out of the facility, including transfers from within the hospital to other facilities. The site of the disaster can determine where the greater number of patients may self-refer.
- **Security plans:** A coordinated security plan involving facility and community agencies is key to the control of an otherwise chaotic situation.
- **Identification of external resources:** Resources outside of the facility are identified, including local, state, and central government resources and information about how to activate these resources.
- **Plan for people management and traffic flow:** "People management" includes strategies to manage the patients, the public, the media, and personnel. Specific areas are assigned and a designated person is delegated to manage each of these groups
- **Data management strategy:** A data management plan for every aspect of the disaster will save time at every step. A backup system for documenting, tracking, and staffing is developed if the facility utilizes an electronic health record.
- **Demobilization response:** Deactivation of the response is as important as activation; resources should not be unnecessarily exhausted. The person who decides when the facility resumes daily activities is clearly identified. Any possible residual effects of a disaster must be considered before this decision is made.
- **After-action report or corrective plan:** Facilities often see increased volumes of patients 3 months or more after an incident. Postincident response must include a critique and a debriefing for all parties involved, immediately and again at a later date.
- **Plan for practice drills:** Practice drills that include community participation allow for troubleshooting any issues before a real-life incident occurs.
- **Anticipated resources:** Food and water must be available for staff, families, and others who may be at the facility for an extended period.
- **MCI planning:** MCI planning includes such issues as planning for mass fatalities and morgue readiness.
- **Education plan for all of the above:** A strong education plan for all personnel regarding each step of the plan allows for improved readiness and additional input for fine-tuning of the EOP.

As noted previously, hospitals are required to periodically hold disaster drills. Results from these drills can identify flaws within the EOP as well as unanticipated needs prior to any real disaster situation. Full-scale regional exercises that coordinate responses from both hospitals and emergency medical services (EMS) have been demonstrated as the most effective drills because they clearly identify breakdowns in communication (Nadworny, Davis, Miers, et al., 2014).

Initiating the Emergency Operations Plan

Notification of a disaster situation to a health care facility varies with each situation. In general, the notification to the facility comes from outside sources unless the initial incident occurred at the facility. The disaster activation plan should clearly state how the EOP is to be initiated. If communication is functioning, field incident command will give notice of the approximate number of patients who are arriving, although the number of patients who are self-referring will not be known.

Identifying Patients and Documenting Patient Information

Patient tracking is a critical component of casualty management. Disaster tags, which are numbered and include triage priority, name, address, age, location and description of injuries, and treatments or medications given, are used to communicate patient information. The tag should be securely placed on the patient and remain with the patient at all times. The tag number and the patient's name, if known, are recorded in a disaster log. The log is used by the command center to track patients, assign beds, and provide families with information.

Triage

Triage is the sorting of patients to determine the priority of their health care needs and the proper site for treatment. In non-disaster situations, health care workers assign a high priority and allocate the most resources to those who are the most critically ill (see Chapter 60). For example, under ordinary circumstances, a young adult who has a chest injury and is in cardiac arrest would receive advanced cardiopulmonary resuscitation, including medications, chest tubes, intravenous (IV) fluids, blood, and possibly emergency surgery in an effort to restore life. However, in a disaster, when health care providers are faced with a large number of casualties, the fundamental principle guiding resource allocation is to do the greatest good for the greatest number of people. Decisions are based on the likelihood of survival and consumption of available resources. Therefore, this same patient, and others with conditions associated with a high mortality rate, will be assigned a low triage priority in a disaster situation, even if the person is conscious. Although this may sound uncaring, from an ethical standpoint, the expenditure of limited resources on people with a low chance of survival, and denial of those resources to others with serious but treatable conditions, cannot be justified.

The triage officer rapidly assesses those injured at the disaster scene. Patients are immediately tagged and transported or given lifesaving interventions. One person performs the initial triage while other EMS personnel perform immediate lifesaving measures (e.g., intubation) and transport patients. Although EMS personnel carry out initial field triage, secondary and continuous triage at all subsequent levels of care is essential.

Staff should control all entrances to the acute care facility so that patients who are incoming are directed to the triage area first. Traffic control within the facility is one of the most important components of managing the disaster and resources (ACS, 2010). The triage area may be outside the entry or just at the door of the ED. This facilitates the triage of all patients—those arriving by medical transport and those who walk into the ED. Some patients who have already been seen in the field may be reclassified in the triage area based on their current presentation.

Triage categories separate patients according to severity of injury. A special color-coded tagging system is used during an MCI so that the triage category is immediately obvious. There are several triage systems in use across the country, and every nurse should be aware of the system used by their facility and community. The North Atlantic Treaty Organization (NATO) triage system is one that is widely used. It consists of four colors: red, yellow, green, and black. Each color signifies a

TABLE 61-1 Triage Categories During a Mass Casualty Incident

Triage Category	Priority	Color	Typical Conditions
Immediate: Injuries are life threatening but survivable with minimal intervention. Individuals in this group can progress rapidly to expectant if treatment is delayed.	1	Red	Sucking chest wound, airway obstruction secondary to mechanical cause, shock, hemothorax, tension pneumothorax, asphyxia, unstable chest and abdominal wounds, incomplete amputations, open fractures of long bones, and 2nd/3rd-degree burns of 15–40% total body surface area
Delayed: Injuries are significant and require medical care but can wait hours without threat to life or limb. Individuals in this group receive treatment only after immediate casualties are treated.	2	Yellow	Stable abdominal wounds without evidence of significant hemorrhage; soft tissue injuries; maxillofacial wounds without airway compromise; vascular injuries with adequate collateral circulation; genitourinary tract disruption; fractures requiring open reduction, débridement, and external fixation; most eye and central nervous system injuries
Minimal: Injuries are minor, and treatment can be delayed hours to days. Individuals in this group should be moved away from the main triage area.	3	Green	Upper extremity fractures, minor burns, sprains, small lacerations without significant bleeding, behavioral disorders or psychological disturbances
Expectant: Injuries are extensive, and chances of survival are unlikely even with definitive care. Persons in this group should be separated from other casualties, but not abandoned. Comfort measures should be provided when possible.	4	Black	Patients who are unresponsive with penetrating head wounds, high spinal cord injuries, wounds involving multiple anatomic sites and organs, 2nd/3rd-degree burns in excess of 60% of body surface area, seizures or vomiting within 24 hours after radiation exposure, profound shock with multiple injuries, agonal respirations; no pulse, no blood pressure, pupils fixed and dilated

Adapted from American College of Surgeons. (2010). Disaster management and emergency preparedness course. Chicago: Author.

different level of priority. Table 61-1 describes each category and gives examples of how different injuries would be classified (see Chapter 60).

Managing Internal Problems

The Red Cross has developed a basic survival/shelter resource kit; however, each facility must determine its supply lists based on its own needs assessment. The EOP committee should determine the top 10 critical medications used during normal day-to-day operations and then anticipate which other medications may be required in a disaster or an MCI. For example, the health care facility might plan to have available a stockpile of antidotes (e.g., cyanide kits) or antibiotics used in treating biologic agents. Information should be available about stocking or restocking any of the basic and special supplies, how those supplies are requested, and the time required to receive those supplies.

Communicating with the Media and Family

Communication is a key component of disaster management. Communication within the vast team of disaster responders is paramount; however, effective, informative communication with the media and worried family members is also crucial.

Managing Media Requests for Information

Although the media have an obligation to report the news and can play a significant positive role in communication, the number of reporters and newscasters and their support teams can be acute, possibly compromising operations and patient confidentiality. The disaster plan should include a clearly defined process for managing media requests, including a designated spokesperson, the public information officer, a site for the dissemination of information (away from patient care areas), and a regular schedule for providing updates.

The EOP helps prevent the release of contradictory or inaccurate information. Initial statements should focus on current efforts and what is being done to better understand the scope and impact of the situation. Information about casualties should not be released. Security staff should not allow media personnel access to patient care areas. However, media resources may be mobilized to notify the general population when disease containment is needed in case of an epidemic or the potential for one, including the location of shelters, necessity of quarantines, and point of dispensing units in the case of bioterrorism (ACS, 2010).

Caring for Families

Friends and family members converging on the scene must be cared for by the facility. The public information officer's role is to provide direction for the families and provide them with information as it becomes available. They may be feeling intense anxiety, shock, or grief and should be provided with information and updates about their loved ones as soon as possible and regularly thereafter. They should not be in the triage or treatment areas but in a designated area staffed by available social workers, counselors, or therapists. Access to this area should be controlled to prevent families from being disturbed. Information regarding loved ones can also be obtained at this time, which assists in identification of both the injured and deceased. Chart 61-2 discusses cultural variables to consider when coping with disaster-related injuries and death.

The Nurse's Role in Disaster Response Plans

Nurses make up the largest component of the health care workforce across the globe (Veenema, 2013). The role of the nurse during a disaster varies. Nurses may be asked to perform duties outside their areas of expertise and may take on responsibilities normally held by physicians or advanced practice nurses. For example, a critical care nurse may intubate a patient or even insert a chest tube. A nurse may perform wound débridement or suturing. A nurse may serve as the triage officer. In these situations, it is imperative that nurses strive to maximize patient safety and be aware of state regulations related to nursing practice (American Nurses Association, 2010).

Although the exact role of a nurse in disaster management depends on the specific needs of the facility at the time, it should

Chart 61-2

Cultural Considerations

Any disaster or mass casualty incident can be expected to involve members of diverse religious, ethnic, and cultural groups or may be targeted at and predominately affect a specific religious or ethnic group. Health care providers likewise include members of all religious, ethnic, and cultural backgrounds and should bear in mind that victims may have needs relating to the following:

- Language difficulties that increase fears and frustrations
- Specific religious practices related to medical treatment, hygiene, or diet
- Specific places/times for prayer
- Rituals about handling the dead
- Timing of funeral services
- Family roles and extended family importance
- Privacy

Some religious communities have plans for emergencies and disasters, and local hospitals should integrate these plans to the extent possible into their emergency operations plans.

Chart 61-3

Caring for People with Disabilities During a Disaster

When a disaster occurs, the multiple agencies involved attempt to provide food, water, and shelter to all those affected. People with disabilities have specific needs that require attention. It is recommended that people with disabilities have a personal support network to check on them after a disaster and to provide needed assistance. They should also have a backup system and an evacuation plan.

Evacuation assistance is imperative for people with disabilities. Directions to personal equipment (e.g., communication aids, medications, oxygen) should be available to rescue personnel. In a rapid evacuation, mobility devices, oxygen, suction, and medications will be needed at the shelters. Special efforts to keep those with vision or hearing impairment informed should be implemented. People skilled in sign language are also valuable resources during a disaster. On their websites, the American Red Cross and the National Organization on Disability provide information for disaster preparedness for people with disabilities (see the Resources section).

Adapted from U.S. Department of Homeland Security Federal Emergency Management Agency (FEMA) & the American Red Cross. (2004). *Preparing for disaster for people with disabilities and other special needs*. Retrieved on 11/26/2016 at: www.redcross.org/images/MEDIA_CustomProductCatalog/m4240199_A4497.pdf; World Health Organization. (2005). *Disasters, disability and rehabilitation*. Retrieved on 11/26/2016 at: www.who.int/violence_injury_prevention/other_injury/disaster_disability2.pdf

be clear which nurse or physician is in charge of a given patient care area and which procedures each individual nurse may or may not perform. Assistance can be obtained through the home guards or St Johns ambulance, and nonmedical personnel can provide services where possible. For example, family members can provide non skilled interventions for their loved ones. Nurses should remember that nursing care in a disaster focuses on essential care from a perspective of what is best for all patients. In addition, acquiring knowledge of the hospital disaster plan, participating in drills, and honing competencies relating to disaster management are essential (Emergency Nurses Association [ENA], 2014). Nurse leaders/administrators should be cognizant of potential security issues and assess and plan for surge capacity capability and in-house resources such as water, supplies, pharmaceuticals, and generator power. They also should predetermine means to evacuate the hospital if necessary, including an ultimate destination or destinations. The hospital must take into account in its plans shortages of all kinds—staff, medications, water/food, and equipment (ACS-COT, 2014); (ENA, 2014).

New settings and atypical roles for nurses arise during a disaster—for example, the nurse may provide shelter care in a temporary housing area or bereavement support and assistance with identification of deceased loved ones. People may require crisis intervention, or the nurse may participate in counseling other staff members and in Critical Incident Stress Management (CISM). Special care may be warranted for at-risk populations during a disaster (see Chart 61-3).

Managing Behavioral Issues

Although most people pull together and function well during a disaster, both people and communities suffer immediate and sometimes long-term psychological trauma that most often relates to fear and anxiety (ENA, 2014). Common responses to disaster include:

- Anxiety
- Depression
- Impaired performance
- Interpersonal conflicts
- Posttraumatic stress disorder
- Somatization (fatigue, general malaise, headaches, gastrointestinal disturbances, skin rashes)
- Substance abuse

Factors that influence a person's response to disaster include the degree and nature of the exposure to the disaster; loss of friends, family members, and pets; existing coping strategies; available resources and support; and the personal meaning attached to the event. Other factors, such as loss of home and valued possessions, extended exposure to danger, and exposure to toxic contamination, also influence response and increase the risk of adjustment problems. Those exposed to the dead and injured, those endangered by the event, older adults, children, emergency first responders, and health care personnel caring for victims are considered to be at higher risk for emotional sequelae. A person's normal response to stress and bereavement will also affect the response after a disaster. A bioterrorism attack can have psychological effects, resulting in psychogenic illnesses such as panic, fear, and/or anger (ENA, 2013).

Nurses can assist victims of disaster through active listening and providing emotional support, giving information, and referring patients to therapists or social workers. Health care workers must refer people to mental health care services because experience has shown that few victims of disaster seek these services, and early intervention minimizes psychological consequences. Nurses can also discourage victims from subjecting themselves to repeated exposure to the event through media replays and news articles, as well as encourage them to return to normal activities and social roles when appropriate (ENA, 2013).

Critical Incident Stress Management

CISM is an approach to preventing and treating the emotional trauma that can affect emergency responders as a consequence of their jobs and that can also occur to anyone involved in a disaster or MCI. CISM is handled by teams, which are available to the OEM. All branches of emergency services have CISM teams, as do the military and other industries (e.g., airline industry).

Components of a management plan include education (preparedness) before an incident occurs about critical incident stress and coping strategies; field support (ensuring that staff

get adequate rest, food, and fluids, and rotating workloads) during an incident; and defusings, debriefings, demobilization, supportive services to the family, and follow-up care after the incident (Veenema, 2013).

Defusing is a process by which the person receives education about recognition of stress reactions and management strategies for handling stress. Debriefing is a more complicated intervention; it involves a 2- to 3-hour process during which participants are asked about their emotional reactions to the incident, what symptoms they may be experiencing (e.g., flashbacks, difficulty sleeping, intrusive thoughts), and other psychological ramifications. In follow-up, members of the CISM team contact the participants of a debriefing and schedule a follow-up meeting if necessary. People with ongoing stress reactions are referred to mental health specialists.

Preparedness and Response

Recognition and Awareness

Preparedness for natural disasters and acts of terrorism includes devising specific community contingency plans that prepare residents, particularly those who are vulnerable (e.g., older adults, people with disabilities) for access to necessary life-sustaining resources and for evacuation, as necessary (see Chart 61-4). Preparedness also includes an awareness of the potential for covert use of WMD, self-protection, and early detection, containment, or decontamination of substances and agents that may affect others by secondary exposure. The strength of many toxins, mobility of many members of society, and long incubation periods for some organisms and diseases can result in an epidemic that can quickly and silently spread across the entire country. For example, a formerly healthy person with a rapid onset of flulike symptoms can have an ominous illness, such as anthrax (see later discussion).

Nurses should have a heightened awareness of trends that may suggest deliberate dispersal of toxic or infectious agents or pandemic onset that may include the following:

- An unusual increase in the number of people seeking care for fever, respiratory, or gastrointestinal symptoms
- Clusters of patients who present with the same unusual illness from a single location. For example, clusters can be from a specific geographic location, such as a city, or from a single sporting or entertainment event.
- A large number of fatalities, especially when death occurs within 72 hours after hospital admission
- Any increase in disease incidence in a normally healthy population. These cases should be reported to the directorate of public health at the state level.
- If any of these trends are noted, an extensive patient history is taken in an attempt to identify the possible agent involved. This history includes an occupational, work, and environmental assessment, in addition to the regular admission history. An exposure history contains, at a minimum, information about current and past exposures to possible hazards and an assessment of the patient's typical day and any deviations in routines. The work history includes, at a minimum, a description of all previous jobs, including short-term, seasonal, and part-time employment and any military service. The environmental history includes assessment of present and previous home locations, water supply, and any hobbies, to name a few factors. The admission history should include

Chart 61-4 NURSING RESEARCH PROFILE

Preparedness for Loss of Electricity After a Natural Disaster

Zidek, C., West, E., Holmes, J., et al. (2014). A survey comparison of rural versus urban residents and household preparedness. Home Healthcare Nurse, 32(7), 420–429.

Purpose

In 2012, the U.S. Department of Homeland Security began a national campaign to prepare citizens for emergencies, including natural disasters. In response to this, the Pennsylvania State Office of Homeland Security launched the *ReadyPA* campaign, which targeted Pennsylvanians deemed most vulnerable to adverse effects from a natural disaster, including older adults and citizens with disabilities. The aims of this study were to determine the effectiveness of *ReadyPA* in preparing rural and urban residents reliant on electronic medical equipment (ME) and rural and urban ME supply companies for natural disasters that cause loss of electrical power.

Design

This was a descriptive study that used a stratified random sample of adults who resided in one rural and one urban county and who had landline phone numbers listed in the phone book. Those ME supply companies that were listed in the white pages of those same rural and urban county phone books were all sampled. A telephone survey was designed that asked prospective participants whether they used electronic ME and to describe plans made to use ME in the event of power failure. Nursing students were trained to call prospective rural, urban, and ME supply company participants and began to gather data once Institutional Review Board approval was obtained.

Findings

Of the rural county participants (n = 958), 128 used electronic ME in their homes; whereas, of the urban county participants (n = 1000), 179 used electronic ME in their homes. Commonly used electronic ME included intravenous pumps, oxygen, blood glucose monitors, pressure-relieving mattresses, to name a few. There were eight rural ME and 24 urban ME supply companies that comprised the sample. Results included that 23% of rural participants and 45% of urban participants who used electronic ME had no home preparedness contingency plan made for loss of electrical power. Only 62.5% of both rural and urban ME supply companies indicated they were prepared to supply alternative ME to their users during periods of power failure. Furthermore, only half (50%) of rural ME supply companies and 12.5% of urban ME supply companies kept a nonelectronic list of their most vulnerable customers for retrieval during times of power failure.

Nursing Implications

Findings from this study suggest that one state's efforts to prepare its most vulnerable citizens to be prepared for loss of electrical power from a natural disaster has not resulted in widespread adoption of adequate preparatory practices. Despite the goals of the *ReadyPA* campaign, many Pennsylvanians who use electronic ME and their respective ME supply companies are not adequately prepared to respond to loss of power. Nurses must take the leadership initiative to launch advocacy efforts in their home communities to educate citizens who use electronic ME and the ME supply companies so that they make contingency plans for loss of electric power.

such information as recent travel and contact with others who have been ill or have recently died of a fatal illness. This is just a brief review of the extensive history that may need to be obtained to identify an exposure agent (Agency for Toxic Substances and Disease Registry, 2016).

Suspicions or findings are reported to the appropriate resources in the facility and to proper authorities in the community. Resources can include the infection control department, the state government, Department of Health and Family Welfare or Directorate of Public Health and Preventive Medicine. The district medical officer provides information to employees and health care providers regarding specific chemical agents; it includes the chemical name, physical data, chemical ingredients, fire and explosive hazard data, health and reactive data, spill or leak procedures, special protection information, and special precautions. Reporting furnishes data elements to those agencies responsible for epidemiology and response. Reporting also allows for sharing of information among facilities and jurisdictions and can help determine the source of infections or exposure and prevent further exposures and even deaths.

Personal Protective Equipment

Another component of preparedness and response involves the protection of the health care provider by additional personal protective equipment (PPE). Chemical or biologic agents and radiation are silent killers and are generally colorless and odorless. The purpose of PPE is to shield health care workers from the chemical, physical, biologic, and radiologic hazards that may exist when caring for patients who have been contaminated.

- **Level A** protection is worn when the highest level of respiratory, skin, eye, and mucous membrane protection is required. This includes a self-contained breathing apparatus (SCBA) and a fully encapsulating, vapor-tight, chemical-resistant suit with chemical-resistant gloves and boots.
- **Level B** protection requires the highest level of respiratory protection but a lesser level of skin and eye protection than with level A situations. This level of protection includes the SCBA and a chemical-resistant suit, but the suit is not vapor tight.
- **Level C** protection requires the air-purified respirator, which uses filters or sorbent materials to remove harmful substances from the air. A chemical-resistant coverall with splash hood, chemical-resistant gloves, and boots are included in level C protection.
- **Level D** protection is the typical work uniform.

Levels C and D PPE are the levels most often used in hospital facilities. Protective equipment must be donned before contact with a patient who has been contaminated. The acute care facility's standard precaution PPE (level D) generally is not adequate for protection from a patient who has been chemically, biologically, or radiologically contaminated. Level C PPE is adequate for the average patient exposure. The health care provider must use equipment that is capable of providing protection against the agent involved. This may mean using a splash suit along with a full-face positive- or negative-pressure respirator (a filter-type gas mask) or even an SCBA for medical personnel in the field.

No single PPE is capable of protecting against all hazards. Under no circumstances should responders wear any PPE without proper training, practice, and fit testing of respirator masks as necessary (Valdez, 2015).

Decontamination

Decontamination, the process of removing accumulated contaminants or rendering them harmless, is critical to the health and safety of health care providers by preventing secondary contamination. The decontamination plan should establish procedures and educate employees about decontamination procedures, identify the equipment needed and methods to be used, and establish methods for disposal of contaminated materials (Veenema, 2013).

Although many principles and theories surround decontamination of a patient, authorities agree that to be effective, decontamination must include a minimum of two steps. The first step is removal of the patient's clothing and jewelry and then rinsing the patient with water. Depending on the type of exposure, this step alone can remove a large amount of the contamination and decrease secondary contamination. The second step consists of a thorough soap-and-water wash and rinse. The hospital must be prepared to perform additional decontamination prior to entry into the facility. The hospital personnel may also treat "walking wounded" who did not receive any decontamination at the scene.

Nursing Alert: When patients arrive at the facility after being assessed and treated by a prehospital provider, it should not be assumed that they have been thoroughly decontaminated.

Natural Disasters

Natural disasters may result in mass casualties. Natural disasters can occur anywhere at any time and include events such as tornadoes, hurricanes, floods, avalanches, tidal waves (e.g., tsunamis), earthquakes, and volcanic eruptions (see Table 61-2). In the event of a natural disaster, loss of communications, potable water, and electricity is usually the greatest obstacle to a well-coordinated emergency response, and preparatory planning is essential. Wireless technology (e.g., cellular phones, computers, other communication devices) may not be functional.

The majority of the immediate casualties are trauma related. These mass casualties tax the trauma system to provide triage, transport of patients (in poor weather and road conditions), and management within the trauma centers. Most patients usually begin arriving within an hour of the event. However, the "walking wounded" may not seek care for 5 days to 2 weeks after the event or may seek care for injuries received during cleanup activities. Casualties arrive at hospitals in three waves. The first wave consists of people who are minimally (generally) injured who arrive of their own accord. The second wave consists of patients who are severely injured. The third wave consists of patients who are injured and who arrive after they are discovered by rescuers. For example, in the event of earthquakes, buildings collapse and cause the majority of fatalities from injuries primarily involving the head and chest (Veenema, 2013).

Excessive exposure to the natural elements and the need for food and water (by both patients and emergency responders) are critical issues. Without cover (e.g., buildings may be unsafe or destroyed) or potable water (e.g., water may be either contaminated or unavailable), injuries from exposure to heat, cold, or contaminated food or water can occur. Safety equipment that protects rescue workers from injury, exposure, and potentially dangerous animals (e.g., snakes, alligators, spiders) must be readily available. Rescue workers may also injure themselves in the process of extrication or cleanup (e.g.,

TABLE 61-2 Natural Disasters

Event	Issues and Injuries
Hurricanes	Causes flooding and tornadoes (see later discussion) Failure to evacuate Food and water safety *Injuries:* From recovery activities (e.g., chainsaws), stress-related disorders, and GI and other vector-borne disease; physical injury; bites from traumatized pets
Earthquakes	Associated with multiple aftershocks, tsunami Buildings require tethering in earthquake-prone areas *Injuries:* Physical injury; dehydration; pulmonary problems
Flooding	Can accompany other natural disasters Results in home and community destruction *Injuries:* Nonfatal drowning/drowning (e.g., people swept away in currents); waterborne and vector-borne disease (e.g., shigellosis, *Escherichia coli* infection, hepatitis A, giardiasis, leptospirosis, malaria, plague, dengue fever); physical injury from debris
Tsunami	As with flooding (above) but with much more rapid onset resulting in immediate large volume of water on land *Injuries:* Physical injury from debris; vector-borne disease (see the Flooding section); cholera
Tornadoes	Minimal warning, fast moving (approximately 50 km/hr and travel approximately 20 km) Massive destruction, shelter loss *Injuries:* Physical injury; blast like effects from pressure (see discussion of blast injuries in text)
Volcanic eruptions	Hazards from lava, openings in ground, gases, ash up to a 20 mile radius *Injuries:* Acid rain; toxic gases result in inhalation injury; physical injury
Exposure—heat/cold	*Cold:* Frostbite, hypothermia, (see Chapter 60) *Heat:* Burns (see Chapter 47), heat exhaustion/stroke (see Chapter 60)
Epidemic/Pandemic	Foodborne poisonings Acute outbreak, unexpected; local or distant transmission due to travel *Risk:* Determined by population density, travel, method of transmission *Illness:* Depends on organism involved (see Chapter 39)

Adapted from American College of Surgeons. (2010). Disaster management and emergency preparedness course. Chicago: Author; Veenema, T. G. (2013). Disaster nursing and emergency preparedness (3rd ed.). New York: Springer.

chain saws, building collapse). Hypothermia can occur rapidly in workers who are exposed to water at temperatures of 23.9°C (75°F) or less. As is true during all disasters, mental health workers and shelters are needed throughout the community. Veterinary assistance is also essential because pets are frequently abandoned and injured. In addition, emergency response workers must be prepared to treat the most common ailments experienced after exposure to a specific natural disaster. For instance, pulmonary problems peak with earthquakes and volcanic eruptions because of the increased particulate matter in the air. Most volcano-related deaths are from suffocation and exposure to noxious gases. After floods or water disasters, waterborne transmission of agents such as *Escherichia coli,* salmonella, shigella, typhoid, leptospirosis, malaria, and tularemia are common and cause widespread disease.

In some instances, early warning systems have assisted in decreasing the number of deaths from tornadoes and hurricanes. Even with the advent of early warning systems, some people are unable or unwilling to leave prior to the occurrence of the natural disaster.

When buildings collapse, rapid response to identify and remove trapped victims is the only means of improving survivability. There is a direct relationship between time trapped and survival; fewer than 50% of people survive if they are trapped more than 2 to 6 hours (ACS, 2010). Water-damaged buildings are not safe and require extensive examination before experts can ensure safe occupancy. Larger-scale issues that can cause significant later morbidity and mortality include the absence of water purification, waste removal, removal of human and animal remains, and vector control. Removal or disposal of biologic, chemical, and nuclear agents must also be considered.

Weapons of Terror

Although biologic, chemical, and radiologic events are not everyday events, they can occur at any facility, and every nurse needs to know the basics of caring for patients who have been affected. An explosion may spread dangerous material. Therefore, treatment of blast injuries must be anticipated and planned.

Blast Injury

A blast may result from terrorism but can also occur anywhere at any time if the right (or wrong) circumstances come together (e.g., welding inside of a tank that formerly contained tar but was not properly cleaned can result in an explosion as well as severe tar burns to the worker).

Types of Explosive Devices

The bomb most commonly utilized by terrorists is the pipe bomb, which contains low-velocity explosives and may also contain nails or other implements that cause more damage when the explosive ignites. Another type of commonly used explosive device is the Molotov cocktail, which uses a common flammable liquid such as gasoline in a glass bottle and a source of ignition, such as a rag. This forms a simple yet effective incendiary device. Other types of explosive devices include fertilizer bombs and dirty bombs, which include a radioactive source that spreads radiation after the initial blast.

Hazards following a bombing include secondary devices (set to explode at a predetermined time, typically after the arrival of rescue personnel); building collapse; contamination from biologic, chemical, or radiologic weapons; and the presence of terrorists among the patients and bystanders. The entire scene of the bombing is a crime scene and is treated as such. Triage of patients involved in a bombing is the same as for all disasters, with a heightened awareness that serious internal injuries from the blast wave may not be immediately evident.

Physical Injuries

Distance from the blast, whether the blast space was enclosed, composition of the explosive, whether a building collapsed, and the efficiency of medical resources available after the blast all affect patient outcomes after a blast injury. The actual blast that occurs during the initial seconds of the bombing or explosion causes a pressure wave or primary blast wave. Injuries can result from the impact of the explosion, the primary blast wave, or shrapnel (i.e., debris from the bomb). The majority of injuries

are caused by the primary blast wave (ACS, 2010). A blast wave has four effects. These include spalling, which refers to the pressure wave itself; implosion, which refers to rupture of organs from entrapped gases; shearing, which refers to the blast response of different body tissues, dependent on their density; and irreversible work, which refers to the presence of forces that exceed the tensile strength of an organ or tissue. If the blast occurs in an enclosed space, the wave has the opportunity to be reflected and thus amplified (Veenema, 2013). The various phases of blasts and related injuries are detailed in Table 61-3.

Although approximately 50% to 70% of deaths result from head injuries, most head injuries are not life threatening (ACS, 2010).

Blast Lung

Blast lung results from the blast wave as it passes through air-filled lungs. The result is hemorrhage and tearing of the lung, ventilation–perfusion mismatch, and possible air emboli. Typical signs and symptoms include dyspnea, hypoxia, tachypnea or apnea (depending on severity), cough, chest pain, and hemodynamic instability. Management involves providing respiratory support that includes administration of supplemental oxygen with nonrebreathing mask but may also require endotracheal intubation and mechanical ventilation. If a hemothorax or pneumothorax is present, a chest tube must be inserted to re-expand the lung. In the event of an air embolus, the patient should be immediately placed in the prone left lateral position to prevent migration of the embolus and will require emergent treatment in a hyperbaric chamber (CDC, 2012). Complications following blast lung can include respiratory failure as well as acute respiratory distress syndrome (see Chapters 11 and 12).

TABLE 61-3 Phases of Blasts and Associated Common Injuries

Phase of Blast Injury	Common Injuries
Primary: Results from pressure wave	Pulmonary barotraumas, including pulmonary contusions Head injuries, including concussion, other severe brain injuries Tympanic membrane rupture, middle ear injury Abdominal hollow organ perforation, hemorrhage
Secondary: Results from debris from the scene or shrapnel from the bomb	Penetrating trunk, skin, and soft tissue injuries Fractures, traumatic amputations
Tertiary: Results from pressure wave that causes the victim to be thrown	Head injuries Fractures, including skull
Quaternary: Results from pre-existing conditions exacerbated by the force of the blast or by postblast injury complications	Severe injuries with complex injury patterns—burns, crush injuries, head injuries Common pre-existing conditions that become exacerbated—COPD, asthma, cardiac conditions, diabetes, and hypertension

COPD, chronic obstructive pulmonary disease.

Adapted from Pennardt, A., & Lavonas, E. J. (2016). Blast injuries. Medscape. Retrieved on 4/2/2017 at: emedicine.medscape.com/article/822587-overview

Tympanic Membrane Rupture

TM rupture is the most frequent injury after subjection to a pressure wave because the TM is the body's most sensitive organ to pressure. There is an increased incidence of TM rupture when a blast occurs in close proximity to the patient and when it occurs in an enclosed space. Signs and symptoms include hearing loss, tinnitus, pain, dizziness, and otorrhea (CDC, 2012). The majority of TM ruptures heal spontaneously. Approximately 5% of patients with TM rupture from a blast will require hearing aids, whereas the majority will suffer only mild high-frequency hearing loss (Dodd-Murphy, 2014); (ENA, 2014). Other ear injuries may include ossicular disruption and impaction of foreign bodies.

Abdominal and Head Injuries

Blast abdomen may be evidenced by abdominal hemorrhage and internal organ injury. The typical signs and symptoms of internal abdominal injury can include pain, guarding, rebound tenderness, rectal bleeding, nausea, and vomiting (CDC, 2012) (see Chapter 60).

Head injuries are typically minor, but those that are severe result in the majority of post blast deaths. These injuries can occur without a direct blow to the head and may result from the blast itself, building collapse, or flying debris. Concussions commonly occur post blast, and the usual follow-up evaluation and treatment for post concussive syndrome is indicated (see Chapter 51). Approximately 30% of head injuries involve vascular structures (e.g., arteriovenous fistula, pseudoaneurysm, or dissection) (Veenema, 2013).

Special Populations

Special populations may have different blast-associated risks. For instance, older adults are particularly susceptible to bone fractures because they tend to have decreased bone density. They also tend to have more pre-existing morbid conditions that may be exacerbated by the explosion. Patients who are pregnant are particularly susceptible to placental shear forces that may result in abruptio placentae. People with mobility disabilities may have difficulty extricating themselves from the site of the blast (CDC, 2012).

Biologic Weapons

Biologic weapons are weapons that spread disease among the general population or the military. They can be used for sabotage, such as food or water contamination with a small target area, or may be used by global terrorists with intentions to enable global objectives.

Effects

Biologic weapons are easily obtained and easily disseminated and can result in significant mortality and morbidity (see Table 61-4). The potential use of biologic weapons calls for continuous increased surveillance by health departments and an increased index of suspicion by clinicians. Many biologic weapons result in signs and symptoms similar to those of common disease processes. Appropriate management of a biologic threat includes rapid recognition of the potential weapon; the use of proper PPE; decontamination, isolation, or quarantine of patients who are infected when appropriate; and the administration of appropriate vaccinations, antidotes, or medications to people at risk.

Biologic weapons are delivered in either a liquid or dry state, applied to foods or water, or vaporized for inhalation or direct

TABLE 61-4 Categories of Biologic Weapons

Category	Mortality and Morbidity	Examples of Biologic Agents That May Be Weaponized
Category A	High mortality	*Bacillus anthracis* (anthrax) *Clostridium botulinum* (botulism) *Francisella tularensis* (tularemia) Viral hemorrhagic fevers (e.g., dengue, Ebola) Variola (i.e., smallpox) *Yersinia pestis* (plague)
Category B	Low mortality, moderate morbidity	*Brucella* species (brucellosis) *Coxiella burnetii* (Q fever) *Staphylococcus aureus, Vibrio* species (food poisoning) *Rickettsia typhi* (typhus) Arboviruses (viral encephalitis) *Cryptosporidium parvum* (Cryptosporidiosis)
Category C	Low mortality, low morbidity	Hantavirus

Adapted from Veenema, T. G. (2013). Disaster nursing and emergency preparedness (3rd ed.). New York: Springer.

contact. Vaporization may be accomplished through spray or explosives loaded with the weapon. Because of increases in business and pleasure travel by people in industrialized nations, a biologic weapon could be released in one city and affect people in other cities thousands of miles away. The vector can be an insect, animal, or person, or there may be direct contact with the weapon itself.

Two of the biologic agents most likely to be used or weaponized are discussed in the next section. Table 61-5 describes other easily weaponized biologic agents.

Types

Anthrax

Anthrax is recognized as the most likely weaponized biologic agent available and has been recognized as a highly debilitating agent for centuries. *Bacillus anthracis* is a naturally occurring gram-positive, encapsulated rod that lives in the soil in the spore state throughout the world. The bacterium sporulates (i.e., is liberated) when exposed to air and is infective only in the spore form. Contact with infected animal products (raw meat) or inhalation of the spores results in infection. Cattle and other herbivores are vaccinated against anthrax to prevent transmission through contaminated meat. As an aerosol, anthrax is odorless and invisible and can travel a great distance before disseminating; hence, the site of release and the site of infection can be miles apart.

Clinical Manifestations

Anthrax is caused by replicating bacteria that release toxin, resulting in hemorrhage, edema, and necrosis. The incubation period is 1 to 6 days. There are three main methods of infection: skin contact, gastrointestinal ingestion, and inhalation. Skin lesions (the most common infection) cause edema with pruritus and macule or papule formation, resulting in ulceration with 1- to 3-mm vesicles. A painless eschar develops, which falls off in 1 to 2 weeks (Auerbach, 2017).

Ingestion of anthrax results in fever, nausea and vomiting, abdominal pain, bloody diarrhea, and occasionally ascites. If severe diarrhea develops, decreased intravascular volume becomes the major treatment concern. The bacterium targets the terminal ileum and cecum. Sepsis can occur.

Inhaling anthrax results in severe clinical manifestations. Its symptoms mimic those of the flu, and usually treatment is sought only when the second stage of severe respiratory distress occurs. Antibiotic therapy does not halt the progress of the disease. Inhaled anthrax can incubate for up to 60 days, making it difficult to identify its source. Initial signs and symptoms include cough, headache, fever, vomiting, chills, weakness, mild chest discomfort, dyspnea, and syncope, without rhinorrhea or nasal congestion. Most patients have a brief recovery period followed by the second stage within 1 to 3 days, characterized by fever, severe respiratory distress, stridor, hypoxia, cyanosis, diaphoresis, hypotension, and shock. These patients require optimization of oxygenation, correction of electrolyte imbalances, and ventilatory and hemodynamic support. More than 50% of these patients have hemorrhagic mediastinitis on a chest x-ray (a hallmark sign). The disease can also progress to include meningitis with subarachnoid hemorrhage. Death results approximately 24 to 36 hours after the onset of severe respiratory distress. The mortality rate approaches 100% (Auerbach, 2017).

Treatment

At present, anthrax is penicillin sensitive; however, strains of penicillin-resistant anthrax are thought to exist. Recommended treatment includes penicillin (Penicillin V), erythromycin (Erythrocin), gentamicin (Garamycin), or doxycycline (Vibramycin). If antibiotic treatment begins within 24 hours after exposure, death can be prevented. In a mass casualty situation, treatment with ciprofloxacin (Cipro) or doxycycline is recommended, because these easily given oral antibiotic agents are stockpiled and there should be sufficient dosages to fully treat many patients who have been anthrax-exposed. Treatment is continued for 60 days. For patients who have been directly exposed to anthrax but have no signs and symptoms of disease, ciprofloxacin or doxycycline is used for prophylaxis for 60 days (Auerbach, 2017).

Standard precautions are the only ones indicated to protect the caregiver exposed to a patient infected with anthrax. The patient is not contagious, and the disease cannot spread from person to person. Equipment should be cleaned using standard hospital disinfectant. After death, cremation is recommended because the spores can survive for decades and represent a threat to morticians and forensic medicine personnel. There is a vaccine for anthrax that has been used in the military; however, it is not yet widely used because it requires multiple time-interval–sensitive boosters.

Smallpox

Smallpox (variola) is classified as a deoxyribonucleic acid (DNA) virus. It has an incubation period of approximately 12 days. It is extremely contagious and is spread by direct contact, by contact with clothing or linens, or by droplets from person to person only after the fever has decreased and the rash phase has begun. Aerosolization of the virus would result in widespread dissemination.

The World Health Organization (WHO) declared smallpox eradicated in 1977 and stopped worldwide vaccination in 1980. Therefore, a large portion of the current population has no immunity to the virus. A smallpox vaccination plan introduced

TABLE 61-5 Selected Examples of Biologic Agents That Can Be Used As Weapons

Agent/Organism	Contagion	Decontamination and Protective Equipment	Signs and Symptoms	Treatment (Mortality Rate)
Tularemia—*Francisella tularensis:* Gram-negative coccobacillus, one of the most infectious bacteria known.	Direct contact with infected animals or aerosolized as a bioterror weapon; bites Not contagious through human-to-human contact Found in Oklahoma, Missouri, Arkansas	Standard barrier precautions. Clothing and linens should be laundered under the usual hospital protocol.	*Initial:* Abrupt onset of fever, fatigue, chills, headache, lower backache, malaise, rigor, coryza, dry cough, and sore throat without adenopathy. Nausea and vomiting or diarrhea possible. *As disease progresses:* Sweating, fever, progressive weakness, anorexia, and weight loss demonstrate continued illness. *Mortality secondary to:* Pneumonitis (if inhalation is the source) with copious watery or purulent sputum, hemoptysis, respiratory insufficiency, sepsis, and shock.	Streptomycin or gentamicin/aminoglycoside for 10–14 days. Inhalation tularemia must be treated within 48 hours of onset. In mass casualty situations, doxycycline or ciprofloxacin is recommended. For persons exposed to tularemia, tetracycline or doxycycline is recommended for 14 days. (Mortality rate = 2%)
Botulism—*Clostridium botulinum:* Botulinum blocks acetylcholine-containing vesicles from fusing with the terminal membranes of the motor neuron end-plate, resulting in a flaccid paralysis.	Direct contact Not contagious through human-to-human contact	Any skin exposure to the botulism toxin can be treated with soap and water or a 0.1% hypochlorite solution. Standard precautions are used when treating patients with botulism.	*Gastrointestinal botulism:* Abdominal cramps, nausea, vomiting, and diarrhea *Inhalation botulism:* Fever; symmetric descending flaccid paralysis with multiple cranial nerve palsies. *Classic signs and symptoms include* diplopia, dysphagia, dry mouth, lack of fever, and alert mental status. *Other possible symptoms include* ptosis of the eyelids, blurred vision, enlarged sluggish pupils, dysarthria, and dysphonia. *Mortality secondary to:* Airway obstruction and inadequate tidal volume	Supportive ventilatory therapy is necessary if respiratory infection occurs. Aminoglycosides and clindamycin are contraindicated because they exacerbate neuromuscular blockage. Equine antitoxin is used to minimize subsequent nerve damage. There is a 2% rate of anaphylaxis to the antitoxin; therefore, diphenhydramine (Benadryl) and epinephrine must be immediately available for use. Supportive care—mechanical ventilation, nutrition, fluids, prevention of complications (Mortality rate = 5%).
Plague—*Yersinia pestis:* nonsporulating gram-negative coccobacillus. The bacterium causes destruction and necrosis of the lymph nodes.	Contagious *Bubonic plague:* Transmitted through flea bites with no person-to-person transmission *Pneumonic plague:* Transmitted through respiratory droplet contact	Isolation barrier precautions with full face respirators; the patient should wear a mask. Rooms should receive a terminal cleaning. Clothing and linens with body fluids on them should be cleaned with the usual disinfectant. Routine precautions should be used in the case of death.	*Bubonic plague:* Sudden fever and chills, weakness, a swollen and tender lymph node (bubo) in the groin, axilla, or cervical area. The resultant bacteremia progresses to septicemia from the endotoxin and, finally, shock and death. *Primary septicemic plague:* Disseminated intravascular coagulation, necrosis of small vessels, purpura, and gangrene of the digits and nose (black death). *Pneumonic plague:* Severe bronchospasm, chest pain, dyspnea, cough, and hemoptysis. There is a 100% mortality associated with pneumonic plague if not treated within the first 24 hours.	Streptomycin or gentamicin for 10–14 days. Start within 12–24 hours. Tetracycline or doxycycline is an acceptable alternative if an aminoglycoside cannot be given. People with close contact exposure (<2 m) require prophylaxis with doxycycline for 7 days. (Mortality rate = 50%)

Adapted from Dire, D. J. (2016). CBRNE—Biological warfare agents. Medscape. Retrieved on 11/26/2016 at: emedicine.medscape.com/article/829613-overview; Emergency Nurses Association. (2013). Sheehy's manual of emergency care (7th ed.). St. Louis, MO: Elsevier Mosby; Emergency Nurses Association. (2014). Trauma nursing core course (7th ed.). Chicago: Author; and Veenema, T. G. (2013). Disaster nursing and emergency preparedness (3rd ed.). New York: Springer.

in 2003 proposed that a designated number of ED staff receive the first vaccinations to ensure that ED staff would be immunized in the event of a smallpox outbreak. The government estimated that 0.1% of those people receiving the vaccine would have serious side effects. Of these, approximately 4% would have life-threatening complications, and 0.1% would die. Currently, only people with a high likelihood of exposure to smallpox are encouraged to receive the vaccination (CDC, 2016).

Clinical Manifestations

Signs and symptoms of smallpox infection include high fever, malaise, headache, backache, and prostration. After 1 to 2 days, a maculopapular rash appears, evolving at the same rate, beginning on the face, mouth, pharynx, and forearms. Only then does the rash progress to the trunk and also become vesicular to pustular (Veenema, 2013). There is a large amount of the virus in the saliva and pustules. Smallpox is contagious only after the appearance of the rash. There are two forms of smallpox: variola major and variola minor. Variola major is more common, results in a higher fever and more extensive rash, and has a 30% case fatality rate (i.e., the likelihood of fatality per case diagnosed). Hemorrhagic smallpox, a subtype of variola major, includes all of the above signs and symptoms plus a dusky erythema and petechiae leading to frank hemorrhage of the skin and mucous membranes, and it results in death by day 5 or 6 (Veenema, 2013).

Treatment

Treatment includes supportive care with antibiotic agents for any additional infection. The patient must be isolated with the use of transmission precautions. Laundry and biologic wastes should be autoclaved before being washed with hot water and bleach. Standard decontamination of the room is effective. All people who have household or face-to-face contact with the patient after the fever begins should be vaccinated within 4 days to prevent infection and death. A patient with a temperature of 38°C (101°F) or higher within 17 days after exposure must be placed in isolation. Cremation is preferred for all deaths, because the virus can survive in scabs for up to 13 years (Veenema, 2013).

Chemical Weapons

Chemical weapons may be used as agents in warfare or for terrorist purposes; they are overt agents in that the effects are more apparent and occur more quickly than those caused by biologic weapons (see Table 61-6). Poisonous exposure to everyday chemicals also may occur; the same management principles discussed later apply when patients are exposed to these chemical agents even when not used as weapons. Typical exposures in these instances include industrial chemicals, gasoline, turpentine, kerosene, and insecticides (ENA, 2014).

Characteristics of Chemicals

Volatility

Volatility is the tendency for a chemical to become a vapor. The most common volatile agents are phosgene and cyanide. Most chemicals are heavier than air, except for hydrogen cyanide. Therefore, in the presence of most chemicals, people should stand up to avoid heavy exposure (because the chemical will sink toward the floor or ground).

TABLE 61-6 Common Chemical Agents

Agent	Action	Signs and Symptoms	Decontamination and Treatment
Nerve Agents			
Sarin Soman	Inhibition of cholinesterase	Increased secretions (salivation, lacrimation, emesis, urination), gastrointestinal motility, diarrhea, bronchospasm	Soap and water Supportive care Benzodiazepines Pralidoxime Atropine
Blood Agent			
Cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures; bright red skin; can progress to respiratory arrest, respiratory failure, cardiac arrest, death	Soap and water Sodium nitrite Sodium thiocyanate Amyl nitrate Hydroxocobalamin
Vesicant Agents			
Lewisite Sulfur mustard Nitrogen mustard Phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce; conjunctivitis, nasal irritation	Soap and water Blot; do not rub dry
Pulmonary Agents			
Phosgene Chlorine	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm, chest tightness, burning sensation, blurry vision; Phosgene can result in pain, then blisters followed by partial to full-thickness burn	Copious flushing Move to fresh air—away from gases Airway management Ventilatory support Bronchoscopy

Adapted from Ciottone, G. R., & Arnold, J. L. (2015). CBRNE – Chemical warfare agents. Medscape. Retrieved on 11/26/2015 at emedicine.medscape.com/article/829454-overview; Emergency Nurses Association. (2013). Sheehy's manual of emergency care (7th ed.). St Louis, MO: Elsevier Mosby; Emergency Nurses Association. (2014). Trauma nursing core course (7th ed.). Chicago: Author; and Veenema, T. G. (2013). Disaster nursing and emergency preparedness (3rd ed.). New York: Springer.

Persistence

Persistence means that the chemical is less likely to vaporize and disperse. More volatile chemicals do not evaporate very quickly. Most industrial chemicals (e.g., cyanide) are not very persistent. Weaponized agents (chemicals developed as weapons by the military or terrorists [e.g., mustard gas]) are more likely than industrial chemicals to penetrate skin and mucous membranes and also cause secondary exposure.

Toxicity

Toxicity is the potential of an agent to cause injury to the body. The median lethal dose (LD_{50}) is the amount of the chemical that will cause death in 50% of those who are exposed. For example, cyanogen chloride has the highest LD_{50}, twice that of hydrogen cyanide and eight times higher than sulfur mustard (ACS, 2010). The median effective dose (ED_{50}) is the amount of the chemical that will cause signs and symptoms in 50% of those who are exposed. The concentration time (CT) is the concentration released multiplied by the time exposed (in milligrams per minute). For example, if 1000 mg of a chemical is released and the time a person is exposed to this amount of chemical is 10 minutes, then the CT would be 10,000 mg/min.

Latency

Latency is the time from absorption to the appearance of signs and symptoms. Sulfur mustards and pulmonary agents have the longest latency, whereas other vesicants, nerve agents, and cyanide produce signs and symptoms within seconds.

Limiting Exposure

Evacuation is essential, as is removal of the person's clothing and decontamination as close to the scene as possible and before transport of the person who has been exposed. Soap and water are effective means of decontamination in most cases. Staff involved in decontamination efforts must wear PPE and contain and dispose of the runoff after decontamination procedures (ENA, 2013).

Types of Chemicals

Vesicants

Vesicants are chemicals that cause blistering and result in burning, conjunctivitis, bronchitis, pneumonia, hematopoietic suppression, and death. Examples of vesicants include lewisite, phosgene, nitrogen mustard, and sulfur mustard. In World War I and in the Iran–Iraq conflict of 1980 to 1988, vesicants were used to disable opponents. Vesicants were the main incapacitating agents, resulting in minimal (less than 5%) death but large numbers of injuries (Veenema, 2013). Liquid sulfur mustard was the most frequently used vesicant in these conflicts.

Clinical Manifestations

The initial presentation after exposure to a vesicant is similar to that of a large superficial to partial-thickness burn in the warm and moist areas of the body (i.e., perineum, axillae, antecubital spaces). There is stinging and erythema for approximately 24 hours, followed by pruritus, painful burning, and small vesicle formation after 2 to 18 hours. These vesicles can coalesce into large, fluid-filled bullae. Lewisite and phosgene result in immediate pain after exposure. Tissue damage occurs within minutes.

If the eye is exposed, there is pain, photophobia, lacrimation, and decreased vision. This progresses to conjunctivitis, blepharospasm, corneal ulcer, and corneal edema.

Respiratory effects are more serious and often are the cause of mortality with vesicant exposure. Purulent fibrinous pseudomembrane discharge may cause obstruction of the airways. Bacterial pneumonia may be the cause of death within approximately a week of pulmonary exposure (ACS, 2010). Gastrointestinal exposure may cause nausea and vomiting, leukopenia, and upper gastrointestinal bleeding.

Treatment

Appropriate decontamination includes soap and water. Scrubbing and the use of hypochlorite solutions should be avoided because they increase penetration. Once the substance has penetrated, it cannot be removed. Eye exposure requires copious irrigation. For respiratory exposure, intubation and bronchoscopy to remove necrotic tissue are essential. With lewisite exposure, dimercaprol (BAL In Oil) is administered IV for systemic toxicity and topically for skin lesions. All persons with sulfur mustard exposures should be monitored for 24 hours for delayed (latent) effects (ENA, 2013).

Nerve Agents

The most toxic agents in existence are the nerve agents such as sarin, soman, tabun, and VX. They are inexpensive, effective in small quantities, and easily dispersed. In the liquid form, nerve agents evaporate into a colorless, odorless vapor. Organophosphates (pesticides) are similar in nature to the nerve agents used in warfare and are readily available in the farming industry.

Nerve agents can be inhaled or absorbed percutaneously or subcutaneously. These agents bond with acetylcholinesterase so that acetylcholine is not inactivated; the adverse result is continuous stimulation (hyperstimulation) of the nerve endings. Carbamates, which are insecticides originally extracted from the Calabar bean, are derivatives of carbamic acid; they are nerve agents that specifically inhibit acetylcholinesterase for several hours and then spontaneously become unbound from the acetylcholinesterase. However, organophosphates require the formation of new enzyme (acetylcholinesterase) before nervous system function can be restored.

A very small drop of a nerve agent is enough to result in sweating and twitching at the site of exposure. A larger amount results in more systemic symptoms. Effects can begin anywhere from 30 minutes up to 18 hours after exposure. The more common organophosphates and carbamates (e.g., Sevin and malathion) that are used in agriculture result in less severe symptoms than do those used in warfare or in terrorist attacks. In an ordinary situation (e.g., nonwarfare, nonterrorist attack situation), a patient could arrive at the ED having been unintentionally exposed to organophosphates or intentionally exposed to these agents in a suicidal attempt (ENA, 2013).

Clinical Manifestations

Signs and symptoms of nerve gas exposure are those of cholinergic crisis and include bilateral miosis, visual disturbances, increased gastrointestinal motility, nausea and vomiting, diarrhea, substernal spasm, indigestion, bradycardia and atrioventricular block, bronchoconstriction, laryngeal spasm, weakness, fasciculations, and incontinence. The patient must be examined in a dark area to truly identify miosis. Neurologic responses include insomnia, forgetfulness, impaired judgment, depression, and irritability. A lethal dose results in loss of consciousness, seizures, copious secretions, fasciculations, flaccid muscles, and apnea (ENA, 2014).

Treatment

Decontamination with copious amounts of soap and water or saline solution for 8 to 20 minutes is essential. The water is blotted off, not wiped off, the skin. Wiping may have the unintended effect of rubbing more of the agent into the skin. Fresh 0.5% hypochlorite solution (bleach) can also be used. The airway is maintained, and suctioning is frequently required. Plastic airway equipment should not be used, because plastic will absorb sarin gas and may result in continued exposure to the agent.

Atropine 2 to 4 mg is administered by IV, followed by 2 mg every 3 to 8 minutes for up to 24 hours of treatment. Alternatively, IV atropine 1 to 2 mg per hour may be given until clear signs of anticholinergic activity have returned (decreased secretions, tachycardia, and decreased gastrointestinal motility). Another medication that may serve as an antidote is pralidoxime (Protopam), which allows cholinesterase to become active against acetylcholine. Pralidoxime 1 to 2 g in 100 to 150 mL of normal saline solution is given over 15 to 30 minutes. Pralidoxime has no effect on secretions and may have any of the following side effects: hypertension, tachycardia, weakness, dizziness, blurred vision, and diplopia. Diazepam (Valium) or other benzodiazepines are used to control seizures, to decrease fasciculations, and to alleviate apprehension and agitation (ENA, 2013).

Blood Agents

Blood agents such as hydrogen cyanide and cyanogen chloride have a direct effect on cellular metabolism, resulting in asphyxiation through alterations in hemoglobin. Cyanide is an agent that has profound systemic effects. It is commonly used in the mining of gold and silver and in the plastics and dye industries.

A cyanide release is often associated with the odor of bitter almonds. In house fires, cyanide is released during the combustion of plastics, rugs, silk, furniture, and other construction materials. There is a significant correlation between blood cyanide and carbon monoxide levels in patients who survive fires, and in some cases, the cause of death is cyanide poisoning.

Clinical Manifestations

Cyanide can be ingested, inhaled, or absorbed through the skin and mucous membranes. Cyanide is protein bound and inhibits aerobic metabolism, leading to respiratory muscle failure, respiratory arrest, cardiac arrest, and death. Its inhalation results in flushing, tachypnea, tachycardia, nonspecific neurologic symptoms, stupor, coma, and seizure preceding respiratory arrest (ENA, 2014).

Treatment

Rapid administration of amyl nitrate, sodium nitrite, and sodium thiosulfate is essential to the successful management of cyanide exposure. First, the patient is intubated and placed on a ventilator. Next, amyl nitrate pearls are crushed and placed in the ventilator reservoir to induce methemoglobinemia. Cyanide has a 20% to 25% higher affinity for methemoglobin than it does for hemoglobin; it binds methemoglobin to form either cyanomethemoglobin or sulfmethemoglobin. The cyanomethemoglobin is then detoxified in the liver by the enzyme rhodanese. Next, IV sodium nitrite is given to induce the rapid formation of methemoglobin. IV sodium thiosulfate is then given; it has a higher affinity for cyanide than methemoglobin and stimulates the conversion of cyanide to sodium thiocyanate, which can be excreted by the kidneys (ENA, 2014); (Tintinalli, Stapczyski, Ma, et al., 2016). Although they may be lifesaving, these emergency medications do have side effects—sodium nitrite can result in severe hypotension, and thiocyanate can cause vomiting, psychosis, arthralgia, and myalgia.

The production of methemoglobin is contraindicated in patients with smoke inhalation, because they already have decreased oxygen-carrying capacity secondary to the carboxyhemoglobin produced by smoke inhalation. In facilities where a hyperbaric chamber is available, it may be used to provide oxygenation while the previously discussed therapies are initiated. An alternative suggested treatment for cyanide poisoning is hydroxocobalamin (vitamin B_{12a}). Hydroxocobalamin binds cyanide to form cyanocobalamin (vitamin B_{12}). It must be administered IV in large doses (Tintinalli et al., 2016). Administration of vitamin B_{12} can result in a transient pink discoloration of mucous membranes, skin, and urine. In high doses, tachycardia and hypertension can occur, but they usually resolve within 48 hours.

Pulmonary Agents

Pulmonary agents such as phosgene and chlorine destroy the pulmonary membrane that separates the alveolus from the capillary bed, disrupting alveolar–capillary oxygen transport mechanisms. Capillary leakage results in fluid-filled alveoli. Phosgene and chlorine both vaporize, rapidly causing this pulmonary injury. Phosgene has the odor of freshly mown hay.

Signs and symptoms include pulmonary edema with shortness of breath, especially during exertion. An initial hacking cough is followed by frothy sputum production. A particulate air filter mask is the only protection required to protect health care personnel. Phosgene does not injure the eyes. In a review of a chlorine spill in South Carolina that exposed 155 patients, the most useful tool for identifying worsening symptoms was the pulse oximeter. Ordinary triage systems did not predict the severity of exposure (Culley, Svendsen, Craig, et al., 2014).

Nuclear Radiation Exposure

The threat of nuclear warfare or exposure to a radiologic weapon is very real with the availability of nuclear material and easily concealed simple devices, such as the so-called dirty bomb, for dispersal. A dirty bomb is a conventional explosive (e.g., dynamite) that is packaged with radioactive material that scatters when the bomb is detonated. It disperses radioactive material and may be called a radiologic weapon, but it is not a *nuclear* weapon, which uses a complex nuclear fission reaction that is thousands of times more devastating than the dirty bomb.

Sources of radioactive material include not only nuclear weapons but also reactors and simple radioactive samples, such as weapons-grade plutonium or uranium, freshly spent nuclear fuel, or medical supplies (e.g., radium, certain cesium isotopes) used in cancer treatments and radiology. Exposure to a large number of people can be accomplished by placing a radioactive sample in a public place. Thousands may be exposed this way; some may be immediately affected, and others may require health monitoring for many years to assess long-term effects.

Any terrorist act or unintentional radiation release can be sizable and may require the entire hospital and prehospital staff to be prepared, recognize signs and symptoms of exposure, and rapidly treat victims without contamination of personnel, visitors, patients, or the facility itself.

Types of Radiation

Atoms consist of protons, neutrons, and electrons. The protons and neutrons are in balance in the nucleus. The protons repel

each other because they are all positively charged. The number of protons is specific for each element in the periodic table. There is a specific ratio of protons and neutrons for each different atom, and the result is element stability. When an element is radioactive, there is an imbalance in the nucleus, resulting from an excess of neutrons.

To achieve stability, a radioactive nuclide can eject particles until the most stable number (an even number) of protons and neutrons exists. A proton can become a neutron by ejecting a positron; conversely, a neutron can become a proton by ejecting a negative electron. An alpha particle is released when two protons and two electrons are ejected (beta particles are electrons).

Alpha particles cannot penetrate the skin. A thin layer of paper or clothing is all that is necessary to protect the skin from alpha radiation. However, this low-level radiation can enter the body through inhalation, ingestion, or injection (open wound). Only localized damage occurs.

Beta particles have the ability to moderately penetrate the skin to the layer in which skin cells are being produced. This high-energy radiation can cause skin damage if the skin is exposed for a prolonged period and can cause injury if beta particles penetrate the skin.

Gamma radiation is a short-wavelength electromagnetic energy that is emitted when there is excess core nucleus energy. Gamma particles are penetrating. Therefore, it is difficult to shield against gamma radiation. X-rays are an example of gamma radiation. Gamma radiation often accompanies both alpha particle and beta particle emission.

Measurement and Detection

Radiation is measured in several different units. The *rad* is the basic unit of measurement. A rad is equivalent to 0.01 J of energy per kilogram of tissue. To determine the damaging effect of the rad, a conversion to the *rem* (roentgen equivalents man) is necessary. The rem reflects the type of radiation absorbed and the potential for damage. For example, 200,000 mrem results in mild radiation sickness (1 rem = 1000 mrem) (ACS, 2010). Typical natural yearly exposure for a person is 360 mrem. Another important concept is *half-life*. The half-life of a radioactive product is the time it takes to lose half of its radioactivity.

The only way to detect radiation is through a device that determines the exposure per minute. There are various devices for this purpose. The Geiger counter (or Geiger-Mueller survey meter) can measure background radiation quickly through detection of gamma radiation and some beta radiation. With high-level radiation, the Geiger counter may underestimate exposure. Other devices include the ionization chamber survey meter, alpha monitors, and dose rate meters. Personal dosimeters are simple tools that identify radiation exposure and are worn by radiology personnel every day.

Exposure

Exposure is affected by time, distance, and shielding. The longer a person is within the radiation area, the higher the exposure. In addition, the larger the amount of radioactive material in the area, the greater the exposure. The farther away the person is from the radiation source, the lower the exposure. Shielding from the radiation source also decreases exposure.

Three types of radiation-induced injury can occur: external irradiation, contamination with radioactive materials, and incorporation of radioactive material into body cells, tissues, or organs:

- *External irradiation* exposure occurs when all or part of the body is exposed to radiation that penetrates or passes completely through the body. In this type of exposure, the person is not radioactive and does not require special isolation or decontamination measures. Irradiation does not necessarily constitute a medical emergency.
- *Contamination* occurs when the body is exposed to radioactive gases, liquids, or solids either externally or internally. If internal, the contaminant can be deposited within the body. Contamination requires immediate medical management to prevent incorporation.
- *Incorporation* is the actual uptake of radioactive material into the cells, tissues, and susceptible organs. The organs involved are usually the kidneys, bones, liver, and thyroid.

Sequelae of contamination and incorporation can occur days to years later. The thyroid gland can be largely protected from radiation exposure by administration of stable iodine (potassium iodide, or KI) before or promptly after the intake of radioactive iodine. Priorities in the treatment of any type of radiation exposure are always treatment for life-threatening injuries and illnesses first, followed by measures to limit exposure, contamination control, and finally decontamination.

Decontamination

Hospital and community disaster plans should be in effect when managing a radiation disaster. Access restriction is essential to prevent contamination of other areas of the hospital. Triage outside the hospital is the most effective means of preventing contamination of the facility itself. Floors are covered to prevent tracking of contaminants throughout the treatment areas. Strict isolation precautions should be in effect. All air ducts and vents must be sealed to prevent spread. Waste is controlled through double-bagging and the use of plastic-lined containers outside of the facility. All radiation-contaminated waste must be disposed in appropriate color-coded yellow and magenta canisters.

Staff are required to wear protective clothing, such as water-resistant gowns, two pairs of gloves, masks, caps, goggles, and booties. Dosimetry devices should be worn by all staff members participating in patient care. The radiation safety officer in the hospital should be notified immediately to assist with surveys (using a radiation survey meter) of the incoming patients and to provide dosimeters to all staff personnel involved in direct care of patients who have been exposed. There is minimal risk to staff if the patients are properly surveyed and decontaminated.

Each patient arriving at the hospital should first be surveyed with the radiation survey meter for external contamination and then directed toward the decontamination area as needed. The majority of patients can be safely decontaminated with soap and water. Decontamination occurs outside of the ED with a shower, collection pool, tarp, and collection containers for patient belongings, as well as soap, towels, and disposable paper gowns for patients. Water runoff needs to be contained. Patients who are uninjured can perform self-decontamination with handheld showers. After the patient has showered, a resurvey is conducted to determine whether the radioactive contaminants have been removed. Additional washings should occur until the patient is free of contamination. It is important to ensure that during showers, previously clean areas are not contaminated with runoff from the washed contaminated areas (e.g., hair should be washed in a position that protects the body from

contamination). Wounds are irrigated and then covered with a water-resistant dressing prior to total body decontamination.

Internal contamination or incorporation requires decontamination through catharsis, gastric lavage with chelating agents (agents that bind with radioactive substances and are then excreted), or both. Samples of urine, feces, and vomitus are surveyed to determine internal contamination levels. Biologic samples are taken through nasal and throat swabs, and a complete blood count with differential is obtained.

Acute Radiation Syndrome

Acute radiation syndrome (ARS) can occur after exposure to radiation. It is the dose, rather than the source, that determines whether ARS develops. Factors that determine whether the patient's response to exposure will result in ARS include a high dose (minimum 100 rad) and rate of radiation with total body exposure and penetrating-type radiation. Age, medical history, and genetics also affect the outcome after exposure. The course is predictable. Table 61-7 identifies the phases of ARS.

Each body system is affected differently in ARS. Systems with cells that rapidly reproduce are most commonly affected. The hematopoietic system is the first system affected and serves as an indicator of the severity of radiation exposure (Veenema, 2013). A predictor of outcome is the absolute lymphocyte count at 48 hours after exposure. A significant exposure would be indicated by blood lymphocyte counts of 300 to 1200/mm^3. Barrier precautions should be implemented to protect the patient from infection. Neutrophils decrease within 1 week, platelets decrease within 2 weeks, and red blood cells decrease within 3 weeks. Hemorrhagic complications including fever and sepsis are common.

The gastrointestinal system, with its rapidly reproducing cells, is also readily affected by radiation. Doses of radiation required to produce symptoms are approximately 600 rad or higher. The gastrointestinal symptoms usually occur at the same time as the changes in the hematopoietic system. Nausea and vomiting occur within 2 hours after exposure. Sepsis, fluid and electrolyte imbalance, and opportunistic infections can occur as complications. An ominous sign is the presence of high fever and bloody diarrhea; these typically appear on day 10 after exposure (ENA, 2014).

The central nervous system is affected when the dose exceeds 1000 rad (ENA, 2014). The symptoms occur when damage to the blood vessels of the brain results in fluid leakage. Signs and symptoms include cerebral edema; nausea; vomiting; headache; and increased intracranial pressure, which heralds a poor outcome and imminent death. Central nervous system injury with this amount of exposure is irreversible and occurs before hematopoietic or gastrointestinal system symptoms appear. Cardiovascular collapse is usually seen in conjunction with these injuries.

Skin effects can also indicate the dose of radiation exposure. With exposure of 600 to 1000 rad, erythema occurs; it can disappear within hours and then reappear. The patient who has been exposed must be evaluated hourly for the presence of erythema. With exposures greater than 1000 rad, desquamation (radiation dermatitis) of the skin occurs. Necrosis becomes evident within a few days to months at doses greater than 5000 rad.

Secondary injury can occur when the radiation exposure occurs during a traumatic event such as a blast or burn. Trauma in addition to radiation exposure increases patient mortality. Attention must first be directed toward the primary assessment for trauma. Airway, breathing, circulation, and fracture reduction require immediate attention. All definitive treatments must occur within the first 48 hours. Thereafter, all surgical procedures should be delayed for 2 to 3 months because of the potential for delayed wound healing and the possible development of opportunistic infections several weeks after exposure.

TABLE 61-7 Phases of Effects of Radiation Exposure

Phase	Time of Occurrence	Signs and Symptoms
Prodromal phase (presenting symptoms)	48–72 hours after exposure	Nausea, vomiting, loss of appetite, diarrhea, fatigue High-dose radiation—fever, respiratory distress, and increased excitability
Latent phase (a symptom-free period)	After resolution of prodromal phase; can last up to 3 weeks With high-dose radiation, latent period is shorter	Decreasing lymphocytes, leukocytes, thrombocytes, red blood cells
Manifest illness phase	After latent period phase	Infection, fluid and electrolyte imbalance, bleeding, diarrhea, shock, and altered level of consciousness
Recovery phase	After manifest illness phase	Can take weeks to months for full recovery
Death	After manifest illness phase	Increased intracranial pressure is a sign of impending death

Survival

There are three categories of predicted survival after radiation exposure: probable, possible, and improbable. Triage of victims at the scene, after decontamination, is conducted using the routine system for disaster triage. Presenting signs and symptoms determine the potential for survival and therefore the category of predicted survival during triage.

Probable survivors have either no initial symptoms or only minimal symptoms (e.g., nausea and vomiting), or these symptoms resolve within a few hours. These patients should have a complete blood count drawn and may be discharged with instructions to return if any symptoms recur.

Possible survivors present with nausea and vomiting that persist for 24 to 48 hours. They experience a latent period, during which leukopenia, thrombocytopenia, and lymphocytopenia occur. Barrier precautions and protective isolation are implemented if the patient's lymphocyte count is less than 1200/mm^3. Supportive treatment includes administration of blood products, prevention of infection, and provision of enhanced nutrition.

Improbable survivors have received more than 800 rad of total-body penetrating irradiation. People in this group demonstrate an acute onset of vomiting, bloody diarrhea, and shock. Any neurologic symptoms suggest a lethal dose of radiation (ENA, 2014). These patients still require decontamination to prevent further contamination of the area and of others. Personal protection is essential, because it is virtually impossible to fully decontaminate these patients; all of their internal organs have

been irradiated. The survival time is variable; however, death usually occurs swiftly due to shock. If there are no neurologic symptoms, patients may be alert and oriented, similar to a patient with extensive burns. In a mass casualty situation, these patients would be triaged into the black category, where they will receive comfort measures and emotional support. If it is not a mass casualty situation, aggressive fluid and electrolyte therapies are essential.

Legal Issues in Disaster Management

Legal and ethical guidelines are essential for effective disaster management. Law plays a major role in protecting the vulnerable population and to ensure equitable relief for all those affected by disaster. Integration of legal and ethical guidelines in all the phases of disaster cycle is essential for seamless disaster response. Legal guidelines aid in the disaster recovery process. The Indian Disaster Management Act provides clear-cut guidelines for the disaster relief work. This Act delineates and has streamlined the responsibility from the central government, state government, district, and local bodies so that relief work flows in an orderly fashion.

In times of disaster, many international and national agencies, NGOs, churches, and other agencies come forward to provide relief work. The aids need to be provided without any discrimination to the affected families and persons. The disaster relief materials need to be provided without seeking political or religious affiliations and without interfering in the internal matters of the country.

The government needs to ensure that aid is not used to collect sensitive information about the state or country which is not necessary for disaster recovery. The aid should be provided in coordination with the local body legally permitted to provide relief work by the state and central governments. The relief workers who have volunteered to provide specialized services like that of anesthesiologist, surgeon, nurse, etc., need to have the license certificate from the respective councils as legal credentials for their work. The relief worker if found to be causing injury or harm due to negligence is liable for punishment (Dalal & Krishnamoorthy, 2018). The nurses and other health care professionals involved in relief work are expected to follow the ethical code of conduct. They are expected to provide relief works without discriminating the victims on the basis of economic, social, religious, or linguistic barriers.

Ethical Issues in Disaster

Disasters can present a disparity between the resources of the health care agency and the needs of the victims. This generates ethical dilemmas for nurses and other health care providers. Issues include conflicts related to the following:

- Assisted suicide
- Confidentiality
- Consent
- Duty
- Futile therapy
- Rationing care
- Resuscitation

Nurses may find it difficult not to provide care to the dying or to withhold information to avoid spreading fear and panic. Vulnerable populations, especially the children, pregnant women, and elderly, are given priority in rescue operations, whereas everyone deserves quick relief from crisis. Children may get separated from parents and may be exploited in the disaster scenario. As nurses, we need to ensure that the vulnerable population needs to be safeguarded. Clinical scenarios that are unimaginable in normal circumstances confront the nurse in extreme instances. Other ethical dilemmas may arise out of health care providers' instincts for self-protection and protection of their families (ANA, 2010). For example, what should a nurse who is pregnant do when incoming disaster victims have been exposed to radiation yet too few nurses are available?

Nurses can plan for the ethical dilemmas they will face during disasters by establishing a framework for evaluating ethical questions before they arise and by identifying and exploring possible responses to difficult clinical situations. They can consider how the fundamental ethical principles of nonmaleficence, beneficence, and distributive justice will influence their decisions and care in disaster response.

CRITICAL THINKING EXERCISES

1. You work in an occupational health clinic that provides support to a chemical plant that manufactures chlorine. A patient walks to the clinic after being told to report for an examination by his supervisor since he temporarily removed his PPE while at work. Although he walked to the clinic, he tells you that now his eyes are burning and he is experiencing blurry vision. What evidence-based assessments and interventions would you now implement and why?
2. You are a home health nurse. Several patients who comprise your caseload are dependent upon electronic medical equipment, including one patient who requires home mechanical ventilation and three who require home intravenous therapy. You live in a coastal area and a category 4 hurricane is threatening to hit your community within the next 48 hours. Describe the precautions you would take to ensure that these patients are not deprived of the use of their electronic medical equipment in case of a loss of power.
3. You are working in the emergency department (ED) of a community hospital. One evening, a radio call from EMS sends an alert that there is a possible multiple shooting at a restaurant a block away from the hospital. What are your priorities and first actions? What might be done to ensure safety of the ED staff and patients? How would you prepare for the arrival of patients who may have been injured from this event?

Care of Elderly

Chapter 62 Health Care of the Older Adult 2035

CHAPTER 62

Health Care of the Older Adult

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Specify the demographic trends and the physiologic aspects of aging in India.
2. Describe the significance of preventive health care and health promotion for the older adult.
3. Compare and contrast the common physical and mental health problems of aging and their effects on the functioning of older adults and their families.
4. Identify the role of the nurse in meeting the health care needs of the older patient.
5. Describe the services provided for the elderly under the National Programme for Health Care of the Elderly.
6. Examine common health issues of older adults and their families in the home and the community, in the acute care setting, and in the long-term care facility.

GLOSSARY

activities of daily living (ADLs): personal care activities such as bathing, dressing, grooming, eating, toileting, and transferring
ageism: a bias that discriminates, stigmatizes, and disadvantages older adults based solely on their chronologic age
comorbidity: having more than one illness at the same time (e.g., diabetes and congestive heart failure)
delirium: an acute, confused state that begins with disorientation and if not recognized and treated early can progress to changes in level of consciousness, irreversible brain damage, and sometimes death
dementia: broad term for a syndrome characterized by a general decline in higher brain functioning, such as reasoning, with a pattern of eventual decline in the ability to perform even basic activities of daily living, such as toileting and eating
depression: the most common affective (mood) disorder of old age; results from changes in reuptake of the neurochemical serotonin in response to chronic illness and emotional stresses
durable power of attorney: a formal, legally endorsed document that identifies a proxy decision maker who can make decisions if the signer becomes incapacitated
elder abuse: the physical, emotional, or financial harm to an older person by one or more of the individual's children, caregivers, or others; includes neglect
geriatric syndromes: common conditions found in older adults that tend to be multifactorial and do not fall under discrete disease categories; these conditions include falls, delirium, frailty, dizziness, and urinary incontinence
geriatrics: a field of practice that focuses on the physiology, pathology, diagnosis, and management of the disorders and diseases of older adults
gerontologic/geriatric nursing: the field of nursing that relates to the assessment, planning, implementation, and evaluation of older adults in all environments, including acute, intermediate, and skilled care, as well as within the community
gerontology: the combined biologic, psychological, and sociologic study of older adults within their environment
instrumental activities of daily living (IADLs): complex skills needed for independent living, such as shopping, cooking, housework, using the telephone, managing medications and finances, and being able to travel by car or public transportation
orientation: a person's ability to recognize who and where he or she is in a time continuum; used to evaluate one's basic cognitive status
polypharmacy: the use of multiple medications
presbycusis: the decreased ability to hear high-pitched tones that naturally begins in midlife as a result of irreversible inner ear changes
presbyopia: the decrease in visual accommodation that occurs with advancing age
urinary incontinence: the unplanned loss of urine

Introduction

Aging, the normal process of time-related change, begins with birth and continues throughout life. Average life expectancy of an Indian was only 53 years in 1978, which has increased to 59 years after the period of 40 years, and geriatric population is rapidly expanding in India. Whenever nurses work with adults, they are likely to encounter older adult patients. This chapter presents demographics of aging, normal age-related changes, health problems associated with aging, and ways that nurses can address the health issues of older adults.

Overview of Aging

Demographics of Aging

The proportion of Indians 60 years of age and older has significantly increased in last few decades because of ever increasing life expectancy of people in the country. As the older adult population increases, the number of people who live to a very old age is also dramatically increasing. Life expectancy has risen dramatically in the past 100 years. In 1900, average life expectancy was 58 years, and by 2017, that figure had increased to 69.6 years. The older adult population is becoming more

diverse, reflecting changing demographics in India. Presently, in India, 8.6% (103.9 million people) population is elderly; furthermore, 8.8% of the rural population is elderly and 8.1% of the urban dwellers are elderly (Ministry of Statistics and Programme Implementation, 2016).

Health Status of the Older Adult

Although many older adults enjoy good health, most have at least one chronic illness, and many have multiple health conditions. Chronic conditions, many of which are preventable or treatable, are the major cause of disability and pain among older adults (see Fig. 62-1).

Many chronic conditions commonly found among older people can be managed, limited, and even prevented. Older people are more likely to maintain good health and functional independence if encouraged to do so and if appropriate community-based support services are available (Miller, 2015). Nurses are challenged to promote positive lifelong health behaviors, because the impact of unhealthy behaviors and choices can result in chronic disease.

Nursing Care of the Older Adult

Gerontology, the study of the aging process, is a multidisciplinary field that draws from the biologic, psychological, and sociologic sciences. Geriatrics is the practice (medical or nursing) that focuses on the physiology, pathology, diagnosis, and management of the disorders and diseases of older adults. Care for older adults should not be limited to one discipline but is best provided through a cooperative effort. An interdisciplinary approach to providing care combines expertise and resources to provide comprehensive geriatric assessment and intervention. Nurses collaborate with the team to obtain appropriate services for patients and provide a holistic approach to care.

Gerontologic/geriatric nursing is the field of nursing that specializes in the care of older adults. The Scope and Standards of Gerontological Nursing Practice was originally developed in 1969 by the American Nurses Association (ANA) and revised in 2010 (ANA, 2010). The nurse gerontologist can be either a specialist or a generalist providing comprehensive nursing care to older adults by combining the basic nursing process with a specialized knowledge of aging. Gerontologic nursing is provided in acute care, skilled and assisted living, the community, and home settings. The goals of care include promoting and maintaining functional status as well as helping older adults identify and use their strengths to achieve optimal independence.

Nurses who are certified in geriatric nursing have specialized knowledge of the acute and chronic changes specific to older adults. The use of advanced practice nurses who have been educated in geriatric nursing concepts has proved to be very effective when dealing with the complex care needs of an older patient. When best practices are used and current scientific knowledge applied to clinical problems, there is significantly less deterioration in the overall health of aging patients (ANA, 2010).

In addition to specialists, nurses who work in all areas of adult medical-surgical nursing encounter older adult patients. Nurses must be knowledgeable and skilled in meeting the complex needs of these patients. Nurses and caregivers who work with older patients must understand that aging is not synonymous with disease and that the effects of the aging process alone are not the only or even the primary contributors to disability and disease. Aging is a highly individualized and multifaceted process (Cline, 2014).

Functional assessment is a common framework for assessing older adults. Age-related changes, as well as additional risk factors such as disease and the effects of medications, can

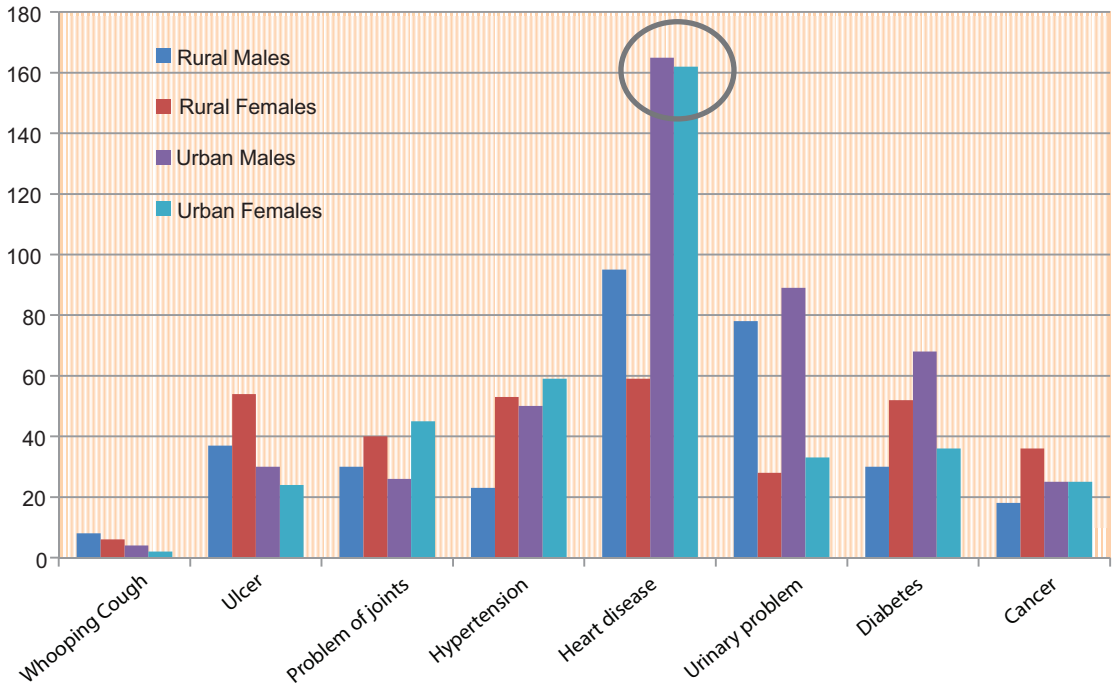

Figure 62-1 • Number of elderly persons reporting a chronic disease (per 1,000 persons). Source: Ministry of Statistics & Programme Implementation (2011). Situation analysis of the elderly in India. Retrieved at: http://mospi.nic.in/sites/default/files/publication_reports/ElderlyinIndia_2016.pdf.

reduce function. Assessing the functional consequences of aging and proposing practical interventions help maintain and improve the health of older adults. The goal is to help older adults sustain maximum functional level and dignity despite physical, social, and psychological losses. Early intervention can prevent complications of many health problems and help maximize the quality of life.

Theories of Aging

Aging has been defined chronologically by the passing of time—subjectively, as in how a person feels, and functionally, as in changes in physical or mental capabilities. Many theories attempt to provide a framework in which to understand aging from different perspectives. Clinicians can use each theory to gain insight into different aspects of aging.

Biological Theories of Aging

The biological theories of aging are focusing on the functional changes that occur over time in various systems of the human body. They are divided into two:

Stochastic Theories

These theories presume that events related to aging occur over time. There are four theories under this category (Jin, 2010):

- **Error theory:** This theory proposes that the error in DNA synthesis is perpetuated and leads to decline in function in the elderly.
- **Free radical theory:** During the metabolism, free radicals emerge and get accumulated. Accumulated free radicals damage the cell membranes and thereby reduce the functional efficacy of the cells and systems leading to aging. The body tries to limit its antioxidant secretion which removes the free radicals.
- **Cross-linkage theory:** According to this theory, some proteins get cross-linked which results in accumulation of waste substances and poor functional ability of the cells.
- **Wear and tear theory:** According to this theory, the human body is a machine. As machine undergoes wear and tear, the cells and system of the body also become insufficient and decline in function.

Nonstochastic Theories

These theories presume aging as a certain predetermined, timed phenomenon. There are two theories under this category (Jin, 2010):

- **Programmed theory:** As per this theory, the cells are programmed so that they replicate only a limited number of times. After a certain number of cell divisions, the cells stop dividing.
- **Immunity theory:** The immune system of our body, especially the T lymphocytes, undergoes lot of changes which lead to irreversible damage.

Sociological Theories

- **Disengagement theory:** This theory proposes that as a person withdraws himself or herself from the society, the society in turn disengages with him or her, leading to age-related functional decline.
- **Activity theory or developmental task theory:** This theory proposes that one needs to keep oneself active to remain healthy and to have a positive self-concept. By being active, an older person can retain a positive self-concept and stay healthy.
- **Continuity theory:** Old age is viewed as the continuation of the earlier phase of life and not as the terminal phase. Individuals continue to remain to have some habits and activities in the same way as earlier.
- **Age stratification theory:** The society is stratified according to age and roles and an individual progresses through the society in groups or cohorts.
- **Environment fit theory:** Each individual has the competency to function effectively within the environment. As the person gets aged, he or she may feel threatened and become incompetent, leading to withdrawal from the society.

Psychological Theories of Aging

The basic assumption of psychological theories of aging is that the development of an individual through middle age to old age is a continuous and dynamic process.

- **Maslow's hierarchy of needs:** According to Maslow, there are five needs, with basic human needs at the bottom of the pyramid followed by safety and security, love and belonging, self-esteem, and self-actualization. Each individual will have his or her internal priority which motivates him or her to reach the next level of achievement.
- **Jung's theory of individualism:** According to Jung, aging is not just associated with decline of the body and mind strength and relevancy but also a time to grow one's own self-awareness. Jung considers that refinement of self-awareness and self-knowledge is the essence of aging.
- **Ericson's psychosocial development theory:** According to Eric Ericson, an individual passes through eight stages of development. Each stage of life development presents a crisis. If the individual gets mastery of the corresponding task, he or she moves smoothly to the next stage. The last phase of development is marked by ego integrity versus despair. If the task of this stage is not mastered, it leads to desperation.
- **Selective optimization with compensation:** The physical strength reduces with age. To compensate for this loss, an individual can adapt through selection, optimization, and compensation.

In addition to the biologic, developmental, and sociologic theories of aging, Miller (2015) developed the Functional Consequences Theory, which encourages nurses to consider the effects of normal age-related changes as well as the damage incurred through disease or environmental and behavioral risk factors when planning care. This theory suggests that nurses can alter the outcome for patients through nursing interventions that address the consequences of these changes. Age-related changes and risk factors may negatively interfere with patient outcomes and impair patient activity and quality of life. For example, normal age-related changes in vision may increase sensitivity to glare. Alterations in the environment that reduce glare may enhance patient comfort and safety. In contrast, the development of cataracts, which is not a normal age-related change, also may increase sensitivity to glare. The nurse must differentiate between normal, irreversible age-related changes and modifiable risk factors. Doing so helps the nurse design appropriate nursing interventions that have a positive impact on outcomes for older patients—most importantly, for their quality of life.

Age-Related Changes

The well-being of older adults depends on physical, psychosocial, mental, social, economic, and environmental factors. A total

assessment includes an evaluation of all major body systems, social and mental status, and the person's ability to function independently (Weber & Kelley, 2014).

Physical Aspects of Aging

Intrinsic aging (from within the person) refers to those changes caused by the normal aging process that are genetically programmed and essentially universal within a species. Universality is the major criterion used to distinguish normal aging from pathologic changes associated with illness. However, people age quite differently and at different rates; thus, chronologic age is often less predictive of obvious age characteristics than other factors, such as one's genetics (see Chart 62-1) and lifestyle.

Cellular and extracellular changes that occur with aging cause functional decline and measurable changes in physical appearance, including changes in shape and body makeup. Cellular aging and tissue deficits also diminish the body's ability to maintain homeostasis and prevent organ systems from functioning at full efficiency. As cells become less able to replace themselves, they accumulate a pigment known as lipofuscin. A degradation of elastin and collagen causes connective tissue to become stiffer and less elastic. These changes result in diminished capacity for organ function and increased vulnerability to disease and stress. Age-related changes in the hematopoietic system influence red blood cell production, leading to increased rates of anemia (Grossman & Porth, 2014).

Table 62-1 summarizes subjective and objective findings related to age-related changes in the body systems. More in-depth information about age-related changes can be found in the chapters pertaining to each organ system.

When assessing the physical aspects of aging, nurses should know that tactile sensation is reduced and changes in the ability to sense pressure, pain, and temperature all lead to a decreased ability to identify and attend to physical symptoms (Oster & Oster, 2015).

Cardiovascular System

Heart disease is the leading cause of death in older adults. Age-related changes reduce the efficiency of the heart and contribute to decreased compliance of the heart muscle. These changes include myocardial hypertrophy, which changes left ventricular strength and function; increased fibrosis and calcified tissues that infiltrate muscles and conductive tissues causing stenosis of the valves; and decreased pacemaker cells. As a result, the heart valves become thicker and stiffer, and the heart muscle and arteries lose their elasticity, resulting in a reduced stroke volume. Calcium and fat deposits accumulate within arterial walls, and veins become increasingly stiff and tortuous, increasing arterial resistance; this leads to hypertension and increases the workload of the heart (Capriotti & Frizzell, 2015).

It is difficult to differentiate between age- and disease-related changes in cardiovascular function because of the significant influence of behavioral factors on cardiovascular health. When cross-cultural studies are conducted, cardiovascular

Chart 62-1 GENETICS IN NURSING PRACTICE

Genetics Concepts and the Older Adult

Genetic conditions in the older adult may occur from a specific gene mutation or arise as a result of a genetic predisposition combined with other factors (multifactorial). The following are examples of some adult-onset genetic conditions:

- Colon cancer
- Hemochromatosis
- Huntington disease
- Polycystic kidney disease
- Alzheimer disease

The following are some examples of diseases with multifactorial components, which may include a genetic predisposition, in the older adult:

- Diabetes
- Emphysema
- Heart disease

Nursing Assessments

Refer to Chart 3-2: Genetics in Nursing Practice: Genetic Aspects of Health Assessment

Family History Assessment Specific to the Older Adult

- Collect and assess family history on both maternal and paternal sides of the family for three generations.
- Determine whether genetic testing has occurred with other family members.
- Assess for individual and family perceptions and beliefs around topics related to genetics.

Patient Assessment Specific to the Older Adult and Genetic Illness

- Assess older adult patient's knowledge and understanding of genetics, genetic testing, and gene-based therapies.
- Assess the patient's understanding of genetic information and decipher health literacy needs.
- Perform cultural, social, and spiritual assessment.
- Assess patient's communication capacities so that communication strategies about genetics are tailored to their needs and abilities.
- Identify patient's support system.

Management Issues Specific to Genetics and the Older Adult

- Refer for further genetic counseling and evaluation as warranted so that family members can discuss inheritance, risk to other family members, and availability of genetic testing and gene-based interventions.
- Offer appropriate genetic information and resources that take into consideration older patient's literacy needs.
- Evaluate older patient's understanding before, during, and after the introduction of genetic information and services.
- Take the time to clearly explain the concepts of genetic testing to older patients and provide written information that reinforces the topic of discussion.
- Participate in the management and coordination of care of older patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

TABLE 62-1 Age-Related Changes in Body Systems and Health Promotion Strategies

Changes	Subjective and Objective Findings	Health Promotion Strategies
Cardiovascular System		
Decreased cardiac output; diminished ability to respond to stress; heart rate and stroke volume do not increase with maximum demand; slower heart recovery rate; increased blood pressure	Complaints of fatigue with increased activity Increased heart rate recovery time *Optimal blood pressure:* ≤120/80 mm Hg *Prehypertension:* >120–139/80–89 mm Hg *Hypertension:* ≥140/90 mm Hg	Exercise regularly; pace activities; avoid smoking; eat a low-fat, low-salt diet; participate in stress-reduction activities; check blood pressure regularly; adherence to medications; weight control (body mass index <25 kg/m^2).
Respiratory System		
Increase in residual lung volume; decrease in muscle strength, endurance, and vital capacity; decreased gas exchange and diffusing capacity; decreased cough efficiency	Fatigue and breathlessness with sustained activity; decreased respiratory excursion and chest/lung expansion with less effective exhalation; difficulty coughing up secretions	Exercise regularly; avoid smoking; take adequate fluids to liquefy secretions; receive yearly influenza immunization and pneumonia vaccine at 65 years of age; avoid exposure to upper respiratory tract infections.
Integumentary System		
Decreased subcutaneous fat, interstitial fluid, muscle tone, glandular activity, and sensory receptors, resulting in atrophy and decreased protection against trauma, sun exposure, and temperature extremes; diminished secretion of natural oils and perspiration; capillary fragility	Thin, wrinkled, and dry skin; increased fragility, more easily bruised, and sunburned; complaints of intolerance to heat; prominent bone structure	Limit sun exposure to 10–15 minutes daily for vitamin D (use protective clothing and sunscreen); dress appropriately for temperature; stay hydrated; maintain a safe indoor temperature; take shower rather than hot tub bath if possible; lubricate skin with lotions that contain petroleum or mineral oil.
Reproductive System		
Female: Vaginal narrowing and decreased elasticity; decreased vaginal secretions *Male:* Gradual decline in fertility, less firm testes, and decreased sperm production *Male and female:* Slower sexual response	*Female:* Painful intercourse; vaginal bleeding following intercourse; vaginal itching and irritation; delayed orgasm *Male:* Less firm erection and delayed erection and achievement of orgasm	*Female:* May require vaginal estrogen replacement; gynecology/urology follow-up; use a lubricant with sexual intercourse.
Musculoskeletal System		
Loss of bone density; loss of muscle strength and size; degenerated joint cartilage	Height loss; prone to fractures; kyphosis; back pain; loss of strength, flexibility, and endurance; joint pain	Weight-bearing exercise regularly (3 times a week); recommend bone density screening; take calcium and vitamin D supplements as prescribed.
Genitourinary System		
Decrease in detrusor muscle contractility, bladder capacity, flow rate, ability to withhold voiding; increase in residual urine *Male:* Benign prostatic hyperplasia *Female:* Relaxed perineal muscles; detrusor instability leads to urge incontinence; urethral dysfunction (stress urinary incontinence)	Urinary retention; irritative voiding symptoms including frequency, feeling of incomplete bladder emptying, multiple nighttime voiding Urgency/frequency syndrome; decreased "warning time"; drops of urine lost with cough, laugh, position change	Drink adequate fluids but limit drinking in evening; avoid bladder irritants (e.g., caffeinated beverages, alcohol, artificial sweeteners); do not wait long periods between voiding; empty bladder completely when voiding; wear easily manipulated clothing; consider urologic workup. Women: perform pelvic floor muscle exercises, preferably learned via biofeedback
Gastrointestinal System		
Decreased sense of thirst, smell, and taste; decreased salivation; difficulty swallowing food; delayed esophageal and gastric emptying; reduced gastrointestinal motility	Risk of dehydration, electrolyte imbalances, and poor nutritional intake; complaints of dry mouth; complaints of fullness, heartburn, and indigestion; constipation, flatulence, and abdominal discomfort; risk for aspiration	Use ice chips, mouthwash; brush, floss, and massage gums daily; receive regular dental care; eat small, frequent meals; sit up while and after eating and avoid heavy activity after eating; limit antacids; eat a high-fiber, low-fat diet; limit laxatives; toilet regularly; drink adequate fluids.
Nervous System		
Decrease in brain volume and cerebral blood flow. Reduced speed in nerve conduction	Slower to respond and react; learning may take longer; increased vulnerability to delirium with illness, anesthesia, even changes in environmental cues such as a room change; increased risk of fainting and falls	Pace teaching; with hospitalization, encourage visitors; enhance sensory stimulation; with sudden confusion, look for cause; encourage slow rising from a resting position and practice fall prevention measures

(Continued)

(Continued)

Special Senses		
Vision: Presbyopia; diminished ability to focus on close objects; decreased ability to tolerate glare; pupils become more rigid and lenses more opaque; decreased contrast sensitivity; decrease in aqueous humor	Holds objects far away from face; complains of glare; poor night vision and "dry" eye; difficulty adjusting to changes in light intensity; decreased ability to distinguish colors	Wear eyeglasses and use sunglasses outdoors; avoid abrupt changes from dark to light; use adequate indoor lighting with area lights and nightlights; use large-print books; use magnifier for reading; avoid night driving; use contrasting colors for color coding; avoid glare of shiny surfaces and direct sunlight.
Hearing: Presbycusis; decreased ability to hear high-frequency sounds; tympanic membrane thinning and loss of resiliency; difficulty with sound discrimination especially in noisy environment	Gives inappropriate responses; asks people to repeat words; strains forward to hear; can result in social isolation and increases vulnerability for delirium during hospitalization	Recommend a hearing examination; reduce background noise; face person; enunciate clearly; speak with a low-pitched voice; use nonverbal cues; rephrase questions.
Taste and smell: Decreased ability to taste and smell	Decreased recognition of familiar smells including recognizing spoiled food or a gas stove left on; decreased enjoyment of food; uses excessive sugar and salt	Encourage use of lemon, spices, herbs; recommend smoking cessation.

Adapted from Carpenter, H. (2015). Summer sun safety. American Nurse Today, 10(7), 46. Oster, K. A., & Oster, C. A. (2015). Special needs population: Care of the geriatric patient population in the perioperative setting. AORN Journal, 101(4), 444–456.

changes that in the past were thought to be age related do not consistently appear. For example, the higher blood pressure found in older adults in Western societies does not occur in less-developed societies and may be a result of different lifestyle behaviors rather than normal age-related changes (Miller, 2015). The cardiovascular system can adapt to many normal age-related changes and often an older person is unaware of any significant decline in cardiovascular performance. However, when challenged, for instance, during exercise or stress, the cardiovascular system of an older person is less efficient and may be unable to respond sufficiently when life-sustaining activities are needed.

Careful assessment of older adults is necessary because they often present with different symptoms than those seen in younger patients. Older adults are more likely to have dyspnea or neurologic symptoms associated with heart disease, and they may experience mental status changes or report vague symptoms such as fatigue, nausea, and syncope. Rather than the typical substernal chest pain associated with myocardial ischemia, older patients may report burning or sharp pain or discomfort in an area of the upper body. Complicating the assessment is the fact that many older patients have more than one underlying disease. When a patient complains of symptoms related to digestion and breathing and upper extremity pain, cardiac disease must be considered. The absence of chest pain in an older patient is not a reliable indicator of the absence of heart disease.

Orthostatic and postprandial hypotension may be a concern as well because of decreased baroreflex sensitivity and risk factors such as medications (Miller, 2015). Therefore, it is important to assess blood pressure in two positions. A patient experiencing hypotension should be counseled to rise slowly (from a lying, to a sitting, to a standing position), avoid straining when having a bowel movement, and consider having five or six small meals each day, rather than three, to minimize the hypotension that can occur after a large meal. Extremes in temperature, including hot showers and whirlpool baths, should be avoided.

Respiratory System

The respiratory system compensates well for the functional changes of aging. In general, healthy, nonsmoking older adults show very little decline in respiratory function; however, there are substantial individual variations and aerobic capacity declines with each decade by about 10% from peak performance in the early to mid-20s (Capriotti & Frizzell, 2015). The age-related changes that do occur are subtle and gradual, and healthy older adults are able to compensate for these changes. Diminished respiratory efficiency and reduced maximal inspiratory and expiratory force may occur as a result of calcification and weakening of the muscles of the chest wall. Lung mass decreases and residual volume increases (Grossmann & Porth, 2014).

Conditions of stress, such as illness, may increase the demand for oxygen and affect the overall function of other systems. Like cardiovascular diseases, respiratory diseases manifest more subtly in older adults than in younger adults and do not necessarily follow the typical pattern of cough, chills, and fever. Older adults may exhibit fatigue, lethargy, anorexia, dehydration, and mental status changes (Miller, 2015).

Smoking is the most significant risk factor for respiratory diseases and older adults have a higher rate of smoking, about 20%, compared to the national average of 18% (Cataldo, Peterson, Hunter, et al., 2015). Therefore, a major focus of health promotion activities should be on smoking cessation and avoidance of environmental smoke. Despite marketing by manufacturers, e-cigarettes are not an effective smoking cessation aid nor do they promote health (Cataldo et al., 2015).

Additional activities that help older adults maintain adequate respiratory function include regular exercise, appropriate fluid intake, pneumococcal vaccination, yearly influenza immunizations, and avoidance of people who are ill. Hospitalized older adults should be frequently reminded to cough and take deep breaths, particularly postoperatively, because their decreased lung capacity and decreased cough efficiency predispose them to atelectasis and respiratory infections.

Integumentary System

The functions of the skin include protection, temperature regulation, sensation, and excretion. Aging can interrupt all functions of the skin and affect appearance (Grossman & Porth, 2014). Epidermal proliferation decreases, and the dermis becomes thinner. Elastic fibers are reduced in number and collagen becomes stiffer. Subcutaneous fat diminishes, particularly in the extremities, and less vasodilation renders

the body less able to produce or conserve body heat. These changes lead to lack of fever in circumstances in which fever would normally be present in younger individuals and reduced tolerance to temperature extremes, which increases the likelihood of hypothermia and hyperthermia (Capriotti & Frizzell, 2015). There is also a loss of resiliency with wrinkling and sagging of the skin. The skin becomes drier and more susceptible to burns, injury, and infection. Hair pigmentation may change and balding may occur; genetic factors strongly influence these changes. These changes in the integument reduce tolerance to temperature extremes and sun exposure.

Lifestyle practices are likely to have a large impact on skin changes. Strategies to promote healthy skin function include not smoking, avoiding exposure to the sun, using a sun protection factor of 15 or higher, wearing protective clothing, using emollient skin cream containing petrolatum or mineral oil, avoiding hot soaks in the bathtub, and maintaining optimal nutrition and hydration (Carpenter, 2015). Older adults should be encouraged to have any changes in the skin examined, because early detection and treatment of precancerous or cancerous lesions are essential for the best outcome.

Reproductive System

An outdated perception is that older adults are asexual, but older adults report that a fairly stable and active sex life is an important quality of life issue. Sexual activity declines with the loss of a partner, primarily for women as a result of widowhood and for men as a result of poor heath, erectile dysfunction, medications, and emotional factors. However, although good health is a predictor of sexual activity, older adults with chronic illnesses may be able to have a sexually active life as well. Because of the many factors that influence the ability to be sexually active, nurses and the older person need to understand the physiologic, psychological, and social factors that affect reproductive and sexual functioning as aging progresses (Miller, 2015); (Mola, 2015).

Ovarian production of estrogen and progesterone declines with menopause. Changes that occur in the female reproductive system include thinning of the vaginal wall, along with a shortening of the vagina and a loss of elasticity; decreased vaginal secretions, resulting in vaginal dryness, itching, and decreased acidity; involution (atrophy) of the uterus and ovaries; and decreased pubococcygeal muscle tone, resulting in a relaxed vagina and perineum. Without the use of water-soluble lubricants, these changes may contribute to vaginal bleeding and painful intercourse.

In older men, the testes become less firm but may continue to produce viable sperm up to 90 years of age. At about 50 years of age, production of testosterone begins to diminish (Tabloski, 2013). Decreased libido and erectile dysfunction may develop but are more likely to be associated with factors other than age-related changes. These risk factors include obesity, smoking, cardiovascular disease, neurologic disorders, diabetes, respiratory disease, chronic pain, and many medications (i.e., vasodilators, antihypertensive agents, and tricyclic antidepressants) (Miller, 2015); (Mola, 2015).

In both older men and women, it may take longer to become sexually aroused, longer to complete intercourse, and longer before sexual arousal can occur again. Although a less intense response to sexual stimulation and a decline in sexual activity occurs with increasing age, sexual desire does not disappear. Many couples are unaware of the causes of decreased libido or erectile dysfunction and are often reluctant to discuss decreased sexual function. In fact, one survey revealed that in men with erectile dysfunction, less than half of men had discussed the dysfunction with their primary provider (Mola, 2015). Many nonpharmacologic, pharmacologic, and surgical methods are available to improve sexual relationships. Assessment and communication require sensitivity and expert knowledge in the field of sexual dysfunction. If sexual dysfunction is present, referral to a gynecologist, urologist, or sex therapist may be warranted.

Genitourinary System

The genitourinary system continues to function adequately in older adults, although kidney mass is decreased, primarily because of a loss of nephrons. However, the loss of nephrons does not typically become significant until about 90 years of age, and changes in kidney function vary widely; approximately one third of older adults show no decrease in renal function (Tabloski, 2013). Changes in renal function may be attributable to a combination of aging and pathologic conditions such as hypertension. The changes most commonly seen include a decreased filtration rate, diminished tubular function with less efficiency in reabsorbing and concentrating the urine, and a slower restoration of acid–base balance in response to stress. In addition, older adults who take medications may experience serious consequences owing to decline in renal function because of impaired absorption, decreased ability to maintain fluid and electrolyte balance, and decreased ability to concentrate urine.

Certain genitourinary disorders are more common in older adults than in the general population. In India, nearly half (42.8%) of the women 60 years of age and older suffer from urinary incontinence (i.e., urine leakage or problems controlling urine flow) (Singh, Agarwal, Verma, et al., 2013). This condition should not be mistaken as a normal consequence of aging (Weber & Kelley, 2014). Costly and often embarrassing, it should be evaluated, because in many cases it is reversible or can be treated. (See Chapter 45 for further discussion of urinary incontinence.) Benign prostatic hyperplasia (enlarged prostate gland), a common finding in older men, causes a gradual increase in urine retention and overflow incontinence. Changes in the urinary tract increase the susceptibility to urinary tract infections. Adequate consumption of fluids is an important nursing intervention that reduces the risk of bladder infections and also helps decrease urinary incontinence.

Gastrointestinal System

Digestion of food is less influenced by changes associated with aging than by the risk of poor nutrition. Older adults can adjust to changes in the gastrointestinal system but may have difficulty purchasing, preparing, and enjoying their meals. The sense of smell diminishes as a result of neurologic changes and environmental factors such as smoking, medications, and vitamin B_{12} deficiencies. The ability to recognize sweet, sour, bitter, or salty foods diminishes over time, altering satisfaction with food. Salivary flow does not decrease in healthy adults; however, approximately 31% to 37% of older adults may experience a dry mouth as a result of medications and diseases (Miller, 2015). Difficulties with chewing and swallowing are generally associated with lack of teeth and disease.

Experts disagree on the extent of gastric changes that occur as a result of normal aging. However, gastric motility appears to slow modestly, which results in delayed emptying of stomach contents

and early satiety (feeling of fullness). Diminished secretion of gastric acid and pepsin, seemingly the result of pathologic conditions rather than normal aging, reduces the absorption of iron, calcium, and vitamin B_{12}. Absorption of nutrients in the small intestine, particularly calcium and vitamin D, appears to diminish with age. Functions of the liver, gallbladder, and pancreas are generally maintained, although absorption and tolerance to fat may decrease. The incidence of gallstones and common bile duct stones increases progressively with advancing years.

Difficulty swallowing, or dysphagia, increases with age and is a major health care problem in older patients. Normal aging alters some aspects of the swallowing function. In addition, dysphagia is a frequent complication of stroke and a significant risk factor for the development of aspiration pneumonia that can be life-threatening. Dysphagia is caused by interruption or dysfunction of neural pathways. It may also result from dysfunction of the striated and smooth muscles of the gastrointestinal tract in patients with Parkinson disease. Aspiration of food or fluid is the most serious complication and can occur in the absence of coughing or choking.

Constipation is a common pathologic condition that affects many older people as they age. Symptoms of mild constipation are abdominal discomfort and flatulence; more serious constipation leads to fecal impaction that contributes to diarrhea around the impaction, fecal incontinence, and obstruction. Predisposing factors for constipation include lack of dietary bulk, prolonged use of laxatives, some medications, inactivity, insufficient fluid intake, and excessive dietary fat. Ignoring the urge to defecate may also be a contributing factor.

Practices that promote gastrointestinal health include regular tooth brushing and flossing; receiving regular dental care; drinking sufficient fluids; eating small, frequent meals that are high in fiber and low in fat; avoiding heavy activity or lying flat after eating; and avoiding the use of laxatives and antacids. Understanding that there is a direct correlation between loss of smell and taste perception and food intake helps caregivers intervene to maintain the nutritional health of older patients.

Nutritional Health

The social, psychological, and physiologic functions of eating influence the dietary habits of older adults. Increasing age alters nutrient requirements; older adults require fewer calories and a more nutrient-rich, healthy diet in response to alterations in body mass and a more sedentary lifestyle. Recommendations include reducing fat intake while consuming sufficient protein, vitamins, minerals, and dietary fiber for health and prevention of disease. Decreased physical activity and a slower metabolic rate reduce the number of calories needed by older adults to maintain an ideal weight. As stated previously, age-related changes that alter pleasure in eating include a decrease in taste and smell. Older adults are likely to maintain a taste for sweetness but require more sugar to achieve a sweet flavor. They also may lose the ability to differentiate sour, salty, and bitter tastes. Apathy, immobility, depression, loneliness, poverty, inadequate knowledge, and poor oral health also contribute to suboptimal nutrient intake. Budgetary constraints and physical limitations may interfere with food shopping and meal preparation.

Nursing Alert: Drinking water before a meal may help curb appetite but is not recommended as a way to decrease salt intake. Replacing salt with other flavors, such as herbs and spices, pepper, and lemon, can help decrease salt intake.

Health promotion for older adults is based on the individual's physiologic, pathologic, and psychosocial conditions (Cline, 2014). The goals of nutrition therapy are to maintain or restore maximal independent functioning and health and to maintain the sense of dignity and quality of life by imposing as few restrictions as possible. Dietary changes should be incorporated into the older adult's existing food pattern as much as possible. Figure 62-2 lists modified dietary guidelines for older adults.

Women older than 50 years and men older than 70 years should have a daily calcium intake of 1200 mg. To foster the absorption of calcium, adults should have 600 IU of vitamin D until 70 years of age and 800 IU after 70 years of age to maintain bone health (National Institutes of Health, 2014).

Undernutrition, which can lead to malnutrition, may be a problem for older adults. Hospitalized older adults are at particular risk of malnutrition, especially those with cognitive impairment or dementia (Oster & Oster, 2015). A recent unintentional weight loss may be a result of an illness or other factors, such as depression, that may have serious consequences and affect a person's ability to maintain health and fight illness (Grossman & Porth, 2014). Many people are unaware of dietary deficits. Nurses are in an ideal position to identify nutritional problems among their patients and to work within the patient's own framework of knowledge of their health status to improve health behaviors. (See Chapter 3 for more information on nutritional assessment.)

Sleep

Older adults have increased complaints about their sleep as they age, and as many as 50% of those living at home and 65% of those living in nursing homes complain of sleep disturbances (Daglar, Sabancoigullari, Pinar, et al., 2014). Many factors affect sleep quality in older adults including respiratory problems during sleep, restless leg syndrome, nocturia, pain, osteoarthritis, heart failure, incontinence, prostate hypertrophy, menopause-related problems, pruritus, allergies, AD, depression, dementia, social isolation, loneliness, being bedridden, experiences of loss, drug use, and living in nursing homes (e.g., inadequate lighting, keeping light on during the night, noises). Some of the consequences of poor sleep quality in older adults include cognitive decline, increased risk of falls, daytime fatigue, and reduced physical and mental health and health-related quality of life status (Daglar et al., 2014).

The incidence of sleep apnea (a sleep disorder characterized by brief periods in which respirations are absent) increases with age. Having insomnia symptoms and a sleep-related disorder (snoring, choking, or pauses in breathing) is associated with significantly impaired daytime functioning and longer psychomotor reaction times compared with having either condition. (Sleep apnea is discussed in more detail in Chapter 40.)

The nurse often observes patients while they are sleeping and can identify problems. The nurse can provide health education on sleep hygiene behaviors such as avoiding use of the bed for activities other than sleeping (or sex), maintaining a consistent bedtime routine, avoiding or limiting daytime napping, and limiting alcohol intake to one drink a day. Additional suggestions include avoiding stimulants such as caffeine and nicotine after noon; curbing the amount of liquids in the evening to avoid nocturia; and engaging in regular physical activity, preferably in bright outside light (Daglar et al., 2014).

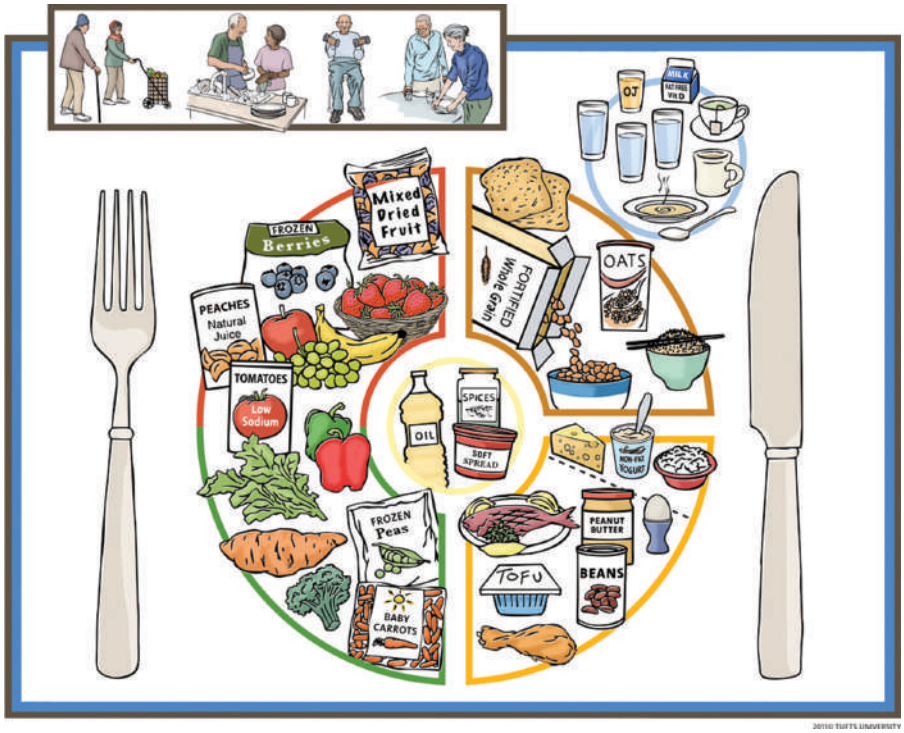

Figure 62-2 • My Plate for older adults. Used with permission from the Jean Mayer USDA Human Nutrition Research Center on Aging (HNRCA) at Tufts University.

Musculoskeletal System

Intact musculoskeletal and neurologic systems are essential for the maintenance of safe mobility, performance of activities of daily living (ADLs) (basic personal care activities), and instrumental activities of daily living (IADLs) (complex skills such as shopping, cooking, housework, using the telephone, managing medications and finances, and being able to travel by car or public transportation), thus allowing older adults to remain safe and live independently in the community. Age-related changes that affect mobility include alterations in bone remodeling, leading to decreased bone density, loss of muscle mass, deterioration of muscle fibers and cell membranes, and degeneration in the function and efficiency of joints. (These factors are discussed in detail in Unit 10.)

Without exercise, a gradual, progressive decrease in bone mass begins before 40 years of age. The cartilage of joints also progressively deteriorates in middle age. Degenerative joint disease is found in most adults older than 70 years, and weight-bearing joint and back pain is a common complaint. Excessive loss of bone density results in osteoporosis, which leads to potentially life-altering hip and vertebral fractures. Osteoporosis is preventable.

The axiom "use it or lose it" is very relevant to the physical capacity of older adults. Nurses play an important role by encouraging older adults to participate in a regular exercise program. The benefits of regular exercise cannot be overstated. Aerobic exercises are the foundation of programs of cardiovascular conditioning; however, resistance and strength training and flexibility exercises are essential components of an exercise program. Even late in life, in adults who may be frail, it is believed that exercise has benefits of increasing strength, aerobic capacity, flexibility, and balance. In addition, older adults who are hospitalized benefit from getting out of bed as soon as possible and in-hospital physical activity (Oster & Oster, 2015).

Nervous System

Homeostasis is difficult to maintain with aging, but older people have a tremendous ability to adapt and function adequately, retaining their cognitive and intellectual abilities in the absence of pathologic changes. However, normal aging changes in the nervous system can affect all parts of the body. The structure, chemistry, and function of the nervous system change with advanced age. Nerve cells in the brain decrease but the decrease is compensated for by other neurons; there is high variability among individuals and the quantity of neuronal loss varies in different parts of the brain. Overall, the decreases contribute to a small loss of brain mass (Capriotti & Frizzell, 2015). Chemical changes include a decrease in the synthesis and metabolism of the major neurotransmitters. Because nerve impulses are conducted more slowly, older people take longer to respond and react (Miller, 2015). The autonomic nervous system performs less efficiently, and postural hypotension, discussed earlier, may occur. Neurologic changes can affect gait and balance, which may interfere with mobility and safety. Nurses must advise older adults to allow a longer time to respond to a stimulus and to move more deliberately. Adequate nutrition and absorption of vitamin B_{12} is important for neurologic health. Nurses should advise older adults about proper nutrition and intake of vitamin B_{12}, especially for older adults who follow a vegetarian diet.

Slowed reaction time puts older adults at risk for falls and injuries, as well as driving errors. Although older adults spend

less time driving than younger people, older adults are just as likely to be involved in motor vehicle crashes that result in serious injury or death. Older adults who are driving unsafely should receive a driving fitness evaluation (Miller, 2015). The evaluation is often given by an occupational therapist in conjunction with a neuropsychologist, who conducts more detailed cognitive testing.

Mental function may be threatened by physical or emotional stresses. A sudden onset of confusion may be the first symptom of an infection or change in physical condition (e.g., pneumonia, urinary tract infection, medication interactions, and dehydration).

Sensory System

People interact with the world through their senses. Losses associated with old age affect all sensory organs, and it can be devastating not to be able to see to read or watch television, hear conversation well enough to communicate, or discriminate taste well enough to enjoy food. Nearly half of older men and one third of older women report difficulty hearing without a hearing aid. Most older adults have a decrease in visual acuity, a narrowing of the visual field, and may have trouble seeing at night (Oster & Oster, 2015). An uncompensated sensory loss negatively affects the functional ability and quality of life of the older adult. However, assistive devices such as visual and hearing aids can compensate for a sensory loss (Oster & Oster, 2015).

Sensory Loss Versus Sensory Deprivation

In contrast to sensory loss, sensory deprivation is the absence of stimuli in the environment or the inability to interpret existing stimuli (perhaps as a result of a sensory loss). Sensory deprivation can lead to boredom, confusion, irritability, disorientation, and anxiety. A decline in sensory input can mimic a decline in cognition that is in fact not present. Meaningful sensory stimulation provided to the older person is often helpful in correcting this problem. In some situations, one sense can substitute for another in observing and interpreting stimuli. Nurses can enhance sensory stimulation in the environment with colors, pictures, textures, tastes, smells, and sounds. The stimuli are most meaningful if they are appropriate for older adults and the stimuli are changed often. Cognitively impaired people tend to respond well to touch and to familiar music.

Vision

As new cells form on the outside surface of the lens of the eye, the older central cells accumulate and become yellow, rigid, dense, and cloudy, leaving only the outer portion of the lens elastic enough to change shape (accommodate) and focus at near and far distances. As the lens becomes less flexible, the near point of focus gets farther away. This common condition—presbyopia—usually begins in the fifth decade of life and requires the person to wear reading glasses to magnify objects (Miller, 2015). In addition, the yellowing, cloudy lens causes light to scatter and sensitivity to glare. The ability to distinguish colors decreases, particularly blue from green. The pupil dilates slowly and less completely because of increased stiffness of the muscles of the iris, thus the older person takes more time to adjust when going to and from light and dark settings and needs brighter light for close vision. Pathologic visual conditions are not a part of normal aging; however, the incidence of eye disease (most commonly cataracts, glaucoma, diabetic retinopathy, and age-related macular degeneration) increases in older adults.

Age-related macular degeneration is the primary cause of vision loss in older adults. An estimated 1.8 million Americans 40 years of age and older are affected by macular degeneration, and that number may reach 2.95 million by 2020 (Centers for Disease Control and Prevention [CDC], 2013). Macular degeneration does not affect peripheral vision, which means that it does not cause blindness. However, it affects central vision, color perception, and fine detail, greatly affecting common visual skills such as reading, driving, and seeing faces. Risk factors include sunlight exposure, cigarette smoking, and heredity. People with fair skin and blue eyes may be at increased risk. Sunglasses and hats with visors provide some protection, and stopping smoking is paramount in preventing the disease. Although there is no definitive treatment and no cure that restores vision, several treatment options are available, depending on factors such as the location of the abnormal blood vessels. Laser photocoagulation and photodynamic therapy are commonly used (Centers for Disease Control and Prevention [CDC], 2013). The earlier this condition is diagnosed, the greater the chances of preserving sight. (See Chapter 42 for more information on altered vision.)

Hearing

Auditory changes begin to be noticed at about 40 years of age. Environmental factors, such as exposure to noise, medications, and infections, as well as genetics, may contribute to hearing loss as much as age-related changes. Presbycusis is a gradual sensorineural loss that progresses from the loss of the ability to hear high-frequency tones to a generalized loss of hearing. It is attributed to irreversible inner ear changes. Older adults often cannot follow conversation because tones of high-frequency consonants (the sounds *f, s, th, ch, sh, b, t, p*) all sound alike. Hearing loss may cause older adults to respond inappropriately, misunderstand conversation, and avoid social interaction. This behavior may be erroneously interpreted as confusion. Wax buildup or other correctable problems may also be responsible for hearing difficulties. A properly prescribed and fitted hearing aid may be useful in reducing some types of hearing deficits. (See Chapter 41 for discussion of alterations in hearing.)

Taste and Smell

The senses of taste and smell are reduced in older adults. Of the four basic tastes (sweet, sour, salty, and bitter), sweet tastes are particularly dulled in older adults. Blunted taste may contribute to the preference for salty, highly seasoned foods, but herbs, onions, garlic, and lemon can be used as substitutes for salt to flavor food.

Changes in the sense of smell, generally greater than the loss of taste, are related to cell loss in the nasal passages and in the olfactory bulb in the brain (Grossman & Porth, 2014). Environmental factors such as long-term exposure to toxins (e.g., dust, pollen, and smoke) contribute to the cellular damage.

Psychosocial Aspects of Aging

Successful psychological aging is reflected in the ability of older adults to adapt to physical, social, and emotional losses and to achieve life satisfaction. Because changes in life patterns are inevitable over a lifetime, older adults need resiliency and coping skills when confronting stresses and change. A positive self-image enhances risk taking and participation in new, untested roles.

Although attitudes toward older adults differ in ethnic subcultures, a subtle theme of ageism—prejudice or discrimination against older adults—predominates in society, and many myths surround aging. Ageism is based on stereotypes—simplified and often untrue beliefs that reinforce society's negative image of older adults. Although older adults make up an extremely heterogeneous and increasingly a racially and ethnically diverse group, these negative stereotypes are sometimes attributed to all older adults.

Fear of aging and the inability of many to confront their own aging process may trigger ageist beliefs. Retirement and perceived nonproductivity are also responsible for negative feelings, because a younger working person may falsely see older people as not contributing to society, as draining economic resources, and may actually feel that they are in competition with children for resources. Concern about the large numbers of older persons leaving the workforce (baby boomers began to turn 65 years of age in 2010) is fueling this debate.

Negative images are so common in society that older adults themselves often believe and perpetuate them. An understanding of the aging process and respect for each person as an individual can dispel the myths of aging. Nurses can facilitate successful aging by recommending health promotion strategies such as anticipatory planning for retirement, including ensuring adequate income, developing routines not associated with work, and relying on other people and groups in addition to spouse to fill leisure time (Pender, Murdaugh, & Parsons, 2014).

Stress and Coping in the Older Adult

Coping patterns and the ability to adapt to stress develop over the course of a lifetime and remain consistent later in life. Experiencing success in younger adulthood helps a person develop a positive self-image that remains solid through old age. A person's abilities to adapt to change, make decisions, and respond predictably are also determined by past experiences. A flexible, well-functioning person will probably continue as such. However, losses may accumulate within a short period of time and become acute. The older person often has fewer choices and diminished resources to deal with stressful events. Common stressors of old age include normal aging changes that impair physical function, activities, and appearance; disabilities from injury or chronic illness; social and environmental losses related to loss of income and decreased ability to perform previous roles and activities; and the deaths of significant others. Many older adults rely strongly on their families and spiritual beliefs for comfort during stressful times.

Living Arrangements

Many older adults relocate in response to changes in their lives such as retirement or widowhood, a significant deterioration in health, or disability. The type of housing they choose depends on their reason for moving. With increasing disability and illness, older adults may move to retirement facilities or assisted living communities that provide some support such as meals, transportation, and housekeeping but otherwise allow them to live somewhat independently. If they develop a serious illness or disability and can no longer live independently or semi-independently, they may need to move to a setting where additional support is available, such as a relative's home or a long-term care or assisted living facility. Often they will seek a location near an adult child's home.

Living at Home or with Family

Most older adults want to remain in their own homes; in fact, they function best in their own environment. The family home and familiar community may have strong emotional significance for them, and this should not be ignored. However, with advanced age and increasing disability, adjustments to the environment may be required to allow older adults to remain in their own homes or apartments (see Chart 62-2). Additional family support or more formal support may be necessary to compensate for declining function and mobility. Many services and organizations can assist older adults to successfully "age in place" in their own homes or in assisted living facilities (see Resources at the end of this chapter).

Chart 62-2 NURSING RESEARCH PROFILE

Care Transitions for Older Adults Discharged Home from the Emergency Department

Cadogan, M. P., Phillips, L. R. & Ziminski, C. E. (2016). A perfect storm: Care transitions for vulnerable older adults discharged home from the emergency department without a hospital admission. The Gerontologist, 56(2), 326–334.

Purpose

Transitions are a vulnerable time for older adults. The purpose of the study was to identify factors that influenced the quality and safety of transitions home for older adults who were discharged directly from the emergency department (ED).

Design

This qualitative descriptive study collected data through nine focus group interviews, with ED staff representing multiple interdisciplinary team members including nurses, physicians, social workers, therapists, and pharmacists. The research was conducted in a level 1 trauma center with approximately 78,000 ED visits per year. The ED is located in an ethnically and economically diverse community in California and does not have a geriatric service.

Findings

Based on the findings from the focus groups, the researchers identified a model of five overlapping concepts that influence the quality and safety for vulnerable older adults who are directly discharged home. The five concepts are the "nature of the geriatric presentation" (e.g., complex and multidimensional), "provider knowledge-base" (information about the patient including home situation), "consumer knowledge-base (ability to successfully manage the health problems), resource-base" (staff mix, time to adequately care for an older, slower patient), and "system fractures" (deficiencies and lack of connections within the health system).

Nursing Implications

Nurses need to understand the underlying factors that contribute to hospital readmission or repeat ED visits for older adult patients who visit the ED. Successful discharge to home uses interventions targeted to the needs of the patient population that clearly extend beyond the ED visit. Some recommended practices include making a follow-up appointment before the patient leaves the ED or referral for a nurse follow-up home visit.

Figure 62-3 • Families are an important source of psychosocial and physical support for all people. Caring interaction among grandchildren, grandparents, and other family members typically contributes to the health of all.

Sometimes older adults or couples move in with adult children. This can be a rewarding experience as the children, their parents, and the grandchildren interact and share household responsibilities (see Fig. 62-3). It can also be stressful, depending on family dynamics. Adult children and their older parents may choose to pool their financial resources by moving into a house that has an attached "in-law suite." This arrangement provides security for the older adult and privacy for both families. Many older adults and their adult children make housing decisions in times of crisis, such as during a serious illness or after the death of a spouse. Caring for an older adult may also be stressful; older adults and their families often are unaware of the emotional and physical demands of shared housing and assuming care for an increasingly dependent person, especially given the uncertain and extended length of time that may be associated with caring for a person with a chronic illness. Families can be helped by anticipatory guidance and long-term planning before a crisis occurs. Older adults should participate in decisions that affect them as much as possible.

Assisted Living Facilities

In the western world, assisted living facilities are an option when an older person's physical or cognitive changes necessitate at least minimal supervision or assistance. Assisted living allows for a degree of independence while providing minimal nursing assistance with administration of medication, assistance with ADLs, or other chronic health care needs. Other services, such as laundry, cleaning, and meals, may also be included. Options of assisted living are costly and primarily paid out of pocket.

Long-Term Care Facilities

In the western world, there is availability of many types of nursing homes, nursing facilities, or long-term care facilities that offer continuous nursing care for elderly. Short-term nursing care facilities are also available to offer care during episodes of acute sickness for older people, which is reimbursed by government health care schemes or some of the older people have their insurance to pay for such short-term sickness care. However, costs of long-term care for older adults who are living in nursing homes and are medically stable, despite having multiple chronic and debilitating health issues, are primarily paid by the patients out of their pockets. In India, such long-term care facilities are not many for elderly and acute or chronic care facilities are availed by them by paying out-of-pocket or from their insurance but very few of them have health insurance.

The Role of the Family

Planning for care and understanding the psychosocial issues confronting older adults must be accomplished within the context of the family. If dependency needs occur, the spouse often assumes the role of primary caregiver. In the absence of a surviving spouse, an adult child may assume caregiver responsibilities and need help in providing or arranging for care and support.

The rapid urbanization and rapidly changing social structure in India has two serious issues: first is that adult children and their aged parents are socially alienated and that adult children abandon their parents when health and other dependency problems arise. However, still the family has been and continues to be an important source of support for older adults; similarly, older family members provide a great deal of support to younger family members.

In most of the cases, adult children are even financially responsible for their older parents and social attitudes and cultural values often dictate that adult children should provide services and assume the burden of care if their aged parents cannot care for themselves. Caregiving, which may continue for many years, can become a source of family stress and is a well-known risk for psychiatric and physical morbidity. Evidence-based interventions to reduce distress and enhance well-being in caregivers have been identified. Three broad types of effective programs include (1) psychoeducational skill building, (2) cognitive behavioral therapy, and (3) using a combination of at least two approaches such as education, family meetings, and skill building sessions (Bakas, Clark, Kelly-Hayes, et al., 2014). Web-based programs can be effective, efficient, and a better fit for the hectic lives of caregivers (Gies, Pierce, Steiner, et al., 2014).

Cognitive Aspects of Aging

Cognition can be affected by many variables, including sensory impairment, physiologic health, environment, sleep, and psychosocial influences. Older adults may experience temporary changes in cognitive function (i.e., delirium) when hospitalized or admitted to skilled nursing facilities, rehabilitation centers, or long-term care facilities. These changes are related to differences in the environment or in medical therapy or to alteration in role performance. A commonly used assessment tool is the Mini-Mental State Examination (MMSE) (see Chart 62-3).

Good sleep hygiene can improve cognition, as can treatment of depression and anxiety. Several researchers are evaluating memory enhancement programs for older adults (McDougall, Vance, Wayde, et al., 2015).

When intelligence test scores from people of all ages are compared, test scores for older adults show a progressive decline beginning in midlife. However, research has shown that environment and health have a considerable influence on scores, and that certain types of intelligence (e.g., spatial perceptions and retention of nonintellectual information) decline, whereas others (e.g., problem-solving ability based on past experiences, verbal comprehension, and mathematical ability) do not. Cardiovascular health, a stimulating environment, and high

Chart 62-4 HEALTH PROMOTION

Nursing Strategies for Promoting Cognitive Function

Nurses can support the processes by which older adults learn by using the following strategies:

- Supply mnemonics to enhance recall of related data.
- Encourage ongoing learning.
- Link new information with familiar information.
- Use visual, auditory, and other sensory cues.
- Encourage learners to wear prescription glasses and hearing aids.
- Provide glare-free lighting.
- Provide a quiet, nondistracting environment.
- Set short-term goals with input from the learner.
- Prioritize the most important information and focus on the priority information.
- Keep teaching periods short.
- Pace learning tasks according to the endurance of the learner.
- Encourage verbal participation by learners.
- Reinforce successful learning in a positive manner.

levels of education, occupational status, and income all appear to have a positive effect on intelligence scores in later life.

Significant age-related declines in intelligence, learning, and memory are not inevitable. Many factors affect the ability of older adults to learn and remember and to perform well in testing situations. Older adults who have higher levels of education, good sensory function, good nutrition, and jobs that require complex problem-solving skills continue to demonstrate intelligence, memory, and the capacity for learning. Part of the challenge in testing older adults is determining what is actually being tested (e.g., speed of response) and whether the test results are indicative of a normal age-related change, a sensory deficit, or poor health. However, age differences continue to emerge even with untimed tests and when the tests are controlled for variations in motor and sensory function. In general, fluid intelligence—the biologically determined intelligence used for flexibility in thinking and problem solving—declines. Researchers suggest this decline is related to circulatory and nervous system disorders and is not a normal age-related change (Bergman & Almkvist, 2013). Therefore, preventing or managing these diseases may positively affect the decline in fluid intelligence. Crystallized intelligence—gained through education and lifelong experiences (e.g., verbal skills)—remains intact. These differences exemplify the classic aging pattern of intelligence. Despite these slight declines, many older adults continue to learn and participate in varied educational experiences. Good health and motivation are important influences on learning (see Chart 62-4). An important consideration for learning is allowing adequate time, particularly when new technology is involved (Harris, Thomas, & Fox, 2015).

Pharmacologic Aspects of Aging

Because an increasing number of chronic conditions affect older adults, they use more medications than any other age group. Although medications improve health and well-being by relieving pain and discomfort, treating chronic illnesses, and curing infectious processes, adverse drug reactions are common because of medication interactions, multiple medication effects, incorrect dosages, and the use of multiple medications.

Drug Interactions and Adverse Effects

Polypharmacy is the prescription, use, or administration of more medications than is clinically indicated. Over or incorrect prescribing occurs commonly in older adults (Miller, 2015). The potential for drug–drug interactions increases with increased medication use and with multiple coexisting diseases (comorbidity) that affect the absorption, distribution, metabolism, and elimination of the medications. Such interactions are responsible for numerous emergency department and physician visits, which cost huge money annually.

Any medication is capable of altering nutritional status, and the nutritional health of an older adult may already be compromised by a marginal diet or by chronic disease and its treatment. Medications can affect the appetite, cause nausea and vomiting, irritate the stomach, cause constipation or diarrhea, and decrease absorption of nutrients. In addition, these medications may alter electrolyte balance as well as carbohydrate and fat metabolism. For example, antacids may cause thiamine deficiency; laxatives diminish absorption; antibiotics and phenytoin (Dilantin) reduce utilization of folic acid; and phenothiazines, estrogens, and corticosteroids increase appetite and cause weight gain.

Combining multiple medications with alcohol, as well as with over-the-counter and herbal medications, further complicates gastrointestinal problems.

Altered Pharmacokinetics

Alterations in absorption, metabolism, distribution, and excretion occur as a result of normal aging and may also result from drug and food interactions (Oster & Oster, 2015). Absorption may be affected by changes in gastric pH and a decrease in gastrointestinal motility. Drug distribution may be altered as a result of decrease in body water and increase in body fat. Normal age-related changes and diseases that alter blood flow, liver and renal function, or cardiac output may affect distribution and metabolism (see Table 62-2).

Nursing Implications

Principles that have been identified as appropriate for older patients include starting with a low dose, going slowly,

TABLE 62-2 Altered Drug Responses in Older Adults

Age-Related Changes	Effect of Age-Related Change	Applicable Medications
Absorption		
Reduced gastric acid; increased pH (less acid)	Rate of drug absorption—possibly delayed	Vitamins
Reduced gastrointestinal motility; prolonged gastric emptying	Extent of drug absorption—not affected	Calcium
Distribution		
Decreased circulating plasma proteins and total body water	Serious alterations in drug binding to plasma proteins (the unbound drug gives the pharmacologic response); highly protein-bound medications have fewer binding sites, leading to increased effects and accelerated metabolism and excretion.	*Selected highly protein-binding medications:* Oral anticoagulants (warfarin) Oral hypoglycemic agents (sulfonylureas) Barbiturates Calcium channel blockers Furosemide (Lasix) Nonsteroidal anti-inflammatory drugs (NSAIDs) Sulfonamides Quinidine Phenytoin (Dilantin)
Reduced cardiac output	Decreased perfusion of many bodily organs	
Impaired peripheral blood flow	Decreased perfusion	
Increased or decreased percentage of body fat	Proportion of body fat increases with age, resulting in increased ability to store fat-soluble medications; this causes drug accumulation, prolonged storage, and delayed excretion.	*Selected fat-soluble medications:* Barbiturates Diazepam (Valium) Lidocaine Phenothiazines (antipsychotics) Ethanol Morphine
Decreased lean body mass	Decreased body volume allows higher peak levels of medications.	
Metabolism		
Decreased cardiac output; decreased size of the liver; diminished intestinal and portal vein blood flow	Decreased metabolism and delay of breakdown of medications, resulting in prolonged duration of action, accumulation, and drug toxicity	All medications metabolized by the liver
Excretion		
Decreased renal blood flow; loss of functioning nephrons; decreased renal efficiency	Decreased rates of elimination and increased duration of action; danger of accumulation and drug toxicity	*Selected medications with prolonged action:* Aminoglycoside antibiotics Cimetidine (Tagamet) Chlorpropamide (Diabinese) Digoxin Lithium Procainamide

Adapted from Comerford, K. C. (2015). Nursing 2015 drug handbook. Philadelphia, PA: Wolters Kluwer.

keeping the medication regimen as simple as possible, and reconciling new and previous medication regimens at the time of discharge from an acute hospital stay (Foust & Kilbourne, 2015). A comprehensive assessment that begins with a thorough medication history, including use of alcohol, recreational drugs, and over-the-counter and herbal medications, is essential. It is best to ask the patient or reliable informants to provide all medications for review. Assessing the patient's understanding of when and how to take each medication, as well as the purpose of each medication, allows the nurse to assess the patient's health literacy and compliance with the medication regimen. The patient's beliefs and concerns about the medications should be identified, including beliefs on whether a given medication is helpful.

Nonadherence with medication regimens can lead to significant morbidity and mortality among older adults. The many contributing factors include the number of medications prescribed, the complexity of the regimen, difficulty opening containers, inadequate patient education, financial cost, and the disease or medication interfering with the patient's life. Visual and hearing problems may make it difficult to read or to hear directions. Multifaceted interventions tailored to the individual patient are the most effective strategies in improving adherence (Foust & Kilbourne, 2015) (see Chart 62-5). Allowing enough time for the older adult to learn new skills, particularly when technology is involved, is essential (Harris et al., 2015); (Oster & Oster, 2015).

Mental Health Problems in the Older Adult

Severe mood swings, uncontrolled laughing or crying, changes in cognitive ability, and excessive forgetfulness are not a part of normal aging. These symptoms should not be dismissed as age-related changes; a thorough assessment may reveal a

Chart 62-5

Nursing Strategies for Improving Medication Management and Adherence

The following strategies can help patients manage their medications and improve adherence:

- Assess self-management abilities, psychomotor skills, and current medication knowledge.
- Explain the purpose, adverse effects, and dosage of each medication, particularly those that are newly prescribed.
- Provide the medication schedule in writing.
- Encourage the use of standard containers without safety lids (if there are no children in the household).
- Suggest the use of a multiple-day, multiple-dose medication dispenser to help the patient adhere to the medication schedule.
- Destroy or remove old, unused medications.
- Encourage the patient to inform the primary provider about the use of over-the-counter medications and herbal agents, alcohol, and recreational drugs.
- Encourage the patient to keep a current list of all medications, including over-the-counter and herbal medications, in their purse or wallet to share with the primary provider at each visit and in case of an emergency.
- Reconcile medication schedule upon discharge from hospital or rehabilitation facility.
- Recommend using one supplier for prescriptions; pharmacies frequently track patients and are likely to notice a prescription problem such as duplication or contraindications in the medication regimen.
- If the patient's competence is doubtful, identify a reliable family member or friend who might assist the patient with adherence.

Adapted from Foust, J. B., & Kilbourne, G. A. (2015). Improving posthospital medication management for chronically ill older adults. American Nursing Today. 10(3), 26–29.

treatable, reversible condition. Changes in mental status can be related to many factors, such as alterations in diet and fluid and electrolyte balance, fever, or low oxygen levels associated with many cardiovascular and pulmonary diseases. Older adults are less likely than younger people to acknowledge or seek treatment for mental health symptoms. Changes may be reversible when the underlying condition is identified and treated. Nurses must recognize, assess, refer, collaborate, treat, and support older adults who exhibit signs and symptoms of depression, substance abuse, delirium, or dementia.

Depression

Depression is the most common affective or mood disorder of old age. The percentage of older adults with depressive symptoms varies widely depending upon the measures used and the population studied. Modiga, Midlov, and Kristensson (2014) reported that between 7% and 29% of older adults have depressive symptoms. Depression among older adults can follow a major precipitating event or loss and is often related to chronic illness or pain. It may also be secondary to a medication interaction or an undiagnosed physical condition. Rather than obvious sadness, an older person may exhibit more subtle signs of depression such as fatigue, diminished memory and concentration, feelings of worthlessness, sleep disturbances, appetite disturbances with excessive weight loss or gain, restlessness, impaired attention span, and suicidal ideation. Mild depression with symptoms that do not meet the criteria for a major depression is often underrecognized and undertreated, which results in reduced quality of life and function (Modiga et al., 2014).

The risk of suicide is increased in older adults. There is a need for routine assessment of patients for depression and risk for suicide. Geriatric depression may be confused with dementia. However, the cognitive impairment resulting from depression is related to apathy rather than decline in brain function. When depression and medical illnesses coexist, as they often do, neglect of the depression can impede physical recovery. Assessing the patient's mental status, including depression, is vital and must not be overlooked. A commonly used assessment tool is the Geriatric Depression Scale (GDS) (see Chart 62-6).

Older adults with depression can respond appropriately to treatment. Initial management involves evaluation of the patient's medication regimen and eliminating or changing any medications that contribute to depression. Furthermore, treatment of underlying medical conditions that may produce depressive symptoms may alleviate the depression. For mild depression, nonpharmacologic measures such as exercise, bright lighting, increasing interpersonal interactions, cognitive therapy, and reminiscence therapy are effective. However, for major depression, antidepressants and short-term psychotherapy, particularly in combination, are effective in older adults. Antidepressants, such as bupropion hydrobromide (Wellbutrin), venlafaxine hydrochloride (Effexor), and mirtazapine (Remeron), as well as selective serotonin reuptake inhibitors, such as paroxetine hydrochloride (Paxil), can be effective (Comerford, 2015). Tricyclic antidepressants can be useful for treating major depression in some patients. Electroconvulsive therapy is highly effective when antidepressant medications are not tolerated, not effective, or pose a significant medical risk (Miller, 2015).

Most antidepressant medications have anticholinergic, cardiac, and orthostatic adverse effects (Comerford, 2015). They also interact with other medications and, therefore, should be used with care to avoid medication toxicity, hypotensive events, and falls. Older patients prescribed antidepressants should be carefully monitored for side effects. Good patient education is needed to make sure older adults understand that it may take even longer than the typical 4 to 6 weeks for symptoms to diminish. During this period, nurses should offer support, encouragement, and strategies to maintain safety, such as changing positions slowly and maintaining adequate hydration (Miller, 2015).

Substance Abuse

Substance abuse caused by misuse of alcohol and drugs may be related to depression. Large number of elderly are reported to have alcohol, tobacco, and other substance abuse. Moderate levels of alcohol consumption may be associated with positive health risks, such as lowering the risks for cardiovascular disease. Alcohol abuse, while rare, is especially dangerous in older adults because of age-related changes in renal and liver function as well as the high risk of interactions with prescription medications and the resultant adverse effects. Alcohol and drug-related problems in older adults often remain hidden because many older adults deny their habit when questioned. Assessing for drug and alcohol use with direct questions in a nonaccusatory manner should be part of the routine physical assessment (AoA, 2012b). (See Chapter 3 for more information and specific assessment tools.)

Chart 62-6

Geriatric Depression Scale

Choose the best answer for how you felt this past week.

[a]1. Are you basically satisfied with your life?	YES	NO
2. Have you dropped many of your activities and interests?	YES	NO
3. Do you feel that your life is empty?	YES	NO
4. Do you often get bored?	YES	NO
[a]5. Are you hopeful about the future?	YES	NO
6. Are you bothered by thoughts you can't get out of your head?	YES	NO
[a]7. Are you in good spirits most of the time?	YES	NO
8. Are you afraid that something bad is going to happen to you?	YES	NO
[a]9. Do you feel happy most of the time?	YES	NO
10. Do you often feel helpless?	YES	NO
11. Do you often get restless and fidgety?	YES	NO
12. Do you prefer to stay at home, rather than going out and doing new things?	YES	NO
13. Do you frequently worry about the future?	YES	NO
14. Do you feel you have more problems with memory than most?	YES	NO
[a]15. Do you think it is wonderful to be alive now?	YES	NO
16. Do you often feel downhearted and blue?	YES	NO
17. Do you feel pretty worthless the way you are now?	YES	NO
18. Do you worry a lot about the past?	YES	NO
[a]19. Do you find life very exciting?	YES	NO
20. Is it hard for you to get started on new projects?	YES	NO
[a]21. Do you feel full of energy?	YES	NO
22. Do you feel that your situation is hopeless?	YES	NO
23. Do you think that most people are better off than you are?	YES	NO
24. Do you frequently get upset over little things?	YES	NO
25. Do you frequently feel like crying?	YES	NO
26. Do you have trouble concentrating?	YES	NO
[a]27. Do you enjoy getting up in the morning?	YES	NO
28. Do you prefer to avoid social gatherings?	YES	NO
[a]29. Is it easy for you to make decisions?	YES	NO
[a]30. Is your mind as clear as it used to be?	YES	NO

Score: _____ (*Number of "depressed" answers*)

Norms

Normal: 5 ± 4

Mildly depressed: 15 ± 6

Very depressed: 23 ± 5

[a]Appropriate (nondepressed) answers = yes; all others = no.

From Yesavage, J., Brink, T. L., Rose, T. L., et al. (1983). Development and validation of a geriatric screening scale: A preliminary report. Journal of Psychiatric Research, 17(1), 37–49. Reprinted with permission from Pergamon Press Ltd., Headington Hill Hall, Oxford OX3 OBW, UK.

Delirium

Delirium, often called *acute confusional state,* begins with disorientation and if not recognized and treated can progress to changes in level of consciousness, irreversible brain damage, and sometimes death. Patients may experience an altered level of consciousness, ranging from stupor (hypoalert–hypoactive) to excessive activity (hyperalert–hyperactive); alternatively, they may have a combination of these two types (mixed). Thinking is disorganized, and the attention span is short. Hallucinations, delusions, fear, anxiety, and paranoia may also be evident. Patients who tend to be hyperalert and hyperactive demand more attention from nurses and thus are easier to diagnose, whereas those who are hypoalert or hypoactive tend to be less problematic and pose diagnostic difficulties. Recognition of delirium can also be complicated in patients with the mixed disorders. Patients with the hypoalert–hypoactive type of delirium have higher mortality rates and even poorer outcomes of care because the delirium tends not to be recognized and treated (Layne et al., 2015).

Attentive clinical assessment is essential because delirium is sometimes mistaken for dementia; Table 62-3 compares dementia and delirium. It helps to know an individual patient's usual mental status and whether the changes noted are long term, which probably represents dementia, or are abrupt in onset, which is more likely delirium.

TABLE 62-3 Summary of Differences Between Dementia and Delirium

	Dementia		
	Alzheimer's Disease (AD)	Vascular (Multi-Infarct) Dementia	Delirium
Etiology	Early onset (familial, genetic [chromosomes 14, 19, 21]) Late-onset sporadic–etiology unknown	Cardiovascular (CV) disease Cerebrovascular disease Hypertension	Drug toxicity and interactions; acute disease; trauma; chronic disease exacerbation Fluid and electrolyte disorders
Risk factors	Advanced age; genetics	Pre-existing CV disease	Pre-existing cognitive impairment
Occurrence	70% of dementias	10–20% of dementias	7–61% among hospitalized people
Onset	Slow	Often abrupt Follows a stroke or transient ischemic attack	Rapid, acute onset A harbinger of acute medical illness
Age of onset	Early-onset AD: 30s–65 years Late-onset AD: 65+ years Most commonly: 85+ years	Most commonly 50–70 years	Any age, although predominantly in older persons
Gender	Males and females equally	Predominantly males	Males and females equally
Course	Chronic, irreversible; progressive, regular, downhill	Chronic, irreversible Fluctuating, stepwise progression	Acute onset Hypoalert—hypoactive Hyperalert–hyperactive Mixed hypo–hyper
Duration	2–20 years	Variable; years	Lasts 1 day to 1 month
Symptom progress	Onset insidious: *Early*—mild and subtle *Middle and late*—intensified Progression to death (infection or malnutrition)	Depends on location of infarct and success of treatment; death attributed to underlying CV disease	Symptoms are fully reversible with adequate treatment; can progress to chronicity or death if underlying condition is ignored.
Mood	Depression common	Labile: mood swings	Variable
Speech/language	Speech remains intact until late in disease: *Early*—mild anomia (cannot name objects); deficits progress until speech lacks meaning; echoes and repeats words and sounds; mutism	May have speech deficit/aphasia depending on location of lesion	Fluctuating; often cannot concentrate long enough to speak May be somnolent
Physical signs	*Early*—no motor deficits *Middle*—apraxia (cannot perform purposeful movement) *Late*—Dysarthria (impaired speech) *End stage*—loss of all voluntary activity; positive neurologic signs	According to location of lesion: focal neurologic signs, seizures Commonly exhibits motor deficits	Signs and symptoms of underlying disease
Orientation	Becomes lost in familiar places (topographic disorientation) Has difficulty drawing three-dimensional objects (visual and spatial disorientation) Disorientation to time, place, and person—with disease progression		May fluctuate between lucidity and complete disorientation to time, place, and person
Memory	Loss is an early sign of dementia; loss of recent memory is soon followed by progressive decline in recent and remote memory		Impaired recent and remote memory; may fluctuate between lucidity and confusion
Personality	Apathy, indifference, irritability: *Early disease*—social behavior intact; hides cognitive deficits *Advanced disease*—disengages from activity and relationships; suspicious; paranoid delusions caused by memory loss; aggressive; catastrophic reactions		Fluctuating; cannot focus attention to converse; alarmed by symptoms (when lucid); hallucinations; paranoid
Functional status, activities of daily living	Poor judgment in everyday activities; has progressive decline in ability to handle money, use telephone, use computer and other electronic devices, function in home and workplace		Impaired
Attention span	Distractible; short attention span		Highly impaired; cannot maintain or shift attention
Psychomotor activity		Wandering, hyperactivity, pacing, restlessness, agitation	Variable; alternates between high agitation, hyperactivity, restlessness, and lethargy
Sleep–wake cycle	Often impaired; wandering and agitation at nighttime		Takes brief naps throughout day and night

Adapted from Grossman, S. C., & Porth, C. M. (2014). Pathophysiology: Concepts of altered health states (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Delirium occurs secondary to numerous causes, including physical illness, surgery, medication or alcohol toxicity, dehydration, fecal impaction, malnutrition, infection, head trauma, lack of environmental cues, and sensory deprivation or overload. Older adults are particularly vulnerable to acute confusion because of their decreased biologic reserve and the large number of medications they may take. Nurses must recognize the symptoms of delirium and report them immediately. The

Confusion Assessment Method is a commonly used screening tool (Inouye, van Dyck, Alessi, et al., 1990); (Layne et al., 2015). (See Chart 62-7). Because of the acute and unexpected onset of symptoms and the unknown underlying cause, delirium is a medical emergency. If the delirium goes unrecognized and the underlying cause is not treated, permanent, irreversible brain damage or death can follow.

The most effective approach is prevention. Strategies include providing therapeutic activities for cognitive impairment, reorienting the patient as needed, ensuring early mobilization, controlling pain, minimizing the use of psychoactive drugs, preventing sleep deprivation, enhancing communication methods (particularly eye glasses and hearing aids) for vision and hearing impairment, maintaining oxygen levels and fluid and electrolyte balance, and preventing surgical complications (Layne et al., 2015); (Miller, 2015).

Once delirium occurs, treatment of the underlying cause is most important. Therapeutic interventions vary depending on the cause. Delirium increases the risk of falls; therefore, management of patient safety and behavioral problems is essential. Because medication interactions and toxicity are often implicated, the nurse should alert the prescriber about any nonessential medications that could be discontinued. Nutritional and fluid intake should be supervised and monitored. The environment should be quiet and calm. To increase function and comfort, the nurse provides familiar environmental cues and encourages family members or friends to touch and talk to the patient (see Fig. 62-4). Ongoing mental status assessments using prior mental cognitive status as a baseline are helpful in evaluating responses to treatment and upon admission to a hospital or extended care facility. If the underlying problem is adequately treated, the patient often returns to baseline within several days. Several resources specific to delirium are included in the Resources section at the end of the chapter.

Dementia

The cognitive, functional, and behavioral changes that characterize dementia eventually destroy a person's ability to function. The symptoms are usually subtle in onset and often progress slowly until they are obvious and devastating. The most common type of dementia is AD that accounts for up to

Chart 62-7 ASSESSMENT

Confusion Assessment Method

Acute Onset

1. Is there evidence of an acute change in mental status from the patient's baseline?

Inattention[a]

2. A. Did the patient have difficulty focusing attention, for example, being easily distractible, or having difficulty keeping track of:
   What was being said?
   Not present at any time during interview.
   Present at some time during interview but in mild form.
   Present at some time during interview, in marked form.
   Uncertain.
   B. (If present or abnormal) Did this behavior fluctuate during the interview, that is, tend to come and go or increase and decrease in severity?
   Yes.
   No.
   Uncertain.
   Not applicable.
   C. (If present or abnormal) Please describe this behavior:

Disorganized Thinking

3. Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Altered Level of Consciousness

4. Overall, how would you rate this patient's level of consciousness?
   Alert (normal).
   Vigilant (hyperalert, overly sensitive to environmental stimuli, startled very easily).
   Lethargic (drowsy, easily aroused).
   Stupor (difficult to arouse).
   Coma (unarousable).
   Uncertain.

Disorientation

5. Was the patient disoriented at any time during the interview, such as thinking that he or she was somewhere other than the hospital, using the wrong bed, or misjudging the time of day?

Memory Impairment

6. Did the patient demonstrate any memory problems during the interview, such as inability to remember events in the hospital or difficulty remembering instructions?

Perceptual Disturbances

7. Did the patient have any evidence of perceptual disturbances, for example, hallucinations, illusions, or misinterpretations (such as thinking something was moving when it was not)?

Psychomotor Agitation

8. Part 1.
   At any time during the interview, did the patient have an unusually increased level of motor activity, such as restlessness, picking at bedclothes, tapping fingers, or making frequent sudden changes of position?

Psychomotor Retardation

8. Part 2.
   At any time during the interview, did the patient have an unusually decreased level of motor activity, such as sluggishness, staring into space, staying in one position for a long time, or moving very slowly?

Altered Sleep–Wake Cycle

9. Did the patient have evidence of disturbance of the sleep–wake cycle, such as excessive daytime sleepiness with insomnia at night?

[a]The questions listed under this topic were repeated for each topic where applicable.

From Inouye, S. K., van Dyck, C. H., Alessi, C. A., et al. (1990). Clarifying confusion: The confusion assessment method. Annals of Internal Medicine, 113(12), 941–948. Used with permission.

Figure 62-4 • Talking to family members may increase the comfort of patients with delirium.

70% of older adults with dementia (Grossman & Porth, 2014). Other non-Alzheimer dementias include degenerative, vascular, neoplastic, demyelinating, infectious, inflammatory, toxic, metabolic, and psychiatric disorders. It is important to identify reversible dementia, which occurs when pathologic conditions masquerade as dementia.

Vascular Dementia

Vascular dementia is the second most common cause of dementia and is characterized by an uneven, stepwise downward decline in mental function (Grossman & Porth, 2014). Multi-infarct dementia, the most common form of vascular dementia, has an unpredictable course and is characterized by variable impairment depending on the affected sites in the brain. The patient may present with a deficit in only one domain such as word retrieval whereas other cognitive abilities may be intact. Diagnosis may be even more difficult if a patient has both vascular dementia and AD.

Because vascular dementia is associated with hypertension and cardiovascular disease, risk factors (e.g., hypercholesterolemia, smoking, heart disease, diabetes) are similar. Prevention and management are also similar. Measures to decrease blood pressure, control diabetes, and lower cholesterol levels may slow cognitive decline.

Additional Aspects of Health Care of the Older Adult

The nurse needs to consider other health issues of older adults. These include pseudobulbar affect, geriatric syndromes, elder neglect and abuse, as well as ethical and legal issues.

Pseudobulbar Affect

The condition known as pseudobulbar affect involves inappropriate or exaggerated emotional expression, usually episodes of laughing or crying. It is associated with brain injury (e.g., stroke, traumatic brain injury, multiple sclerosis [MS], amyotrophic lateral sclerosis [ALS], AD, and Parkinson disease). The term "pseudobulbar" refers to damage that occurs in the corticobulbar tracts in the brain (see Chapter 53). The emotional outbursts can cause embarrassment, anxiety, and depression, and often impair quality of life (Yang & Deeks, 2015).

Older adults with pseudobulbar affect can respond appropriately to treatment. Initial management involves evaluation and recognition that this condition can coexist with mood disorders, such as depression, although crying in these patients should not be considered indicative of depression. Pharmacology studies have reported effective management with Nuedexta (dextromethorphan HBr and quinidine sulfate) in patients with ALS, MS, and dementia (Yang & Deeks, 2015).

Geriatric Syndromes

Older adults tend to acquire multiple problems and illnesses as they age. The decline of physical function leads to a loss of independence and increasing frailty as well as to susceptibility to both acute and chronic health problems, which generally result from several factors rather than from a single cause. When combined with a decrease in host resistance, these factors can lead to illness or injury. Some problems commonly experienced by older adults are becoming recognized as geriatric syndromes. These conditions do not fit into discrete disease categories and require a multidisciplinary and comprehensive assessment to identify the underlying cause or causes. Examples include skin impairment, poor nutrition, falls or functional decline, incontinence, cognitive impairment, skin impairment, and sleep disturbances (Brown-O'Hara, 2014). Although these conditions may develop slowly, the onset of symptoms is often acute. Furthermore, the presenting symptoms may appear in other body systems before becoming apparent in the affected system. For example, an older patient may present with confusion, and the underlying disease may be a urinary tract infection, dehydration, or a heart attack (Carlson, Merel, & Yukawa, 2015).

The term *geriatric triad* includes changes in cognitive status, falls, and incontinence. This term is used to focus awareness on these three conditions, which need particular attention and the implementation of prevention measures during the hospitalization of older patients.

Impaired Mobility

The causes of decreased mobility are many and varied. Common causes include strokes, Parkinson disease, diabetic neuropathy, cardiovascular compromise, osteoarthritis, osteoporosis, and sensory deficits. To avoid immobility, older people should be encouraged to stay as active as possible. During illness, bed rest should be kept to a minimum, even with hospitalized patients, because brief periods of bed rest quickly lead to deconditioning and, consequently, to a wide range of complications. When bed rest cannot be avoided, patients should perform active range-of-motion and strengthening exercises with the unaffected extremities, and nurses or family caregivers should perform passive range-of-motion exercises on the affected extremities. Frequent position changes help offset the hazards of immobility. Both the health care staff and the patient's family can assist in maintaining the current level of mobility.

Dizziness

Older adults frequently seek help for dizziness, which presents a particular challenge because there are numerous possible causes. For many, the problem is complicated by an inability to differentiate between true dizziness (a sensation of disorientation in relation to position) and vertigo (a spinning

sensation). Other similar sensations include near-syncope and disequilibrium. The causes for these sensations range in severity from minor (e.g., buildup of ear wax) to severe (e.g., dysfunction of the cerebral cortex, cerebellum, brain stem, proprioceptive receptors, or vestibular system). Even a minor reversible cause, such as ear wax impaction, can result in a loss of balance and a subsequent fall and injury. Because dizziness has many predisposing factors, nurses should seek to identify any potentially treatable factors related to the condition.

Falls and Falling

Accidental injuries rank eighth as a cause of death for older people, and falls are the most common cause of nonfatal injuries and hospital admissions. The incidence of falls rises with increasing age. One out of five falls in older adults results in serious injury such as broken bones or a head injury (CDC, 2015).

Although many falls by older adults do not result in injury, between 20% and 30% of older adults who fall sustain moderate to serious injury. Overall, older women who fall sustain a greater degree of injury than do older men; however, men are more likely to die of a fall injury (CDC, 2015). Hip fracture is a common type of fracture that can occur as a result of a fall. Many older adults who fall and sustain a hip fracture are unable to regain their prefracture ability. Causes of falls are multifactorial. Both extrinsic factors such as changes in the environment or poor lighting and intrinsic factors such as physical illness, neurologic changes, or sensory impairment play a role. Mobility difficulties, medication effects, foot problems or unsafe footwear, postural hypotension, visual problems, and tripping hazards are common and treatable causes. Polypharmacy, medication interactions, and the use of alcohol precipitate falls by causing drowsiness, decreased coordination, and postural hypotension. Falls have physical dangers as well as serious psychological and social consequences. It is not uncommon for an older person who has experienced a fall to become fearful and lose self-confidence (Miller, 2015).

Nurses can encourage older adults and their families to make lifestyle and environmental changes to prevent falls. Adequate lighting with minimal glare and shadow can be achieved through the use of small area lamps, indirect lighting, sheer curtains to diffuse direct sunlight, dull rather than shiny surfaces, and nightlights. Sharply contrasting colors can be used to mark the edges of stairs. Grab bars by the bathtub, shower, and toilet are useful. Loose clothing, improperly fitting shoes, scatter rugs, small objects, and pets create hazards and increase the risk of falls. Older adults function best in familiar settings when the arrangement of furniture and objects remains unchanged.

Nursing Alert: In hospitalized and institutionalized older adults, physical restraints (lap belts; geriatric chairs; side rails, vest, waist, and jacket restraints) and chemical restraints (medications) precipitate many of the injuries they were meant to prevent. Because of the acute negative consequences of restraint use, accrediting agencies of nursing homes and acute care facilities now maintain stringent guidelines for correct application and use.

Urinary Incontinence

Urinary incontinence may be acute, occurring during an illness, or may develop chronically over a period of years. Older patients often do not report this very common problem unless specifically asked. Transient causes may be attributed to *d*elirium and *d*ehydration; *r*estricted mobility; *i*nflammation, *i*nfection, and *i*mpaction; and *p*harmaceuticals and *p*olyuria (the acronym *drip* may be used to remember them). Once identified, the causative factor can be eliminated.

Older patients with incontinence should be urged to seek help from appropriate health care providers because incontinence can be both emotionally devastating and physically debilitating. Nurses who specialize in behavioral approaches to urinary incontinence management can help patients regain full continence or significantly improve the level of continence. Although medications such as anticholinergics may decrease some of the symptoms of urge incontinence (detrusor instability), the adverse effects of these medications (dry mouth, slowed gastrointestinal motility, and confusion) may make them inappropriate choices for older adults. Various surgical procedures are also used to manage urinary incontinence, particularly stress urinary incontinence.

Detrusor hyperactivity with impaired contractility is a type of urge incontinence that is seen predominantly in the older adult population. In this variation of urge incontinence, patients have no warning that they are about to urinate. They often void only a small volume of urine or none at all and then experience a large volume of incontinence after leaving the bathroom. Nurses should be familiar with this form of incontinence and not show disapproval when it occurs. Many patients with dementia suffer from this type of incontinence, because both incontinence and dementia are a result of dysfunction in similar areas of the brain. Prompted, timed voiding can be of assistance in these patients, although clean intermittent catheterization may be necessary because of postvoid residual urine. (See Chapter 45 for information on management of urinary disorders.)

Increased Susceptibility to Infection

Infectious diseases present a significant threat of morbidity and mortality to older adults, in part because of the blunted response of host defenses caused by a reduction in both cell-mediated and humoral immunity (see Chapters 54 and 55). Age-related loss of physiologic reserve and chronic illnesses also contribute to increased susceptibility. Pneumonia, urinary tract infections, gastrointestinal infections, and skin infections are some of the common infections in older adults.

Because of a weakened immune response, the effects of influenza and pneumococcal infections on older adults are significant. Vaccination can help prevent both infections. There is a national goal to increase vaccination rates among persons 65 years of age and older. More than 70% of those 65 years of age and older reported receiving an influenza vaccination between January and June 2014 and 61% reported that they had received a pneumococcal vaccination (Administration on Aging [AoA], 2014).

Influenza and pneumococcal vaccinations lower the risks of hospitalization and death in older adults. The influenza vaccine, which is prepared yearly to adjust for the specific immunologic characteristics of the influenza viruses at that time, should be given annually in autumn. Recent research suggests that better protection is provided with the high-dose, trivalent, inactivated influenza vaccine versus the standard vaccine in older adults (DiazGranados, Dunning, Kimmel, et al., 2014). The pneumococcal vaccine should be given every 5 years. Both of these injections can be received at the same time in separate

injection sites. Nurses should urge older adults to be vaccinated. All health care providers working with older adults or high-risk chronically ill people should also be immunized.

AIDS occurs across the age spectrum. It is increasingly recognized that AIDS does not spare the older segment of society, and many who are living with HIV/AIDS are aging.

Atypical Responses

Many altered physical, emotional, and systemic reactions to disease are attributed to age-related changes in older adults. Physical indicators of illness that are useful and reliable in young and middle-aged people cannot be relied on for the diagnosis of potential life-threatening problems in older adults. The response to pain in older adults may be lessened because of reduced acuity of touch, alterations in neural pathways, and diminished processing of sensory data.

Older adults who are experiencing a myocardial infarction may not have chest pain but present with confusion. Hiatal hernia or upper gastrointestinal distress is often the cause of chest pain. Therefore, acute abdominal conditions may go unrecognized in older adults because of atypical signs and absence of pain.

The baseline body temperature for older adults is about 1°F lower than it is for younger people (Weber & Kelley, 2014). In the event of illness, the body temperature of an older person may not be high enough to qualify as a traditionally defined fever. A temperature of 37.8°C (100°F) in combination with systemic symptoms may signal infection. A temperature of 38.3°C (101°F) almost certainly indicates a serious infection that needs prompt attention. A blunted fever in the face of an infection often indicates a poor prognosis. Temperatures rarely exceed 39.5°C (103°F). Nurses must be alert to other subtle signs of infection, such as mental confusion, increased respirations, tachycardia, and a change in skin color.

Altered Emotional Impact

The emotional component of illness in older adults may differ from that in younger people. Many older adults equate good health with the ability to perform their daily activities and believe that "you are as old as you feel." An illness that requires hospitalization or a change in lifestyle is an imminent threat to well-being. Older adults admitted to the hospital are at high risk for disorientation, confusion, change in level of consciousness, and other symptoms of delirium, as well as anxiety and fear. In addition, economic concerns and fear of becoming a burden to families often lead to high anxiety in older adults. Nurses must recognize the implications of fear, anxiety, and dependency in older patients. They should encourage autonomy, independent decision making, and early mobilization. A positive and confident demeanor in nurses and family members promotes a positive mental outlook in older patients.

Altered Systemic Response

In an older person, illness has far-reaching repercussions. The decline in organ function that occurs in every system of the aging body eventually depletes the body's ability to respond at full capacity. Illness places new demands on body systems that have little or no reserve to meet the crisis. Homeostasis is jeopardized. Older adults may be unable to respond effectively to an acute illness or, if a chronic health condition is present, they may be unable to sustain appropriate responses over a long period. Furthermore, their ability to respond to definitive treatment is impaired. The altered responses of older adults reinforce the need for nurses to monitor all body system functions closely, being alert to signs of impending systemic complication.

Elder Neglect and Abuse

Older adults are at risk for abuse and neglect both in the community setting and in nursing homes (Burnes, Phillemer, Caccamise, et al., 2015). Because of different definitions and terminology and the pattern of underreporting, a clear picture of the incidence and prevalence of abuse among older adults is lacking. Furthermore, one of the major barriers to fully understanding elder abuse is that most professionals in all professions, including law enforcement, are not equipped to recognize and report this type of abuse. Often victims are reluctant to report the abuse and clinicians are unaware of the frequency of the problems.

Neglect is the most common type of abuse. Other forms of abuse include physical, psychological or emotional, sexual, abandonment, and financial exploitation or abuse. Burnes and colleagues (2015) reported factors associated with physical and emotional abuse included being separated or divorced, living in a low income household, functional impairment, and younger age for community dwelling older adults. Neglect was associated with poor health, living below the poverty level, being separated or divorced, and younger age. Neglect was lowest in Hispanic households (Burnes et al., 2015).

Physical abuse associated with staff misconduct in long-term care facilities has received much attention in the past decade, but one study examined a less commonly investigated problem, that of resident on resident abuse (Schiamberg, von Heydrich, Chee, et al., 2015). This is a significant problem as Schiamberg and colleagues (2015) reported that the rate of this type of abuse was 17% in a sample of more than 450 family members interviewed. Factors associated with resident on resident abuse in a nursing home setting were reported as previous staff physical or emotional abuse; younger age; limitations in ADLs and IADLs; and the emotional closeness of the resident to their family (Schiamberg et al., 2015). Older adults with disabilities of all types are at increased risk for abuse from family members, paid caregivers, and staff, whether they live in the community or a long-term care facility.

Nurses should be alert to possible elder abuse and neglect. During the health history, the older adult should be asked about abuse during a private portion of the interview. Most states require that care providers, including nurses, report suspected abuse. Preventive action should be taken when caregiver strain is evident—before elder abuse occurs. Early detection and intervention may provide sufficient resources to the family or the person at risk to ensure patient safety. Interdisciplinary team members, including the psychologist, social worker, can be enlisted to help the caregiver develop self-awareness, increased insight, and an understanding of the disease or aging process.

National Programme for Health Care of the Elderly and Social Schemes for the Elderly

The National Programme for Health Care of the Elderly (NPHCE) was launched by the Ministry of Health and Family Welfare during 2010–2011. The program is trying to integrate the elderly care services through the existing National Rural Heath Mission, AYUSH, and Ministry of Social Justice so that active and healthy aging is achieved. It is implemented through the state health societies and district health societies.

Objectives of the National Health Programme for Elderly

These are as follows:

1. Provide accessible, affordable, and high-quality long-term, comprehensive, and dedicated care services to an aging population.
2. Create an enabling environment for the elderly.

Strategies for Implementation of National Health Programme for Elderly

- **Preventive and promotive care:** Provide awareness to the elderly and their caregivers on the importance of regular exercise, balanced diet, lifestyle changes such as cessation of smoking and alcohol, and teach regarding how to prevent falls. In addition, regular monitoring and assessment of the elderly through the weekly geriatric clinics is recommended.
- **Curative services to elderly:** Dedicated geriatric OPDs will be developed at the primary health centers, community health centers, and OPD and IP services in district hospitals and regional geriatric centers. The district hospital will be functioning with a dedicated geriatric OPD and 10-bedded IP services to manage and treat chronic disabling diseases with the funds from the state and central governments.
- **Developing needed health manpower:** Medical and paramedical personnel will be trained in geriatric management using standardized modules. At regional geriatric centers, the MD geriatric medicine courses will be offered to meet the need for specialized geriatric doctors.
- **Rehabilitative services:** Therapeutic exercises, training the elderly on ADL, and pain treatment through the physiotherapy modalities will be delivered at CHC, district-level hospitals, and regional geriatric centers. The needed equipment and supplies are provided to enable the provision of rehabilitative services.
- **Development of IEC material:** IEC material related to the elderly care is prepared and sent to the public for use.

Services Provided Under the National Programme for Elderly

The program is implemented by setting up of state-level and district-level health societies. Under this program, 20 regional geriatric care centers have been established with 30-bedded inpatient and outpatient facilities. These centers train doctors in MD geriatric medicine, conduct geriatric researches, etc. (Ministry of Health and Family Welfare, 2017). District-level hospitals (325 no.) are equipped with dedicated geriatric OPD and 10-bedded IP facility. Inpatient care, OPD services, and physiotherapy services are provided to the elderly in the district hospitals.

Several other pension schemes are launched by the government for elderly from time to time, such as Integrated Programme for Older Persons (IPOP), Rashtriya Vayoshri Yojana (RVY), and The Pradhan Mantri Vaya Vandana Yojana (PMVVY) which provide financial security to elderly.

Health Care Costs of Aging

Health care is a major expenditure for older adults, especially for those with chronic illness and limited financial resources. Older adults, who make up about >8% of the population, accounted for major health care costs, particularly in the last year of life. There are several other pension schemes and recently launched National Programme for the Health Care of Elderly (NPHCE) by government of India. However, major health care cost is borne by elderly themselves through out-of-pocket expenditure or their insurance.

Home Health Care

The use of home care services and skilled nursing home care increases with age. Most of the home healthcare is met by private care providers and untrained staff available in the community, and the cost of home care is primarily borne by the elderly through out-of-pocket expenditure.

Hospice Services

Hospice is a program of supportive and palliative services for patients with advanced illness and their families. In most cases, patients are not expected to live longer than 6 months. Hospice care focuses on quality of life, and by necessity, it usually includes realistic emotional, social, spiritual, and financial preparation for death. The goal of hospice is to improve the quality of life by focusing on symptom management, pain control, and emotional support. Hospice services may be incorporated into the care of residents in long-term care facilities and include care for end-stage dementia and other chronic diseases such as end-stage heart failure (Ersek & Carpenter, 2014). (For an in-depth discussion of end-of-life care, see Chapter 59.)

Aging with a Disability

As the life expectancy of people with all types of physical, cognitive, and mental disabilities has increased, individuals must deal with the normal changes associated with aging in addition to their preexisting disabilities. There are still large gaps in our understanding of the interaction between disabilities and aging, including how this interaction varies depending on the type and degree of disability and other factors such as socioeconomics and gender. For adults without disabilities, the changes associated with aging may be minor inconveniences. For adults with disorders such as MS, aging is associated with higher rates of secondary health conditions compared to those aging without a disability (Newland, Jenson, Budhathoki, et al., 2015). Many people with disabilities are greatly concerned about what will happen to them as they age and whether assistance will be available when they need care.

It has been proposed that nurses view people with disabilities as capable, responsible individuals who are able to function effectively despite having a disability. Both the interface and the biopsychosocial models of disability can serve as a basis for the role of nurses as advocates for removal of barriers to health care (Sharts-Hopko, Smeltzer, Ott, et al., 2010). The use of such models would also encourage public policies that support full participation of all citizens through greater availability of personal assistants and affordable and accessible transportation.

Today, children born with intellectual and physical disabilities and those who acquire them early in life are also living into middle and older age. Often, their care has been provided by the family, primarily by the parents. As parents age and can no longer provide the needed care, they seek additional help with the care or long-term care alternatives for their children.

However, few services are available at present to support a smooth transition between caregiving by parents and then by others. Research and public policy must focus on supports and interventions that allow people with disabilities who are aging to increase or maintain function within their personal environment as well as in the outside community. Important questions include who will provide the care and how will it be financed. The National Institute on Aging has identified aging with a disability as a focus and is striving to provide streamlined information and access to those with a disability and their family caregivers.

Ethical and Legal Issues Affecting the Older Adult

Nurses play an important role in supporting and informing patients and families when making treatment decisions. This nursing role becomes even more important in the care of aging patients who are facing life-altering and possibly end-of-life decisions. Loss of rights, victimization, and other serious problems might occur if a patient has not made plans for personal and property management in the event of disability or death. As advocates, nurses should encourage end-of-life discussions and educate older adults to prepare advance directives before incapacitation (Miller, 2015).

When such serious decisions are made, possibilities exist for significant conflict of values among patients, family members, health care providers, and the legal representative. Autonomy and self-determination are Western concepts, and people from different cultures may view advance directives as a method for denial of care. Older adults from some cultures may be unwilling to consider the future, or they may wish to protect relatives and not want them to be informed about a serious illness. Nurses can facilitate the decision-making process by being sensitive to the complexity of patients' values and respecting their decisions. Directives must be focused on the wishes of the patient, not those of the family or the designated proxy.

If no advance arrangement has been made and the older person appears unable to make decisions, the court may be petitioned for a competency hearing. If the court rules that an older adult is incompetent, the judge appoints a guardian—a third party who is given powers by the court to assume responsibility for making financial or personal decisions for that person.

People with communication difficulties or mild dementia tend to be viewed as incapable of self-determination. However, people with mild dementia may have sufficient cognitive capability to make some, but perhaps not all, decisions. For example, a patient may be able to identify a proxy decision maker and yet be unable to select specific treatment options. People with mild dementia may be competent to understand the nature and significance of different options for care.

Nursing homes are also mandated to enhance residents' autonomy by increasing their involvement in health care decision making. In both nursing homes and hospitals, the documentation and placement of advance directives in the medical record and the education of patients about advance directives vary considerably. Periodically, it is important to ensure that the directives reflect the current wishes of the patient and that all providers have a copy so that they are aware of the patient's wishes.

CRITICAL THINKING EXERCISES

1. As a new nurse working in a busy medical-surgical unit, you notice that some of the older patients are presenting with a relatively flat affect. What do you suspect may be the cause of this flattened affect? What screening tool(s) would you recommend for these patients? Would you recommend that these tools be used for every older patient? Why? What follow-up would you recommend? What is the strength of the evidence base guiding your assessment, actions, and recommendations?
2. An 82-year-old woman has been admitted to the emergency department three times in the past 6 months for a fall without a major injury. What are some possible causes of these frequent falls? What essential assessments would you perform? What referrals would you make and why?
3. During a posthospitalization home visit for an 81-year-old man with diabetes and an extensive cardiac history, you attempt to do medication reconciliation. The patient admits to some forgetfulness and even confusion about his complex medication schedule. How should you proceed? Identify priorities and strategies that may be helpful to the patient so that he can adhere to the regimen.

UNIT

XXI Critical Care Nursing

Chapter 63 Assessment and Management of Patients with Critical Illness 2061

CHAPTER

63

Assessment and Management of Patients with Critical Illness

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the concept and principles of critical care.
2. Describe the organization of an intensive care unit (ICU).
3. Discuss the protocols and standards of ICU.
4. Elucidate the infection control measures in ICU.
5. Detail the role of nurse in assessment and management of critically ill patients.
6. Describe the steps of basic and advanced cardiac life support.
7. Identify the legal and ethical issues arising in the critical care nursing practice.
8. Recognize the impact of critical illness on patient and family.
9. Appreciate the importance of effective communication in the critical care unit.
10. Explain the dosage, mechanism, action, side effects, and nursing implication of the drugs used in critical care unit.

GLOSSARY

advanced cardiac life support: series of clinical interventions in emergency situations such as stroke or a cardiac arrest applying a highly specialized knowledge and skill set by trained healthcare team members

advance directive: a legal document executed by a competent person that provides guidance for medical and healthcare decisions (such as the termination of life support or organ donation) in the event the person becomes incompetent to make such decisions

cardiopulmonary arrest: cessation of heart and lung function characterized by absence of patient responses, pupillary dilatation, and carotid pulse, with no spontaneous breathing

cardiopulmonary resuscitation: emergency measures to bring back the spontaneous breathing and circulation in a patient whose heart stops beating and not breathing by self; includes prompt recognition, artificial breathing, and cardiac compression

catheter-associated urinary tract infection (CAUTI) bundle: set of evidence-based interventions proposed to prevent urinary tract infection among patients as a result of introduction and presence of urinary catheter

catheter-related bloodstream infection or central line–associated bloodstream infection (CRBSI/CLABSI) bundle: set of evidence-based interventions aimed at prevention of laboratory confirmed bloodstream infection in which central line is in place within 48 hours before the development of the bloodstream infection.

central venous pressure: blood pressure in the larger central veins such as in the internal jugular or subclavian vein; reflects the adequacy of circulating blood volume

continuous cardiac monitoring: continuous observation of cardiac functions using the recording of electrical activity of heart

critical care nursing: a specialty of nursing that focuses on care of patients with life-threatening health problems requiring continuous monitoring and advanced treatment

do not resuscitate (DNR): the cessation and removal of an ongoing medical therapy such as withdrawal of dialysis for a patient with renal failure or withdrawal of ventilator support to a patient with acute respiratory failure with an intent of allowing the patient to embrace natural death due to underlying illness

endotracheal intubation: insertion of a breathing tube (type of artificial airway) through the nose or mouth into the trachea

ethical dilemma: a situation that presents with difficulty in decision making between the two alternatives with neither one being absolutely acceptable and both contradicting with each other in professional values

euthanasia: an intentional killing of a person whose life is perceived to be not worth living by an act of commission or omission

health surrogate: legally authorized person to take healthcare decision on behalf of another individual through a living will or advance directive when he or she becomes incompetent

hemodynamic monitoring: process of measuring the various pressures that reflect the circulatory status of the patient at any point of time

hypoxemia: decreased oxygen level in the blood

mechanical ventilation: process of delivering air in and out of lung through a mechanical device connected to the patient who could not sustain spontaneous breathing

nosocomial infection or hospital-acquired infection: an infection acquired in hospital by a patient who was admitted for a reason other than that infection; an infection occurring in a patient 48 hours after admission in a hospital or other healthcare facility in whom the specific organism was not present or incubating at the time of admission

pulseless electrical activity (PEA) condition: defect in which electrical activity is present on an electrocardiogram, but there is not an adequate pulse or blood pressure

ventilator-associated pneumonia (VAP) bundle: set of evidence-based interventions aimed at prevention of VAP

Introduction

Critical care nursing is a well-developed specialty of nursing that focuses on care of patients with life-threatening health problems requiring continuous monitoring and advanced treatment. With invention of various lifesaving gadgets and development of technology, management of the critically ill has become more sophisticated. The intricate nature of critical care necessitates advanced preparation and specialized training of nurses to deal with the critically ill.

Intensive care, also known as critical care, is a multidisciplinary and interprofessional specialty dedicated to the comprehensive management of patients having, or at risk of developing, acute, life-threatening organ dysfunction. Intensive

care uses an array of gadgets that provide support of failing organ systems, particularly the lungs, cardiovascular system, and kidneys (Marshall, Bosco, Adhikari, et al., 2017).

The concept of critical care was introduced by Ms. Florence Nightingale in the 1800s. During the Crimean War, she created a space adjacent to the nurses' station and pooled all the soldiers with severe injuries, thereby enabling the nurses to monitor and care for them more intensively. The precursor concept of Nightingale was enriched and advanced to critical care nursing in the current days. During the polio epidemic in 1952, the first intensive care unit (ICU) was organized in Copenhagen. The polio-afflicted patients were nursed in iron lungs. Within the subsequent decades, in most of the European countries and America, ICUs were developed. Now the critical care units are an integral part of any healthcare facility.

In the 1960s, physicians started having training in critical care such as coronary care, nephrology, and postoperative care. Alongside, the nurses also started having additional training in critical care. Having specialized skill sets and knowledge, nurses started giving emergency resuscitation and assumed the expanded roles. Today, the critical care is collaborative care rendered by the team consisting of intensivist, other specialists, critical care nurses, critical care nurse specialist, and other trained allied health personnel.

Principles of Critical Care Nursing

1. **Astute assessment and continuous monitoring:** Nurses need to be smart in making quick but accurate assessment of patient status. The dynamic nature of alterations in vital organ functions warrants early identification and treatment. Delay in identification and initiation of appropriate intervention may lead to catastrophic consequences. By virtue of the specialized training, critical care nurses monitor closely and continuously the critically ill patients. Critical care nurses must apply the advanced assessment skills and carefully observe the cardiopulmonary, neurological, and renal system functions and document these parameters from time to time. Proficiency in advanced assessment and complex procedures and competency in handling gadgets such as ventilators, hemodynamic monitors, defibrillators, extracorporeal membrane oxygenator (ECMO) machine, bedside dialysis unit, and intra-aortic balloon pump forms a core component of critical care nursing skills.
2. **Anticipation of complications:** Anticipation and identification of evolving complications facilitates timely intervention to avert deterioration in the patient's condition. Critical care nurse collaborates with the critical care consultants, other specialist physicians, and other health team members. Utilizing the specialized advanced knowledge and critical thinking, nurses analyze the trends in various parameters and distinguish early the deviations and alerting parameters of complications. Critical care nurse initiates proactive measures using the evidence-based guidelines, critical care pathways, and care bundles before complications erupt as a consequence of aggressive management of critical condition and use of technology. Nurses need to be aware of and vigilant for possible unexpected outcomes, anticipate adverse reaction, and monitor for side effects for best outcome. Initiation of infection care bundles, deep vein thrombosis prophylaxis, pressure ulcer prevention, sepsis prevention bundle, and delirium prevention bundles are to be implemented efficiently to ensure quality care.
3. **Collaboration:** Critical care warrants a team approach and every member of the team deserves recognition for his or her irreplaceable contribution for the provision of high-quality critical care. Patients may get admitted to the critical care unit with life-threatening single-organ or multiple organ dysfunction. Prompt diagnosis of critical illness, initiation of treatment, and evaluation of the effectiveness of medical and nursing intervention need perfect collaboration and team approach. Critical care nurses in association with other team members take active participation to salvage the patient. If even one member breaches the standardized protocols, the success becomes immaterial. Contribution of every member of the team, including the housekeeping personnel, is mandatory for successful infection control. All those involved in the care of the critically ill have to be abreast of the latest protocols and new changes in policies and guidelines. Periodic training and induction training of all categories of workers are essential for quality care.
4. **Comprehensive care:** Provide comprehensive care by applying independent and interdependent nursing interventions including selected proven alternative care modalities. Most of the patients in ICU may be incapable of complaining their pain, fatigue, or anxiety. Prompt pain assessment, implementation of nonpharmacological measures to improve comfort and alleviate anxiety, prevention of bed sore, emotional support, and reassurance to the suffering patients and family are essential elements for quick recovery.
5. **Communication:** Skillful communication within the critical care team is the basis of all quality care in ICU. It facilitates smooth functioning of ICU team and prevents the patient safety mishaps. Proper communication within the nursing team members leads to quality outcomes. Standardized communication between handoffs can provide smooth continuous care.

   Because of the critical nature of illness, patients may not communicate verbally, or may present with altered consciousness. Reassurance and informing them of the elements of care and their purposes go a long way in improving patient satisfaction and cooperation. Uncertainty thrown upon their face may lead to shock state in many family members. Communicate with the patient and family members truthfully and empathetically. Convey compassion and communicate in such a way that the patient's and family members' anxiety and stress are diminished. Nurses have to apply strategic communication technique to help solve the crisis and in deserving special occasions, collaborate with clinical psychologist/counselor with advanced crisis intervention techniques.
6. **Ethical and humanistic care:**
   - Provide humanistic care in the high-tech environment. The critical care environment is frightening to almost all critically ill patients and their relatives. The human dimensions of care such as love, sense of belonging, and making sense of the intervention by involving the patient to the extent possible to him or her are essential elements in the ICUs that cannot be compromised for high-tech care.
   - ICU is the area in any healthcare facility where the highest number of deaths and disability occur. Handling death or serious loss of body function is complicated and requires competency and delicacy in handling the bereaved ones. Breaking bad news has to follow a certain

protocol so that the bereaved family members are supported well physically, emotionally, and spiritually. Nurses help in meeting the spiritual needs of the dying patients according to their beliefs and cultural norms.

Intensive Care Unit

Definition

An intensive care unit or critical care unit is a geographical area in a hospital where the patients with life-threatening illness or injuries are cared. ICU is the area of the hospital where the sickest patient and gadgets capable to manage them are more concentrated. The Intensive Care Society of the United Kingdom (2013) defines an ICU as a specially staffed and equipped self-contained area in a hospital dedicated to the management and monitoring of patients with life-threatening illness. It provides vital functions and uses the skills of medical, nursing, and other personnel experienced in the management of those problems.

Classification

ICUs may be classified according to the availability of qualified staff, the complexity to the care delivered, and the specialty:

- **Level I ICU:** It is located in a small hospital, providing resuscitation and short-term pulmonary support for less than 24 hours.
- **Level II ICU:** It is an adult ICU located in a larger hospital with a qualified intensivist and provides multisystem support. It may lack in some form of advanced therapy.
- **Level III ICU:** It is an adult ICU located in a large tertiary care center with the capability of providing comprehensive critical care for a prolonged period of time. This type of ICU is manned by a qualified multidisciplinary team consisting of critical care medicine consultant, fellowship trainee, specialist from other discipline, critical care specialized nurses, nurse practitioners, and other qualified allied health personnel.

Other Types of Classification of ICU

- **Open ICU:** Open ICU is one where a group of critically ill patients may be treated and managed not by critical care medicine qualified consultants but by different specialists. Sometimes, the patient may be followed up by the treating primary physician.
- **Closed ICU:** Closed ICU is an ICU that is managed by a qualified critical care specialized physician round the clock 24 × 7. Patient care management decisions are taken primarily by the intensive care consultant.

Single Specialty ICU Versus Multidisciplinary ICU

Based on the type of patients, the ICU can be classified as multidisciplinary critical care unit or single specialty critical units such as medical ICU, surgical ICU, cardiothoracic ICU, and renal ICU. Since the pathophysiological processes and the management modalities are the same, and the gadgets needed to support failing organs are the same irrespective of cause, multidisciplinary ICU is considered cost-effective compared with single specialty ICU (Manimala & Subashini, 2003).

High-Dependency Unit

A high-dependency unit (HDU) provides intermediary care, a unit that can provide smooth transition from ICU to the general ward. It can be a step-down unit for the patients at risk of developing another acute episode of a serious ailment. In the HDU, invasive monitoring and support for single-organ failure is offered for those with a high risk of clinical deterioration or unpredicted clinical course. For all practical purposes, the HDU should be an extension of ICU and it should be managed by a qualified intensivist.

Organization of a Critical Care Unit

Design Consideration

Critical care unit is a vital arena in the hospital and organization of a critical care unit is a strategically planned process. The bed strength, the type of patients, and services intended decide the ICU needs in terms of floor space, equipment, monitors, manpower, etc. The accrediting agencies, JCI, and critical care societies of the countries also have recommended minimum set norms. The Indian hospitals follow the minimum set criteria of the National Accreditation Board for Hospitals (NABH) and Indian Society of Critical Care Medicine (ISCCM), which vary from country to country (Arora, 2012) (see Fig. 63-1).

Bed Strength

To provide effective care, ICU should have 6 to 14 beds (Rungta, Govil, Nainan, et al., 2010). In an ICU with a larger number of beds, it has to be divided into pods containing 10 to 15 beds with sufficient staffs, devoted medical registrar, and intensive care specialist for effective care.

Location

- Critical care unit has to be ideally located in a separate area with easy accessibility to the emergency department (ED), operation room (OR), radiology department, catheterization laboratory, and blood bank.
- There should be sufficiently big lift, ramps, and a wide corridor that can facilitate smooth transfer in and out of the critically ill patients.
- ICU should have a single entry and exit with an anteroom.
- There should be provision for emergency exits in case of disasters.

The Floor Space

- Recommendations vary between countries and the agencies.

Figure 63-1 • ICU in a tertiary care center. (*Courtesy*: Kovai Medical Center and Hospital, Coimbatore.)

- Floor space: 125 to 150 sq ft. per patient is recommended (Rungta et al., 2010). It may vary up to 250 ft^2 per patient. The floor space for a separate room should be much higher, at least 300 ft^2 per patient.
- Between-bed space: There should be 4 to 4.5 ft space between two beds and the beds separated with a removable partition. The head end should also have enough space for easy patient access for intubation or resuscitation.
- Separate rooms: There should be one or two separate rooms to nurse patients requiring isolation precaution or to nurse immunocompromised patients. The room should be big with handwashing facility and area to accommodate the ventilators, monitors, and other gadgets.
- It may be wise to have one or two bigger rooms or an area that may be utilized for patients who may undergo big bedside procedures such as ECMO and renal replacement therapy and those who have large number of gadgets attached to them.
- One hundred percent to 150% extra space is recommended for other than patient care area for nurses' station, storage space, and free patient movement.

Nurses' Station

There should be a central nursing station with telemonitoring devices. This will enable monitoring of patients placed ideally in a "C" or "L" fashion.

Other Facilities

- Storage space for ventilators, monitors, and infusion pumps, room for doctor's office, nurse's office, and toilets have to be provided.
- There should be medical storage (e.g., gloves, medicines, airways, suction tips, catheters, Ryles tubes) facility, medicine preparation area, equipment storage (infusion pump and other equipment), secretarial and computational facility, clean linen storage, seminar room with a small library, and dirty utility room available within the ICU.
- It is always preferred to have clear-cut zoning with patient care areas, support areas, and dirty utility and toilets in other areas. For movement of dirty utilities, there should be a separate pathway.
- There may be provision of RO-purified water access within the ICU.
- There should be a minimum of two to three oxygen outlets, two to three vacuum outlets, and one to three compressed air outlets.
- Sixteen to 18 electric outlets per patient are recommended.
- There should be sufficient natural lighting available. Wall-mounted or ceiling-mounted pendent-type lights are preferable to save space and for good illumination.
- Handwashing facility should be easily accessible. Isolation ICU should have separate handwashing facility.

Environmental Criteria

The ICUs should be fully air conditioned with control of humidity and moisture. Twelve to 16 air exchanges and 55% to 60% humidity are recommended. Laminar flow is preferable.

Equipment and Supplies

Equipment numbers and types are decided based on the existing standards of the country and the type of services provided.

There should be a functional system in place to ensure the safe and accurate functioning of the machines and equipment. Periodically, the monitors have to be calibrated.

Basic equipment needed to organize a level III ICU is as follows:

- Ventilators, at least one per bed, with at least 40% of the ventilators having built-in noninvasive ventilation capability
- Noninvasive ventilators
- Multichannel monitor with at least two pressure monitoring devices
- Defibrillators and pacemakers
- Infusion pumps/syringe pumps, at least four to eight per bed
- Fluid and bed warmers
- Portable transfer monitors
- Portable ventilators (at least one)
- Specialized beds
- Bedside trolleys, drug cart, and emergency cart
- Patient-lifting devices
- Portable X-ray machine a
- Picture Archiving and Communication system is preferable
- Bedside ultrasound and echo machines
- Renal replacement therapy
- IABP or ventricular assist device
- Bedside bronchoscopy machines

For every patient, the following monitors should be available:

- ECG monitor
- Pressure monitor
- Temperature monitor
- End-tidal CO_2 monitor
- Pulse oximeter
- Noninvasive arterial pressure monitoring
- Bedside arterial blood gas (ABG) lab and ECMO are optional and may be available (see Fig. 63-2).
- For safe handling and maintenance of equipment the medical, nursing, and other allied health personnel have to be trained periodically,.
- Various sizes of endotracheal (ET) tubes, tracheostomy tubes, nasogastric tubes, different types of airways, suction tips, and ICD tubes should be available.
- Catheters, ECG leads, gloves, gowns, masks, goggles, drugs, IV fluids, and refrigerator should be available to store medications.
- Adequate amount of supplies may be stored at the bedside as well as in the central stores.

Figure 63-2 • Extracorporeal membrane oxygenator (ECMO) and ventilator.

Organization of Human Resources

Manpower requirements again depend on the number of patients and the type of patients nursed. The unit has to be headed by the intensive care–qualified consultant.

Critical Care Medical Team

- Head of critical care medicine or Director, who will manage the unit
- Critical care medicine consultant
- Intensive care medicine specialist
- Other specialists
- Residents or critical care medicine fellowship trainees
- Junior medical officer

The Critical Care Nursing Team

- Critical care specialized nurse manager of the unit
- Senior charge nurses with critical care training
- Full-time critical care nurse educator, 1 for every 50 ICU nurses, to take care of the teaching and training needs of the registered nurses
- Nurse:patient ratio: Registered nurses in the ratio of 1:1 for ventilated patients, 1:2 for nonventilated patients, and 2:1 for patients on ECMO support
- Preferable to have more than half of the total strength of nurses to have specialized training after the RN qualification

Other Personnel

These include the following:

- Respiratory therapist
- Physiotherapist
- ICU technician
- Dietician
- Clinical pharmacist
- Radiographer
- Computer operator and receptionist
- Biomedical engineer
- Hospital attendant, 2 in each shift for the first and second shifts, and 1 in night shift for every 10 ICU beds
- Sanitary attendant, 2 in each shift for the first and second shifts, and 1 in night shift for every 10 ICU beds
- Security guards to cover 24 hours

Protocols and Policies of a Critical Care Unit

Critical care is becoming increasingly complex and challenging. The multitude of patient safety problems and unexpected outcomes that arise while applying the advanced technology and the intricate nature of the critical ailments necessitate development of a standardized way of managing the patients. Clinical protocols, guidelines, and care bundles are developed to achieve quality patient care in ICUs.

Protocol is a set of written rules or precisely delineated steps usually developed and tested by well-controlled clinical research for desired clinical outcome. Stress ulcer prevention protocol, deep vein thrombosis prevention protocol, sedation interruption protocol, weaning protocol, oral hygiene protocol, basic life support (BLS) protocol, and advanced cardiac life support (ACLS) protocol are some of the successfully implemented protocols in the ICUs. Checklists facilitate consistent application of protocol. By applying protocol, the similar types of patients are treated in the same way to achieve the same outcome by avoiding omission or commission errors. Protocols also facilitate clinical reasoning and appropriate decision making (Chang, Sevransky, & Martin, et al., 2012). Major disadvantages of protocols are that they are too rigid and do not allow patient-centered care (PCC).

Critical care bundles are another type of tools for implementing standardized care. Care bundles are a group of evidence-based interventions directed to achieve the desired goals such as ventilator-associated pneumonia (VAP) prevention bundle, catheter-associated urinary tract infection (CAUTI) prevention bundle, and delirium prevention bundle.

Guidelines are written policy statements. They help in smooth functioning of the unit and avoid confusions in delivery of care. In level III critical care units, various policies are followed, which include the following:

- Admission policy
- Discharge policy
- Organ donation policy
- Treatment policy
- End-of-life care policy

Quality Indicators of Critical Care

Providing quality care is the essential responsibility of the entire critical care unit team including its head. Earlier, the mortality in the ICU was considered a major quality benchmark. Certainly, the mortality rate has a large bearing on the care provided in an ICU. The ISCCM and hospital accrediting agencies put forth a set of benchmarks to assess and improve the quality of care on a continuous basis. Various categories and the quality indicators delineated by the ISCCM (Ray, Samaddar, Todi, et al., 2009) are given in Table 63-1.

Hospital-Acquired Infection in Critical Care Units

Hospital-acquired infection (HAI) is considered as a safety threat by the patients as well as the healthcare provider. Every member of the healthcare team is held accountable for this preventable medical error (Labeau, Blot, Rello, et al., 2010). Nosocomial infection or HAI can be defined as any newly acquired infection that arises after 48 hours of admission to the hospital.

HAI increases the cost of care, length of ICU stay, and hospital stay, and diminishes the favorable outcome of care. Nurses play a major role in infection control in the critical care unit. Simple nursing interventions such as elevating the head end to 30° to 45° have shown to reduce the most serious HAI, the VAP, that occurs in critical care unit.

Critical care units are the seat of many HAI because of two reasons; the first one is that the number of invasive procedures occurring in the critical care units is more and, second, the critical nature of illness renders the patient susceptible to nosocomial infections. Four major types of HAI occurring in critical care units are the following:

1. VAP
2. CAUTI
3. Central catheter-related bloodstream infection (CRBSI)
4. Surgical site infection (SSI)

Sources

- ICU environment, the ventilators, monitors, floors, and doorknobs, which may harbor some notorious infectious agents

TABLE 63-1 Quality Indicators of Critical Care

Category	Quality Indicators
Outcome indicators	Standardized mortality rate Morbidity indicators • Iatrogenic pneumothorax • Incidence of renal failure in noncoronary patients • Incidence of pressure ulcer • Incidence of VAP • Incidence rate of CLABSI
Process	Length of ICU stay Compliance to various protocols • Hand hygiene compliance • Prevention of CAUTI • VAP prevention bundle • CRBSI prevention bundle ICU readmission rate
Patient safety	Patient falls Medication error Adverse events Needlestick injury Accidental unplanned extubation Reintubation rate
Human resource	Employee satisfaction Absenteeism/turnover
Consumer satisfaction	Patient satisfaction Family satisfaction

CAUTI, catheter-associated urinary tract infection; CLABSI, central line–associated bloodstream infection; CRBSI, catheter-related bloodstream infection; ICU, intensive care unit; VAP, ventilator-associated pneumonia.

- Possibility of some organisms being harbored by patients themselves, which may be transmitted endogenously to elsewhere
- Other patients
- Healthcare professionals
- Visitors

Risk Factors

- Acuity of illness
- Physiological stress response
- Too many invasive procedures and lines in situ
- Malnutrition
- Comorbidities
- Antibiotic abuse
- Immobilization
- Immunocompromised state
- Other external factors such as understaffing and breach in implementation of infection control protocols

Ventilator-Associated Pneumonia

VAP is one of the serious infections occurring in ICU. It is defined as pneumonia that occurs 48 hours or more after ET intubation or tracheostomy, caused by infectious agents not present or incubating at the time when mechanical ventilation was started (Ranjan, Chaudhary, Chaudhry, et al., 2014). In the United States, VAP rate of 4 to 14 days/1,000 ventilated days was reported, whereas in the Indian population, it was reported to be 31.7/1,000 ventilated days. The overall mortality rate in those with VAP was much higher compared with in those in the non-VAP group with 48.33% versus 20%, respectively (Ranjan et al., 2014).

Pathophysiology

The artificial airway introduced into the respiratory tract negates the protective reflexes such as gag reflex, coughing reflex, humidification, and filtering of air available to the patient. Aspiration of the pooled secretion above the inflated cuff and gastric content from the Ryles tube leads to colonization of the lower airway and results in pneumonia.

The pathophysiology of VAP is illustrated in Figure 63-3.

Clinical Features

- Newly occurring infiltration on lung fields in the chest X-ray
- Fever
- Leukocytosis/leukopenia
- Purulent tracheal secretion
- Positive culture for tracheal aspirate

Prevention

The recommended VAP prevention bundle is as follows. P (Gunasekera and Gatrix, 2016; Boltey, Yasusheva, & Costa, 2017).

- Keep head end of the bed elevated at 30° to 45° to prevent aspiration of gastric content and gastric reflux.
- Provide oral care with chlorhexidine solution of strength 0.12% twice or thrice as per unit protocol. The oral cavity colonization can be reduced with the usage of chlorhexidine and regular oral cavity assessment.
- Reduce the duration of intubation through early weaning protocol using daily sedation vacation and spontaneous breathing trial.
- Reduce unplanned extubation and reintubation.
- Institute gastric ulcer prophylaxis.
- Monitor ET tube cuff pressure and maintain it >20 but <30 mmHg to avoid entry of bacterial pathogens into the lower respiratory tract without causing tracheal necrosis.
- Avoid pooling of secretion above the cuff by periodic suctioning through the subglottic port. See Figure 63-4 showing the conventional ET tube and ET tube with subglottic suctioning port.

Catheter-Related Bloodstream Infection or Central Line–Associated Bloodstream Infection (CLABSI)

CLABSI is the most serious HAI. It is preventable through complete adherence to aseptic protocols, surveillance, and management measures.

Definition

CLABSI is a laboratory-confirmed bloodstream infection (unrelated to an infection elsewhere) in which central line is in place within 48 hours before the development of the bloodstream infection (Haddadin and Regunath, 2017).

CRBSI is defined as the bloodstream infection fulfilling at least one of the three criteria stated below. Same organism has grown in the quantitative blood culture drawn through the central line and the peripheral vein with colony count three times higher in the central line culture

- Same organism extracted from the percutaneous blood culture and the catheter tip

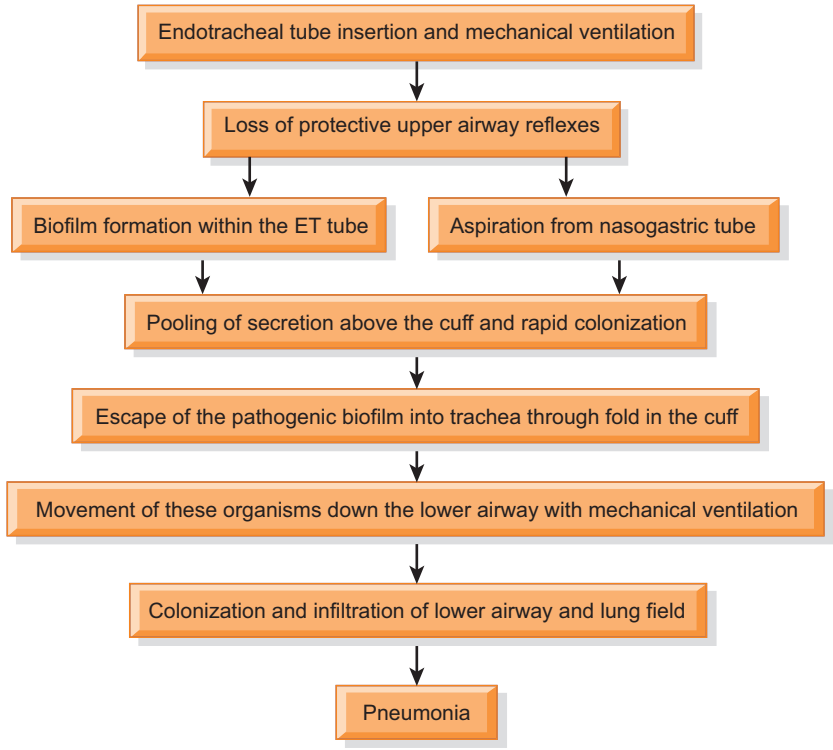

Figure 63-3 • Pathophysiology of ventilator-associated pneumonia.

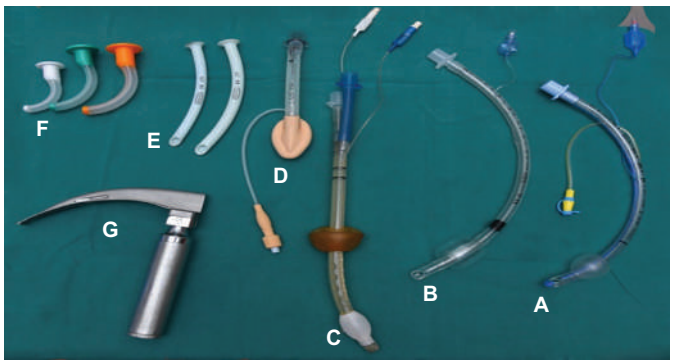

Figure 63-4 • **A**. ET tube with subglottic suctioning port; **B**. regular ET tube; **C**. Combitube; **D**. laryngeal mask airway; **E**. nasal airway; **F**. oral airway; and **G**. laryngoscope.

- Shorter time to positive culture from the central line sample than from the peripheral line sample (>2 hours earlier)

Causes

The following are some common causative organisms:

- Coagulase-negative staphylococci
- Enterococci (vancomycin-resistant enterococci)
- MRSA-positive *Staphylococcus aureus*
- *Klebsiella*
- *Pseudomonas*
- *Aceinetobacter*
- *E. coli*

Risk Factors Present in the Host

- Immunocompromised state—neutropenia, diabetes mellitus, and bone marrow transplant or organ transplant recipient
- Prolonged hospitalization before catheter insertion
- Total parenteral nutrition and dialysis
- Chronic illnesses
- Extremes of age
- Burns and other skin pathology

Pathophysiology

The most important factors causing the CLABSI are as follows:

1. Breach in aseptic precaution at the time of insertion
2. Hub contamination through breach in aseptic handling of catheter
3. Infusing contaminated fluids (rare)
4. Migration of organism from the contaminated skin through the exit point around the lumen of catheter

The tunneled and non-tunneled central venous catheters are available. Tunneled catheters enter through the subcutaneous tissue and the cuff in the catheter prevents entry of microbes beyond that point. In the non-tunneled catheter, the bacteria found on the skin migrate along the catheter from the skin exit point and enter the blood vessel causing colonization and infection. Improper hub manipulation causing breach in the aseptic precautions leads to intraluminal spread of infection. Another mechanism of intraluminal spread is infusing contaminated fluid. Femoral catheter insertion, especially in obese patients, causes extraluminal spread of fungal infection more easily (Haddadin and Regunath, 2017).

Clinical Manifestations

- Fever with chills the typical manifestation
- In extremes of age and in patients with neutropenia, presence of altered mental status, hypotension, lethargy, and fatigue
- On local examination, pus or drainage around the exit site
- Redness, induration, and swelling around the insertion site
- Complaint of pain along the course of the vein by the patient
- Poor or no return blood flow from the venous access.

Management

- After taking blood culture, empirical antibiotic therapy may be started.
- On receiving culture report based on the sensitivity, systemic antibiotic therapy should be started and may be given for 2-week duration.
- If CLABSI is proven, the catheter can be removed and tip sent for culture and sensitivity.
- In hemodialysis, topical and systemic antibiotic therapy may be initially attempted.
- In case of tunneled catheter getting infected, it needs to be removed.

Prevention

The Society for Health Care Epidemiology of America and Infectious Diseases Society of America (SHEA/IDSA)–recommended guidelines (Marschall, Mermel, Fakih, et al., 2014) are given as follows:

- **CLABSI/CRBSI prevention:** At the time of central line insertion
  - Perform hand hygiene with soap and water or foam- or alcohol-based gels.
  - Ensure adherence to infection control protocol while central line insertion using a checklist.
  - Use of gloves does not prevent hand hygiene.
  - Avoid using the femoral vein for central venous access in obese adult patients
  - Do not use peripherally inserted CVCs (PICCs) as a strategy to reduce the risk of CLABSI.
  - Use maximum sterile barrier precautions during CVC insertion, which include wearing sterile PPE and draping the whole body with a large sterile sheet.
  - For smooth complication-free internal jugular catheter insertion, use ultrasound guidance.
  - Apply an alcohol based or chlorhexidine antiseptic solution for skin preparation before puncture.
  - Allow the antiseptic solution to dry before making the skin puncture.
- **CLABSI/CRBSI prevention:** Catheter maintenance bundle
  - Maintain appropriate nurse: patient ratio.
  - Before touching the patient and the central venous access, perform hand hygiene.
  - Catheter hubs, needleless connectors, and injection ports need to be disinfected by using sterile swab and 70% alcohol or povidone–iodine/chlorhexidine-based solution before accessing the central line.
  - Apply mechanical friction for no less than 5 seconds before touching any part of tubing, hubs or connectors or ports to reduce contamination.
  - Use the central vascular access to the period most necessary.
  - Remove unwanted extension catheters.
  - Regularly assess the need for central venous access and if not necessary, remove it at the earliest.
  - For non-tunneled catheter, change the soiled dressing at once. If there is gauze dressing, change the dressing with all aseptic precautions once in 2 days. In case of transparent dressing, it can be changed once in 5 to 7 days' time.
  - Blood sets have to be changed in 24 hours' time.
  - IV sets used for infusing lipid emulsion, propofol, need to be changed in 12 hours' time.
  - IV lines can be changed at least within 96 hours.
  - Use antimicrobial locks.

Catheter-Associated Urinary Tract Infection Prevention

The CAUTI is the other most important infection for which nurses are accountable. It is considered preventable and hence the cost incurred on account of it is not reimbursed by third-party payment agencies. Insertion and maintenance of urinary catheter need to be scrupulous. CAUTI bundle consists of insertion bundle and maintenance bundle (Gould, Umscheild, Agarwal, et al., 2017). Detailed account of UTI is given in Chapter 45.

CAUTI Urinary Catheter Insertion Bundle

- Perform hand hygiene immediately before and after insertion or any manipulation of the catheter device or site.
- Ensure that only properly trained persons who know the correct technique of aseptic catheter insertion and maintenance are given this responsibility.
- Insert urinary catheters using aseptic technique and sterile equipment.
- Use sterile gloves, drape, sponges, and an appropriate antiseptic or sterile solution for periurethral cleaning, and a single-use packet of lubricant jelly for insertion.
- Routine use of antiseptic lubricants is not necessary.
- Properly secure indwelling catheters after insertion to prevent movement and urethral traction.
- Consider using the smallest-bore catheter possible, consistent with good drainage, to minimize bladder neck and urethral trauma.

CAUTI—Urinary Catheter Maintenance

- Following aseptic insertion of the urinary catheter, maintain a closed drainage system.
- If breaks in aseptic technique, disconnection, or leakage occur, replace the catheter and collecting system using aseptic technique and sterile equipment.
- Consider using urinary catheter systems with preconnected, sealed catheter–tubing junctions.
- Maintain unobstructed urine flow by the following:
  - Keep the catheter and collecting tube free from kinking.
  - Keep the collecting bag below the level of the bladder at all times.
  - Do not rest the bag on the floor.
- Empty the collecting bag regularly using a separate, clean collecting container for each patient; avoid splashing, and prevent contact of the drainage spigot with the nonsterile collecting container.
- Use standard precautions, including the use of gloves and gown as appropriate, during any manipulation of the catheter or collecting system.
- Changing indwelling catheters or drainage bags at routine, fixed intervals is not recommended. Rather, it is suggested to change catheters and drainage bags based on clinical indications such as infection, obstruction, or when the closed system is compromised.
- Unless clinical indications exist (e.g., in patients with bacteriuria on catheter removal posturological surgery), do not use systemic antimicrobials routinely to prevent CAUTI in patients requiring either short- or long-term catheterization.
- Do not clean the periurethral area with antiseptics to prevent CAUTI while the catheter is in place. Routine hygiene (e.g., cleansing of the meatus during daily bathing) is appropriate.

- Unless obstruction is anticipated (e.g., as might occur with bleeding after prostatic or bladder surgery), bladder irrigation is not recommended.

Infection Control in ICU

Infection control measures include the general measures and specific preventive measures for selected infections. General measures aim at prevention of all types of HAI in the ICU.

General Measures for Infection Control

1. **Early identification and isolation of patients with signs of infection:**
   - Perform vigilant and continuous monitoring of all critically ill patients for early signs of infections such as leukocytosis, diarrhea, skin rashes, fever, known carrier of pathogenic bacteria, and neutropenia (Mehta, Gupta, Todi, et al., 2014).
   - Identify those with evidence of infections at an early stage and isolate (symptomatic isolation).
   - For those with neutropenia, follow reverse isolation to protect the patients from acquiring infection from others.
2. **Strict adherence of standard precautions:** Standard precautions should be followed to prevent the transmission of blood-borne pathogens. The basic assumption of standard precaution is that every patient handled in the healthcare facility may be potentially harboring blood-borne pathogens. The standard precautions include the following:
   - Minimize contact with the blood, body secretions, and patient care areas.
   - Adhere to strict hand hygiene before touching the patient, after touching the patient, before any sterile procedure, in between long personal care activities, after handing the drainage systems, etc., and also after removing the gloves, before leaving the ICU.
     - See Figure 63-5 for five moments of hand hygiene.
   - Wear personal protective equipment. According to the procedure and the expected mode of contamination wear personal protective equipment namely glove, gown, mask and goggles. Wear gloves during blood or other specimen collections. In case flash of body fluid is expected as during a tracheal suctioning procedure, wear mask, gown, and goggles along with gloves.
   - Appropriately handle equipment and linen used for patient care.
   - Perform appropriate biomedical waste management through segregation of waste at the site of generation and proper disposal as per protocol.
   - Prevent needlestick/sharp injuries.
   - Perform appropriate spill management and environmental cleaning.
3. **Biomedical waste disposal:**
   - There should be strict adherence to segregation of waste at the point of generation and disposal of waste as per the biomedical waste management protocol.
   - All laboratory specimens should be packed in spillage-free container and transported at the earliest.
   - Specimens taken from patients known to harbor HBV, HCV, and HIV are to be labeled with biohazard symbol and sent separately.
4. **Disinfection and cleaning of instrument and linen:**
   - Used contaminated instruments such as bronchoscopes and endoscopes can be cleaned thoroughly and dried before immersing in chemical disinfectants. It is preferable to use 2% gluteraldehyde for more than 20 minutes.
   - Linens contaminated visibly with blood and body fluids need to be treated with 2% sodium hypochlorite

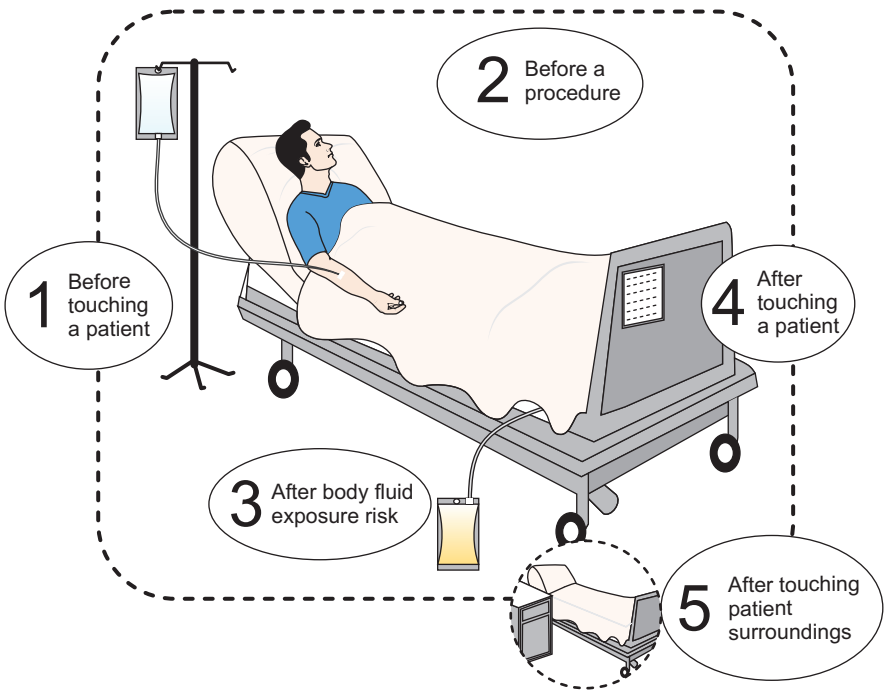

Figure 63-5 • Five movements of hand hygiene.

solution before further cleaning and sterilization to kill the blood-borne pathogen.

5. **Maintenance of ICU environment:** The surfaces wherever frequent contacts or contamination is expected such as door knobs, bed surfaces, and side rails require frequent thorough cleaning with detergent followed by disinfection recommended at least twice a day.
   - Floor cleaning more than once a day is needed.
   - Window sills and exhaust vents have to be cleaned using detergent-impregnated cloth or mop head.
   - Terminal disinfection on death or discharge/transfer of the patient has to be thorough enough to clean and disinfect all the items used.
   - There should be restriction of street clothes for all visitors and healthcare professionals.
   - There should be provision for hand hygiene at the entrance of the critical care unit.
   - It is desirable to have automated doors with sensors fitted on the doors.
   - There should be provision of alcohol-based hand rubs at each bed side.
   - Properly disinfect blood spills or body fluid spills on the floor. Treat the area with sodium hypochlorite solution followed by routine cleaning of floors.
6. **Training and education of all healthcare workers:** Hand hygiene and other infection control policies need to be oriented to all new employees and periodical refresher course on infection control is essential to implement the infection control program effectively.
7. **Antibiotic stewardship:** Antibiotic abuse will lead to development of antibiotic-resistant strains. Follow institutional policy for effective antibiotic use. Nurse's role is to follow correct schedule at the appropriate time.
8. **Institute an active infection control committee** and appropriate infection control surveillance.

Specific Preventive Measures

Certain airborne infectious agents spread through droplets; nuclei measuring more than 5 μm that are expelled into air during coughing and sneezing and can spread infection to susceptible patients or healthcare providers. Similarly, certain infections spread through direct contact. Specific measures need to be instituted to address such infectious microbes.

Airborne/Droplet Protection

- Patients harboring agents that spread through air droplets such as *Mycobacterium tuberculosis*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Mycoplasma pneumoniae* have to be isolated in a private room.
- The room has to have glass partition and tight doors for sealing of air. The isolation room should have negative-pressure ventilation.
- Visitors and care providers have to wear N95 respirator mask, which is capable of protecting both small and large particles. The mask has to be worn snuggly around the mouth and nose before entering the patient's room.
- Limit the movement of patients.

Contact Precautions

Some organisms that spread through direct contact with an infected patient or indirect contact, that is, through the personal care items. herpes zoster, rotavirus, and hepatitis A virus, can spread through direct and indirect contact. To prevent the spread of such organisms, the following measures need to be followed:

- Isolate the patient.
- Avoid use of equipment and patient care items of other patients.
- In unavoidable circumstances, proper disinfection of the items should be done.
- Limit the movement of patients.

Assessment of Critical Illness in General Medical-Surgical Wards

Before the occurrence of a catastrophic event such as a cardiopulmonary arrest, there are predictable changes in vital parameters many hours earlier (Franklin & Mathew, 1994). If the vital signs are observed carefully, recognizing and instituting prompt treatment of evolving critical illness is possible (Frost & Wise, 2007). These simple clinical parameters are easy to observe and can be assessed clinically. General medical-surgical unit staff can often miss the opportunity to identify the critical illness because of lack of time, overburdened staff, and lack of systematic approach in assessment (Frost & Wise, 2007).

Physiological alterations that occur prior to critical illness or a cardiopulmonary arrest are hypotension, tachycardia or bradycardia, altered respiratory rate (RR), labored breathing, reduced urine output, and new changes in neurological status. Subbe et al. (2001) have developed and validated a system of early earning scoring with five parameters, namely, systolic blood pressure, RR, heart rate, temperature, and neurological status, using AVPU score. In the AVPU scoring system:

- A: Alert
- V: Verbal response positive
- P: Painful stimuli positive
- U: Unresponsive for all stimuli

Different modified early warning scoring (MEWS) systems have been developed with inclusion of SpO_2, urine output, and O_2 therapy (Xu, Tam, Thabane, et al., 2015). The important advantage of early warning systems or MEWS is that early identification and intervention improves outcome from critical illness. In the United States, the United Kingdom, Spain, Singapore, Israel, Australia, India, and other countries, some early warning scoring system has been adopted to predict critical illness early. A team of more experienced ICU health team members is formed as Rapid Response Team (RRT) has now become a common practice in many multispecialty medical centers. The nurse in the general ward can alert the RRT if there is any high-risk MEWS score. The team will assess the patient to decide on the further course of action such as transfer to ICU and definitive care in ICU or more close observation and conservative measures (see Fig. 63-6). Whenever alteration in vital signs is observed by the general ward nurses, they can alert the RRT and can initiate measures such as airway management, oxygen administration, and establishing a venous access. Application of MEWS can help nurses to identify deterioration of those patients who are recently transferred from the ICUs.

Assessment of Critically Ill Patients in the ICU

Assessment of critically ill patients is a challenging task that requires critical thinking, competence, and accuracy. A

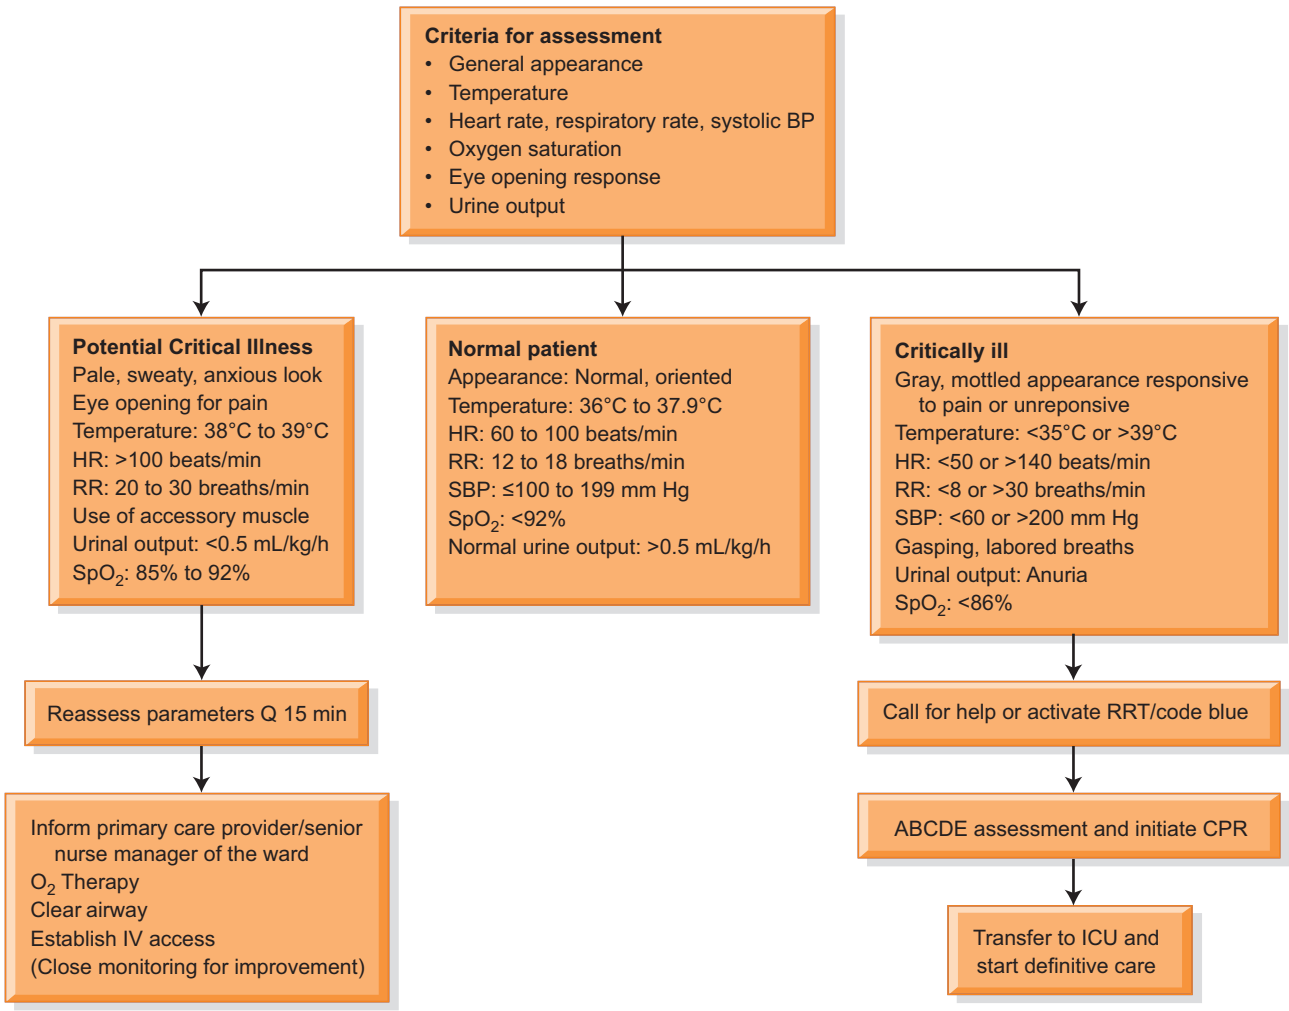

Figure 63-6 • Nurses' guide for early recognition of critical illness in general medical-surgical ward patients. Adapted from Frost, P., & Wise, M. P. (2007). Recognition and early management of critically ill ward patient. British Journal of Hospital Medicine, 68(10), M180–M183; Subbe, C. P., Kruger, M., Rutherford, P., & Gemmel, L. (2001). Validation of a modified early warning score of medical admissions. Quarterly Journal of Medicine, 94, 521–526.

significant difference in assessment of the critically ill and routine nursing assessment is that it is a nonlinear spiral approach where the assessment and management go hand in hand and revisit the steps of primary survey for further planning for management. Patients may be received directly from the ED.

The first step is to enquire from the patient the following: How are you? Or what is your name? Or what happened?

If the patient could answer properly, it can be inferred that his or her airway, breathing, and cerebral perfusion are alright. If the patient is unresponsive, it indicates critical ailment and needs quick assessment and intervention.

If the patient is unconscious and unresponsive, and is not breathing normally (occasional gasps are not normal), start cardiopulmonary resuscitation (CPR) according to the resuscitation guidelines which is discussed in the subsequent section of this chapter. See Table 63-2 for further details on initial assessment of critically ill.

Initial Assessment Using ABCDE Approach

The acronym represents the following:

- A: Airway
- B: Breathing
- C: Circulation
- D: Disability or neurological deficits
- E: Environmental exposure

Secondary Survey

When primary survey is completed with simultaneous resuscitation, secondary survey has to be carried out. It consists of the following:

- Relevant history
- Thorough head-to-toe examination
- Reassessment of ABCDE and vitals
- Blood test
  - Complete blood count
  - Serum electrolytes
  - Blood glucose, urea, and creatinine
  - Bleeding time (BT), clotting time (CT), and partial thromboplastin time (PTT)
  - Liver function tests
  - Serum amylase
  - ABO grouping and cross-matching
  - Toxicology screening
  - ABG analysis

TABLE 63-2 Initial Assessment and Concurrent Management of Critically Ill

	Assessment	Management
Airway	• Look, listen, and feel for obstruction • Seesaw respiration of chest and abdominal muscles that indicates airway obstruction • Noisy respiration indicates partial obstruction • Stridor, rattling noise indicate secretion clogging the airway • No breath sounds indicate complete obstruction • Feel for air movement with your hand closer to the mouth	• Secure the cervical spine in case of suspected injury with a hard collar • Open airway using head-tilt/chin-lift maneuver or jaw-thrust maneuver in suspected cervical injury • Clear foreign body if any using finger sweep technique • Apply oropharyngeal suction • Insert oral airway or, if needed, endotracheal airway
Breathing	• Look for bilateral chest movements • In case of pneumothorax, sucking of chest wall may be present • Check respiratory rate and rhythm; RR <8 or >25 breaths/min indicates ventilation problems • Listen for the breath sounds, crackles, wheeze, etc. • Observe for cyanosis or mottled skin appearance; indicates poor oxygenation • Check the oxygen saturation using a pulse oximeter	• Administer high-concentration oxygen • In case of COPD, lower concentration of oxygen using venturi mask may be administered (2 to 3 L/min) • If all these measures are failed, administer O_2 through NIV or mechanical ventilator • In case of suspected pneumothorax or hemothorax, insertion of intercostal drainage tube may be necessary
Circulation	• Observe the color of the digits, as well as the oral mucosa, lips for peripheral and central cyanosis • Assess the pulse rate, rhythm; <60 or >120/min indicates compromised circulation • Barely palpable carotid pulses suggest a poor cardiac output, while a bounding pulse may indicate sepsis • Feel for peripheral warmth. Cool and clammy extremity indicates poor cardiac output • Assess the urine output by passing a urinary catheter. If it is <0.5 mL/kg/h, it indicates poor cardiac output • Check the blood pressure. Low BP with collapsed central veins indicates circulatory compromise • Auscultate for the heart sound; crackles indicate pulmonary edema • Observe for internal or external blood loss • Assess the ECG pattern	• Insert a large-bore needle and send blood for investigations including grouping and cross-matching • Connect the patient to continuous ECG monitor and BP monitor • Replace the lost fluid volume • If the cause of compromised circulation is cardiac with presence of dyspnea, crackles, and increased JVP, do not force fluid. Instead, start inotropic agents In those patients with chest pain, start nitroglycerine and ACS management If there is internal or external bleeding, prepare the patient for eventual surgical intervention to arrest bleeding
Disability or neurological status	• Review ABC • Assess the level of consciousness using GCS and pupillary reaction • Assess AVPU, where A, *a*lert/eye opening; response to *v*erbal stimuli/for *p*ain only/U, *u*nresponsive • Check blood glucose values to rule out hypoglycemia or hyperglycemia • Check for sedative medications • Identify and check for consumption of poison/drug • Check for traumatic brain injury	• Correct the derangements in ABC • Nurse the patient with head-end elevated position • Correct hypoglycemia with 10% dextrose or inj. glucagon
Exposure	• Complete assessment including the back for injury with total body exposed after ensuring complete privacy and dignity • Assess the temperature for hypothermia	• Maintain body temperature with blanket or warmer

ACS, acute coronary syndrome; BP, blood pressure; COPD, chronic obstructive pulmonary disorder; ECG, electrocardiogram; GCS, Glasgow coma scale; JVP, jugular venous pressure; NIV, noninvasive ventilation; RR, respiratory rate.

- X-rays
- ECG
- Echo/ultrasound
- CT/MRI

History

Pertinent history includes allergies, medications, present and past history, pregnancy if woman of child-bearing age, last meal time, events, and the environment where the critical event happened.

When the patient is transferred into the ICU from ED after complete stabilization or from OR, the nurse taking charge of the patient should collect all the details from the ED or OR nurse. It can be summarized by the pneumonic ISBAR:

- *I*: **Identifying details**, that is, name and gender
- *S*: **Situation warranted admission**
  - Mechanism of injury
  - Chief complaints
  - Loss of consciousness if any, and duration
  - GCS score at the time of admission/injury
  - Completed blood tests with the results
  - Diagnostic procedures and treatment carried out
  - Medications administered, especially the opioid analgesics or sedatives
- *B*: **Background details**
  - Significant past medical and surgical history
  - Home medications

- *A*: **Assessment details**
  - Current vitals
  - Current GCS
  - Pupillary assessment
  - Airway and ventilator settings
  - Fluid status: Intake and output
  - Other major findings
  - Family members' level of coping and understanding about the patient's condition and treatment
- *R*: **Recommendation**
  - Plan of care
  - Fluid volume to be administered
    - Recommended blood and blood products (if any)
  - Inotropic agent and medications being infused or advised

Monitoring Patients With Critical Illness

Proactive monitoring on the part of the nurses for early identification and management of complications ensures patient safety and enhances quality of care delivered in critical care unit.

Critical care nurse should monitor the following parameters periodically:

- Vital signs: Pulse, RR, temperature, and blood pressure
- Peripheral pulse and warmth to assess cardiac adequacy
- Verbal pain assessment in patients who can vocalize and nonverbal pain assessment in those who cannot speak
- Continuous ECG monitoring and oxygen saturation (SpO_2)
- Hourly intake and output chart
- GCS and pupillary response
- Mini-Mental Status Examination
- Muscle power and reflexes
- Hemodynamic parameters
- Monitor the following ventilator parameters
  - The mode of ventilation, set parameters such as tidal volume, FiO_2, pressure support, RR, PEEP, I:E ratio, minute ventilation, peak airway pressure, sensitivity triggers, and alarm settings.
  - Check that appropriate alarm setting are kept.
  - Check the humidifier is not filled with condensed water vapor.
  - Ensure the lip level is marked on the chart at the time of intubation and monitored frequently to ascertain that the ET tube has not slide down beyond carina
  - Check the cuff pressure
- Check for bilateral air entry through chest movements and auscultations.
- ABG analysis
- Nutritional status of the patient and nutritional need
- Communication status of patient
- Psychological issues of patient such as anxiety, depression, and fear
- Pressure ulcer risk using risk assessment scales such as Braden scale
- Second-hourly skin checks over the bony prominences to prevent pressure ulcer development
- Assess frequently for the hygienic needs, presence of soiled linen,

Hemodynamic Monitoring

Continuous arterial pressure monitoring, central venous pressure, and pulmonary artery pressure monitoring play a vital role in appropriate management of patient. See Table 63-3 for the clinical significance and normal values of the hemodynamic parameters.

Parts of Hemodynamic Monitoring System

- An invasive catheter and high-pressure tubing that connect the patient to the transducer
- The transducer that converts the physiological signal from the patient into electrical signals
- The flushing system that maintains the patency of the fluid-filled tubing and catheter
- A bedside monitor that receives electrical energy from the transducer and displays it in waveform and in digital scale

Nursing Alerts in Hemodynamic Monitoring

- Calibrate the equipment periodically for accurate hemodynamic measurements at the start of every shift.
- Maintain the phlebostatic axis for accurate measurement. It means that the transducer is kept at a height that corresponds to the left atrial level.

TABLE 63-3 Clinical Significance of Various Hemodynamic Parameters

Hemodynamic Parameter	Significance	Normal Values
Mean arterial pressure (MAP)	Average blood pressure created in the cardiac cycle	70 to 100 mmHg
Central venous pressure (CVP)	Pressure in the central vein and it is equal to the pressure in the right atrium that indicates circulating fluid volume. High value indicates circulatory overload	2 to 5 mmHg or 3 to 8 cm H_2O
• Pulmonary artery (PA) pressure—blood pressure exerted in pulmonary artery using the indwelling catheter • Pulmonary capillary wedge pressure (PCWP)—pressure exerted in the left side of the heart when the pulmonary arteriole is occluded using an inflated balloon present in pulmonary artery wedge port	• Increased pulmonary artery pressure shows that the pulmonary vasculature is narrowed, leading to increased resistance • Pulmonary hypertension can lead to heart failure and increase the workload of the heart • Nursing alert while checking PCWP • Deflate the balloon as soon as PCWP is recorded. Avoid inflating the balloon often	• PA systolic pressure: 20 to 30 mmHg • PA diastolic pressure: 5 to 10 mmHg • PCWP: 5 to 12 mmHg
Left atrial (LA) pressure	Pressure created by volume of blood present in left atrium when the mitral valve opens. If it increases, the ejection fraction reduces. Commonly measured in post–mitral/aortic valve surgery	5 to 12 mmHg

- Monitor the hemodynamic parameters and record them.
- Compare the hemodynamic waveforms and hemodynamic parameters with other clinical parameters.
- Maintain the appropriate hand hygiene while handling the monitoring system and maintain the closed system all times.
- Maintain the flushing system and the hemodynamic monitoring system and the intravascular catheter free of air or clot.
- Monitor the peripheral pulse, peripheral warmth, and capillary refill distal to the catheter insertion site.
- Maintain sterility of port while handling it for flushing, taking samples for ABG, etc., by cleaning it with alcohol swab and by taking samples aseptically. After taking samples or handling the port, wrap it with a sterile towel.
- Perform sterile dressing changes to the catheter insertion site.
- Inspect the catheter insertion area for signs of infection such as redness, induration, warmth at the site, and fever.
- Prevent air embolism by purging out the air bubbles. Let out the air bubbles from the whole flush solution and system before connecting it.
- Maintain the transducer without getting damped to maintain accurate recording.
- Do not introduce dextrose-containing solution into the monitoring system.

Management of Critically Ill Patients

Critically ill patients often present with impairment in ventilation, oxygenation, and circulation irrespective of the pathophysiological sequence. They may have single-organ or multiorgan dysfunction that needs to be managed simultaneously. Whatever may be the system involvement, they may require intubation and mechanical ventilator support. See Chapter 11 for further details on mechanical ventilation They may also face circulatory collapse. Because of primary brain pathology or secondary to circulatory or respiratory failure, the patient may have loss of consciousness. For the purpose of continuous BP monitoring and to draw samples for ABG analysis, an arterial line may be inserted. Peripheral and central venous access may be established to administer medications and to monitor circulatory status. Urinary catheterization is done to monitor the urine output. The patient may be connected to a continuous ECG monitor.

Nursing Diagnoses

Based on the patient assessment described above the commonly encountered nursing diagnoses in a critically ill patient are as follows:

- Ineffective airway clearance related to diminished gag reflex and/or excessive secretion as evidenced by visible or audible secretion, increased RR, increased airway pressure alarm in ventilated patients, and restlessness
- Impaired gas exchange related to ventilation–perfusion mismatch as evidenced by cyanosis in the oral mucosa, lips, SpO_2 <93%, hypoxemia, hypercapnia, decreased mentation, restlessness, and abnormal RR and rhythm
- Decreased cardiac output–related decreased fluid volume or poor contractility of heart and/or dysrhythmia as evidenced by hypotension, increased or decreased heart rate, feeble peripheral pulse and cool extremities, and urine output <30 mL/h or <0.5 mL/kg/h
- Impaired cerebral tissue perfusion related to increased intracranial pressure (ICP) or CNS depression/CNS infection as evidenced by changes in the level of consciousness, bradycardia, changes in rate and pattern of respiration, changes in the pupillary reflex and size, and shape of pupils
- Self-care deficit (global) related to critical illness and loss of consciousness
- Anxiety related to threat to life and fear of death
- Pain related to tissue damage
- Impaired physical mobility related to changes in the level of consciousness or poor cardiac reserve or increased work of breathing and fatigue or trauma
- Impaired verbal communication related to presence of artificial airway
- Sensory perceptual disturbances related to noisy gadgets, ICU environment, etc.
- Risk for infection related to presence of invasive lines and physiological stress
- Risk for fall related to changes in the level of consciousness.

Airway Management

To maintain patent airways, the following nursing interventions have to be followed:

- Place an oropharyngeal airway to prevent tongue falling back/to prevent biting the ET tube.
- Elevate the head end of the bed 30° to 40° to prevent aspiration of gastric content and gastric reflux.
- If oral secretions are more, apply suctioning using a Yankauer suction tip.
- If the patient is intubated and on ventilator, perform gentle ET suctioning. While introducing, do not apply suction as the suction tip is withdrawn. Apply suction and rotate the tube 360° and complete suction. The duration of suction should be limited to 15 seconds.
- At the end of ET suctioning, oropharyngeal suctioning can be done.
- If secretion is thick, provide nebulization therapy.
- If the patient is on ET tube, mark the lip level and record it and maintain the same to identify and prevent the descent of ET beyond carina.
- Auscultate the breath sounds.
- Provide chest physiotherapy to loosen the secretion.

Gas Exchange and Ventilator Management

- Assess the mode and ventilator parameters, the ventilator connections, and circuits.
- Place the patient in low Fowler's position.
- Monitor that the patient is delivered set tidal volume and pressure.
- Monitor the positive end-expiratory pressure (PEEP).
- Monitor the ABG, SpO_2, and bilateral air entry.
- Set the alarms at the appropriate level.
- Before silencing the alarm, check the reason for alarms and manage appropriately.
- Ensure that the set tidal volume is delivered by inflating the cuff with appropriate pressure (20 to 25 mmHg) using minimal leak or minimal occlusive volume technique so as to prevent air leak or aspiration of pooled secretion.
- As and when required (high airway pressure alarm, patient fighting with ventilator, audible or visible secretion, decrease in SpO_2), perform gentle ET suctioning to keep the airway patent.
- Administer nebulizer as per prescription.

Maintaining Adequate Cardiac Output/ Fluid Management

- Monitor the blood pressure continuously using invasive or noninvasive technique.
- Establish venous access either central or peripheral, and administer normal saline at the prescribed rate.
- Replace electrolytes lost through infusion of IV fluids.
- If there is a blood loss, arrange and transfuse compatible blood.
- In case hypovolemia is not the cause for the decreased cardiac output, do not rush the IV fluids; it may be counterproductive. In such a case, inotropic agent and correction of dysrhythmia are useful.
- Administer inotropic agents such as inj. dopamine, dobutamine, or adrenaline or noradrenaline as per the prescribed dose.
- Monitor the CVP pressure, and check peripheral pulse, peripheral warmth, and urine output hourly.
- Maintain optimum fluid volume.
- Monitor strict intake–output chart. The urine output of 1 mL/kg/h is considered normal. Urine output <0.5 mL/kg/h is critical low.
- If the patient had ACS or dysrhythmia, appropriate prescribed drug therapy may be administered.

Maintenance of Cerebral Tissue Perfusion

- Elevate the head end of the patient at 30° to improve venous return from the head.
- Maintain the head, neck, and body in normal alignment to facilitate venous return.
- Monitor neurological status, vital signs, SpO_2, pupillary signs, and reflexes.
- Maintain patent airway by oropharyngeal or ET suctioning (as indicated).
- Administer the prescribed supplemental oxygen so as to have SpO_2 >95% and avoid hypercapnia that will dilate the cerebral blood vessels and increase ICP.
- Reduce the high-volume alarm sounds so that excessive stimulation is avoided.
- Maintain the blood pressure within normal limit so that appropriate cerebral perfusion pressure is maintained.
- Maintain normothermia. If the patient has hyperthermia, initiate aggressive hypothermia measures to bring back the temperature to normal level as hyperthermia will further aggravate the ICP.
- Administer prescribed anticonvulsants and anti-inflammatory or diuretic agents in case increased intracranial signs and symptoms are present.

Maintenance of Physical Mobility and Prevention of Deep Vein Thrombosis/Pressure Sore

- The patient may be kept on absolute bed rest if the condition warrants such as ACS.
- Encourage bed mobility as much as possible.
- In unconscious patients, provide passive exercise and every second hourly, change the position.
- Apply thromboembolic stockings.
- Observe the skin color over all the bony prominences every second hour at the time of position change. Be alert to identify stage 1 pressure ulcer through purple discoloration.
- Improve comfort in bed.

Pain Management in Critically Ill

Effective pain management in the critically ill not only reduces the length of ICU stay but also improves the quality of care and patient satisfaction. Poorly managed pain during ICU stay leaves fearful experiences for days or even months after ICU discharge. Optimal pain management in critically ill patients is a collaborative responsibility of all members of the critical care team. Prompt assessment, timely intervention, and documentation of the intervention are the keys for successful pain management.

Critically ill patients experience pain during rest, routine ICU procedures, and special procedures (Barr, Fraser, Puntillo, et al., 2013). Verbal self-report of pain is a reliable and easy way of assessing pain. Pain assessment is challenging as critically ill patients are most often on ventilator assistance and unable to communicate. Based on the survey done by Rose et al. (2012), it was clear that majority of nurses did not assess pain among patients who could not communicate verbally, whereas 89% of the nurses were comfortable assessing the verbal pain report of patients. The survey further reports that only fewer nurses were aware of the professional society practice guidelines regarding pain assessment and management.

Society for critical care medicine clinical practice guidelines (Barr et al., 2013) recommend that pain be monitored routinely among all critically ill patients. There are many pain assessment tools available for use in critically ill adult patients such as Adult Nonverbal Pain Scale, Pain Behavior Assessment Tool developed by Punitillo, Behavioral Pain Rating Scale (Payen, Bru, Bosson, et al., 2001), and Critical Care Pain Observation Tool. Critical Care Pain Observation Tool and Behavioral Pain Rating Scale were found to be valid tools for pain assessment in patients who cannot verbally report their pain (Barr, Fraser, Puntillo, et al., 2013) (Arif, Joseph, Grap, et al., 2014). In the Behavioral Pain Scale, facial expression, upper limb movement, and compliance with ventilator are the three areas assessed. The least score is 1 in each area, maximum is 4, and the total score is 3 to 12. Minimum score is 3, which indicates no pain, and maximum score is 12. Scores of 6 and above need an analgesic.

The choice of analgesics varies according to the pain intensity and the intended procedure. The opioid analgesics, namely, fentanyl, morphine, hydromorphone, methadone, and remifentanil, may be used alone or in conjunction with nonopioid analgesics. Pain has to be effectively managed in minor procedures by preemptive analgesics along with nonpharmacological interventions. In mechanically ventilated patients, light sedation, that is, sedation level at which the patient is kept in an arousable state and able to follow simple commands, is recommended. Light sedation among mechanically ventilated patients has been shown to reduce the duration of mechanical ventilation and length of stay in ICU. In patients on mechanical ventilator, benzodiazepine sedatives such as propofol or dexmedetomidine are preferred over benzodiazepine sedatives, namely, midazolam and lorazepam (Barr et al., 2013).

Nonopioid analgesics such as ketamine (IV), acetaminophen/paracetamol (IV/per oral), ketorolac (IV/IM), and ibuprofen (IV/per oral) may be given to reduce the dose of opioid analgesics. To manage pain arising from neurological ailments, opioids along with gabapentin or carbamazepine may be prescribed.

Nutritional Management of Critically Ill Patients

In critically ill patients, the stress response and infections place the patient's nutrition in jeopardy. Prompt nutritional assessment and early management of nutritional needs of critically ill patients in combating the inflammatory response associated with catabolic state are essential for a better outcome. Traditionally, nutritional support is deemed as a

measure of supply of exogenous fuel for the patients. Now it can be considered as an adjunct therapy aimed at mitigating the devastating effect of metabolic and inflammatory response associated with critical ailments (McClave, Taylor, Martindale, et al., 2016). To prevent loss of excessive lean body mass and to limit the oxidative stress, more than 1 g/kg body weight of protein is needed (Preiser, Van Zanten, Berger, et al., 2015).

Nutritional assessment should be carried out based on the disease severity, previous nutritional intake, comorbidity, and functional status of GI tract. Critical care nurses play a pivotal role in meeting the nutritional needs by collaborating with other members of the team. Nutritional assessment should be based on the previous food intake, severity of the underlying illness, comorbidities, and the functional status of the GI tract. The evidence-based current guidelines of Society for Critical Care Medicine and American Society for Parenteral and Enteral Nutrition recommend the following (McClave et al., 2016):

- Enteral nutrition is preferred over parenteral nutrition and should be initiated as early as 24 to 72 hours following admission or onset of a major critical illness.
- Among patients with hemodynamic instability, after completing the resuscitation, enteral nutrition should be started.
- Regardless of the presence of bowel sounds or passage of flatus or stool, enteral feeding is recommended (McClave et al., 2016).
- In patients with a high risk of aspiration, small bowel feeding is preferred over gastric feedings.
- Continuous enteral feeding is recommended over periodical feeds.
- Whenever the patients are in severe protein–energy malnutrition and enteral feeds are not feasible, parenteral nutrition should be initiated as soon as possible following resuscitation.
- In patients subjected to major GI surgeries for whom enteral feeds are not possible, parenteral nutrition should be initiated.
- The calorie requirement is 25 to 30 kcal/kg/day.
  - The protein requirement is 1.2 to 2.0 g/kg/day.
- Micronutrients and antioxidants are essential to combat infection and to facilitate recovery.
- In obese patients, enteral formulas with less calorie and more protein are recommended.
- In patients with ARDS, specially prepared enteral fluid formulas with very high calorie and with all other micronutrients have to be given in small quantities.

Monitoring Tolerance and Adequacy of Fluid Intake

- On an ongoing basis, nurses need to monitor the adequacy of enteral feeds.
- Monitor the blood glucose levels and maintain between 140 and 180 mg/dL.
- When patients are on parenteral feeds, maintain the flow rate optimally. Too fast administration may lead to hyperglycemia and fluid overload. Similarly, too slow administration of parenteral nutrition may lead to hypoglycemic spells.
- Avoid injecting drugs in the venous access through which the parenteral fluids are administered.
- Ensure that the patients do not aspirate by initiating the monitoring of:
  - Head-end elevation to 30° to 45°
  - Postpyloric feeds
  - Continuous feeds rather than interrupted feeds
  - Prescribed prokinetic drugs such as metolachlor, bromide, and erythromycin, which may be administered in time

Communication in ICU

Communicating With Patients and Their Family Members

Critically ill patients describe impairment in communication as a terrifying experience. Communicating effectively is a significant factor in the assessment of pain and other symptoms and in patients' participation in decision making about treatment in the ICU (Happ, Tuite, Dobbin, et al., 2004). Studies have shown that patient satisfaction and family satisfaction have been shown to be improved with effective communication (Rodriguez, Rowe, Thomas, et al., 2016; Wilson, Haut, & Akintade, 2017).

Barriers in Communicating With Critically Ill Patients

- Impaired cognition
- Patients in delirium
- Sedation
- Altered level of consciousness
- Language barriers
- Educational and cultural variation
- Presence of tracheostomy, or ET tube following head and neck cancer surgery or a stroke or to facilitate mechanical ventilation
- Poor skills of nurses in interpreting nonverbal communication
- Lack of time for nurses to understand nonverbal communication

The American College of Critical Care recommends PCC for improved outcomes in critical care. High-quality nurse–patient interaction is an essential component of PCC (Hobbs, 2009). Based on the PCC model, five domains for effective patient-centered communication were shown to improve the patient and family outcomes (Hobbs, 2009; Slatore, Hansen, Ganzini, et al., 2012). They are as follows:

- *Biopsychosocial perspective*: There should be information exchange and effective and accurate risk communication.
- *Patient as person*: Listen to the patient's worries and concerns, and encourage questions.
- *Shared decision making*: Patients or their surrogates and the clinician have shared responsibility for improved patient outcome.
- *Therapeutic alliance*: Clinician knows the patient's desires and the patient understands care plan.
- *Provider as person*: Know limitations of knowledge and appropriate involvement of other clinicians.

The patient-centered communication is the central component that connects all the five domains identified that ultimately lead to improved patient satisfaction and family satisfaction with care, decreased anxiety and depression, and improved decision making.

Innovative and effective communication techniques are needed for speechless patients.

Methods of Communication by Patients With Problems in Verbal Communication

- Head nods, gestures, and mouthing words
- Paper and pencil writing
- Pictorial communication boards
- Electronic voice output communication aids or a prerecorded human voice aid
- Digitalized computer-generated voice message
- Cuffless fenestrated tracheostomy tubes and Speak-EZ tracheal and talking tracheostomy tube (Morris, Bedon, Mclntosh, et al., 2015)

Chart 63-1 NURSING RESEARCH PROFILE

Innovative Communication Intervention for Speechless Critically Ill Patients

Background: Sudden speechlessness is common in critically ill patients who are intubated or have had surgery for head and neck cancer. Sudden inability to speak poses challenges for hospitalized patients because strategies to facilitate communication are often limited and unreliable.

Objective: The aim is to determine the impact of a technology-based communication intervention on patients' perception of communication difficulty, satisfaction with communication methods, and frustration with communication.

Methods: A quasi experimental, four-cohort (control and intervention) repeated-measures design was used. Data were collected daily for up to 10 days. Patients in adult critical care units were followed up as they were transferred to other units within the institutions selected for the study. The impact of a technology-based communication system (intervention) was compared with that of usual care (control). Patients' communication outcomes pertinent to communication with nursing staff that were evaluated included perception of communication ease, satisfaction with methods used for communication, and frustration with communication.

Results: Compared with participants in the control group, participants in the intervention group reported lower mean frustration levels (−2.68; SE, 0.17; 95% CI, −3.02 to −2.34; $P < 0.001$) and higher mean satisfaction levels (0.59; SE, 0.16; 95% CI, 0.27 to 0.91; $P < 0.001$) with use of the communication intervention. Participants in the intervention group reported a consistent increase in perception of communication ease during the hospital stay.

Conclusions: The results facilitated evaluation of a bedside technology-based communication intervention tailored to the needs of suddenly speechless critically ill patients.

Source: Rodriguez, C. S., Rowe, M., Thomas, L., Shuster, J., Koeppel, B., Cairns, P. (2016). Enhancing the communication of suddenly speechless Critical Care Patients: American Journal of Critical Care, 25(3), 40–47.

A study by Rodriguez et al. (2016) tested and demonstrated the effectiveness of personal tablet computer using a communication software. It was reported that those who used the communication software found less difficulty in communication, less frustration in communication, and a higher mean satisfaction level with their communication method (see Chart 63-1).

Communicating With Other Healthcare Team Members

Critical care is essentially collaborative including communication. Effective flow of communication within the critical care team is imperative for safe and quality care. Timely, accurate, and clear communication is necessary. Apker et al. (2006) recommend **4Cs** for nurses for health team communication. They are as follows:

- *Collaboration*: Collaborate with other team members and participate in patient care decisions.
- *Coordination*: Coordinate with other team members, assign responsibilities, mentor junior nurses and interns, and encourage their inputs.
- *Compassion*: Demonstrate consideration and compassion for other team members.
- *Credibility*: Communicate assertively and clearly.

Tips for Nurse Communication for Safe Care

- Handoff practices should follow some systems such as ISBAR (I, identify; S, situation; B, background; A, assessment; R, recommendations) or RSVP (R, reason; S, story; V, vital parameters; P, plan of care).
- While communicating to physicians, gather all relevant information, changes in the parameters, trends of vital signs, ECG changes, pressure value trends, abnormal lab results, and pertinent history and present them.
- Sensitive information and crucial results should be double checked and clearly communicated, emphasizing the need for immediate attention.
- Double check orders in doubt before carrying them out.
- Correct identification of the patient using name and register number before reporting or recording can prevent errors in care.

Meeting Needs of Family Members of Critically Ill Patients

Having a family member in critical illness is stress provoking. They are overwhelmed with emotions and inability to understand the clinical condition and outcomes often makes them feel incompetent to make healthcare decisions on behalf of the patient. They experience hopelessness, anxiety, and depression. Studies have shown that the family member's posttraumatic stress scores were high among those who felt that the information provided to them was incomplete (McAdam & Puntillo, 2009). Family members of critically ill patients consistently identify the need for information and reassurance as the highest-priority needs during an ICU hospitalization, yet the need for information is often unmet. Schnock et al. (2017) have identified that the family members lack coordinated, consistent, and complete information from the critical care team members while their loved ones were managed in the critical care units. They recommended standard information through a digital learning portal on three basic aspects, namely, the ICU arrival, ICU care, and transition from ICU.

Family Needs

- Communication that maintains hope
- Questions to be answered honestly
- Accurate and consistent information about the patient's condition, possible treatment alternatives, and prognosis
- Timely notifications regarding the changes in the patient's condition
- Visits and time to spend with their loved ones
- Empathetic comfort care

ICU family meetings are associated with beneficial outcomes for patients, patients' families, and healthcare system. Family meetings have to be conducted at the earliest possible and whenever there is change in health status of patients and whenever the need arises to change the course of treatment (see Fig. 63-7). For effective family communication, the following are necessary:

- There should be consensus between the multidisciplinary team.
- Allow open-ended questions from the family members.
- Patiently listen the family members' concerns and questions.

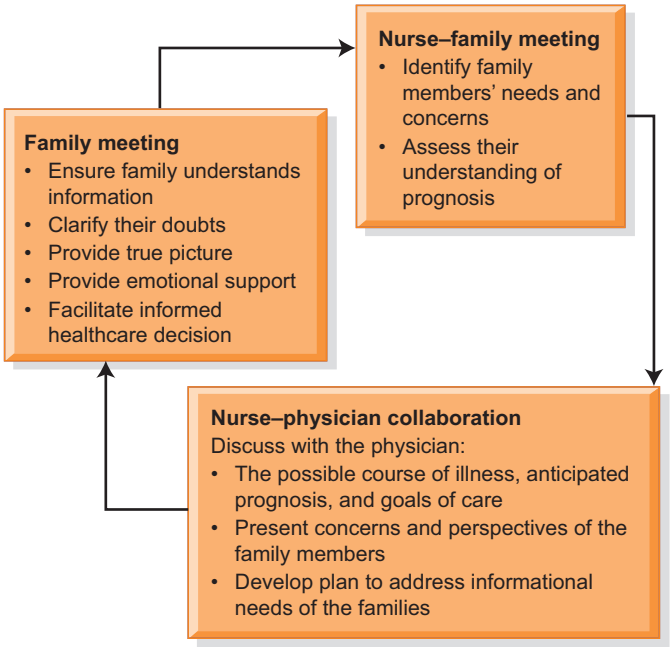

Figure 63-7 • Critical care nurses' role in communication with family members of patient in ICU. Adopted from Milic, Puntillo, Turner, et al., (2015). Communicating with Patients' Families and Physicians about Prognosis and Goals of Care. American Journal of Critical Care, 24(4).

- Reflect the questions to dispel any misconception.
- Understand others' perspectives.
- Show empathy to the expressions.
- Clearly and accurately answer their queries.
- Ensure that family members understand it in the right perspective.
- Show respect and support them throughout the meeting.
- Uphold honesty in communication with the patient as well as other team members.

Transitional Care From ICU

Transitional care includes a set of activities that ensure continuity of care with proper coordination while the patient is transferred between two different levels of care in the same health care setting or different locations (WHO, 2016). The transition from ICU to general medical surgical wards involves a lot of risk as the patients are just out of critical illness and may have still fluctuations in the health status. Transitional care quality is considered as one of the indices that reflects the overall quality of care delivered by the hospital (Hervé, Zucatti, & Lima, 2020).

Inadequate transitional care can lead to lot of serious adverse events such as medication errors, falls, duplication of care or omission of care, deterioration in the clinical status, readmissions to ICU, and cardiac arrest. Eventually it will result in poor patient and family satisfaction. For effective transitional care from ICU, discharge needs to be well planned and comprehensive. A scoping systematic review (Hervé et al., 2020) has shown that poor discharge planning such as discharge at night or weekends is associated with negative outcomes, whereas delayed ICU discharge is associated with the incidence of delirium. Well-planned consensus transfer protocols from ICU, ensuring the availability of logistic arrangements and resources at the transfer destination, are very important for safe transitional care. Patient assessment for discharge readiness from ICU, proper discharge planning, appropriate discharge execution, and postdischarge follow-up are the components of transitional care from ICU.

The holistic structured communication is one of the pillars of effective transitional care. Transfer checklist and structured communication can ensure effective transfer of vital patient clinical information. Medication reconciliation, stabilizing vital signs and reducing the need for ICU care, and discharge to intermediary care unit or step-down ICU are some of the factors that have a positive impact on transitional care (Hervé et al., 2020). Patients and family members need to be reassured when transferring the patient from ICU and educated about their role in the provision of safe-care.

Breaking Bad News

Any news or information about the patient that evokes negative emotions should be considered as bad. It may vary based on the circumstances. Usually, death or information on dying is considered as bad news (Collini, Parker, & Oliver, 2021). Informing the bad news to the patient's family is quite challenging to the health care providers. Death of the patients or futile care is many a time devastating to health team members and they may get burnt out. Additional training is needed to handle people in crisis.

On hearing the bad news, most of the time the relatives may be stunned, or may show disbelief, anger, and grief. Individual patients and their family may prefer to receive the bad news differently based on their cultural beliefs and other personal preferences (Joszt, 2020). Some common principles need to be observed while delivering the bad information. The health care provider needs to ensure privacy and a comforting environment. As much as possible, the health care professional needs to be honest and give accurate information, show empathy, and provide time to accept the bad news. Distressing information needs to be divulged in a systematic manner so that the patient and relatives will get satisfied.

Frameworks for Breaking Bad News

For breaking the bad news, the health care professionals need to develop their skill in interpersonal communication. Role play–based training is shown to improve the confidence level in dealing with such situations for emergency room personnel (Collini et al., 2021).

There are different models proposed and employed. The SPIKES model proposed initially for the use of oncology department by Baile, Buckman, Lenzi, et al. (2000) has been widely used in critical care also. It consists of six steps. In India, as per the legal frameworks, only the doctors are empowered to break the bad news. The first stage is setting up the stage for interview. It includes the preparation of a calm, private environment. The health care personnel who is designated to break the news is also expected to be calm and composed. The second step is perception assessment. It can be done through asking open-ended questions about what the family know about the patient's condition. The third step is obtaining patients'/relatives' invitation to talk about the issues. After ascertaining that they are ready, the fourth step is knowledge and information sharing about the patient. Brief and clear information will be helpful to solve the purpose. The fifth step is emotional support and empathetic communication. After pronouncing the death or bad prognosis of the patient, the family members may break down. They may be in disbelief or be hostile or grief struck. Give them time to allow them to express their feelings

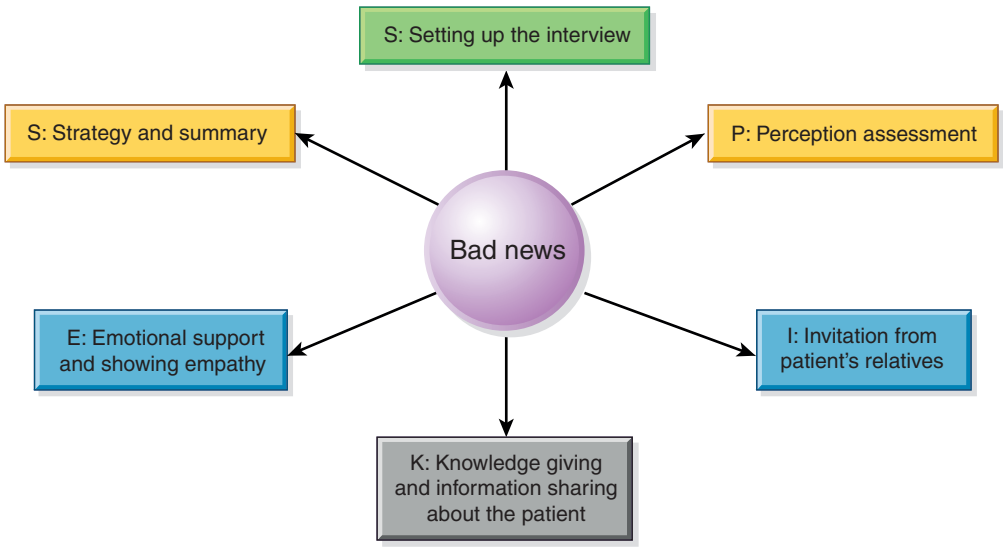

Figure 63-8 • SPIKES model of breaking bad news.

empathetically. The last step is strategy and summary. The relatives may have a lot of questions. Clarify all their doubts and support the family members and summarize the meeting proceedings. Throughout the interview, the nonverbal cues and verbal cues of the health team member need to be reassuring and supportive to the family members so as to enable them to accept and adopt the crisis situation. Figure 63-8 depicts the SPIKES model of breaking bad news.

Ethical and Legal Issues in Critical Care Nursing

Critical care unit is the most expensive unit in the hospital budget and availability of critical cervices is uneven. In many countries, the availability of critical care bed number is <1 per 1,000 beds (Datta, Chaturvedi, Rudra, et al., 2013). Technological advancement available in ICU symbolizes promise and hope from death, but, at the same time, it is viewed as an arena that imposes endless suffering for the human being. Technological advancement helps clinicians to deal with challenging situations effectively but along with that brings a lot of ethical and legal issues. Nurses, being the most inevitable member of the critical care team, play an important role in resolving ethical dilemma. They need to play their role prudently to avoid the legal hinges.

Fundamental Ethical Principles

- **Beneficence:** Nurses have an obligation to render the most appropriate interventions that will facilitate recovery for the patient
- **Nonmaleficence:** Refraining from anything that may injure or cause harm/unfavorable situations for the patients
- **Autonomy:** Respecting the patient's right to determine the course of treatment and care at ICU
- **Justice:** Fair allocation of scarce resources

Nurses who follow the Good Samaritan law, that is, doing everything for the good of the people whom they serve, still may encounter a lot of challenging situations and dilemma. Certain conditions such as persistent vegetative states and brain death where the hope for survival is almost nil, do not resuscitate (DNR) order, euthanasia, or withdrawal of life-sustaining interventions are examples of such ethically and legally challenging situations. As per the principle of autonomy, the patient's right to refuse treatment is supposed to be respected, but from the beneficence point of view, nurses have to carry out the possible interventions to prolong the life. The nurse caring in this situation may feel the dilemma. Fair allocation of resources when the ICU beds are limited also may present as an ethical dilemma.

Common Ethical and Legal Challenges

- **DNR order:** Allowing the person to die without initiating active resuscitation presents a lot of stress and dilemma to critical care team members. In the United States, 85% of deaths happen without initiating resuscitation and nearly 90% of patients had withdrawal of life-sustaining interventions, whereas in India, 78% of patients had full resuscitation instituted and only 1.6% had no active resuscitation (Datta et al., 2013). If the patient has expressed in a written document his or her healthcare choice in the event of a critical illness, which is called advance directive, or verbally passed on a message to his or her surrogate, then the DNR is accepted. In the Indian context, it is still not a legally valid practice.
- **Withdrawal of life support:** It is the cessation and removal of an ongoing medical therapy such as withdrawal of dialysis for a patient with renal failure or ventilator support to a patient with acute respiratory failure with an intent of allowing the patient to embrace natural death due to underlying illness.
- **Euthanasia:** It is an intentional killing of a person whose life is perceived to be not worth living by an act of commission or omission, that is, an intentional killing of a patient by the direct intervention of a doctor, ostensibly for the good of the patient or others (Mani, Amin, Chawla, et al., 2012). The active euthanasia is an act of commission when termination of life is done at the patient's request. It is otherwise known as physician-assisted suicide. In most of the Western countries, it is legally permitted based on the advance directive or living will or a consensus decision taken by the patient's surrogate empowered to take healthcare decisions on behalf of the patient and the treating team.

Nurses' Role in Resolving Ethical Dilemma

- As a team member, critical care nurses are not solely responsible for the end-of-life decisions in ICU. The critical care nurse may take initiative for the clear communication of the possible course of illness, the prognosis, etc., with the family members.
- He or she arranges for a consultation with the treating physician who is legally empowered to divulge the information such as the poor prognosis of the underlying condition.
- Nurse assists families to weigh the burdens and benefits of medical interventions and provides them with a framework of the patient's preferences and interests.
- Nurses provide comfort care and symptomatic relief to those patients whose surrogates or the patient himself or herself makes decision for the withdrawal of life support.
- They arrange for psychologist consultation to cope up with a situation.
- They provide moral and empathetic emotional support to the family members.

Commonly Encountered Legal Issues

- **Negligence:** It is an unintentional act of commission or omission of a nurse that is falling short of the expected standard that has resulted in injury or fatal outcome in the patient. It can be a medication error, failure to recognize a serious complication, failure to intervene promptly to avoid complications, failure to communicate a salient assessment finding or critical lab parameter to the treating physician, failure to initiate fall prevention measure that has resulted in patient falling, or loss of vision due to lack of eye care in unconscious patients.
- **Malpractice or felony:** A serious intentional act of crime is considered as malpractice such as knowingly administering a harmful drug.
- **Deformation:** Revealing highly sensitive personal information such as details of diagnosis and clinical condition without the concurrence of the patient to others that may be claimed to damage the public image or reputation of the individual. Discussing in public or with people other than the patient or his or her health surrogate is ethically an unacceptable act.

Legal Issues: Indian Perspective

The common law binding the nurses in ICU is the Consumer Protection Act (1986). The Consumer Protection Act was passed in the Parliament of India and made a law to protect the best interests of the patient who as per this law is considered as the consumer of health. The practice of nursing is also brought under the ambit of this law. Earlier, only the hospitals and treating physicians were legally accountable for what happened to a patient and nurses were having only vicarious liability. Now, nurses also are responsible for any errors committed by them. Nurses face crime charges when they fall short of the standards of care. Few examples are given as follows: (Hemant Kumar, Gokhale, Jain, 2013):

- Medication error caused by a nurse at Spring Meadows Hospital in 1993 resulted in permanent brain damage and the nurse was punished for her below-standard care.
- Nurse was held responsible for the administration of a mismatched blood transfusion that caused death in KC General Hospital, Bengaluru.

Other laws governing nursing practice are Human Organ Transplant Act, 1994, and Right to Information (RTI) Act, 2005.

In *Aruna Shanbaug vs Union Government of India*, a case was filed in the Supreme Court on March 7, 2011, for granting an order for euthanasia of a lady who was in persistent vegetative state for 37 years. In this landmark case, certain progresses have been made. The court of law shall consider the passive euthanasia or withdrawing life support based on the plea of the legal surrogate of the patient and the expert committee's report consisting of a neurologist, a psychiatrist, and a physician. Before this case, withdrawing life support was considered as a crime on the part of the treating doctors and hospital authorities.

Responsibilities of Nurse in Avoiding Legal Issues

- Critical care nurses need to continuously update their knowledge and competency to match the rapidly expanding medical knowledge base. Lack of updating may lead to medication errors and failure to monitor and implement nursing care.
- Accurately monitoring and documenting the parameters as well as the care provided will save the nusres from litigation.
- Informing all relevant people about the patient's condition not only paves way for quality care but also provides legal protection.
- Maintain the prescribed standards of care to the patients.
- Develop trusting and healthy relationship at the workplace.
- System approach to prevent errors has been effective and enhances accountability and direction for each member of the healthcare team in the ICU.

Nurses' Role in Identification and Management of Inpatient Arrest

Tackling cardiac arrest event through prompt identification and effective resuscitation is part of day-to-day affair in the critical care units as well as in ER. The code blue teams are organized with competent trained health manpower for successful resuscitation. Once the cardiac arrest is identified, code blue team is called for to salvage the patient through public call system.

Cardiac Arrest

In cardiac arrest, the heart is unable to pump and circulate blood to the body's organs and tissues. It is often caused by a dysrhythmia such as ventricular fibrillation, progressive bradycardia, or asystole (i.e., absence of cardiac electrical activity and heart muscle contraction). Cardiac arrest can also occur when electrical activity is present on the ECG but cardiac contractions are ineffective, a condition called **pulseless electrical activity (PEA)**. PEA may be caused by a variety of problems such as profound hypovolemia (e.g., hemorrhage). Diagnoses that are associated with cardiac arrest include MI, massive pulmonary emboli, hyperkalemia, hypothermia, severe hypoxia, and medication overdose. Rapid identification of these problems and prompt intervention can restore circulation in some patients. Although survival after cardiac arrests that occur in the hospital is reported to be approximately 22%, survival is more likely when current AHA guidelines are followed (Anderson, Nichol, Dai, et al., 2016).

Clinical Manifestations

In cardiac arrest, consciousness, pulse, and blood pressure are lost immediately. Breathing usually ceases, but ineffective respiratory gasping may occur. The pupils of the eyes begin dilating in less than a minute, and seizures may occur. Pallor and

cyanosis are seen in the skin and mucous membranes. The risk of organ damage, including irreversible brain damage, and of death increases with every minute that passes. A patient's age and overall health determine his or her vulnerability to irreversible damage. As soon as possible, the diagnosis of cardiac arrest must be made and action taken immediately to restore circulation.

See Chapter 23 for the detailed steps of basic cardiac life support.

Advanced Cardiovascular Life Support

Additional care may be indicated for patients in cardiac arrest when the spontaneous circulation and breathing are not evident and the team of providers trained in advanced cardiac life support (ACLS) has arrived on the spot. Components of ACLS include placement of an advanced airway, continuous cardiac monitoring, defibrillation and administration of IV drugs along with high-quality CPR. An ACLS team consists of trained and certified ACLS providers who may be a physician, nurse anesthetist, or respiratory therapist; nurses are empowered to perform ACLS. One among the team assumes the role of the leader who will be responsible for quick assessment and clinical decision making. The cardiac rhythm analysis and defibrillation are vital skills needed for the team leader. The roles of other members are assigned by the team leader. A team member who is competent in the insertion of advanced airway such as an ET tube may be assigned to airway management and for artificial respiration and the other one will be assigned to perform cardiac compression. The next member may be assigned to defibrillate as and when ordered by the team leader. The other team member may insert an IV line and administer the emergency drugs such as adrenaline, adenosine, or lignocaine. Depending on the assessment of the patient's condition, the ACLS team uses various algorithms that are treated as pathways to be followed. If an asystole is detected on the monitor, first ensure that the leads are attached to the chest adequately with enough gel. As per the asystole algorithm, CPR is continued. Epinephrine is given while attempts are made to resolve the basic causes such as severe hypovolemia or hypoxia. Additional information on ACLS may be obtained from the website of the American Heart Association – ACLS algorithms (https://acls-algorithms.com/acls-algorithm-overview/). For details of medications used in ACLS, see Table 63-4.

TABLE 63-4 Drugs Used in Critical Care

Name of the Drug	Mechanism of Action	Indication	Side Effects	Nursing Implications
Adenosine	Slows down the cardiac impulse conduction in AV node, interrupts reentry pathway	Supraventricular tachycardia	Light-headedness, numbness, chest pain, sweating, palpitation, hypotension, nausea, vomiting, increased respiratory rate	Monitor vitals and ECG. Discontinue the drug if there is increase in pulse, respiration
Atropine	Anticholinergic, parasympatholytic, antiarrhythmic	In bradyarrhythmia, organophosphorus poisoning, premedication in surgical patients	Headache, dizziness, confusion, tachycardia, insomnia, dryness of mouth, GI spasm, blurred vision, urinary retention, PVC	I/O chart, ECG monitoring for PVCs, watching for constipation, urinary retention
Aminophylline	Relaxes bronchial smooth muscle, bronchodilation	Bronchial asthma, chronic bronchitis, emphysema	Seizure, tachyarrhythmia, nausea, vomiting	No IM, only slow IV infusion. Monitor I/O chart. If urticaria develops, discontinue the drug
Amiodarone	Antiarrhythmic agent prolongs PR and QT interval, decreases sinus rate and peripheral vascular resistance	Ventricular tachycardia, AF, SVT	Confusion, numbness, headache, dizziness, blurred vision, photophobia	Monitor ECG and electrolyte levels. If confusion, psychosis, and numbness develop, stop the drug
Dopamine	Inotropic agent, increases myocardial contractility, and thereby increases cardiac output. Activates the α and β_1 receptors, and also dopaminergic receptors present in the renal and mesenteric blood vessels. It produces varied dose-related responses At a dose of <3 μg, it produces renal response to increase urine output, and at 3 to 10 μg, it increases cardiac output and BP. Dose more than 10 μg produces vasoconstriction	Shock, hypotension	Palpitation, tachycardia, ectopic beats; wide QRS with extravasation causes tissue necrosis	Monitor vitals, continuous BP monitoring, and ECG monitoring. If BP increases, start tapering the dose. I/O chart Ensure fluid volume adequacy with CVP values before dopamine infusion. Administer in central vein using infusion pump

(*Continued*)

(*Continued*)

Dobutamine	Increases myocardial contractility and cardiac output, β agonist	Heart failure, cardiac surgery	Heartburn, nausea, palpitation, tachycardia, hypertension	Ensure fluid volume adequacy with CVP values and cardiac glycoside before dobutamine infusion. Use central line or a large-bore peripheral IV line using syringe pump. Monitor BP, pulse, ECG, serum electrolytes continuously. With increase in BP, the dose has to be tapered
Furosemide	Potent loop diuretic, enhances excretion of sodium and water	Heart failure, to decrease ICP, to reduce fluid overload in renal failure, hepatic failure	Hypokalemia	K^+ ions are also excreted. Be alert for signs of hypokalemia Monitor urine output
Isoprenaline	A synthetic sympathomimetic amine that is structurally related to epinephrine but acts almost exclusively on beta receptors	Bradycardia, AV nodal block, or refractory torsade de pointes	Angina, flushing, hypertension/ hypotension, pallor, palpitation, paradoxical bradycardia (premature ventricular beats, ventricular arrhythmia) Dizziness, headache, nervousness, restlessness	Monitor heart rate, BP, and ECG
Levetiracetam	It binds to the synaptic vesicle protein namely SV2A and thereby delays the neural conduction across the syapses	Seizure disorder	Somnolence, dizziness, fatigue	Be watchful for allergic reaction such as itching; shortness of breath; wheezing; cough; swelling of face, lips, tongue, or throat; or any other signs. The medicine should be discontinued in case of allergic reaction
Potassium chloride	Replenishes potassium ion in case of hypokalemia	To correct hypokalemia	Highly concentrated solution of K^+ ions. Should be infused slowly. Narrow safety limit can cause hyperkalemia if exceeds the normal limit	Never given as IV bolus, should be given only as infusion slowly. Needs continuous cardiac monitoring and serum K^+ monitoring
Sodium bicarbonate	Hypertonic bicarbonate solution intended to replenish bicarbonate ion in serum	Corrects metabolic acidosis of various causes, lactic acidosis, cardiac arrest	Sodium retention is possible. In patients with congestive heart failure, it should be used with caution	Extravasation can cause tissue necrosis
Lidocaine CV	Antiarrhythmic agent Combines with sodium channel and reduces myocardial excitability and conductivity	Ventricular tachycardia, ventricular fibrillation that occur after cardiac arrest or acute coronary syndrome	Nausea, vomiting	Needs continuous cardiac monitoring Can be given 1 to 1.5 mg/kg two to three times IV
Morphine	Potent narcotic analgesic	Pain relief especially in MI, postoperative analgesia	Respiratory center depression	Monitor for pain relief CNS depression Use with caution in bronchial asthma
Magnesium sulfate	Can reverse refractory VF caused by hypomagnesemia and help to replenish intracellular potassium	Treatment and prevention of hypomagnesemia Prevention and treatment of seizures in severe preeclampsia or eclampsia, pediatric acute nephritis, torsade de pointes, treatment of cardiac arrhythmias (VT/VF) caused by hypomagnesemia	Flushing, hypotension, vasodilation Hypermagnesemia Absence of knee jerk reflex, cardiac arrest, circulatory collapse, CNS depression, complete heart block	Monitor serum magnesium level Slow administration to minimize risk of complications

(*Continued*)

(*Continued*)

Nitroglycerine	Selective coronary vasodilator	Acute myocardial infarction to improve the myocardial perfusion and reduce the chest pain and reduce blood pressure	Produces venous dilatation and may cause hypotension, headache, dizziness	Produces serious drug interaction if the patient is taking sildenafil In case of AMI, it may be given as IV infusion. Monitor the BP and if systolic BP falls below 90 mmHg, it should not be given
Noradrenaline	α-Adrenergic agonist, increases vasoconstriction and thereby increases BP	Hypotension, septic shock, neurogenic shock superior to dopamine	Dizziness, weakness, feeling cold and numbness	Monitor the blood pressure; taper the dose
Vasopressin	Synthetic antidiuretic hormone that increases sodium and water reabsorption in the kidney	Hypotension, acute circulatory failure Bleeding esophageal varices, diabetes insipidus	Slow or uneven heart rate Gasping Swelling Rapid weight gain	Establish baseline data of BP, weight, I&O chart Monitor BP and weight throughout therapy Monitor urine output, specific gravity, and serum osmolality

Defibrillation

Cardiac monitor/defibrillator cables are attached to an electrical source, monitor electrodes are applied to the patient's chest, and the heart rhythm is analyzed. When an automated external defibrillator (AED) is used, the device is turned on, the pads are applied to the patient's chest, and the rhythm is analyzed by the defibrillator to determine whether a shock is indicated. When the ECG shows ventricular fibrillation or ventricular tachycardia, immediate defibrillation is the treatment of choice. The survival time decreases for every minute that defibrillation is delayed. Following defibrillation, high-quality CPR is resumed immediately. Survival after cardiac arrest has been improved by extensive education of health care providers and by the use of AEDs. Nurses need to be alert that none is in contact with the patient or the beds or railing while shock is delivered to the patient

Follow-Up Monitoring and Care

The care provided to the patient following resuscitation is another determinant of survival (Williams et al., 2013). The patient may be transferred to an ICU for close monitoring. Continuous ECG monitoring and frequent blood pressure assessments are essential until hemodynamic stability is established. Factors that precipitated the arrest such as dysrhythmias or electrolyte or metabolic imbalances are identified and treated.

Following resuscitation and return of spontaneous circulation, patients who are comatose may benefit from therapeutic hypothermia protocols. These induce a drop in core body temperature to 32°C to 34°C (89.6°F to 93.2°F) for 12 to 24 hours post resuscitation in order to decrease the cerebral metabolic rate and need for oxygen. Specific protocols have been developed to guide the use of both external cooling and catheter-based cooling methods and reduce associated complications such as shivering (Avery et al., 2015).

Advances in cardiac care, such as new techniques for effective resuscitation and postresuscitation hypothermia, have improved outcomes for patients with potentially lethal cardiac disorders, including those with cardiac arrest. Studies have demonstrated better neurological recovery and overall survival for patients after cardiac arrest, and hope for even better outcomes in the future.

CPR may be stopped when a pulse and blood pressure are detected, respirations are detected, and the patient responds. CPR efforts may also be stopped when rescuers are exhausted or at risk (e.g., a building is at risk of collapsing), or death is considered to be inevitable. If the patient does not respond to therapies given during the arrest, the resuscitation effort may be stopped by the physician or other provider in charge of the resuscitation. Many factors are considered in the decision, such as the initiating dysrhythmia, potential etiology, length of time for initiation of life support, and the patient's response to treatment.

Occupational and Industrial Care

Chapter 64 Management of Patients with Occupational and Industrial Disorders . . . 2087

CHAPTER 64

Management of Patients with Occupational and Industrial Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Define the occupational health and occupational disease.
2. Discuss the importance of health work environment to maintain occupational health.
3. Describe the occupational risk factors causing occupational disease.
4. Explain the nature of various occupational diseases.
5. Identify the measures to prevent and control the occupational diseases among healthcare workers.
6. Explain the global and national strategies for prevention and control of occupational diseases.
7. Elaborate the nurses' role in prevention of occupational and industrial disorders.

GLOSSARY

body mechanics: efficient and coordinated use of body parts while we engage in activities of daily living, preventing undue wear and tear of various joints, muscles, and body parts

ergonomics: the science of refining the design of products to optimize them for human use or rearranging the work environment for efficient use of workplace and machinery for the workers

occupational dermatitis: a form of skin disease for which exposure to any agent present in the work or chemicals could be established as a cause

occupational diseases: any disease contracted primarily as a result of exposure to risk factors arising from work or the work environment

occupational health: as a multidisciplinary activity aimed at protection and promotion of health of workers by preventing and controlling occupational diseases and accidents by eliminating the occupational factors and conditions hazardous to health and safety at work

occupational hygiene: the science of monitoring the work environment for the measurement of occupational hazards and advocating appropriate modification in designing and processing in the industries to make workplace safer

occupational risk factor: any physical, chemical, biological, or other agent that may cause harm to an exposed person in the workplace and is potentially modifiable

occupational safety: preventive measures taken to identify and eliminate the harmful effects of the hazards present in the work processes or work environment

pneumoconiosis: an umbrella term given to a type of occupational lung disease caused by dusts that are breathed in and get deposited deep in the lungs causing damage; usually includes asbestosis, silicosis, and coal workers' pneumoconiosis (CWP), or "black lung disease"

postexposure prophylaxis (PEP): preventive measures taken after accidental exposure of nonintact skin and mucous membrane to body fluids potentially harboring blood-borne pathogens such as HBV, HCV, and HIV

Introduction

Health and well-being of the people living in the country decide the development index of that country. The health of working population plays a vital role in bringing prosperity and development of the nation. Their contribution is directly responsible for improving the economy and the gross domestic product (GDP) of the country. In a developing country like India, health of the working member is much more important to feed the family members and sustain the family. Workers constitute one-third of the world population and are the major contributors of growth and development (Ivanov, 2013).

While the workers are engaged in their work, they get exposed to factors that affect their health and well-being, which leads to absenteeism and loss of workforce, ultimately affecting the productivity. Hence, the World Health Organization (WHO) and the governments of various countries have initiated measures to mitigate the negative effect of work milieu and nature of work on health of the employees. The Government of India also considers it as a basic human right and also integrated occupational health in the National Health Policy 2002.

Historical Perspectives of Global Occupational Health Initiatives

The WHO and the International Labour Organization (ILO) are the two nodal agencies at the global platform responsible for upholding the health and well-being of the working population. In 1950, the Joint Committee of ILO and WHO for occupational health was formed. From then onwards to till date, the efforts of this Joint Committees focus on various issues surrounding workers' health across nations. The ILO conventions held in 1981 and 1985 urged the member countries to draft their national occupational health policies to prevent accidents and injury by minimizing the hazards at workplace. These conventions called for expansion of occupational health services to both public and private sector enterprises. Under occupational health services, emphasis was given to include occupational surveillance of the work environment for harmful elements as well as the workers' health surveillance, provision of occupational hygiene measures, ergonomics at workplace, first aid, and rehabilitation services.

Global declaration of occupational health for all was made in Beijing in 1994 by the WHO (WHO, 1994). It urged member

states to improve occupational health services including accident prevention and psychosocial stress. In 1996, global strategy for occupational health for all was agreed upon by the member countries. Ten priority areas were identified to be strengthened under the ambit of occupational health services. The third priority focused on the lifestyle factors and health promotion at workplace. In 2006 and 2007, global plan of action on workers' health was agreed upon by the WHO collaborating centers atItaly. It urged the need for holistic approach in improving the occupational health and safety by integrating the preventive approach and promotion, along with addressing the social inequalities. Priority areas for action were elucidated with specification of objectives for member nations. The ILO convention held in 2006 also emphasized the need to strengthen the occupational health services in their respective countries.

Occupational Health

Definition

It deals with the promotion of health and prevention and control of work-related injuries and diseases to individuals at their work. The WHO (2001) has defined occupational health as a multidisciplinary activity aimed at protection and promotion of health of workers by preventing and controlling occupational diseases and accidents by eliminating the occupational factors and conditions hazardous to health and safety at work. It also aims at promoting physical, mental, and social well-being of the workers so as to enhance their social and professional work capacity (WHO, 2001).

Occupational health will pave way for the development of individual workers and the enterprises in which they work, thereby contributing to the sustainable development of the community and country.

Stakeholders of Occupational Health

National Governments

As signatories of the WHO 1996 Declaration of Global Strategy for Occupational Health for All, the governments of the countries have a responsibility to ensure implementation of measures to promote occupational health. The legislative measures and occupational health policy should provide for tight control over the use of hazardous material in the work process, and financial sanction for provision of occupational health. Threat to environment and the community also should be tackled by the Ministry of Health. The government initiatives should also focus on the maintenance of green environment and safe processes.

Management of Industries and Enterprises

The management of the factories, whether public or private, needs to take measures to ensure safety at work environment and also to prevent ill effects of occupational exposure to hazardous substances. They have to contribute to promote positive physical, mental, and social well-being of the workers.

Workers/Employees

The employees have to be aware of the possible ill effects of work-related processes and the environment. They have to follow safety norms and create a safe work culture. The workers' role in achieving occupational health cannot be compromised.

Trade Unions

Trade unions should be vigilant to ensure that the necessary occupational health and safety measures are implemented and in case of lapse in safety issues and health measures, they can negotiate with the representatives of the management.

Community

Community members also play a vital role in ensuring safe work environment. A community residing around the factory or industry is invariably affected by the processes and products used in the industry. Hence, maintaining the health of the community depends on the safety at the factories. During the Bhopal gas tragedy in 1984, a lot of people who resided around the Union Carbide factory died. Occupational health promotion indirectly promotes the community health promotion.

Occupational Health Team

The occupational team consists of the following:

- Consultant specialized in occupational medicine
- Occupational or industrial nurse
- Industrial hygienist
- Environmental and safety engineer
- Ergonomist
- Physiotherapist
- Counselor

The members of the team have their unique specified roles to play to ensure occupational health of the working population. The team members work together to prevent occupational diseases, promote health, and rehabilitate in case of any occupational health problems of the workers.

Healthy Workplace

To ensure occupational health, healthy work environment is the prerequisite. Healthy workplace is schematically represented in Figure 64-1. According to the WHO, characteristics of healthy workplace are the following:

- The healthy workplace should be free of physical, chemical, and biological hazards.
- It should be a place where workers and managers collaborate toward mutually acceptable roles, free from conflicts and occupational stress. The work environment should be psychologically and socially favorable so as to make everyone feel energized, positive, and satisfied.

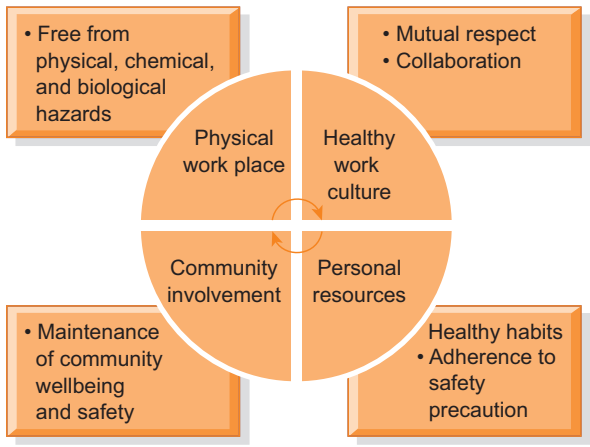

Figure 64-1 • Characteristics of a healthy workplace. Adapted from the WHO model of healthy workplace, 2010.

- The workplace should facilitate healthy lifestyles and enhance personal resources among workers and managers to maintain health and adherence to safety precaution. It may have restrictions for smoking, alcohol, etc.
- A factory or workplace is always surrounded by people. Workplace safety ensures welfare of not only the workers but also the general public residing in that particular community. Involving the community ensures safety for both the workers and the community. There can be health clubs or physical fitness studios in the community. Tree plantation and other measures to ensure safe environment for the community residing closer to the factory are some initiatives to involve community (Burton, 2010).

Occupational Disease

An "occupational disease" is any disease contracted primarily as a result of an exposure to risk factors arising from work activity or the work environment. "Work-related diseases" have multiple causes, where factors in the work environment may play a role, together with other risk factors, in the development of such diseases. Occupational diseases are related to the dose and frequency of exposure to the particular causative factor. Occupational factors in conjunction with nonoccupational or lifestyle factors may increase the chance of occupational disease or worsen the clinical scenario. For example, inhalation of hazardous mineral particles leads to a serious effect when combined with cigarette smoking as the filtration functions of mucociliary apparatus are negated in smokers. So compared with nonsmokers, smokers are more prone to occupational lung mesothelioma (WHO, 2001).

In some conditions, the onset of pathological change may go unnoticed due to long latency period and the patient may be asymptomatic, and in some instances, even after termination of exposure to the hazardous occupational factors, the disease may occur, for example, asbestosis (Cullinn, P., Munoz, X., Agius, et al., 2017).

Most of the time, the occupational diseases are overlooked because the clinical presentation may be very similar to that of general diseases with nonoccupational exposure. For example, bronchial asthma due to certain chemical exposure is no different from other causes.

Occupational diseases are always dose related. Intensity and duration of exposure to hazardous elements in the work processes or work environment decide the nature and severity of illness. For example, occupational hearing loss occurs after many years of exposure to loud noise.

Magnitude of the Problem

Global estimates of occupational diseases and occupational accidents result in over 2.3 million fatalities annually. Approximately 6,300 people die every day because of occupational disease or accident (Nenonen & Saarela, 2014). There are 100 million occupational injuries causing 0.1 million deaths in the world according to the WHO. It is also estimated that in India, 17 million occupational nonfatal injuries (17% of the world) and 45,000 fatal injuries (45% of the total deaths due to occupational injuries in the world) occur each year. Out of 11 million cases of occupational diseases in the world, 1.9 million cases (17%) are contributed by India, and out of 0.7 million deaths in the world, 0.12 million deaths (17%) are contributed by India (National Programme for Control & Treatment of Occupational Diseases, 2014).

Occupational Health Hazards

- *Physical factors*: Heat, light, noise, and radiation
- *Chemical factors*: Industrial dusts, heavy metals such as lead, zinc, iron, benzene, toluene, gases, acids, alkali, and pesticides
- *Biological factors*: Inhalation of live organisms or spores
- *Behavioral factors*: Ergonomics-related factors

Physical Agents Causing Occupational Disease

Extremes of Heat and Cold

- Extreme heat causes vasodilation and later leads to heat stroke and unconsciousness. Traffic policemen patrolling under the hot sun and workers working in high-temperature furnaces become victims of heat stroke. People with concomitant renal or cardiac ailments and elderly are more prone to heat stroke. Welders, foundry workers, and workers in glass factories and steel rolling mills are exposed to extremes of heat. Gradual acclimatization can reduce the acute effect of high temperature.
- Extreme coldness can cause frostbite or death due to vital organ dysfunction. Army men working in Siachen Glacier in Himalayas often lose their foot or life because of extreme hypothermia.

Noise and Vibration

- Continuous exposure to loud noise can result in hearing loss. Our ears cannot withstand sound waves of more than 85 dB intensity. When an individual is exposed to sounds of high intensity for 5–7 years, noise exposure can lead to permanent hearing loss (National Institute of Deafness and Other Communication Disorder, 2017).
- Vibrations associated with jerky movements such as those while drilling and mining can lead to disturbances in hand and wrist functioning and pain.

Radiation

- UV radiation, infrared radiation, and ionizing radiation can cause ill effects.
- Exposure to infrared radiation occurs in men and women working near furnaces in steel mills and glass factories.
- Ionizing radiation arises from atomic power plants. X-rays and radiation therapy units used in medical field also emit ionizing radiation. Health hazards depend on the intensity, exposed area, and length of exposure. A sudden explosion as that happened in the atomic power plant Chernobyl in the USSR in 1986 can lead to death. The small amount of chronic exposure can lead to infertility, skin changes, alopecia, etc.

Light

- Exposure to intense light with UV rays as the light emanating in the process of welding can cause damage to the cornea of the eye, leading to welder's arc. Prolonged exposure for more than 3 hours can cause damage to the cornea (Dahl & Stoppler, 2017).
- Mild to severe pain in the eyes, excessive tearing, redness, and blurring of vision can result from the burns in the cornea. In this condition, bilateral corneal injury occurs.

Ergonomics

- Poor ergonomics can lead to injury.
- Repetitive movements such as those of people involved in data entry operations, blacksmiths, and goldsmiths use the small muscles of the hands, which leads to an inflammation

of the tendon sheath of hands and wrist and leads to carpel tunnel syndrome.
- Lifting excessive weight can lead to injury.
- Eye strain can occur in some occupations.
- High levels of vibration as seen in assembly line movement can cause vibration.

Primary Prevention of Physical Hazards

Noise Control

- Engineering and design changes can be done for noise reduction.
- Shielding can be done around noisy equipment.
- Machines should be kept in a good working condition.
- Silencers should be installed wherever possible.
- Acoustic principles should be applied to contain noise.
- Walls should be soundproof to contain high-intensity noise.
- Exposure to noise should be limited.

Extremes of Heat Control Measures

- To prevent extremes of heat, appropriate clothing can be worn.
- Air conditioning should be installed in the workplace and ventilation should be increased.
- There should be adequate hydration of the workers.
- Shelters and places to rest in between the long working hours should be provided in extremes of temperature.
- To tackle radiation hazard, containment or shielding can be done.
- Employees should be educated about the warning signs of heat stroke and preventive measures.

Radiation/Light Hazard Prevention

- Minimize the number of workers in areas with known risk of radiation.
- The distance between the source and workers should be increased.
- Length and quantum of exposure to radiation should be reduced.
- Shielding the ionizing radiation source will protect people from getting unnecessary exposure.
- Provision of personal protective equipment such as lead jackets and gloves can effectively shield an individual from radiation.
- Welders can be provided with protective goggles while working.

Secondary Prevention

- Early detection of hearing loss and corrective measures
- Identification of heat-induced electrolyte loss and supplementation of electrolytes and water
- Rewarming quickly by infusion of warmed fluids and circulating warm air devices or blankets in case of cold exposure or hypothermia
- In case of processes with radiation hazard, the following measures can be taken:
  - Pre-employment and periodical medical examination
  - Personal monitoring badges
  - Pocket dosimeters and whole-body radiation counters
  - Monitoring radioactivity in the biological fluids
  - Removing a worker from the operations if radiation dose is exceeding the safe limit and monitoring for further effect`

Chemical Hazards Causing Occupational Diseases

- Gaseous agents and vapors: Gases such as methane and nitrogen released from mines and sewages can replace oxygen and cause asphyxiation.
- Carbon monoxide released in coal industry, steel furnaces, and vehicle exhaust fumes can bind with hemoglobin 200 times more rapidly than oxygen (Bluementhal, 2001).
- Hydrocyanic acid used in metal hardening, electroplating, and gold ore extraction may cause death in few minutes with cyanide poisoning.
- Solvents used in various industries can be inhaled and can cause bronchial irritation.
- Metals such as lead, mercury, manganese, and cadmium used in industries produce various undesirable effects.
- Dust and fibers: Respirable minute particles of 2 to 10 μm and thin filaments with length up to 100 μm can be inhaled and reach lungs causing tissue damage or asthma or even lung mesothelioma (WHO, 1999).
- Pesticides and chemical fertilizers can enter the body through the skin, GI tract, and inhalation.

Primary Prevention of Chemical Hazards

- Good housekeeping practices to reduce dust and fibers
- Adequate ventilation and fitting of exhaust fans
- Substitution of harmful chemicals with harmless chemicals
- Automation and mechanization of dusty processes
- Segregation and enclosing the dusty operations
- Provision of appropriate personal protective equipment such as mask
- Education of workers about the need for correct use of personal protective equipment

Biological Hazards

- Vegetables and plant products: Cotton fibers, sugarcane fibers, and flour coming out in the flour mill reach the lung and lead to occupational lung diseases.
- Pollen and tea dust allergy can cause bronchial asthma.
- Animal handlers and veterinarians are at a risk of contracting diseases such as anthrax.
- Healthcare professionals are at a risk of contracting various infections such as HIV, hepatitis B, and hepatitis C.

Primary Prevention

- Machines and dusty areas can be cleaned with cotton or other similar fibers can be cleaned using vacuum cleaners.
- Avoid dry dusting.
- Humidity of the spinning and clothing rooms can be increased.
- Prevent exposures to potential organisms such as anthrax.
- Avoid the dusty areas or pollen or other plant materials.
- Wear N95 masks.
- Wear other personal protective equipment.
- Employees at risk of contracting infection should be vaccinated.

Secondary Prevention

- In case of accidental exposure to organism, postexposure prophylaxis (PEP) needs to be initiated.
- There should be early detection and treatment of conditions such as byssinosis, bagossis, and occupational asthma.

Categories of Common Occupational Health Diseases

Occupational diseases can be grouped as follows based on the nature of health problems and the organs involved:
- Occupational lung diseases
- Occupational dermatoses

- Occupational cancers
- Work-related musculoskeletal disease
- Occupational injuries and accidents

Occupational Lung Diseases

Occupational lung diseases are diseases of the lung primarily occurring due to inhalation of dust particles or fibers that arise in the workplace/factories. They include the occupational asthma, pneumoconiosis arising from silicosis, asbestosis, or coal mine work, bagassosis, byssinosis, etc.

The report of National Programme for Control and Treatment of Occupational Diseases (2014) states that the prevalence of silicosis was highest among slate pencil workers (54.6%), followed by lead and zinc miners (30.4%) and foundry workers (27.2%). In mica miners, silicosis prevalence varies widely between 6.2% and 34%, and in coal miners, it was 9.3%. The report shows a high prevalence of byssinosis among cotton industry workers.

Industrial dust containing aerosol particles of size 1 to 100 μm gets dispersed in the air present in the work environment. Respirable dust with particles of size 2 to 10 μm can reach up to the alveolar region of the lung and get deposited there. Similarly, longer but slender particles or fibers of 2 to 5 μm diameter and with a length of 100 μm can reach deep into the lung, leading to fibrosis, and damage the lung. The dust gains entry into the respiratory system when there is natural air force as in cyclone or with mechanical processes (WHO, 1999).

Types of Dust/Fibers Causing Occupational Lung Diseases

- **Mineral dust:** Silica, coal, and cement dust
- **Metallic dust:** Lead, iron, aluminum, cadmium, nickel, etc.
- **Chemical dust:** Pesticides, chemicals, and paints
- **Biological dust:** Live organism, spores, and mold
- **Agricultural and plant dust:** Flour, wood, cotton, hemp, and tea dusts, pollens, and sugarcane fibers

Industries Associated With Dusty Processes

- Mines—quarrying and tunneling
- Cement industries
- Stone carving and sculpturing
- Building construction and demolition
- Pencil slate industry
- Foundries and other types of metallurgical activity
- Shipbuilding (abrasive blasting)
- Manufacture of glass, ceramics (pottery, porcelain, and enamel), and stone objects
- Manufacture of cleansing agents and abrasives
- Chemical and pharmaceutical industry (handling of powdered chemicals)
- Rubber manufacturing industry
- Manufacture of lead storage batteries (bulk lead oxide)
- Flour mills, bakery works, and salmon processing unit
- Fertilizer industry
- Paint industry, spray painting, and glass painting
- Agricultural industry (ploughing, harvesting, grain storage)
- Sugarcane industry
- Forestry and woodworking

Pneumoconiosis

It is a type of occupational lung disease. The ILO defines pneumoconiosis as "accumulation of dust in the lung and the tissue reaction to its presence." It is an umbrella term that includes various types of pneumoconiosis such as silicosis, coal workers' pneumoconiosis (CWP), asbestosis, byssinosis, and bagassosis. The generalized scheme of pathophysiology of pneumoconiosis is presented in Figure 64-2. The minor differences in the pathophysiological sequences and clinical features and the type of industry involved are presented in Table 64-1. An elaborate discussion on silicosis and asbestosis is present in the following section.

Silicosis

Silicosis is a progressive interstitial lung disease, characterized by shortness of breath, cough, fever, and bluish skin, and can present in three different forms: acute, accelerated, and chronic.

Magnitude of the Problem

Silicosis and silicotuberculosis are very common among developing countries. In India, they are a major occupational menace that needs to be tackled effectively. As many as 1.7 million workers involved in mining or quarrying, 0.6 million workers in the nonmetallic industries such as clay, glass, and mica, and 0.7 workers in the metal industry are at a high risk of silicosis. Apart from this, nearly 5.3 million workers involved in construction works are also at risk. Agate grinding industry and pencil slate manufacturing industry found uniquely in India pose a high risk for the workers in those factories (ICMR Bulletin, 1999) (Sharma, Kundtu, et al., 2016). The WHO and the ILO have initiated the silicosis eradication program in the year 1999. Many countries have national program for silicosis eradication.

Pathophysiology

Silica is naturally available in enormous quantity in the earth's crust. While drilling, blasting, and explosion of earth, the

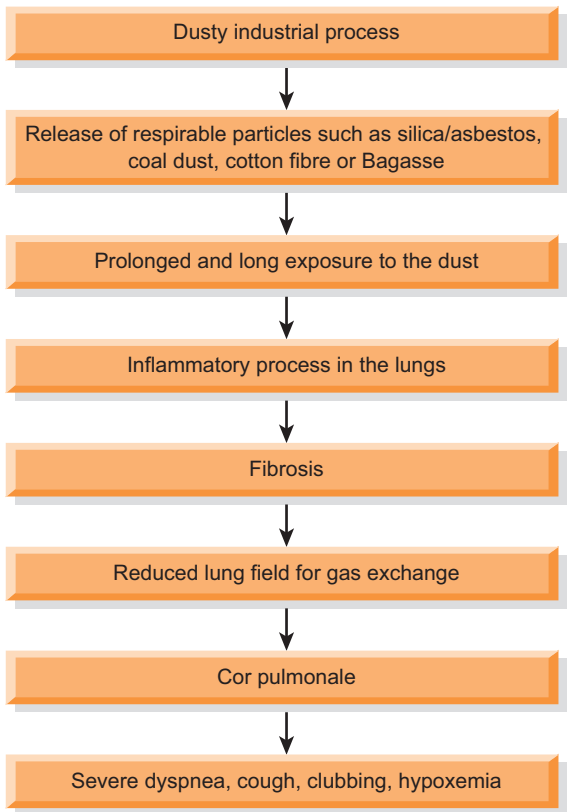

Figure 64-2 • Pathophysiology of pneumoconiosis.

TABLE 64-1 Pneumoconiosis of Different Etiology and Their Clinical Picture at a Glance

Type of Pneumoconiosis (Industries)	Pathophysiological Process	Clinical Features
Silicosis (glass manufacturing, foundry, stone cutting, agate grinding)	Inhaled silica dust produces nodular lesions in the lungs. Nodules enlarge and coalesce. Dense masses form on the upper portion of lungs, resulting in loss of pulmonary volume. Fibrotic destruction of pulmonary tissue can lead to restrictive lung disease, emphysema, pulmonary hypertension, and cor pulmonale	• Acute silicosis: Dyspnea, fever, cough, weight loss • Chronic silicosis – Progressive symptoms indicative of hypoxemia – Severe airflow obstruction and right-sided heart failure
Asbestosis (ship building, building demolition)	Inhaled asbestos fibers enter the alveoli and are surrounded by fibrous tissue. Fibrous changes can also affect the pleura, which thickens and develops plaque. These changes can lead to restrictive lung disease, with a decrease in lung volume, diminished exchange of oxygen and carbon dioxide, hypoxemia, cor pulmonale, and respiratory failure. They also increase the risk of lung cancer, mesothelioma, and pleural effusion	Progressive dyspnea; persistent, dry cough; mild to moderate chest pain; anorexia; weight loss; malaise; clubbing of fingers
Coal workers' pneumoconiosis (coal mine)	It is also known as black lung disease. Inhaled dusts that are a mixture of coal, kaolin, mica, and silica are deposited in alveoli and respiratory bronchioles. When macrophages that engulf the dust can no longer be cleared, they aggregate and fibroblasts appear in the bronchioles and alveoli can become clogged with dust, dying macrophages, and fibroblasts, leading to the formation of coal macules. Fibrotic lesions develop and subsequently localized emphysema develops, with cor pulmonale and respiratory failure	Chronic cough, dyspnea, and expectoration of black or gray sputum, especially in miners who are smokers with cavitation in the lungs
Byssinosis—brown lung (textile industry, cord clothing manufacturers, hemp industry)	Vegetable fibers such as cotton, hemp, and sisal fibers get into the lung, and cause inflammation, wheezing, and chronic bronchitis	Initially milder symptoms on assuming work after weekend, called "Monday feeling" Chest tightness, cough, wheezing, and severe breathing difficulty
Bagassosis—farmer's lung (sugarcane industry, agricultural industry)	Thermophilic actinomycetes found in decaying hay, compost, and sugarcane, especially in winter seasons, liberate a lot of dust. Exposure to allergens present in decomposing sugarcane or hay stimulates cell-mediated and humoral immunity. Neutrophilic and lymphocytic infiltration with prolonged exposure causes destruction of alveolar unit, collagen deposition, and destruction of lung parenchyma; pulmonary fibrosis occurs	Chills, fever, cough, and running nose usually in damp, winter seasons when the individuals handle decaying hay or sugarcane Later, severe breathlessness, crackling sounds, and reduced lung function

fine particulate silica is emanated. The workers in the mining industry, furnace, pottery, ceramics, mica mines, etc., are at a risk of developing silicosis. Silica is available in various sizes and forms. The crystalline silica is notorious for causing silicosis and silica tuberculosis. Fine dust with silica particle size less than 7 mm diameter is called respirable silica (Rees & Murray, 2007).

When respirable crystalline silica is inhaled, it reaches the lung usually in the upper lobes. Since silica is a nonirritant, it may not cause symptoms initially. After 10 to 20 years of exposure, chronic silicosis develops. In some susceptible people, silicosis develops after 3 to 5 years of exposure. In very few individuals, with large inhalation of silica dust, the clinical picture worsens in a short span of time causing an accelerated form of silicosis. Initially, the hilar lymph nodes are involved with lesions measuring 3 mm in diameter. As the disease progresses with prolonged exposure, the nodules may be found in the mid and lower lobes. The respirable silica dust gets accumulated and produces an inflammatory reaction with proteinolysis and fibrogenesis with inflammatory markers lymphocytes and macrophages. As the disease progresses, nodules coalesce with adjacent lung parenchyma and lead to development of massive fibrosis of the lungs. In acute and accelerated forms, the severe inflammatory reaction happens with exposure of a shorter duration, even few months of exposure. The inflammatory changes are mediated through type II pneumocytes. These hypertrophic pneumocytes may produce excessive amounts of proteinaceous material and surfactant protein, and the alveoli may then get filled with a protein-containing material. The nodules contain more of cellular eosinophilic granular material with less fibrotic changes.

Clinical Features

These include dyspnea, fatigue, weight loss, fever, and pleuritic pain. Pathological changes consistent with acute silicosis include the filling of alveolar spaces with eosinophilic granular material, similar to that observed in accelerated silicosis. Chronic silicosis is commonly present with emphysema and tuberculosis as a superadded infection.

Diagnosis

- History of occupational exposure to silica
- Clinical examination and chest X-ray
- Demonstration of silica particles during bronchoalveolar lavage

Management

Silicosis is progressive and incurable. The aim is to monitor the workers on a regular basis with physical assessment, X-ray chest, spirometry, and screening for TB. If anyone is found

to have silicosis, relocation of jobs to less dusty works or similar measure may be helpful. If superadded TB is present, antituberculosis drugs are prescribed.

Primary Prevention
- Education and creating awareness about the preventive measures
- Pre-employment and periodic checkup

Asbestosis

Asbestosis is an occupational lung disease characterized by severe shortness of breath and dry cough, mainly because of interstitial lung fibrosis with decreased diffusing capacity due to deposition of asbestos fibers in the lungs.

Asbestos is a naturally occurring, thick, hydrated silicate that is found as fibers of different shapes and sizes. Two distinct forms of asbestos fibers have a clinically significant impact. The curly, thin, flexible fibers are called serpentine and the short, straight, brittle fibers are called amphiboles.

Magnitude of the Problem
The ILO has predicted that 1 million people will die due to asbestos-related cancers by 2020. The situation in India is the worst with a huge burden of 10 million people with exposure to asbestos (Jadhav & Roy, 2012). The WHO and the ILO have called for the prevention of asbestos usage. Most of the countries have banned the usage of asbestos, but in India the utilization of asbestos has not come down.

Pathophysiology
The asbestos fibers are inhaled along with air in occupational settings such as asbestos factory, ship building, demolition of buildings, and mines, and a respirable fraction of fibers reaches the alveoli of both the lungs. The severity of the disease depends on the shape and size of the inhaled particles, the duration of exposure, and the dustiness of the processes. Lifestyle such as smoking adds to the risk.

Some fibers that got trapped in the upper airway may be cleared by mucociliary action and cough mechanism. But all the fibers may not get eliminated. The stiff amphibole fibers with diameter less than 0.5 μm and length less than 10 μm are highly dangerous as they can reach the deeper areas of the lung and penetrate the interstitial layer. Usually, the lower lobe is affected. In an attempt to eliminate the asbestos fibers, the alveolar inflammatory mechanism is initiated. The macrophages try to engulf and neutralize them. The chemotoxic and fibrogenic mediators are released to eliminate the fibers.

Chronic exposure and inhalation of the asbestos for 10 to 20 years in the industrial setting lead to diffuse interstitial inflammation of the lung and destruction of lung architecture. Fibrogenic mediators released in the inflammatory process result in diffuse fibrosis, causing restrictive lung changes. The ingested fibers get coated with iron and protein material and stay in the fibrosed area of the lung with a golden yellow–colored, bead-like appearance. The patient may develop pulmonary hypertension and cor pulmonale as a sequela of excessive fibrosis.

Clinical Features
- Severe dyspnea
- Dry cough
- Respiratory crackles
- Clubbing of fingers

Diagnosis
- Spirometry
- Chest X-ray
- High-resolution CT of thorax

Management
As the disease is progressive in nature, only symptomatic relief is possible. Oxygen may be administered. Wearing a protective mask, adequate ventilation, reducing the exposure by environmental control, and quitting smoking help in the prevention of the disease.

Prevention and Control
A three-level strategy for effective control and prevention has been suggested (Cullinan, Munoz, Agius, et al., 2017). High priority is given to elimination of dust followed by substitution of dust. The third priority in order is given to occupational hygiene measures. Administrative control and application of personal protective equipment are given a low priority. Asbestos, which is a highly toxic dust, can be replaced with a less toxic, man-made mineral fiber called rock wool (Cullinan et al., 2017). Enclosing a dusty operation prevents dispersion and inhalation of dust.

Occupational Asthma

Occupational asthma is a disease characterized by variable airflow limitation and/or airway hyperresponsiveness due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace (Mapp, Boschetto, Maestrelli, et al., 2005). Occupational asthma accounts for 15% of all adult asthma cases in the developed nations. One in 10 cases of adult-onset asthma or recurrent asthma in adulthood is attributable to work (Nicholson, Cullinan, Taylor, et al., 2005). Prevalence of occupational asthma was found to be 20.83%, of which 29.16% of participants were suffering from bronchial asthma in a silk factory in southern India (Gowda, Vijayeendra, Sarkar, et al., 2014).

Causes
Agents that are most common to cause allergic asthma are isocyanates, aldehydes, flour, grain, dust, colophony, fluxes, animal fur and urine, latex, and wood dust (Nicholson et al., 2005; Reid and Reid, 2013).

Pathophysiology
More than 90% of workmen develop asthma, which is called occupational asthma. Some individuals who have asthma already may have exacerbation of asthma at work. It is called work-aggravated asthma. Typically, there is a latent period after allergic exposure to symptom development in occupational asthma. It is usually immunoglobulin E (IgE) mediated. A small proportion of workers (<7%) may develop asthma in a single episode with a high quantity of exposure to an irritant at the workplace (Mapp et al., 2005).

The mineral, metallic, agricultural, or animal particulate dusts when inhaled or exposed give rise to an allergic reaction and subsequent bronchospasm, wheeze, and breathlessness. Employees who develop rhinitis on occupational exposure are at a risk of developing occupational asthma. A flowchart depicting pathogenesis of occupational asthma is presented in Figure 64-3.

Diagnosis
History. Patients give a history of adult-onset asthma, feeling better when on holidays and worsening during the working days. In health history, try to elicit the factors that improved asthmatic spells rather than the worsening factors (Nicholson et al., 2005).

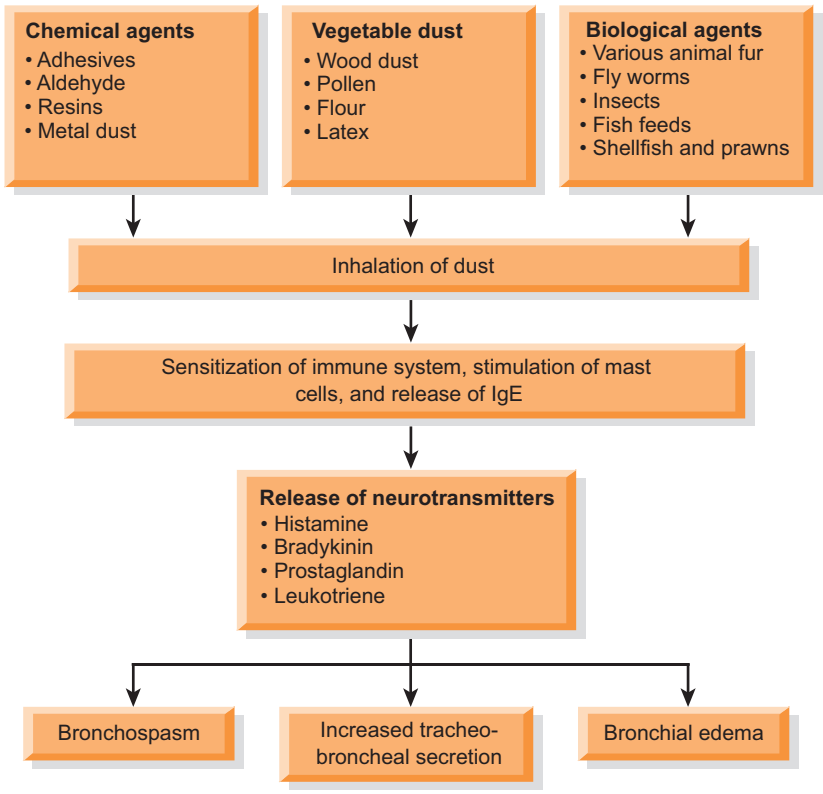

Figure 64-3 • Pathogenesis of occupational asthma.

On investigation, patients may show elevated IgE for a specific irritant inhaled or exposed. Peak expiratory flow rate may improve during holidays. Specific allergens can be injected to elicit the allergic reaction. The severity of asthma varies based on the quantity and length of duration, individual immune status, and susceptibility.

Prevention and Control

- Early identification and avoidance of the allergic agents yields a good prognosis.
- Respiratory protective equipment should be worn appropriately.
- There should be periodical medical checkup and surveillance for occupational asthma for all employees. Frequent surveillance is recommended for those who develop rhinitis (Nicholson et al., 2005).
- Employees should be educated about the need for wearing a protective mask while at work.

Nursing Management

- Nursing management is very similar to care of a patient with asthma.
- Collect data regarding allergic exposure and the quantity of allergen.
- Elevate the head end of the patient and support with cardiac table.
- Monitor vital signs.
- Administer the prescribed bronchodilators, mast cell inhibitors, leukotriene modifiers, and other β-agonists. Administer the prescribed low-flow oxygen and nebulizer therapy as indicated.
- Encourage adequate oral intake of warm water and other warm fluids.
- Encourage to perform pursed lip breathing and coughing.
- Evaluate the effectiveness of therapy.
- Educate about the perfect way of wearing a protective mask and encourage the measures to avoid allergic exposure.

Occupational Dermatitis

Occupational dermatitis is a pathological condition occurring in the skin due to occupational exposure resulting in noninfectious inflammation of the dermis. On examination, the skin lesions occurring on occupational chemical exposure may mimic those of eczema (Foulds, 2005).

Prevalence rate of occupational dermatoses is 7.1% in Europe, 2.5% in Vietnam, and 11% in Thailand. Pesticide-induced dermatosis is common in India with a prevalence rate of 26.7% to 36.6% (Bhatia & Sharma, 2017).

Different kinds of chemicals such as caustic soda, petroleum, and chromium can cause occupational dermatitis. Certain factories or workplaces sites are identified to cause dermatitis among the workers in those factories (Foulds, 2005).

Occupations Known to Cause Occupational Dermatitis

- Glass and porcelain works
- Vehicle assembly line works
- Spray paint works
- Machine tool operation
- Construction and electroplating industry
- Leather tanning industry
- Printing synthetic clothes
- Fertilizer industry
- Petrol refinery units
- Agricultural industry

Pathophysiology

Whenever the chemicals or irritants come in contact with stratum corneum (horny layer), the lipid present on that layer is removed. With repeated exposure to irritants, the keratin from the skin layer is also removed, leading to itching, dry scaling,

and blister formation. This type of dermatitis is called irritant dermatitis.

Some allergens get dissolved and enter the body to combine with mast cells. The mast cells then liberate kinins and histamine, resulting in allergic contact dermatitis.

Clinical Features

- Itching and irritation in the skin
- Dry, scaly skin with small blisters
- Pain
- Weepy skin
- Distribution of the skin lesions mostly in the hands, forearm, and face as these parts are more often exposed to potentially chemicals
- With cracks and aberration in the skin, superadded infection is also possible
- Worsening of symptoms in case of infection
- Discharge from the skin lesions
- Fever and increase in pain

Prevention

- Avoid exposure to irritants and allergenic chemicals and industries.
- Cleanse the skin after exposure. Cleansers should be soft but effective to remove the chemicals in a short period of time without having a too strong greasy effect (Foulds, 2005).
- Topical application of barrier cream should be done.
- Wear personal protective items such as mask and glove. For detailed patient education, refer Chapter 34, Chart 34-3.

Management

- Application of barrier cream containing ceramide or dimethicone may be done.
- Corticosteroid cream also may be useful.
- Encourage protective device application such as gloves or aprons and mask according to the nature of possible exposure and the agents.

Occupational Cancer

Definition

Occupational cancer is any malignancy wholly or partly caused by exposures at the workplace or in occupation (Veys, 1996). There are numerous hazardous agents present in the work environment capable of causing minor ailments and even leading to development of cancers. There are a lot of carcinogenic agents in the work environment, which include hexavalent chromium salts, asbestos, arsenic, benzene, beryllium, cadmium, chromium, diesel exhaust, ethylene oxide, respirable quartz, and ionizing radiation (Veys, 1996). Benzene is a commonly used chemical in industries and is a highly potent carcinogen (Wiwanitkit, 2014). Different industries emit or use different kinds of chemicals and the type of cancer caused also varies accordingly.

Magnitude of the Problem

As per the ILO predictions, 20 million people will be afflicted by asbestosis-related cancer by 2020. In India alone, 10 million people are expected to develop cancer due to excessive exposure to asbestos (Jadhav & Roy, 2012). Among the different asbestos fibers, the amphiboles are found to be associated with mesothelioma. Study findings suggest that firefighters are at risk of inhalation of benzene in the process of combustion, which was shown to increase the risk of leukemia, myeloma, and non-Hodgkin lymphoma (Guidotti, 2007). Leather industry uses various chemicals for tanning and processing such as chromium, benzene, and dimethylformamide. The risk of lung cancer increases with exposure to chromium and benzene. Pancreatic cancer was shown to be high in women who were exposed to chemicals such as formaldehyde, aniline, and azo dyes in leather industry. Testicular cancers in leather industry workers were found to be caused by dimethylformamide (Rastogi, Kesavachandran, Mahdi, et al., 2007).

Healthcare professionals working in the radiation therapy, radiology department, and endoscopy room are at a risk of cancer. Glutaraldehyde and formaldehyde used in the clinical setting have the potential to cause cancer (Gannon, Bright. P., Campbell, et al., 1995). Similarly, those who are involved in preparation and handling of chemotherapeutic drugs on a regular basis are at a risk of skin contact with the potentially hazardous chemicals, and if not protected by masks, inhalation of the drug molecules is possible. Viral agents such as HIV, HBV, and HCV can be occupationally transmitted to healthcare professionals. HIV and HBV are associated with Kaposi sarcoma and liver cancer, respectively.

Occupational cancer presents with symptoms and pathological changes very similar to those in patients with nonoccupational exposure cancer. But certain agents are positively associated with a certain type of cancer based on the causality studies (Veys, 1996).

Primary Prevention

- Avoid direct exposure to known carcinogens.
- Wear appropriate personal protective equipment to prevent inhalation of mineral and metallic dust. Ensure that the mask chosen is capable of filtering the minute respirable particles.
- Avoid exposure to ionizing radiation. In case of systemic radiation therapy, cluster the interventions and limit entry to patient care area.
- Wearing protective jackets, gloves, mask, etc., is mandatory.

Work-Related Musculoskeletal Injuries/Diseases

Musculoskeletal disorders can be defined as injuries and disorders of the muscles, nerves, tendons, ligaments, joints, cartilages, and spinal disc that occur due to work activities or factors in the working environment. Work-related musculoskeletal disorders are the most common cause of absenteeism and poor quality of life. Poor ergonomic factor is an important cause of musculoskeletal disorders.

Ergonomics applies the integrated knowledge of human science such as anatomy, physiology, and psychology to match the job, systems, products, and environment to physical and mental capabilities and limitations of the worker. In short, it is fitting the job to the worker.

Causes and Risk Factors

- Works involving lifting heavy weights, pushing, and pulling
- Works that require frequent bending and twisting
- Heavy physical work
- Working in the same posture for a long time
- Repetitive work
- Vibration
- Poor working ergonomics
- Psychosocial stress

Commonly Affected Population

- Construction workers
- Automotive industry
- Steel industry workers
- Nurses and other healthcare workers
- Workers involved in truck loading and unloading
- Computer operators and IT professionals

Pathogenesis of Work-Related Musculoskeletal Diseases

Lots of factors lead to the development of occupational musculoskeletal diseases. Personal factors such as aging, poor coping ability along with repeated mechanical load, poor ergonomics while handling weight manually, and psychological stress and shear lead to pain in the back, neck, etc., which in turn adds up the stress and hastens the process of development of musculoskeletal diseases. Modernization of offices has led to different work atmosphere. The computer professionals and data entry operators work with small muscles of the upper arm. The neck and the back get strained because of keeping an awkward posture for a long time. Similarly, the small muscles of the fingers are overstrained while using the keyboards. Wrist is made up of tiny carpal bones arranged in a unique way making it like a tunnel through which the tendons of the forearm muscle along with median nerve traverse. Repetitive movements lead to inflammation of the tendon and the median nerve gets compressed. This condition is called carpal tunnel syndrome. The quantum of injury depends on the time or duration of hours spent working on computers. Majority of computer users reported neck pain, shoulder pain, and tingling in the extremities (Subrathy and Korumtollee, 2005). The causes of shoulder and neck pain could be poor workstation, the improper nature of chair, etc. More than 20 minutes of break in between work and a thorough stretch were found to be helpful in reducing shoulder and back pain. The pathophysiology of work-related musculoskeletal disorders is presented in Figure 64-4.

Common Work-Related Musculoskeletal Problems

- Tension neck syndrome: Common among employees in IT field
- Cervical syndrome
- Thoracic outlet syndrome
- Lumbar disc prolapse

} Common among nursing personnel and truck drivers

- Carpel tunnel syndrome: Inflammation of the small joints and tendons with repetitive movements of small joints and fingers and abuse lead to tenosynovitis or carpel tunnel syndrome. These type of injuries are commonly found in computer professionals, data entry operators, blacksmiths, and goldsmiths. Patients may suffer from weakness, numbness of the hands, decreased hand grip, and pain (Subrathy & Korumtollee, 2005) (Ghosh, Das, & Gangopadhyay, 2011).

Assessment

The patient may give a history of repeated manual handling of weight. The patient may present with severe pain in the low back, which may radiate to thighs and legs; certain positions or activities such as bending may aggravate the pain. An X-ray may show degenerative changes and prolapse of one or more lumbar disc. MRI may also reveal intervertebral disc herniation.

Collaborative Management

Back pain in the initial phase can be managed with pelvic traction and analgesics. NSAIDs and mild antidepressants or sedatives may be prescribed. Hot applications may improve comfort. If the nerve root compression with complete disc herniation results in neurological deficit and limitation in movements and walking, surgical intervention is recommended. Common perioperative nursing management details are presented in Chapter 6.

The commonly encountered nursing diagnoses may be the following:

- Acute low back pain related to compression in the intervertebral disc or/and nerve roots
- Ineffective coping related to pain
- Impaired physical mobility related to pain and reduced muscle power in the lower limbs/surgical trauma
- Anxiety related to unexpected outcome of surgery

Nursing Management

If there is acute low back pain related to compression in the intervertebral disc or/and nerve roots, assess the pain intensity

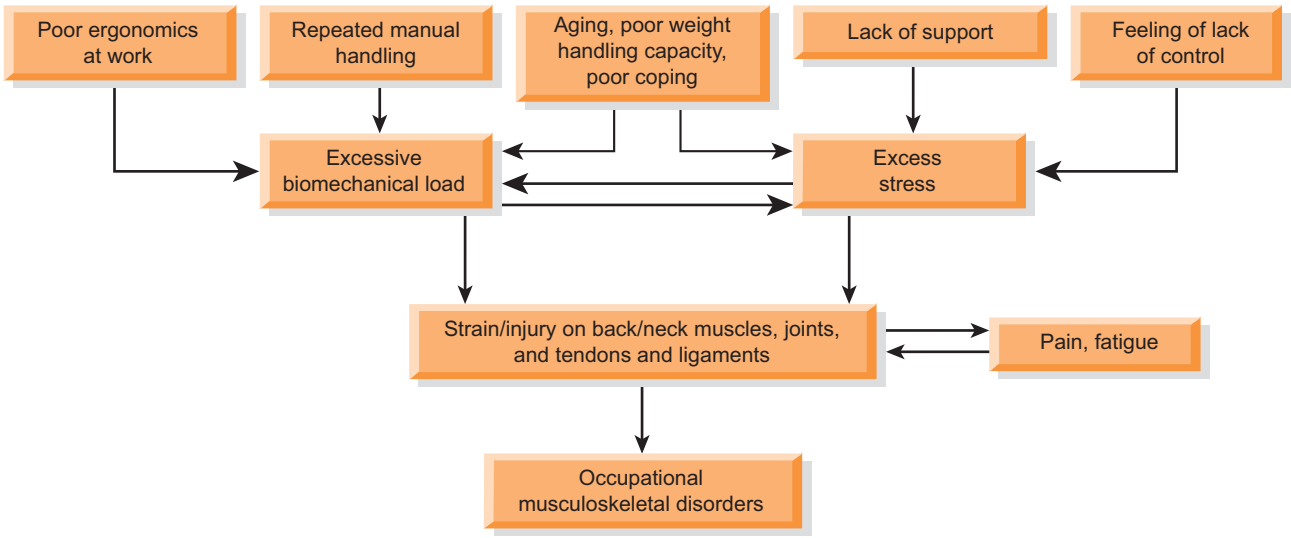

Figure 64-4 • Pathophysiology of occupational musculoskeletal disorders.

and nature. Administer the analgesic agents as prescribed. Encourage the patient to maintain appropriate body alignment while sitting and standing. Encourage the patient to perform isometric exercises to strengthen the back muscles. Educate the patient regarding yoga, relaxation therapy, imagery, or other diversional therapies. Apply a hot water bag. Provide complete bed rest. Encourage the patient to avoid bending or twisting movements. Monitor the effectiveness of pain relief measures periodically.

If the patient is in the postoperative phase following lumbar disc surgery, apply log roll technique for turning the patient. Use of striker frame may help in position change without disturbing the operated site, but with ease and comfort. All other pain relief measures except hot application and traction may be implemented.

Prevention of Work-Related Musculoskeletal Disorders

- Adhere to principles of biomechanics and automate the manual processes of strenuous lifting, pulling, and pushing activities.
- Take measures to enhance the physical fitness and coping such as provision of fitness studio and creating a culture that promotes exercises and positive behaviors.
- Initiate measures to reduce psychosocial factors. Have positive work milieu where everyone's contribution is acknowledged appropriately. Transparency in work and reward allocation will help in reducing conflicting situations.
- Allow for small breaks of 20 minutes in between the long monotonous working hours.
- Those who are aging may be transferred to less strenuous jobs.

Occupational Musculoskeletal Problems Among Nurses and Health Workers

Musculoskeletal problems, especially back injuries, neck injuries, and spinal disc problems, can be debilitating to nurses. The nursing job demands manual handling of patients on a regular basis throughout their career. Realizing the impact of musculoskeletal problem on occupational health of nurses, the ANA has launched a campaign named "Handle With Care" in 2003. The aim of this campaign is to initiate consolidated effort to reduce the risk of musculoskeletal injuries faced by nurses. The campaign seeks to educate, advocate, and facilitate change from traditional practices of manual patient handling to emerging, technology-oriented methods (de Castro, 2004). The campaign seeks to reduce the work-related musculoskeletal injury through collaboration with stakeholders to promote assistive devices in healthcare facilities. Another important aspect is to bring awareness to the nurses and young student nurses on appropriate and safe handling techniques. The aim is to safeguard patients as well as nurses.

Although nursing curricula include the principles of biomechanics and the application in nursing, accomplishment of the necessary skills is questionable (de Castro, 2004). Patient condition also adds to the problem. Unconscious patients, patients on mechanical ventilation, postsurgical patients, and patients with spinal injuries could offer no effort to nurses in mobilizing them. Morbidly obese patients add up the risk of musculoskeletal injury to nurses.

The National Institute of Occupational Safety and Health (NIOSH) proposed a lifting equation, according to which the safe limit for manual handling of weight is no more than 23 kg. It may not be suitable in the nursing care situation. The amount of cooperation that a patient can yield from his or her side varies (de Castro, 2004).

TABLE 64-2 Safe Patient Handling Equipment and Devices

- Inflatable lateral assist devices
- Standing and raising aids for those who have difficulty in standing up
- Repositioning sheet in bed, which facilitates repositioning of bedfast patients
- Ceiling lifts that can lift patients from bed and transfer those highly dependent patients
- Sling lifters that can safely lift patients from floor or chair or bed
- Lateral transfer slings
- Specially designed high-powered bariatric lift devices

Nelson and Baptiste (2004) emphasize the need for a major paradigm shift away from ineffective approaches toward the following evidence-based practices: (1) patient handling equipment/devices, (2) patient care ergonomic assessment protocols, (3) no-lift policies, (4) training on proper use of patient handling equipment/devices, and (5) patient lift teams.

Even with patient-lifting devices, the amount of time nurses spend on preparing the patient for transfer in the bending posture needs to be considered. Among the patient-lifting devices, ceiling lift devices are effective than floor lift devices (Kuijer, Verbeek, Visser, et al., 2014) (see Table 64-2). Various safe patient handling equipment and devices are presented in Figure 64-5.

Pretransfer Assessment Recommended by Nelson and Baptiste

- Assess the ability of the patient to provide assistance.
- Assess the weight-bearing ability of the patient.
- Check for the upper extremity strength of the patient.
- Assess the ability of the patient to cooperate and follow instructions.
- Find out the patient's height and weight.
- Assess for the presence of abdominal wounds, contractures, or tubes that affect repositioning tasks.
- Look for specific physician orders or physical therapy recommendations that relate to transferring or repositioning patients such as those with knee or hip replacement.
- Assess whether the surface is even and nonslippery.

Tips for Nurses to Avoid Work-Related Musculoskeletal Injury

- Get help from other personnel or assist devices. Never try to lift or manually handle patients alone.
- Be mentally and physically prepared for manual handling of patients.
- Give appropriate instructions to your helpers for smooth and coordinated movements.
- Ensure that the floor is nonslippery and obstacle free. Avoid high-heel, slippery *chappals* while at work.
- Use the principles of good body mechanics while handling patients manually.
- Have a wide base of support with legs firmly footed on the ground.
- Avoid twisting or bending at the hip level.
- Use large muscle groups rather than straining the small muscles.
- While transferring patients from bed to stretcher, see that the bed and the stretcher are kept at the same height to avoid extra workload.

A

B

C

D

Figure 64-5 • A. Ceiling lifts. **B**. Standing raising aid. **C**. Passive sling lifter. **D**. Passive floor lifter. Courtesy: Arjohuntleigh Healthcare India Ltd.

- The bed height has a great bearing on kinematics, so height of the bed at hip level is helpful to reduce strain on the L5, S1 area (Roy, Lortie, & Roy, 1988).
- While pushing the patient forward, have the front leg forward, which will increase the base of support.
- While pulling the patient backward, move one leg one step back to increase the base of support.
- Instead of working against gravity, try pushing or pulling.
- Keep the patient to be moved as close to you as possible.
- When the back is kept straight with proper alignment of the back, neck, shoulders, and chest, the center of gravity will fall within the base of the support and strain on the back muscles or ligaments will be minimal.

Occupational Injuries and Accidents

Major accidents happen at workplaces. The Bhopal gas tragedy happened in the Union Carbide factory in Madhya Pradesh, India, in 1984; Chernobyl atomic reactor blast in the USSR had recorded mass fatalities not only to the workers but also to the inhabitants of the localities surrounding those factories. As per the Ministry of Labour, Government of India (2017), the fatal accident rate in the coal mines was 0.18 per 1,000 employees, and in the non–coal mines, it was 0.24 per 1,000 employees.

Causes of Accidents

- **Administrative factors**
  - Default or malfunctioning machines
  - Inadequate workman strength
  - Improper design and engineering
  - Inadequate training to employees
  - Lack of supervision
- **Employee factors**
  - Poor awareness about the risky processes and hazardous substance
  - Nonadherence to safety control mechanism/safety personal protective equipment, sometime due to overconfidence
  - Deadline-oriented work
  - Fatigue factor and oversight
  - Faulty operations
  - Too much diversion of attention from work process
- Sudden default in gadgets

Primary Prevention

- Periodical checking of the functional status of the machines and removing the worn-out ones from operations
- Standardizing the operation and processes
- Regular induction programs for new employees

- Measures to avoid human factor of fatigue, etc., by providing proper working conditions and amenities
- Installation of alerting devices in the event of faulty operation releasing dangerous chemicals or fumes or fire
- Automation of dangerous operations
- Reengineering industries and factories for safe work environment

Occupational Risks for Nurses and Healthcare Workers

Healthcare workers, especially nurses, face a multitude of hazards in their work:

- Musculoskeletal injuries or diseases
- Exposure to microbial agents leading to infections such as HIV, HBV, HCV, and TB
- Exposure to chemical agents such as glutaraldehyde and formaldehyde that can lead to occupational asthma or occupational dermatitis, and contact or inhalation of chemotherapeutic agents
- Radiation hazards

Prevention of High-Risk Occupational Infection Among Nurses/Health Professionals

- Adherence to standard precautions and wearing appropriate personal safety wears such as gowns, masks, gloves, and goggles
- Adherence to hand washing/hand hygiene protocol
- Following biomedical waste management protocol
- Vaccination to diseases such as HBV, TB, seasonal flus, swine flu, bird flu, or varicella
- Precaution while handling sharps and needles
- Not recapping needles
- Discarding used needles in puncture-proof containers
- In case of sharp injury with needles or scalpel contaminated with HBV- or HIV-positive patients, following PEP protocols with antiretroviral agents in case of HIV and immunoglobulin in case of HBV
- Following appropriate sterilization and disinfection protocols including the environment
- Maintaining general well-being and nutritional status

Post exposure Prophylaxis

Body fluid exposure on a nonintact skin or mucous membrane or a sharp injury with a used needle or scalpel or other sharps poses a danger of acquiring blood-borne infections such as HIV, HBV, or HCV. If you know the health status of the patient for whom the needle or sharp was used, appropriate action has to be taken. The infection control nurse has to be informed and appropriate prophylaxis has to be taken. Refer Chapter 55 for a detailed discussion on PEP (Chart 55-6).

Occupational Health Program in India

For strategic prevention of occupational diseases, occupational health program is initiated by the Government of India in collaboration with the WHO and the ILO. Success of occupational health program depends on the cooperation and coordination of government, law-enforcing authorities, industrial organizations, and their employees. Certain regulations and laws are enacted to prevent the ill effects of occupational health hazards such as asbestos abatement regulation and radiation inspection program. Education and awareness of occupational diseases, air quality checks, and noise containment are some efforts initiated collaboratively to improve occupational health.

Employers' Responsibilities

- Follow safety guidelines set forth periodically by the safety council or legislation.
- Provide adequate awareness and education to the employees about the prevailing hazards in the industrial setting.
- Assess the air quality and relevant parameters as recommended and keep vigilance not to cross safety limits.
- Initiate engineering and ergonomic measures to mitigate the negative effects of work hazards.
- Arrange for pre-employment check and periodical health checkups.
- Provide facility for first aid/emergency care and further management either by setting up own medical facility or by third-party arrangement.

Employees' Responsibility

Safety and health is not just for specialists and professionals. It should become the concern of all people at workplaces. We have to collectively develop the conscience of the common people (Mahadevan, 2009). Employees have a great role to play in ensuring occupational safety and to promote occupational health. An employee is expected to:

- Follow the safety guidelines while at work.
- Take active part in ensuring safety and healthy work environment.
- Be aware of the hazards present in the work environment and consistently wear personal protective equipment.
- Sensitize the fellow workmen and employers in case of any unsafe gadgets or malfunctioning machinery or work process occurring in the industrial setting.

Role of Health Team Members

A physician plays a vital role in early detection and appropriate management of the workers affected by occupational diseases. He/she participates in health research and organizes and coordinates unit-based or industry-based surveillance.

Nurses' Role in Occupational Health Program

Occupational health nurses are the largest group of health professionals engaged in the provision of safe health services to working population in many countries in the world (Whitaker & Baranski, 2001). In India, the occupational/industrial nursing is now gaining momentum with many corporates starting employing occupational health nurses along with occupational physician. Traditionally, the occupational nurses work in the hospital or healthcare units of the factories and provide secondary prevention services. Occupational nurses in India are now involved in disease management, environmental management, conduction of safety audits, and hearing preservation initiatives apart from first aid training (Priolcar, 2013).

Occupational health nurses carry out various aspects of the occupational health services starting from maintaining data pertaining to occurrence of occupational disease/injuries, planning, implementing, and evaluating the effectiveness of the appropriate intervention. They play several roles in the occupational health, which include specialist nurse, manager, coordinator of occupational services, advisor, health educator, counselor, and researcher (Whitaker & Baranski, 2001; Priolcar, 2013).

An occupational health nurse administers occupational health services within the legal and professional framework. The nurse's role in occupational healthcare delivery includes the following:

- Conducts periodical health checkup and organizes screening program for the workers
- Assesses the vital environmental parameters to identify any threat to health
- Initiates primary prevention by modifying the work environment or changing the workplace
- Identifies emergencies and provides first aid
- Delivers curative and rehabilitative services in collaboration with the other health team members
- Identifies the risks in the industry and provides advice and information to reduce risk
- Maintains environmental health, thereby playing a role in safeguarding the general well-being of the people living in the communities adjacent to industries
- Advises small- and medium-scale entrepreneurs on methods to contain or reduce risk
- Provides counseling and guidance to workers on complex health issue

Indian Perspective of Occupational Health and Occupational Health Program

As per the National occupational safety and health profile (2015), there are 350,000 registered factories in India in which around 15 million workers are employed. Besides that, there is a huge number of people working in unorganized sector and small scale industries. In the recent years, there has been 10% increase in female workers. Based on the provisions of the Factories Act and the Mines Act of the Government of India, only 10% of the workforces are ensured of health and safety at work and the remaining 9.0% of the workers fall in unorganized sector and still at risk of handling dangerous chemicals and operations. High proportion of workers in unorganized sector and increase in female workers' population have posed a lot of challenges in ensuring optimal occupational health.

The occupational health is still under the purview of the Ministry of Labour and is not under the Ministry of Health. The Directorate of Industrial Safety and Health at state levels implements the occupational health activities through factory inspecting engineers and medical inspectors of factories. Workers in the mining industry, factories, and ports and construction laborers are presently covered by the occupational healthcare delivery system. The port workers are covered by the port trust hospitals located in various ports. Mine workers and factory workers such as those employed in integral coach factories, Bharat Heavy Electricals Limited, and railways are covered by their own health centers. The Employee State Insurance Corporation (ESIC) is a huge organization that provides curative services to around 8 million employees (Occupational health and services-Indian scenario, see Resources section). An industry with an employee strength of 100 or more must have an occupational health center with a full-time occupational physician. If a unit has less strength, it is covered under ESIC but it is not provided with the preventive services.

National Occupational Health Policy on Safety, Health, and Environment at Workplace

The national occupational health policy proclaims that the occupational health and provision of safety at workplace are fundamental rights of workers. The national health policy aims at providing health and safety of workers by eliminating work-related injuries and disasters, and loss of assets and life by proactive efforts. It also aims at ensuring provision of humane and safe work environment for employees and elimination of abuse of children at work. It pledges for sustainable enterprise development through creation of green jobs and thereby improves safety, health, and work environment. Another area of national occupational health policy is continuous improvement of community education and creation of awareness about occupational safety.

National Programme for Control and Treatment of Occupational Diseases

The Ministry of Health and Family Welfare, Government of India, launched "National Programme for Control and Treatment of Occupational Diseases" in 1998–99. The National Institute of Occupational Health, Ahmedabad, functions as the nodal center for the same. Under the National Programme for Control and Treatment of Occupational Diseases, focus is on the following areas:

- Prevention, control, and treatment of silicosis and silicotuberculosis in agate industry
- Occupational health problems of tobacco workers and their prevention
- Identification of hazardous processes and chemicals, database generation, documentation, and information dissemination of the same
- Capacity building to promote research, education, and training at the National Institute of Occupational Health
- Health risk assessment and development of intervention program in cottage industries with a high risk of silicosis

After the Bhopal gas tragedy, the revised factory act has taken measures to ensure occupational health in factory workers by enforcing the following regulations. The owners of the factory with hazardous processes are expected to have an occupational health center with a qualified doctor.

- Prepare and communicate health and safety policy.
- Define the hazardous processes clearly.
- Inform the workers, inspectorate, and the public mandatorily.
- Prepare and practice disaster management programs.
- Conduct medical examinations of the employees and keep updated records with qualification and attendance of doctors specified.
- Keep record of equipment and drugs prescribed.

Training and Capacity Building and Research

The Central Labour Institute and the National Institute of Occupational Health provide training to occupational health professionals. The demand and supply gap is wide and needs further work in this area. The six institutes that function in different cities engage in surveys and research activities in collaboration with international agencies and NGOs.

Challenges in Occupational Health in India

There is a huge unorganized sector that does not come under the legal provisions of occupational health. There is poor awareness on the health hazards by the largely less educated employees and availability of only few trained occupational health manpower. Because of all these factors, implementation of risk assessment and surveillance and installation of preventive strategies in hazardous processes/industry suffer greatly. All the stakeholders

including employees and employers need to be educated about the benefits of preventive strategies.

CRITICAL THINKING EXERCISE

1. You are a nurse employed in a hospital attached to lignite mining factory. Most of the employees are educated up to secondary school level. You have observed that many of them have the habit of smoking and they hardly wear a mask. You have observed one of the employee, Mr. K, with history of childhood asthma present with worsening of cough and respiratory distress recently. As an industrial nurse, what are the common health problems you expect in your mining industry employees. What are the parameters you are most likely to monitor? What are your recommendations to the top management in realtion to maintaining health of thevworkers? How will you tackle the problem of noncompliance? Plan the nursing care of Mr. K applying nursing process.

Appendix A
Diagnostic Studies and Interpretation

Test Value Studied

Reference Ranges—Hematology
Reference Ranges—Serum, Plasma and Whole Blood Chemistries
Reference Ranges—Immunodiagnostic Tests
Reference Ranges—Urine Chemistry
Reference Ranges—Cerebrospinal Fluid (CSF)

Selected Abbreviations Used in Reference Ranges

Conventional Units

kg = kilogram
gm = gram
mg = milligram
µg = microgram
µµg = micromicrogram
ng = nanogram
pg = picogram
dL = 100 milliliters
mL = milliliter
gm = gram
mm^3 = cubic millimeter
fL = femtoliter
mM = millimole
nM = nanomole
mOsm = milliosmole
mm = millimeter
µm = micron or micrometer
mm Hg = millimeters of mercury
U = unit
mU = milliunit
µU = microunit
mEq = milliequivalent
IU = International Unit
mIU = milliInternational Unit

SI Units

g = gram
L = liter
d = day
h = hour
mol = mole
mmol = millimole
µmol = micromole
nmol = nanomole
pmol = picomole

TABLE A-1 Reference Ranges—Hematology[a]

Test	Reference Range		Clinical Significance
	Conventional Units	SI Units	
Bleeding time	3–10 min Ivy method	3–10 min	Prolonged in thrombocytopenia, defective platelet function, and aspirin therapy
Factor V assay (labile factor)	50%–150%		Decreased in liver disease, factor V inhibitors, myeloproliferative disorders, DIC, and fibrinolysis
Factor VIII assay (antihemophiliac factor)	55%–145%	55–145 AU	Increased in late normal pregnancy, thromboembolic conditions, liver disease, postoperative period, and rebound period after sudden cessation of a Coumadin-type drug. Decreased in hemophilia A, immunologic reactions, postpartum, von Willebrand disease, DIC, fibrinolysis, and myeloproliferative disorders
Factor IX assay (Christmas factor)	60%–140%	60–140 AU	Decreased in uncompensated cirrhosis, liver disease, nephrotic syndrome, various anticoagulant drugs, DIC, and vitamin K deficiency
Factor X	45%–155%		Decreased in liver disease, oral anticoagulant drugs, amyloidosis, DIC, and vitamin deficiency
Fibrinogen	200–400 mg/dL	2–4 g/dL	Increased in pregnancy, infections, inflammation, acute MI, nephritic syndrome, cancers, and stroke Decreased in liver disease, DIC, cancer, primary fibrinolysis, and hereditary and congenital hypofibrinogenemia
Fibrin degradation products	<10 µg/mL	<10 mg/mL	Used to establish diagnosis of DIC and other thromboembolic disorders
Fibrinolysis (whole blood clot lysis time)	No lysis in 24 hr		Increased activity associated with hemorrhage and circulatory collapse, surgery, long-term DIC, liver disease, pregnancy complications, and other conditions

(*Continued*)

TABLE A-1 (*Continued*)

Test	Reference Range: Conventional Units	Reference Range: SI Units	Clinical Significance
Partial thromboplastin time (aPTT)	Lower limit of normal: 21–35 sec		Prolonged in deficiency of fibrinogen, factors II, V, VIII, IX, X, XI, and XII, in heparin therapy, DIC, liver disease, and other conditions
Prothrombin (PT)	Lower limit of normal: 11 sec Lower limit of normal: 13 sec		Impaired in deficiency of factors II, V, VIII, IX, and X, DIC, liver disease, and other conditions
INR	0.8–1.2		Prolonged by deficiency of factors I, II, V, VII, and X, fat malabsorption, severe liver disease, warfarin (Coumadin) anticoagulant therapy, and other conditions
Erythrocyte count	Males: 4,600,000–6,200,000/mm^3	4.6–6.2 × 10^{12}/L	Increased in severe diarrhea and dehydration, polycythemia, acute poisoning, pulmonary fibrosis
	Females: 4,200,000–5,400,000/mm^3	4.2–5.4 × 10^{12}/L	Decreased in all anemias, in leukemia, and after hemorrhage when blood volume has been restored
Erythrocyte Indices			
Mean corpuscular volume (MCV)	82–98 mcm^3	82–98 fL	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin (MCH)	26–34 pg/cell	0.40 to 0.53 fmol/cell	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC)	32–36 g/dL	4.9 to 5.5 mmol/L	Decreased in severe hypochromic anemia
Reticulocytes	0.5%–1.5% of RBCs	Number fraction: 0.005–0.015	Increased with any condition stimulating increase in bone marrow activity (e.g., infection, blood loss [acute and chronically following iron therapy in iron deficiency anemia], polycythemia vera) Decreased with any condition depressing bone marrow activity, acute leukemia, late stage of severe anemias
ESR	Males under 50 yrs: 0–15 mm/hr	<15 mm/hr	Increased in tissue destruction, whether inflammatory or degenerative; during menstruation and pregnancy; in acute febrile diseases, and other conditions
	Males over 50 yrs: 0–20 mm/hr	<20 mm/hr	
	Females under 50 yrs: 0–20 mm/hr	<25 mm/hr	
	Females over 50 yrs: 0–30 mm/hr	<30 mm/hr	
Hematocrit	Males: 42%–52% Females: 36%–48%	Volume fraction: 0.42–0.52 Volume fraction: 0.36–0.48	Decreased in anemias, including anemia of pregnancy, acute blood loss, and other conditions Increased in erythrocytosis of any cause, and in dehydration or hemoconcentration associated with shock
Hemoglobin	Males: 14.0–17.4 g/dL Females: 12.0–16 g/dL	140–174 g/L 120–160 g/L	Decreased in anemias, pregnancy, hemorrhage, with excessive fluid intake, and other conditions Increased in polycythemia, chronic obstructive pulmonary disease, failure of oxygenation because of congestive heart failure, and normally in people living at high altitudes
Leukocyte alkaline phosphatase	40–100 units		Increased in polycythemia vera, myelofibrosis, various cancers, and other conditions Decreased in chronic myeloid leukemia, paroxysmal nocturnal hemoglobinuria, idiopathic thrombocytopenic purpura, hereditary hypophosphatasia, progressive muscular dystrophy, marked eosinophilia, nephritic syndrome, and siderocytic anemia
Leukocyte count	Total: 4,500–11,000/mm^3	4.5 × 10^9/L	Neutrophils increase with acute infections, trauma or surgery, leukemia, malignant disease, necrosis; decreased with viral infections, bone marrow suppression, primary bone marrow disease
Neutrophils	45%–73%	Number fraction: 0.45–0.73	
Eosinophils	0%–4%	Number fraction: 0.00–0.04	Eosinophils increased in allergy, parasitic disease, collagen disease, subacute infections; decreased with stress, use of some medications (ACTH, epinephrine, thyroxine)
Basophils	0%–1%	Number fraction: 0.00–0.01	Basophils increased with acute leukemia and following surgery or trauma; decreased with allergic reactions, stress, allergy, parasitic disease, use of corticosteroids
Lymphocytes	20%–40%	Number fraction: 0.2–0.4	Lymphocytes increased with infectious mononucleosis, viral and some bacterial infections, hepatitis; decreased with aplastic anemia, SLE, immune deficiency including AIDS

(*Continued*)

(*Continued*)

Test	Reference Range		Clinical Significance
	Conventional Units	SI Units	
Monocytes	2%–8%	Number fraction: 0.02–0.08	Monocytes increased with viral infections, parasitic disease, collagen and hemolytic disorders; decreased with use of corticosteroids, RA, HIV infection
Platelet count	140,000–400,000/mm^3	0.14–0.4 × 10^{12}/L	Increased in cancer, myeloproliferative disease, RA, and postoperatively Decreased in thrombocytopenic purpura, acute leukemia, aplastic anemia, and during cancer chemotherapy

[a]Laboratory values and reference ranges may vary in different laboratories. AIDS, acquired immune deficiency syndrome; DIC, disseminated intravascular coagulation; INR, international normalized ratio; ESR, erythrocyte sedimentation rate; HIV, human immune deficiency virus; MI, myocardial infarction; RA, rheumatoid arthritis; RBC, red blood cell.

TABLE A-2 Reference Ranges—Serum, Plasma, and Whole Blood Chemistries

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Acetoacetate	0.2–1.0 mg/dL	19.6–98 mcmol/L	Diabetic ketoacidosis, and fasting	
Acetone	0.3–2.0 mg/dL	51.6–3440/mcmol/L	Diabetic ketoacidosis, toxemia of pregnancy, and carbohydrate-free diet, high-fat diet	
Acid, total phosphatase	Males: 2–12 UL Females: 0.3–9.2 UL	Males: 2–12 UL Females: 0.3–9.2 UL	Carcinoma of prostate, advanced Paget disease, hyperparathyroidism, and Gaucher disease	
Acid, phosphatase, prostatic—RIA	<2.5 ng/mL	<2.5 ug/L	Carcinoma of prostate	
Alkaline phosphatase	Adults: 25–100 UL	0.43–1.70 mkat/L	Conditions reflecting increased osteoblastic activity of bone, including many liver diseases, bone diseases, and other conditions	
Adrenocorticotropic hormone (ACTH) (plasma)—RIA[a]	<120 pg/mL	<120 ng/L	Pituitary-dependent Cushing syndrome, ectopic ACTH syndrome, and primary adrenal atrophy	Adrenocortical tumor, adrenal insufficiency secondary to hypopituitarism
Aldolase	3–8 Sibley–Lehninger U/dL at 37°C	22–59 mU/L at 37°C	Hepatic necrosis, granulocytic leukemia, myocardial infarction, and skeletal muscle disease	
Aldosterone (plasma)—RIA	Supine: 3–16 ng/dL Upright: 7–30 ng/dL Adrenal vein: 200–800 ng/dL	0.08–0.30 nmol/L 0.14–0.90 nmol/L 5.54–22.16 nmol/L	Primary and secondary aldosteronism	Addison disease
Alpha-1-antitrypsin	110–140 mg/dL	1.1–1.4 g/L		Certain forms of chronic lung and liver disease in young adults
Alpha-hydroxybutyric dehydrogenase	<140 U/L	<140 U/L	Myocardial infarction, granulocytic leukemia, hemolytic anemias, and muscular dystrophy	
Ammonia (plasma)	15–45 mcg/dL (varies with method)	11–32/mcmol/L	Severe liver disease, and hepatic decompensation	
Amylase	25–125 U/L Older adults: 24–151 U/L	0.4–2.1 μkt/L 0.4–2.5 μkt/L	Acute pancreatitis, mumps, duodenal ulcer, carcinoma of head of pancreas, prolonged elevation with pseudocyst of pancreas, and medications that constrict pancreatic duct sphincters: morphine, codeine, cholinergics	Chronic pancreatitis, pancreatic fibrosis and atrophy, cirrhosis of liver, and pregnancy (2nd and 3rd trimesters)

(*Continued*)

TABLE A-2 (*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Arsenic	<70 mcg/dL; poisoning: 100–150 mcg/dL	<0.93–2.6 mcmol/L; poisoning: 133–6.65 mcmol/L	Intentional or unintentional poisoning, and excessive occupational exposure	
Ascorbic acid (vitamin C)	0.4–1.5 mg/dL	23–85 mcmol/L	Large doses of ascorbic acid as a prophylactic against the common cold	
ALT (alanine aminotransferase), formerly SGPT	Males: 10–40 U/mL Females: 8–35 U/mL	Males: 0.17–0.68 mckat/L Females: 0.14–0.60 mckat/L	Same conditions as AST (SGOT), but increase is more marked in liver disease than AST (SGOT)	
AST (aspartate aminotransferase), formerly SGOT	Males: 10–40 U/L Females: 15–30 U/L	Males: 0.34–0.68 mckat/L Females: 0.25–0.51 mckat/L	Myocardial infarction, skeletal muscle disease, and liver disease	
Bilirubin	Total: 0.3–1.0 mg/dL Direct: <0.5 mg/dL Indirect: 0.1–1 mg/dL	5–17 mcmol/L <6.8 µmol/L 1.7–17.1 µmol/L	Hemolytic anemia (indirect), biliary obstruction and disease, hepatocellular damage (hepatitis), and pernicious anemia	
Brain (B-type) natriuretic peptide (BNP)	<100 pg/mL	100 ng/L	Heart failure, cardiac volume overload	
Calcitonin	Basal: <8.4 pg/mL Stimulation test Males: <190 pg/mL Females: <35 pg/mL	8.4 ng/L <190 ng/L <35 ng/L	Medullary carcinoma of the thyroid, some nonthyroid tumors, Zollinger–Ellison syndrome	
Calcium	8.8–10.2 mg/dL	2.052–2.6 mmol/L	Tumor or hyperplasia of parathyroid, hypervitaminosis D, multiple myeloma, nephritis with uremia, malignant tumors, sarcoidosis, hypoparathyroidism, skeletal immobilization, excess calcium intake: milk alkali syndrome	Hyperthyroidism, diarrhea, celiac disease, vitamin D deficiency, acute pancreatitis, nephrosis, parathyroidectomy
CO_2, venous	Adults: 24–32 mEq/L Infants: 22–24 mEq/L	24–32 mmol/L 22–24 mmol/L	Tetany, respiratory disease, intestinal obstruction, vomiting, and pheochromocytoma	Acidosis, nephritis, eclampsia, diarrhea, and anesthesia
Catecholamines (plasma)—RIA	Epinephrine: <100 pg/mL Norepinephrine: <400 pg/mL Dopamine: <143 pg/mL	<540 pmol/L <2360 pmol/L <935 pmol/L		
Ceruloplasmin	25–63 mg/dL	250–630 mg/L		Wilson disease (hepatolenticular degeneration)
Chloride	96–106 mEq/L	96–106 mmol/L	Nephrosis, nephritis, urinary obstruction, cardiac decompensation, and anemia	Diabetes, diarrhea, vomiting, pneumonia, heavy metal poisoning, Cushing syndrome, intestinal obstruction, and other febrile conditions
Cholesterol	Males: <205 mg/dL Females: <190 mg/dL	<5.3 mmol/L <4.9 mmol/L	Lipemia, obstructive jaundice, diabetes, and hyperthyroidism	Pernicious anemia, hemolytic anemia, hypothyroidism, severe infection, and terminal states of debilitating disease
Cholinesterase	Serum: 0.6–1.6 delta pH Red cells: 0.6–1 delta pH	0.6–1.6 U 0.6–1 U	Nephrosis, and exercise	Nerve gas exposure (greater effect on red cell activity), and insecticide poisoning
Complement, C_3	75–175 mg/dL	0.75–1.75 g/L	Some inflammatory diseases, acute myocardial infarction, cancer	Acute glomerulonephritis, and disseminated lupus erythematosus with renal involvement

(*Continued*)

(*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Complement, C_4	14–40 mg/dL	0.15–0.45 g/L	Some inflammatory diseases, acute myocardial infarction, and cancer	Often decreased in immunologic disease, especially with active systemic lupus erythematosus, and hereditary angioneurotic edema
Complement, total (hemolytic)	90%–94% complement	30–60 U/mL	Some inflammatory diseases	Acute glomerulonephritis, meningitis, and subacute bacterial endocarditis
Copper	70–150 mcg/dL	11–24 mcmol/L	Cirrhosis of liver, and pregnancy	Wilson disease
Cortisol-RIA	8 AM: 5–23/mcg/dL 4 PM: 3–16 mcg/dL	138–635 nmol/L 80–330 nmol/L	Stress: infectious disease, surgery, burns, etc., pregnancy, Cushing syndrome, pancreatitis, and eclampsia	Addison disease, and anterior pituitary hypofunction
C-peptide reactivity	0.78–1.89 ng/mL	0.26–.63 mmol/L	Insulinoma	Diabetes
Creatine		15.3–61 mcmol/L	Pregnancy, skeletal muscle necrosis or atrophy, starvation, and hyperthyroidism	
Creatine phosphokinase (CPK)	Males: 50–325 mU/mL Females: 50–250 mU/mL	50–325 U/L 50–250 U/L	Myocardial infarction, skeletal muscle diseases, intramuscular injections, Crush syndrome, hypothyroidism, alcohol withdrawal delirium, alcoholic myopathy, cerebrovascular disease	
Creatine kinase (CK) isoenzymes	MM band present (skeletal muscle)-MB band absent (heart muscle)		MB band increased in myocardial infarction, ischemia	
Creatinine	Males: 0.4 to 1.0 mg/dL Females: 0.6–1.2 mg/dL	36 to 90 mmol/L 71–106 mmol/L	Nephritis, chronic renal disease	
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		Kidney diseases
Cryoglobulins, qualitative	Negative		Multiple myeloma, chronic lymphocytic leukemia, lymphosarcoma, systemic lupus erythematosus, rheumatoid arthritis, infective subacute endocarditis, some malignancies, and scleroderma	
11-Deoxycortisol	1 mcg/dL	<0.029 mcmol/L	Hypertensive form of virilizing adrenal hyperplasia due to an 11-β-hydroxylase defect	
Dibucaine inhibition	Normal: 79%–84%	0.79–0.84%		Important in detecting carriers of abnormal cholinesterase activity who are at risk for a number of conditions
Dihydrotestosterone	Males: 50–210 ng/dL Females: none detectable	1.72–7.22 nmol/L		Testicular feminization syndrome
Estradiol—RIA	Females: Follicular: 10–90 pg/mL Midcycle: 100–500 pg/mL Luteal: 50–240 pg/mL Follicular phase: 2–20 ng/dL Midcycle: 12–40 ng/dL Luteal phase: 10–30 ng/dL Postmenopausal: 1–5 ng/dL Males: 0.5–5 ng/dL	 37–370 pmol/L 367–1835 pmol/L 184–881 pmol/L	Pregnancy, or ovarian tumor	Ovarian failure
Estriol—RIA	Nonpregnant females: <0.5 ng/mL Pregnant females: 1st trimester: up to 1 ng/mL 2nd trimester: 0.8–7 ng/mL 3rd trimester: 5–25 ng/mL	<1.75 nmol/L Up to 3.5 nmol/L 2.8–24.3 nmol/L 17.4–86.8 nmol/L	Pregnancy	Ovarian failure

(*Continued*)

TABLE A-2 (*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Estrogens, total—RIA	Females: cycle days: Day 1–10: 61–394 pg/mL Day 11–20: 122–437 pg/mL Day 21–30: 156–350 pg/mL Males: 20–80 pg/mL	 61–394 ng/L 122–437 ng/L 156–350 ng/L 20–80 ng/L	Pregnancy, measured on a daily basis, can be used to evaluate response of hypogonadotrophic, hypoestrogenic women to human menopausal or pituitary gonadotropin	Fetal distress, ovarian failure
Estrone—RIA	Females: Day 1–10: 4.3–18 ng/dL Day 11–20: 7.5–19.6 ng/dL Day 21–30: 13–20 ng/dL Males: 2.5–7.5 ng/dL	 15.9–66.6 pmol/L 27.8–72.5 pmol/L 48.1–74 pmol/L 9.3–27.8 pmol/L	Pregnancy	Ovarian failure
Ferritin—RIA	Males: 18–270 ng/mL Females: 18–160 ng/mL	18–270 µg/L 18–160 µg/L	Nephritis, and hemochromatosis Certain neoplastic diseases, acute myeloid leukemia, and multiple myeloma	Iron deficiency
Folic acid—RIA	3–13 ng/mL	6.8–29.5 nmol/L		Megaloblastic anemias of infancy and pregnancy, inadequate diet, liver disease, malabsorption syndrome, and severe hemolytic anemia
Follicle-stimulating hormone (FSH)—RIA	Males: 1.24–7.8 mIU/mL Females: Follicular phase: 1.68–15 mIU/mL Peak of middle cycle: 21.9–56.6 mIU/mL Luteinic phase: 0.61–16.3 mIU/mL Menopausal females: 14.2–52.3 mIU/mL	1.24–7.8 IU/L 1.68–15 IU/L 21.9–56.6 IU/L 0.61–16.3 IU/L 14.2–52.3 IU/L	Menopause and primary ovarian failure	Pituitary failure
Galactose	<5 mg/dL	<0.28 mmol/L		Galactosemia
Gamma glutamyl transpeptidase	Males: 20–30 U/L Females: 1–24 U/L	0.03–0.5 mckat/L 0.02–0.4 mckat/L	Hepatobiliary disease, drug toxicity, myocardial infarction, renal infarction, and Zollinger–Ellison syndrome	
Gastrin—RIA	Fasting: 50–155 pg/mL Postprandial: 80–170 pg/mL	50–155 ng/L 80–170 ng/L	Duodenal ulcer, and pernicious anemia	
Glucose	Fasting: 60–100 mg/dL	≤5.6 mmol/L	Diabetes, nephritis, hypothyroidism, early hyperpituitarism, cerebral lesions, infections, pregnancy, and uremia	Hyperinsulinism, hyperthyroidism, late hyperpituitarism, Addison disease, and extensive hepatic damage
Glucose tolerance (oral)	Features of a normal response 1. Normal fasting between 60–110 mg/dL 2. No sugar in urine 3. Upper limits of normal Fasting = 125 mg/dL 1 hour = 190 mg/dL 2 hours = 140 mg/dL 3 hours = 125 mg/dL	3.3–6.05 mmol/L 6.88 mmol/L 10.45 mmol/L 7.70 mmol/L 6.88 mmol/L	Two-hour value >200 mg/dL (11.1 mmol/L) is diagnostic for diabetes	Decreased 2- and 3-hour values may occur with hypoglycemia in diabetes
Glucose-6-phosphate dehydrogenase (red cells)	Screening: Decolorization in 20–100 min Quantitative: 1.86–2.5 IU/mL RBC	 1860–2500 U/L		Drug-induced hemolytic anemia
Glycoprotein (alpha-1-acid)	50–120 mg/dL	0.5–1.2 g/L	Neoplasm, tuberculosis, diabetes complicated by degenerative vascular disease, pregnancy, rheumatoid arthritis, rheumatic fever, infectious liver disease, and systemic lupus erythematosus	

(*Continued*)

(*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Growth hormone—RIA	Males: 0–4 ng/mL Females: 0–10 ng/mL	0.4 mcg/L 0–18 mcg/L	Acromegaly, pregnancy, and estrogen therapy	Hypopituitarism
Haptoglobin	30–200 mg/dL	0.3–2.0 g/L	Chronic infections, and various inflammatory conditions	Hemolytic anemia, and hemolytic blood transfusion reaction
Hemoglobin (plasma)	Males: 12.4–17.4 g/dL Females: 11.7–16 g/dL	112–174 g/L 117–160 g/L	Transfusion reactions, paroxysmal nocturnal hemoglobinuria, and intravascular hemolysis	Anemia, pregnancy, and chronic renal disease
Glycohemoglobin (GHB, hemoglobin A_{1c}, hemoglobin A1)	Patients without diabetes and patients with diabetes with good glycemic control: 4.4%–6.4%		Suboptimal glucose control	
Hexosaminidase, total	Controls: 333–375 nM/mL/hr	333–375 mcmol/L/hr	Sandhoff disease	Tay–Sachs disease and heterozygotes
Hexosaminidase A	Controls: 55%–76% of total Heterozygotes: 26%–45% of total Tay–Sachs disease: 0%–4% of total Diabetes: 39%–59% of total	Fraction of total: 0.49–0.68 0.26–0.45 0–0.04 0.39–0.59		
High-density lipoprotein cholesterol (HDL cholesterol)	Males: 35–65 mg/dL Females: 35–80 mg/dL	0.91–1.68 mmol/L 0.91–2.07 mmol/L		HDL cholesterol is lower in patients with increased risk for coronary artery disease
17 Hydroxy-progesterone—RIA	Males: 0.5–2.0 ng/mL Females: 0.2–3.0 ng/mL Children: <1.0 ng/mL	1.5–6.0 nmol/L 0.6–9.0 nmol/L <3.0 nmol/L	Congenital adrenal hyperplasia, pregnancy, some cases of adrenal or ovarian adenomas	
Immunoglobulin A	Adults: 80–400 mg/dL	0.8–4.0 g/L	Gamma A myeloma, Wiskott–Aldrich syndrome, autoimmune disease, and hepatic cirrhosis	Ataxia telangiectasis, agammaglobulinemia, hypogammaglobulinemia, transient dysgammaglobulinemia, protein-losing enteropathies
Immunoglobulin D	0.5–12.0 mg/dL	5–120 mg/L	IgD multiple myeloma, some patients with chronic infectious diseases	
Immunoglobulin E	<1.0 mg/mL	<10 mg/L	Allergic reactions, parasitic infections	
Immunoglobulin G	Adults: 600–1800 mg/dL	6–18 g/L	IgG multiple myeloma, following hyperimmunization, autoimmune disease states, chronic infections	Congenital and acquired hypogammaglobulinemia, IgA multiple myelomas, Waldenström (IgM) macroglobulinemia, some malabsorption syndromes, and extensive protein loss
Immunoglobulin M	Adults: 55–250 mg/dL	0.55–2.5 g/L	Waldenström macroglobulinemia, parasitic infections, and hepatitis	Agammaglobulinemias, multiple myeloma, and chronic lymphocytic leukemia
Insulin—RIA	0–35 mcU/mL	144–243 pmol/L	Insulinoma, and acromegaly	Diabetes
Iron	50–150/mcg/dL	9–29 mcmol/L	Pernicious anemia, aplastic anemia, hemolytic anemia, hepatitis, and hemochromatosis	Iron deficiency anemia
Iron-binding capacity	IBC: 250–350 mcg/dL TIBC: 250–450 mcg/dL % Saturation: 10–50	45–63 mcmol/L 54–65 mcmol/L Fraction of total iron-binding capacity: 0.2–0.5	Iron deficiency anemia, acute and chronic blood loss, and hepatitis	Chronic infectious diseases, and cirrhosis
Isocitric dehydrogenase	50–180 U	0.83–3 U/L	Hepatitis, cirrhosis, obstructive jaundice, metastatic carcinoma of the liver, and megaloblastic anemia	

(*Continued*)

TABLE A-2 (*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Lactic acid (whole blood)	Venous: 5–15 mg/dL Arterial: 3–11 mg/dL	0.5–1.7 mmol/L 0.36–1.25 mmol/L	Increased muscular activity, heart failure, hemorrhage, shock, lactic acidosis, some febrile infections, and severe liver disease	
Lactic dehydrogenase (LDH)	<61 mU/mL	90–176 U/L	Untreated pernicious anemia, myocardial infarction, pulmonary infarction, and liver disease	
[a]Lactic dehydrogenase isoenzymes	140–280 mU/mL	140–280 U/L	LDH-1 and LDH-2 are increased in myocardial infarction, megaloblastic anemia, and hemolytic anemia	
Total lactic dehydrogenase		Fraction of total LDH:		
LDH-1	17%–27%	0.17–0.27	LDH-4 and LDH-5 are increased in pulmonary infarction, congestive heart failure, and liver disease	
LDH-2	29%–39%	0.29–0.39		
LDH-3	19%–27%	0.19–0.27		
LDH-4	8%–16%	0.08–0.16		
LDH-5	6%–16%	0.06–0.16		
Lead (whole blood)	Up to 40 mcg/dL	Up to 2 mcmol/L	Lead poisoning	
Leucine aminopeptidase	75–200 U/mL	75–200 kilounits/L	Liver or biliary tract diseases pancreatic disease, metastatic carcinoma of liver and pancreas, biliary obstruction	
[b]Lipase	<140 U/mL	<140 U/L	Acute and chronic pancreatitis, biliary obstruction, cirrhosis, hepatitis, and peptic ulcer	
Lipids, total	400–800 mg/dL	4–8 g/L	Hypothyroidism, diabetes, nephrosis, glomerulonephritis, andhyperlipoproteinemias.	Hyperthyroidism
Low-density lipoprotein cholesterol (LDL cholesterol)	mg/dL desirable levels: <160 if no coronary artery disease (CAD) and <2 risk factors <130 if no CAD and two or more risk factors <100 if CAD present		LDL cholesterol is higher in patients with increased risk for coronary artery disease	
Luteinizing hormone—RIA	Males: 1.5–9.3 mU/mL Females:	1.5–9.3 U/L	Pituitary tumor, or ovarian failure	Pituitary failure
	Follicular phase: 1.9–12.5 mU/mL	1.9–12.5 U/L		
	Midcycle: 8.7–76.3 mU/mL	8.7–76.3 U/L		
Lysozyme (muramidase)	4.0–15.6 mcg/mL	0.28–1.10 mcmol/L	Certain types of leukemia (acute myeloid leukemia), inflammatory states and infections	Acute lymphocytic leukemia
Magnesium	1.8–2.6 mg/dL	0.74–1.07 mmol/L	Excess ingestion of magnesium-containing antacids	Chronic alcoholism, severe renal disease, and diarrhea
Mercury	<10 mcg/L	<50 mcmol/L	Mercury poisoning	
Myoglobin	No myoglobin	0 mcg/mL	Myocardial infarction, myocardial ischemia, rhabdomyolysis, and malignant hyperthermia	Rheumatoid arthritis, and myasthenia gravis
5′ Nucleotidase	3.2–11.6 IU/L	3.2–11.6 U/L	Hepatobiliary disease	
Osmolality	50–1200 mOsm/kg 300–900 mOsm/kg in 24 hr	275–300 mmol/L	Diabetes insipidus, osmotic diuresis	Inappropriate secretion of ADH, Addison disease
Parathyroid hormone	10–50 pg/mL	10–50 ng/L	Hyperparathyroidism, chronic renal disease	Hypoparathyroidism
Phenylalanine	1.2–3.5 mg/dL 1st week 0.7–3.5 mg/dL thereafter	0.07–0.21 mmol/L 0.04–0.21 mmol/L	Phenylketonuria	
Phosphohexose isomerase	20–90 IU/L	20–90 U/L	Malignancy, disease of heart, liver, and skeletal muscles	
Phospholipids	125–300 mg/dL	1.25–3 g/L	Diabetes, or nephritis	
Phosphorus, inorganic	2.7–4.5 mg/dL	0.87–1.45 mmol/L	Chronic nephritis, and hypoparathyroidism	

(*Continued*)

(*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	Renal disease, acidosis, cell lysis, tissue breakdown, or hemolysis	Hyperparathyroidism, vitamin D deficiency, GI losses, diuretic administration
Prealbumin	16–35 mg/dL	160–350 mg/L	Malnutrition, severe or chronic illness, and liver disease	
Progesterone—RIA	Follicular phase: up to 0.8 ng/mL Luteal phase: 10–20 ng/mL End of cycle: <1 ng/mL Pregnant: up to 50 ng/mL in 20th week	2.5 nmol/L 31.8–63.6 nmol/L <3 nmol/L Up to 160 nmol/L	Useful in evaluation of menstrual disorders and infertility and in the evaluation of placental function during pregnancies complicated by toxemia, diabetes, or threatened miscarriage	
Prolactin—RIA	4–30 ng/mL	4–30 mcg/L	Pregnancy, functional or structural disorders of the hypothalamus, pituitary stalk section, and pituitary tumors	
Prostate-specific antigen	Age under 60 <3.6 ng/mL Age over 60 <6.6 ng/mL		Prostatic cancer, benign prostatic hyperplasia, prostatitis	
Protein, total Albumin Globulin	6–8 g/dL 3.5–5.5 g/dL 1.7–3.3 g/dL	60–80 g/L 40–55 g/L 17–33 g/L	Hemoconcentration, shock, globulin fraction increased in multiple myeloma, chronic infection, liver disease	Malnutrition, hemorrhage, loss of plasma from burns, and proteinuria
Protein Electrophoresis		35–55 g/L		
Albumin	3.5–5.5 g/dL	40–55 g/L		
Alpha-1 globulin	0.1–0.3 g/dL	1–3 g/L		
Alpha-2 globulin	0.6–1 g/dL	6–10 g/L		
Beta globulin	0.5–1.0 g/dL	5–10 g/L		
Gamma globulin	0.6–1.3 g/dL	6–13 g/L		
Protoporphyrin erythrocyte (whole blood)	Males: 11–45 mcg/dL Females: 19–52 mcg/dL	0.20–0.80 mcmol/L 0.34–0.92 mcmol/L	Lead toxicity, erythropoietic porphyria	
Pyridoxine	5–30 ng/mL	20–1.21 nmol/L		A wide spectrum of clinical conditions, such as depression, peripheral neuropathy, anemia, and reactions to certain drug therapies
Pyruvic acid (whole blood)	0.3–0.9 mg/dL	34–102 mcmol/L	Diabetes, severe thiamine deficiency, acute phase of some infections, possibly secondary to increased glycogenolysis and glycolysis	
Renin (plasma)—RLA	Normal diet: Supine: 0.3–1.9 ng/mL/h Upright: 0.6–3.6 ng/mL/h Low salt diet Supine: 0.9–4.5 ng/mL/h Upright: 4.1–9.1 ng/mL/h	 0.08–0.52 ng/L/S 0.16–1.00 mcg/L/S 0.25–1.25 mcg/L/S 1.13–2.53 mcg/L/S	Renovascular hypertension, malignant hypertension, untreated Addison disease, primary salt-losing nephropathy, low-salt diet, diuretic therapy, and hemorrhage	Frank primary aldosteronism, increased salt intake, salt–retaining steroid therapy, antidiuretic hormone therapy, and blood transfusion
Sodium	135–145 mEq/L	135–145 mmol/L	Hemoconcentration, nephritis, and pyloric obstruction	Alkali deficit, Addison disease, myxedema
Sulfate (inorganic)	0.5–1.5 mg/dL	0.05–0.15 mmol/L	Nephritis, and nitrogen retention	
Testosterone—RIA	Females: 20–80 ng/dL Males: 240–1200 ng/dL	0.7–2.8 nmol/L 18.3–41.8 nmol/L	Females: Polycystic ovary, and virilizing tumors	Males: Orchidectomy for neoplastic disease of the prostate or breast, estrogen therapy, Klinefelter syndrome, hypopituitarism, hypogonadism, and hepatic cirrhosis
T_3 (triiodothyronine) uptake	24%–34%	Relative uptake fraction: 0.24–0.34	Hyperthyroidism, thyroxine-binding globulin (TBG) deficiency, and androgens and anabolic steroids	Hypothyroidism Pregnancy, TBG excess, estrogens and antiovulatory drugs
T_3 total circulating—RIA	260–480 pg/dL	4.0–7.4 pmol/L	Pregnancy, and hyperthyroidism	Hypothyroidism

(*Continued*)

TABLE A-2 (*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
T_4 (thyroxine)—RIA	5.4–11.5 mcg/dL	57–148 nmol/L	Hyperthyroidism, thyroiditis, elevated thyroxine-binding proteins caused by oral contraceptives, and pregnancy	Primary and pituitary hypothyroidism, idiopathic involvement, cases of diminished thyroxine-binding proteins caused by androgenic and anabolic steroids, hypoproteinemia, and nephrotic syndrome
T_4, free	0.7–2 ng/dL	10–26 pmol/L	Euthyroid patients with normal free thyroxine levels may have abnormal T3 and T4 levels caused by drug preparations	
Thyroid-stimulating hormone (TSH)—RIA	0–15 mIU/L	0–15 mIU/L	Hypothyroidism	Hyperthyroidism
Thyroid-binding globulin	16–32 mcg/dL	120–180/mcg/L	Hypothyroidism, pregnancy, estrogen therapy, oral contraceptive use, and genetic and idiopathic liver disease	Use of androgens and anabolic steroids, nephrotic syndrome, and marked hypoproteinemia
Transferrin	200–380 mg/dL	2.3–3.2 g/L	Pregnancy, iron deficiency anemia due to hemorrhaging, acute hepatitis, polycythemia, and oral contraceptive use	Pernicious anemia in relapse, thalassemic and sickle cell disease, chromatosis, neoplastic and hepatic diseases, and malnutrition
Triglycerides	Males: 44–180 mg/dL Females: 10–190 mg/dL	0.44–2.01 mmol/L 0.11–2.21 mmol/L	Increased risk for atherosclerosis	
Troponin				
Troponin I	<0.35 ng/mL	<0.35 mcg/L	Myocardial infarction	
Troponin T	<0.1 ng/mL	<0.1 mcg/L	Rhabdomyolysis, and severe crushing injuries	
Tryptophan	1.4–3 mg/dL	68.6–147 nmol/L	Tyrosinosis	Tryptophan-specific malabsorption syndrome
Tyrosine	0.5–4 mg/dL	27.6–220.8 mmol/L	Acute glomerulonephritis	Severe hepatic failure
Urea nitrogen (BUN)	8–20 mg/dL	2.9–7.5 mmol/L	Obstructive uropathy, mercury poisoning, and nephrotic syndrome	Pregnancy
Uric acid	Males: 3.4–7.0 mg/dL Females: 2.4–6.0mg/dL	202–416 mcmol/L 143–357 mmol/L	Gouty arthritis, acute leukemia, lymphomas treated by chemotherapy, and toxemia of pregnancy	Defective tubular reabsorption
Viscosity	1.4–1.8 relative to water at 37°C (98.6°F)		Patients with marked increases of the gamma globulins, and hypervitaminosis A	
Vitamin A	30–120 mcg/dL	1.05–4.20 mcmol/L		Vitamin A deficiency, celiac disease, sprue, obstructive jaundice, giardiasis, and parenchymal hepatic disease
Vitamin B_1 (thiamine)	1.6–4 mcg/dL	47.4–135.7 nmol/L		Anorexia, beriberi, polyneuropathy, and cardiomyopathies
Vitamin B_6 (pyridoxal phosphate)	5–30 ng/mL	20–121 nmol/L		Chronic alcoholism, malnutrition, uremia, and malabsorption, such as celiac disease
Vitamin B_{12}—RIA	200–900 pg/mL	148–666 pmol/L	Hepatic cell damage and in association with the myeloproliferative disorders (the highest levels are encountered in myeloid leukemia)	Strict vegetarianism, alcoholism, pernicious anemia, total or partial gastrectomy, ileal resection, sprue and celiac disease, and fish tapeworm infestation
Vitamin E	0.5–1.8 mg/dL	12–42 mcmol/L		Vitamin E deficiency
Xylose absorption test	2 hr, 30–50 mg/dL	2–3.35 mmol/L		Malabsorption syndrome
Zinc	55–150 mcg/dL	7.65–22.95 mcmol/L	Coronary artery disease, arteriosclerosis, and industrial exposure	Metastatic liver disease, tuberculosis, and sprue

[a]By radioimmunoassay.
[b]Varies among methods.

TABLE A-3 Reference Ranges—Immunodiagnostic Test

Test	Normal Value	Clinical Significance
Acetylcholine receptor binding antibody	Negative or <0.03 nmol/L	Considered to be diagnostic for myasthenia gravis in patients with symptoms
Anti–ds-DNA antibody	<70 U by enzyme-linked immunosorbent assay (ELISA) <1:20 by indirect fluorescence	Valuable in supporting diagnosis or monitoring disease activity and prognosis of systemic lupus erythematosus (SLE)
Antiglomerular basement membrane antibody	Negative or <5 UL	Primarily used in the differential diagnosis of glomerular nephritis induced by antiglomerular basement membrane antibodies from other types of glomerular nephritis
Anti-insulin antibody	<3% binding of labeled beef and pork insulin by patient's serum; or <9 mIU/L	Helpful in determining the best therapeutic agent in patients with diabetes and the cause of allergic manifestations. Also used to identify insulin resistance
Antinuclear antibody (ANAs)	Negative, <1:40	Increased in SLE, chronic hepatitis, scleroderma, leukemia, and mononucleosis
Antiparietal cell antibody	Negative	Helpful in diagnosing chronic gastric disease and differentiating autoimmune pernicious anemia from other megaloblastic anemias
Antiribonucleoprotein antibody	Negative	Helpful in differential diagnosis of systemic rheumatic disease
Antiscleroderma antibody	Negative	Highly diagnostic for scleroderma
Anti-Smith antibody	Negative	Highly diagnostic of SLE
Anti–SS-A/anti–SS-B antibody	Negative	SS-A antibodies are found in Sjögren syndrome alone or associated with lupus SS-B antibodies are associated with primary Sjögren syndrome
Antithyroglobulin and antimicrosomal antibodies	<1:100 titer by gelatin or hemagglutination	Presence and concentration is important in evaluation and treatment of various thyroid disorders, such as Hashimoto thyroiditis and Graves' disease. May indicate previous autoimmune disorders
CA 15–3 tumor marker	<30 IU/mL	Increased in metastatic breast cancer
CA 19–9 tumor marker	<37 IU/mL	Increased in pancreatic, hepatobiliary, gastric, and colorectal cancer, gallstones
CA 125	0–35 IU/mL	Increased in colon, upper gastrointestinal (GI), ovarian, and other gynecologic cancers: pregnancy, peritonitis
Carcinoembryonic antigen (CEA)—RLK	0–2.5 mcg/L (nonsmoker) 0–5 mcg/L (smoker)	The repeatedly high incidence of this antigen in cancers of the colon, rectum, pancreas, and stomach suggests that CEA levels may be useful in the therapeutic monitoring of these conditions, but it is not a screening test
Cold agglutinins	Negative or <1:64	Increased in mycoplasma pneumonia, viral illness, mononucleosis, multiple myeloma, scleroderma
C-reactive protein	<1 mg/dL (<10 mg/L)	Increase indicates active inflammation
High sensitivity assay for C-reactive protein (hs-CRP)	0.2–8.0 mg/L	Cardiovascular disease risk
Cytomegalovirus antibodies (CMV IgG)	Negative: <0.9 units/mL	Positive >1:0 unit/mL if exposed to CMV at any time. Acute and convalescent specimens can help identify acute infection
Cytomegalovirus antibodies (CMV IgM)	Negative: <0:79 Equivocal: 0:80–1.20	Positive >1:20 usually indicates acute infection Repeat specimen in 1–2 weeks for equivocal result
Epstein–Barr virus serology (viral capsid antigen IgG and IgM, early antigen IgG, and nuclear antigen IgG)	Negative	Differentiation of acute from chronic or old infection
Hepatitis A virus antibodies, IgM (HAV-Ab/IgM)	Negative	Positive in acute-stage hepatitis A; develops early in disease
Hepatitis A virus antibodies, IgG (HAV-Ab/IgG)	Negative	Positive if previous exposure and immunity to hepatitis A
Hepatitis B surface antigen (HBsAg)	Negative	Positive in acute-stage hepatitis B
Hepatitis B surface antibody (HBsAb)	Negative	Positive if previous exposure and immunity to hepatitis B
Hepatitis C virus antibodies	Negative	Positive in exposure to hepatitis C virus; may indicate acute, chronic, or cleared infection
Hepatitis C virus RNA	Negative	Positive in hepatitis C infection, can be quantitative
Homocysteine	0.54–2.30 mg/L (4–17 mcmol/L)	Cardiovascular disease risk Folic acid deficiency Vitamin B_{12} deficiency
Infectious mononucleosis tests (monospot, monotest, heterophile antigen test, Epstein–Barr virus [EBV], antiviral capsid antigen IgM and IgG)	Negative	Positive monospot and monotest are presumptive, positive EBV IgM and IgG indicate acute and recent or past infection, respectively

(*Continued*)

TABLE A-3 (*Continued*)

Test	Normal Value	Clinical Significance
Lyme disease titer	Negative, <1:256 by indirect fluorescent antibody method; nonreactive by ELISA	Positive results help diagnose Lyme disease. False positive may occur with high rheumatoid factor titers or syphilis Positive ELISA confirmed by Western blot test
Pyroglobulin test	Negative	These abnormal proteins may be associated with myeloma, lymphoma, polycythemia vera, and SLE
Rheumatoid factor	Negative	Elevated in rheumatoid arthritis, lupus endocarditis, tuberculosis, syphilis, sarcoidosis, cancer
T- and B-cell lymphocyte surface markers T-helper/T-suppressor ratio	T- and B-cell lymphocyte surface markers: Percent T cells (CD2) 60%–88% Percent helper cells (CD4) 34%–67% Percent suppressor cells (CD8) 10%–42% Percent B cells (CD19) 3%–21% Absolute counts: Lymphocytes 0.66–4.60 thou/mL T cells 644–2201 cells/mL Helper cells 493–1191 cells/mL Suppressor T cells 182–785 cells/mL B cells 92–392 cells/mL Lymphocyte ratio: T_H/T_S ratio >1	Used to evaluate immune system by identifying the specific cells involved in the immune response. Valuable in diagnosis of lymphocytic leukemia, lymphoma, and immunodeficiency diseases including AIDS, and in the assessment of patient response to chemotherapy and radiation

TABLE A-4 Reference Ranges—Urine Chemistry

	Normal Adult Reference Range		Clinical Significance	
Test	Conventional Units	SI Units	Increased	Decreased
Acetone and acetoacetate	Zero		Diabetic ketoacidosis, starvation.	
Aldosterone	With normal salt diet: Normal: 3–19 mcg/24 hr Reno vascular: 10–40 mcg/24 hr Tumor: 20–100 mcg/24 hr	 11.1–55.5 nmol/24 hr 8–51 nmol/24 hr 55.4–277 nmol/24 hr	Primary aldosteronism (adrenocortical tumor), secondary aldosteronism, salt depletion, potassium loading ACTH in large doses, heart failure, cirrhosis with ascites formation, nephrosis, pregnancy	
Alpha amino nitrogen	50–200 mg/24 hr	3.6–14.3 nmol/24 hr	Leukemia, phenylketonuria, other metabolic diseases	
Amylase	1–17 units excreted per hr	0.017–0.29 U/hr	Acute pancreatitis	
Arylsulfatase A	1 hour test 2–19 U/mL 24-hour test 170–2000/24 hours	2–19 units/hr 2.89–34 mckat/L		
Calcium	100–250 mg/24 hr	2.5–6.2 mmol/24 hr	Hyperparathyroidism, Vitamin D intoxication, Fanconi syndrome	Hypoparathyroidism
Catecholamines	Total: 0–275 mcg/24 hr Epinephrine: 0%–20% Norepinephrine: 60%–90%	0–275 mcg/24 hr Fraction total: 0–20 mcg/24 hr Fraction total: 0.60–0.90	Pheochromocytoma Neuroblastoma	Vitamin D deficiency
Chorionic gonadotrophin, qualitative (pregnancy test)	Negative		Pregnancy, chorionepithelioma, hydatidiform mole	
Copper	15–60 mcg/24 hr	0.22–0.9 mcmol/24 hr	Wilson disease, cirrhosis, nephrosis	
Coproporphyrin	50–300 mcg/24 hr	0.075–0.45 mcmol/24 hr	Poliomyelitis, lead poisoning, porphyria	
Cortisol, free	<50 mcg/24 h	<138 nmol/24 hr	Cushing syndrome	
Creatinine	Males: 14–16 mg/kg body weight/24 hr Females: 11–20 mg/kg body weight/24 hr	124–230 mmol/kg body weight/24 hr 97–177 mmol/kg body weight/24 hr	Muscular dystrophy Fever, carcinoma of liver, pregnancy, hyperthyroidism, myositis	
Creatine	0–270 mg/24 hr	0–2.05 mmol/24 hr	Typhoid fever, salmonella infections, tetanus	Muscular atrophy, anemia, advanced degeneration of kidneys, leukemia

(*Continued*)

(*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		Renal diseases
Cystine and cysteine	10–100 mg/24 hr	0.08–0.83 mmol/24 hr	Cystinuria	
Delta aminolevulinic acid	1.5–7.5 mg/dL	11–57/mcmol/day	Lead poisoning, porphyria hepatica, hepatitis hepatic carcinoma	
11-Desoxycortisol	20–100 mcg/24 hr	0.6–2.9 unit/24 hr	Hypertensive form of virilizing adrenal hyperplasia due to an 11-beta hydroxylase defect.	
Estriol (placental)	Weeks of pregnancy 12 16 20 24 28 32 36 40	mcm/24 hr <1 2–7 4–9 6–13 8–22 12–43 14–45 19–46	mmol/24 hr <3.5 7–24.5 14–32 21–45.5 28–77 42–150 49–158 66.5–160	Decreased values occur with fetal distress of many conditions, including preeclampsia, placental insufficiency, and poorly controlled diabetes
Estrogens, total (fluorometric)	Females: Onset of menstruation: 4–25 mcg/24 hr Ovulation peak: 28–100 mcg/24 hr Luteal peak: 22–105 mcg/24 hr Menopausal: 1.4–19.6 mcg/24 h Males: 5–18 mcg/24 h	 4–25 mcg/24 hr 28–100 mcg/24 hr 22–105 mcg/24 hr 1.4–19.6 mcg/24 hr 5–18 mcg/24 hr	Hyperestrogenism due to gonadal or adrenal neoplasm	Primary or secondary amenorrhea
Etiocholanolone	Males: 1.9–6 mg/24 hr Females: 0.5–4 mg/24 h	6.5–20.6 mcmol/24 hr 1.7–13.8 mcmol/24 h	Adrenogenital syndrome Idiopathic hirsutism	
Follicle-stimulating hormone—RIA	Females: Follicular: 5–20 IU/24 hr Luteal: 5–15 IU/24 hr Midcycle: 15–60 IU/24 hr Menopausal: 50–100 IU/24 hr Males: 5–25 IU/24 hr	 5–20 IU/d 5–15 IU/d 15–60 IU/d 50–100 IU/d 5–25 IU/d	Menopause and primary ovarian failure	Pituitary failure
Glucose	Negative		Diabetes, pituitary disorders, increased ICP, lesion in floor of 4th ventricle	
Hemoglobin and myoglobin	Negative		Extensive burns, ransfusion of incompatible blood, myoglobin increased in severe crushing injuries to muscles	
Homovanillic acid		5.5–27.5 mcmol/d	Neuroblastoma	Addison disease
17-hydroxycorticosteroids	8 mg/24 hr 2–10 mg/24 hr	5.5–27.5 mcmol/d	Cushing syndrome	Anterior pituitary hypofunction
5-Hydroxyindoleacetic acid, qualitative	Negative		Malignant carcinoid tumors	
17-ketosteroids, total	Males: 4–14 mg/24 hr Females: 2–12 mg/24 hr	35–76 mcmol/24 hr 21–55 mcmol/24 hr	Interstitial cell tumor of testes, simple hirsutism, occasionally adrenal hyperplasia, Cushing syndrome, adrenal cancer, virilism, adrenoblastoma	Thyrotoxicosis, female hypogonadism, diabetes, hypertension, debilitating disease of mild to moderate severity, eunuchoidism, Addison disease, panhypopituitarism, myxedema, nephrosis
Lead	<125 mcg/24 hr	<60 mcmol/24 hr	Lead poisoning	
Luteinizing hormone	Males: 5–18 IU/24 hr Females: Follicular phase: 2–25 IU/24 hr Ovulatory peak: 30–95 IU/24 hr Luteal phase: 2–20 IU/24 hr Postmenopausal: 40–110 IU/24 hr	 2–25 IU/d 30–95 IU/d 2–20 IU/d 40–110 IU/d	Pituitary tumor, ovarian failure	Failure of pituitary or hypothalamus, anorexia nervosa

(*Continued*)

TABLE A-4 (*Continued*)

Test	Normal Adult Reference Range		Clinical Significance	
	Conventional Units	SI Units	Increased	Decreased
Metanephrines, total	<1.4 mg/24 hr	<7 mcmol/24 hr	Pheochromocytoma; a few patients with pheochromocytoma may have elevated urinary metanephrines but normal catecholamines and vanillylmandelic acid (VMA)	
Osmolality	50–1,200 mOsm/kg	50–1,200 mmol/kg	Useful in the study of electrolyte and water balance	
Oxalate	Up to 45 mg/24 hr	Up to 500/mcmol/24 hr	Primary hyperoxaluria	
Phenylpyruvic acid qualitative	Negative		Phenylketonuria	
Phosphorus, inorganic	0.9–1.3 g/24 hr	29–42 mmol/24 hr	Hypoparathyroidism, vitamin D intoxication, Paget disease, metastatic neoplasm to bone	Hypoparathyroidism, vitamin D deficiency
Porphobilinogen, qualitative	Negative		Chronic lead poisoning, acute porphyria, liver disease	
Porphobilinogen quantitative	0–1 mg/24 hr	0–4.4 mcmol/24 hr	Acute porphyria, liver disease	
Porphyrins, qualitative	Negative		See porphyrins, quantitative.	
Porphyrins, quantitative (coproporphyrin and uroporphyrin)	Coproporphyrin: 50–160 mcg/24 hr Uroporphyrin: up to 50 mcg/24 hr	0.075–0.24 mcmol/24hr Up to 0.06 mcmol/24 hr	Porphyria, lead poisoning (only coproporphyrin increased)	
Potassium	26–123 mEq/24 hr	26–123 mmol/24 hr	Hemolysis, chronic renal disease, acidosis, Cushing syndrome, corpus luteum cysts	Diarrhea, adrenocortical insufficiency
Pregnanediol	Females: Proliferative phase: 0.5–1.5 mg/24 hr Luteal phase: 2–7 mg/24 hr Menopause: 0.2–1 mg/24 hr	 1.6–4.8 mcmol/24 hr 6–22 mcmol/24 hr 0.6–3.1 mcmol/24 hr	When placental tissue remains in the uterus following parturition, some cases of adrenocortical tumors	Placental dysfunction, threatened abortion, intrauterine death
Pregnancy: Weeks of gestation	mg/24 hr	mcmol/24 hr		
10–12	5–15	15.6–47		
12–18	5–25	15.6–78.0		
18–24	15–33	47.0–103.0		
24–28	20–42	62.4–131.0		
28–32	27–47	84.2–146.6		
Pregnanetriol	Females: 0.1–2.2 mg/24 hr Males: 0.4–2.5 mg/24 hr	0.3–6.5 mcmol/24 hr 1.2–7.5 mcmol/24 hr	Congenital adrenal androgenic hyperplasia	
Protein	<150 mg/24 hr	<150 mg/24 hr	Nephritis, heart failure, mercury poisoning, Bence Jones protein in multiple myeloma, febrile states, hematuria	
Sodium	75–200 mEq/24 hr	75–200 mmol/24 hr	Useful in detecting gross changes in water and salt balance	
Titratable acidity	20–40 mEq/24 hr	20–40 mmol/24 hr	Metabolic acidosis	Metabolic alkalosis
Urea nitrogen	9–16 gm/24 hr	0.32–0.57 mol/L	Excessive protein catabolism	Impaired kidney function
Uric acid	250–750 mg/24 hr	1.48–4.43 mmol/24 hr	Gout	Nephritis
Urobilinogen	Random urine: <0.25 mg/dL 24-hour urine: up to 4 mg/24 hr	<0.42 mol/24 hr Up to 6.76 mcmol/24 hr	Liver and biliary tract disease, hemolytic anemias	Complete or nearly complete biliary obstruction, diarrhea
Vanillylmandelic acid (VMA)	0.7–6.8 mg/24 hr	3.5–34.3 mcmol/24 hr	Pheochromocytoma, neuroblastoma, ingestion of coffee, tea, aspirin, bananas, and several different drugs	Renal insufficiency
Xylose absorption test (5-hour)	16%–33% of ingested xylose	Fraction absorbed: 0.16–0.33		
Zinc	0.15–1.2 mg/24 hr	2.3–18.4 mcmol/24 hr		Malabsorption syndromes

TABLE A-5 Selected Reference Ranges—Cerebrospinal Fluid (CSF)

	Normal Adult Reference Range		Clinical Significance	
Test	Conventional Units	SI Units	Increased	Decreased
RBCs	None	None	Any RBCs are due to traumatic tap or subarachnoid hemorrhage	
WBCs	0–5 cells/mm^3	0–5 × 10^6/L	Tumor, meningitis, subarachnoid hemorrhage, infarct, and abscesses	
Chloride	120–130 mEq/L	120–130 mmol/L	Not neurologically significant	Acute generalized meningitis and tuberculous meningitis
Glucose	50–75 mg/100 ml	3.00–4.00 mmol/L	Not neurologically significant	Associated with bacteria in CSF
Protein	14–45 mg/100 ml	150–450 mg/L	Tubercular meningitis, neurosyphilis, poliomyelitis, Guillain–Barré syndrome, subdural hematoma, tumors, and multiple sclerosis	Can occur in hyperthyroidism and benign intracranial hypertension after removal of large amounts of CSF

RBCs, red blood cells; WBCs, white blood cells.

Appendix B
Assessment and Management of Patients Who are LGBTQ

LEARNING OBJECTIVES

On completion of this topic, the learner will be able to:

1. Describe the importance of providing inclusive healthcare environments for people who are lesbian, gay, bisexual, transgender, and queer.
2. Use inclusive terminology when communicating and conducting an assessment with a person who is lesbian, gay, bisexual, transgender, and queer.
3. Explain and demonstrate the proper techniques to perform a health history and physical assessment and discriminate between normal and abnormal findings identified in the patient who is lesbian, gay, bisexual, transgender, and queer.
4. Describe the various medical procedures and hormone treatments available for the person who is undergoing gender reassignment.
5. Compare and contrast surgical procedures available to people seeking gender reassignment in terms of indications and preoperative and postoperative complications.
6. Use the nursing process as a framework for care of the patient who undergoes gender reassignment surgery.

NURSING CONCEPTS

Assessment
Communication
Development/Human Development
Family
Identity
Professionalism/Professional Behaviors
Sexuality

GLOSSARY

bisexual: people who are romantically, emotionally, or sexually attracted to both male and female genders
cisgender: people who identify with the gender that matches the sex assigned to them at birth
gay: people who are romantically, emotionally, or sexually attracted to the same gender, such as men attracted to men
gender: set of socially constructed norms and behaviors that are taught to women and men
gender dysphoria: distress a person feels due to a mismatch between their gender identity and sex assigned at birth
gender identity: the internal self-conception of one's gender
intersex: a term used for a person who is born with biological traits that do not fit into those that traditionally characterize either male or female
lesbian: a term that gay women, or those women who are romantically, emotionally, or sexually attracted to other women, may prefer to use
LGBTQ: acronym that stands for lesbian, gay, bisexual, transgender, and queer
queer: people who are romantically, emotionally, or sexually attracted to numerous genders (male, female, transgender, intersex, etc.) or people who identify as nonheterosexual but do not want to use labels, such as gay, lesbian, or bisexual
questioning: a person who is unsure or is still exploring their sexual orientation or is concerned about applying a social label to themselves
sex: refers to the physical or biological characteristics that distinguish women and men, such as chromosomes, genitals, and hormones
sexual orientation: umbrella term that refers to romantic, emotional, or sexual attraction to persons of the opposite gender, the same gender, or to both or more than one gender
third-person pronouns: a way of referencing a person other than the self that may or may not use gender-specific labels (e.g., he/him, she/her, they/them)
transgender: umbrella term used to describe the full range of people whose gender identity does not match with the sex assigned to them at birth
transgender man: refers to a person who was assigned a female sex at birth but identifies with a male or masculine gender
transgender woman: refers to a person who was assigned a male sex at birth but identifies with a female or feminine gender
transition: process of aligning a person's gender expression with their self-identified gender identity, which can include social, medical, surgical, and legal changes

Introduction

People who are **LGBTQ** (lesbian, gay, bisexual, transgender, and queer) have unique health care needs. They also experience particular health risks and disparities based on sexuality and gender identity. Increasingly, nursing and medical professionals are recognizing these risks and disparities; furthermore, these professionals are acknowledging the importance of providing culturally appropriate care to people who identify as LGBTQ. Nurses will encounter people who are LGBTQ and their families in every practice setting. As they would for other diverse populations, nurses should be prepared to provide quality and culturally appropriate care. This appendix focuses on the terminology around sexuality and gender identity, culturally appropriate assessment and communication, and assessment and management of patients who identify as LGBTQ, and, in particular, the unique health care needs of those patients seeking gender reassignment. The management of patients seeking gender reassignment using both nonsurgical and surgical treatments is discussed.

Sexuality and Gender Identity

Understanding the meaning and significance of the concepts and terminology for sexuality and gender identity is important to caring for patients who are LGBTQ.

Sexuality

Human sexuality is the way people experience and express themselves sexually. This involves biological, physical, emotional, or social feelings. Sexual orientation, which is a component of sexuality, is different than gender (see discussion below). **Sexual orientation** is an umbrella term that refers to romantic, emotional, or sexual attraction to persons of the opposite gender, the same gender, or to more than one gender. There are many terms that people use to describe their sexual orientation; however, the most commonly used terms are *heterosexual* or *straight*, *gay* or *lesbian*, *bisexual*, and *queer*.

People who are attracted to a different gender, such as women who are attracted to men, typically identify as heterosexual or straight. People who are attracted to the same gender, such as men attracted to men, often identify as gay. Gay women may prefer the term **lesbian**. People who are attracted to both male and female genders usually identify as **bisexual**.

Although the term *queer* was historically used as a word of insult, many people now choose to use it to identify their sexual orientation. People who are **queer** typically experience attractions to numerous genders (male, female, transgender, intersex, etc.). A person who does not want to use labels, such as gay, lesbian, or bisexual, may also use the term queer to identify as a nonheterosexual.

People who are exploring or are unsure of their sexual orientation may refer to themselves as **questioning**. Questioning one's own sexuality can be difficult and confusing and can take years to understand. This term can also apply to people who are concerned about applying a social label (e.g., gay, lesbian, bisexual, queer) to themselves and may prefer to use this term.

Gender Identity

To fully understand the term *gender identity*, the concepts of *sex* and *gender* must be discussed first. **Sex** in the context of gender identity refers to the physical or biological characteristics that distinguish women and men, such as chromosomes, genitals, and hormones (Eliason & Chinn, 2018). For example, women have XX chromosomes, a uterus and ovaries, and the primary sex hormone is estrogen; whereas, men have XY chromosomes, a penis and testicles, and the primary sex hormone is testosterone. In most societies, people are assigned either the male or female sex at birth. However, some persons do not clearly have these defined binary sets of sex chromosomes or may not have clearly distinguishable genitalia. **Intersex** is a term used for a person who is born with biological traits that do not fit into those that traditionally characterize either male or female.

Gender is a set of socially constructed characteristics of women and men (World Health Organization, 2019). Although a person is either assigned as male or female at birth based on sex characteristics, they are taught norms and behaviors that are appropriate for their gender. Gender is usually the first thing we notice about a person based on cues, such as voice, communication style, hairstyle, clothing, and mannerisms. Gender norms, behaviors, and cues vary from society to society and can be changed.

Gender identity refers to how a person feels about themselves or their self-concept as female or male, feminine or masculine, or as something on the continuum between the two extremes (Eliason & Chinn, 2018). **Cisgender** is a term that often refers to people who identify with the gender that matches the sex assigned to them at birth (e.g., a person with a female sex that identifies as a woman). **Transgender** is an umbrella term used to describe the full range of people whose gender identity does not match with the sex assigned to them at birth. Although there is a diversity of terms that transgender people may use to identify their gender (e.g., trans, gender nonconforming, agender, and genderqueer), this appendix will use two main terms: transgender woman and transgender man. **Transgender woman**, or male to female, refers to a person who was assigned a male sex at birth but identifies with a female or feminine gender. **Transgender man**, or female to male, refers to a person who was assigned a female sex at birth but identifies with a male or masculine gender.

It is important to remember that gender identity and sexual orientation are two different self-concepts. Sexual orientation refers to a person's attraction, and gender identity refers to how a person feels about their gender. For example, a transgender man who is attracted only to men has a male gender identity and a gay sexual orientation. Health care professionals should never assume a person's sexual orientation or gender identity based on physical characteristics, mannerisms, communication style, voice, clothing, or hairstyle.

Health Risks

The root cause of health risks or disparities among people who are LGBTQ is stigma (i.e., negative and unfair beliefs).

As compared to people who are heterosexual and cisgender, people who are LGBTQ are at greater risk for certain physical and mental health issues. In terms of mental health disorders, people who are LGBTQ have a higher rate of depression and anxiety (Bostwick, Hughes, Steffen, et al., 2019); (Ross, Salway, Tarasoff, et al., 2018); (Witcomb, Bouman, Claes, et al., 2018) and experience more suicidality (Lyons, Walters, Jack, et al., 2019); (McNeil, Ellis, & Eccles, 2017). Nearly 50% of people who are transgender have reported suicide attempts. Moreover, people who are LGBTQ tend to experience more victimization, such as physical or verbal harassment, which is associated with higher rates of depression and suicidality (Burks, Cramer, Henderson, et al., 2018).

Women who are lesbian, bisexual, or queer tend to be at greater risk for obesity and cardiovascular disease as compared to heterosexual women (Simoni, Smith, Oost, et al., 2017). Obesity in women who are lesbian, bisexual, or queer is linked to dysregulated eating, such as emotional- or binge-eating. The causes of dysregulated eating are complex and include biological, psychological, and social factors. In women who are lesbian, bisexual, or queer, stigma is one of the root causes of obesity. Stigmatizing experiences, such as discrimination or victimization, leads to emotional distress, which in turn is associated with dysregulated eating as a coping strategy (Mason, Smith, & Lavender, 2019).

Men who are gay or bisexual and transgender women have higher rates of infection with the human immune deficiency virus (HIV) as compared to the general population. Men who are gay or bisexual is the population most affected by HIV in the United States (Centers for Disease Control and Prevention [CDC], 2019a). People who are transgender receive an HIV diagnosis at three times the rate of the national average (CDC, 2019b). Among these populations, rates of HIV are even higher among certain subgroups, especially people who are African American and young adult (see Chapter 55 for further discussion on HIV).

Assessment

Nurses should strive to create a welcoming, inclusive, and therapeutic relationship with every patient. To better achieve this type of relationship with people who are LGBTQ, nurses should use inclusive terms and language. This will increase the likelihood of eliciting accurate information from anyone whose experience is different from cultural norms (Eliason & Chinn, 2018). Using inclusive language conveys to the person who is LGBTQ that the interviewer is open to hearing about their sexuality, gender identity, and relationships. If a nurse does not yet know a patient's sexual orientation and gender identity, they should always use neutral language to ensure the patient is comfortable during the assessment (see the Resources section at the end of the appendix for educational materials that promote developing welcoming and inclusive patient–provider relationships).

All over the world, people tend to communicate using a binary gender system (female or male) and based on the assumption that people are heterosexual. This type of communication practice can be harmful to people who are LGBTQ, especially in the health care setting. Nurses should strive to use language terms that avoid assumptions about a patient's gender identity and sexual orientation. For example, nurses should avoid using singular **third-person pronouns** (a way of referencing a person other than the self that may use gender-specific labels) and salutations that use gender-specific labels (e.g., sir/miss/madam, Mr./Mrs./Ms.) until confirming the patient's preferences. They should also avoid using terms that assume sexual orientation of the patient and their family (e.g., wife/husband, boyfriend/girlfriend, mother/father). Table B-1 provides specific examples of neutral questions and statements.

Nurses should routinely assess each patient's sexual orientation and gender identity (SO/GI), including preferred pronouns. Assessing for SO/GI in the health care setting facilitates the provision of enhanced, holistic, person-centered care. For example, people who are LGBTQ may have unique health risks that need attention or may have a diverse family structure.. Thus, nurses should be skilled at properly assessing for SO/GI and preferred pronouns (Chart B-1).

Assessing for family structure and other important relationships should be routine for every patient. People who are LGBTQ may have diverse or nontraditional family structures and may include people who are not biologically related. Nurses should assess for family and family of choice. Family of choice is a commonly used term among people who are LGBTQ. Some people who are LGBTQ have been rejected by their family of origin and thus create their own family network of people who support and care for them (Eliason & Chinn, 2018). Moreover, some people who are LGBTQ fear discrimination and exclusion of not only themselves but also their family. (Eliason & Chinn, 2018).

It is best to start the interview with an open-ended question, such as "Tell me about your family and social support system." As the nurse asks follow-up questions, neutral terms should be used when inquiring about partners/significant others and parents/guardians (examples are listed in Table B-1). Also, the nurse should not assume a person who is LGBTQ does not have children. Many people who are LGBTQ have children through adoption, surrogacy, and previous relationships. If the patient has children, the nurse should avoid making assumptions about the family structure. Finally, the nurse should mirror the language and terms used by the patient and their family. For example, if a male-identifying patient refers to his significant other as "husband," the nurse should not choose to use a different term, such as "partner."

In terms of health assessment, people who are LGBTQ typically do not require specific assessments or diagnostic tests. They should receive nursing and medical person-centered care like any other patient. Depending on the health care setting, the nurse may want to focus parts of their assessment on those health risks mentioned earlier. Time could be spent asking the person who is LGBTQ about anxiety, depression, suicidality, and discrimination and victimization. Since gay and bisexual men and transgender women have higher rates of HIV, sexual activity, safe sex practices, and HIV status should be assessed. People who identify as transgender should be asked about hormone treatment and surgical procedures only if it is relevant to the care being provided.

Chart B-1 PERSONAL INFORMATION

The nurse introduces these assessment questions by stating:

- "I am going to ask you a few questions about your sexual orientation and gender identity so we can provide personalized and affirmative care to you. These are questions I ask every patient. If you do not feel comfortable answering these questions, we can skip them."

The nurse assesses for gender identity using a two-step question:

- "What sex was listed on your birth certificate?"
- "What is your current gender identity?" or "How do you describe your gender identity?"

Assessing for pronouns:

- "What pronouns do you prefer we use?"
- If the patient is unsure of what this means, you can ask, "Do you use the pronouns he/him, she/her, or something else?"

Assessing sexual orientation:

- "What is your sexual orientation?" or "How do you describe your sexual orientation?"

Assessing for preferred name:

- "What name do you preferred to be called?" or "What is the name that you would like us to use?"

TABLE B-1 Sample Questions and Statements Using Gender-Neutral Language

Question/Statement	Question/Statement with Neutral Language
Good morning, sir.	Good morning.
How may I help you, ma'am?	How may I help you?
She is scheduled for an x-ray.	They are scheduled for an x-ray.
Do you have a husband?	Are you in a relationship?
What are the names of your mom and dad?	What are the names of your parents or guardians?

Assessment and Management of Patients Seeking Gender Reassignment

People who are transgender may experience **gender dysphoria**, which is the distress caused by the dissonance between the person's gender identity and that person's sex assigned at birth. To assist people with this distress and find a gender role that is comfortable for them, treatment is available and may include medical and surgical interventions. Treatment is individualized, meaning that interventions that effectively alleviate gender dysphoria in one patient may not work for a different patient.

Health care teams who provide psychological, medical, and surgical treatments to people who are transgender often follow the Standards of Care published by the World Professional Association for Transgender Health (WPATH, 2012). Other important resources include the Guidelines for the Primary and Gender-Affirming Care of Transgender and Gender Nonbinary People from the University of California, San Francisco (Deutsch, 2016) and the Principles of Transgender Medicine and Surgery (Ettner, Monstrey, & Coleman, 2016) (see References and Resources sections at the end of the appendix).

Providing treatment to people who are seeking gender reassignment almost always starts with confirming a diagnosis of gender dysphoria. Many health insurance companies require a gender dysphoria or related diagnosis before covering the costs of gender reassignment treatments. Gender dysphoria is a diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5). Chart B-2 lists the criteria used to diagnose a person with gender dysphoria. In short, to be diagnosed with gender dysphoria, a person must exhibit specific thoughts and feelings about the incongruence of their gender identity and their secondary sex characteristics for a period of at least 6 months (American Psychiatric Association, 2013). An experienced mental health care professional, such as psychologist, or psychiatrist, can assess, diagnose, and provide psychological treatment for gender dysphoria. Before a health care provider prescribes medical or surgical treatments (e.g., hormones, gender reassignment surgery), they usually require that the person has consulted with a mental health care provider and received a diagnosis of gender dysphoria.

When a person wants to address the distress or other negative emotions associated with having a gender that does not align with their sex assigned at birth (gender dysphoria), they will usually work with an interdisciplinary health care team. This team typically includes a mental health care professional, a health care provider experienced in endocrinology, and a surgeon. The mental health care professional will provide psychological support to the person during their gender identity journey; the endocrinology health care provider will prescribe hormones and monitor outcomes; the surgeon will handle gender reassignment surgeries. Depending on the treatment settings, nurses are involved in various capacities along the treatment continuum.

Chart B-2 DSM-5[a] DIAGNOSTIC CRITERIA FOR GENDER DYSPHORIA IN ADOLESCENTS AND ADULTS

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months duration, as manifested by at least two of the following:
   1. Marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
   2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
   3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
   4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
   5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
   6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Medical Management

Hormone Therapy

In addition to alleviating gender dysphoria, the goal of hormone gender-affirming therapy is the acquisition of the secondary sex characteristics of the other gender, to the fullest extent possible (Gooren, 2016). To achieve the secondary sex characteristics of the opposite gender, sex steroids/hormones are needed. There is no known difference in sensitivity to the action of sex hormones on the basis of genetics or gonadal/sex status (Gooren, 2016), meaning that a person can develop secondary sex characteristics of the opposite gender by taking sex hormones. However, certain effects of sex hormones cannot be reversed. For example, in people who are transgender women (male to female), the previous effects of androgens on the skeleton (average greater height; size and shape of hands, feet, and jaw; and pelvic structure) cannot be reversed by hormones (Gooren, 2016) (Table B-2).

TABLE B-2 Physical Effects of Hormone Treatment for Gender Reassignment

Feminizing Hormones (Male to Female)	Masculinizing Hormones (Female to Male)
Reduction in growth and thinning of body hair	Growth of facial and body hair; scalp hair loss
Breast formation	Decrease in glandular activity of breasts
Softening of skin and decreased oiliness	Skin oiliness and acne
Increase in body fat and decrease in muscle mass	Decrease in subcutaneous fat, increase in abdominal fat, and increase in muscle mass
Testicular and prostate volume atrophy	Clitoral enlargement and vaginal atrophy
Decreased sperm production	Cessation of menses
Male sexual dysfunction	Deepening of voice

Adapted from World Professional Association for Transgender Health (WPATH). (2012). Standards of care for the health of transsexual, transgender, and gender-nonconforming people (version 7). Retrieved on 2/17/2020 at: www.wpath.org/publications/soc

For patients who are transgender women, estrogen is prescribed to produce the desired physical changes. The prescribed dose of estrogen is individualized and depends on many different factors, such as the patient's goals, risk/benefit ratio, presence of other medical conditions, presence or absence of gonads, and social and economic issues (WPATH, 2012). Estrogen treatment should produce changes in body hair, breast development, skin, body fat composition, muscle mass, testes, and prostate. In addition to estrogen, androgen-reducing medications to reduce testosterone levels are also often prescribed, which diminish masculine characteristics and minimize the dosage of estrogen needed to suppress testosterone. Common androgen-reducing medications include spironolactone, cyproterone acetate, GnRH agonists (e.g., goserelin, buserelin, triptorelin), and 5-alpha reductase inhibitors (e.g., finasteride, dutasteride) (WPATH, 2012). Progestogen does not add to the feminization process and is typically not recommended due to the higher incidence of breast cancer and cardiovascular disease (Gooren, 2016). See Table B-3 for commonly prescribed medications.

In people who are transgender men (female to male), testosterone is prescribed to produce the desired physical changes. Like estrogen, the prescribed dose of testosterone is individualized and depends on many different factors. Testosterone treatment should produce changes in scalp hair, skin oiliness, facial and body hair, voice, body fat composition, muscle mass, menses, clitoris, and vagina (see Tables B-2 and B-3).

As with any medical treatment, hormones carry risks to the person. The likelihood of a serious adverse event is dependent on numerous factors, such as dose, route of administration (e.g., oral vs. transdermal vs. intramuscular), and the patient's characteristics (e.g., age, comorbidities, health behaviors). People who take estrogen are at increased risk of venous thromboembolism (VTE), gallstones, elevated liver enzymes, weight gain, and hypertriglyceridemia. People who take testosterone are at increased risk for polycythemia, weight gain, acne, androgenic alopecia (male-patterned balding), and sleep apnea. In addition, both estrogen and testosterone can increase the risk of the person developing type 2 diabetes when they have additional risk factors, such as older age (WPATH, 2012).

Hair Removal

Hormone treatment does not typically fully eliminate unwanted hair, and thus people who are transgender may seek additional gender-affirming medical procedures).

Laser hair removal is the leading therapy option for long-term results and works on the principle of selective photothermolysis, whereby photons destroy the hair follicle while sparing the

TABLE B-3 Medications Prescribed to Facilitate Gender Transition

Feminizing Hormone Medications for Male to Female		
Medication	**Adverse Effects[a]**	**Nursing Considerations**
Androgen-Reducing Medications (Antiandrogen)		
Spironolactone (off-label use) Mechanism of action: diuretic that also directly inhibits testosterone secretion and androgen binding to the androgen receptor	Electrolyte imbalances, especially hyperkalemia Decreased blood pressure	This medication is a diuretic and patients must be advised of frequent urination and need to increase water intake. Caution in patients with adrenal insufficiency, diabetes, hyperkalemia, and chronic kidney disease.
Cyproterone acetate Mechanism of action: antiandrogenic and progestogenic/antigonadotropic properties, resulting in blocked binding of the active metabolite of testosterone and decreased production of testicular testosterone	Thromboembolism Hyperlipidemia Hepatotoxicity Glucose intolerance Mood changes	Assess for signs and symptoms of thromboembolism. Monitor mood changes (anxiety, depression, insomnia), especially during the first 4–6 wks. Monitor liver function tests prior to and during therapy for symptoms of hepatotoxicity.
Dutasteride Finasteride Mechanism of action: inhibits the enzyme 5-alpha reductase, which is responsible for converting testosterone to its potent metabolite	Prostatic hyperplasia	Assess for urinary hesitancy, feeling of incomplete bladder emptying, interruption of urinary stream, and dysuria.
Estrogen		
Ethinyl estradiol Mechanism of action: semisynthetic estrogen that binds to estrogen receptors, increasing estrogen levels and decreasing testosterone levels	Thromboembolism Edema Hypertension Pancreatitis	Assess for signs and symptoms of thromboembolism. Assess blood pressure before and during therapy. Monitor hepatic function during therapy.
Masculinizing Hormone Medication for Female to Male		
Medication	**Adverse Effects**	**Nursing Considerations**
Androgen		
Testosterone undecanoate Mechanism of action: synthetic testosterone that binds to androgen receptors throughout body	Hypertension Glucose intolerance	Assess blood pressure before and during therapy. Monitor for hypoglycemia, especially in people taking diabetes medications.

[a]Erectile dysfunction and gynecomastia are side effects of these medications. However, people who are male-to-female transgender are expecting these side effects.
Adapted from Comerford, K. C., & Durkin, M. T. (Eds.). (2020). Nursing2020 drug handbook. Philadelphia, PA: Wolters Kluwer.

surrounding tissue (Thomas & Houreld, 2019). The main risks of this procedure are overheating resulting in redness, blisters, and burns. Treatments should be avoided when photosensitizing medications are being used, such as acne medications (e.g., isotretinoin, minocycline, doxycycline), antibiotics (e.g., tetracyclines, sulfonamides, quinolones), and spironolactone. Nurses should review a patient's medication list and identify those that are photosensitive. Electrolysis involves the use of an electric current that destroys the root of individual hair follicles. This treatment is more time consuming and more painful than laser hair removal. The main risks of electrolysis are redness and pigment changes. To help manage the pain during laser hair removal and electrolysis, topical anesthetics (lidocaine-containing products) and acetaminophen/paracetamol are used (Reeves Deutsch, & Stark, 2016).

Acne Treatment

In transgender men, testosterone is the mainstay of masculinizing hormonal therapy. Although the exact mechanism in the pathogenesis of acne is not yet fully understood, testosterone increases the production of sebum (oily secretion) in sebaceous glands, leading to acne. Facial acne in transgender men who use testosterone peaks within the first 4 months of treatment; over 80% of testosterone-treated transgender men experience facial acne in the first year (Motosko, Zakhem, Pomeranz, et al., 2018). General guidelines for acne treatment can be followed for transgender men (Thiboutot, Dréno, Abanmi, et al., 2018); however, there are some specific considerations and risks. First, combining testosterone with some acne medications, especially minocycline, may lead to hepatotoxicity; thus, frequent monitoring of liver function tests is warranted. Second, some acne medications are teratogenic, such as minocycline, doxycycline, and isotretinoin. For transgender men who are still at risk of pregnancy (intact uterus and ovaries), careful sexual history and counseling should be performed before the initiation of any acne treatment. Third, some acne medications, especially isotretinoin, may delay wound healing and lead to keloid formation after surgery; thus, a discussion about surgical plans is needed before starting acne treatment (Motosko et al., 2018).

Fertility and Reproductive Health

Many people who are transgender will want to have biological children, but because hormone treatment limits fertility, patients should be educated about their options before starting hormone treatment or undergoing surgery to remove or alter their reproductive organs. Although the long-term effects of gender-affirming hormone therapy using testosterone or estrogen on fertility are not known, limited research suggests that testosterone and estrogen can affect the reproductive abilities of ovaries and testes, respectively (Cheng, Pastuszak, Myers, et al., 2019). Patients who are transgender should be fully informed of the possible implications that hormones have on fertility and preservation options.

In the postpuberty age group, transgender men should be educated about oocyte cryopreservation, embryo cryopreservation, and uterus preservation. Transgender women should be educated about sperm cryopreservation.

Gerontologic Considerations

The synthesis and secretion of many endogenous hormones change and the expression of cell receptors in tissues changes in numbers and signaling capacity as the human body ages (Houlberg, 2019).. With aging, the metabolism and excretion of many drugs decrease (Ruscin & Linnebar, 2018). Sex hormones also influence the absorption, metabolism, pharmacodynamics, and adverse effects of medications (Gooren & T'Sjoen, 2018). Nurses may need to take additional precautions to monitor for adverse effects and toxicity of certain medications when working with people who are transgender and taking exogenous sex hormones. The other two considerations are cardiovascular disease and bone health. In transgender women, estrogen increases the risk of cardiovascular morbidity and mortality. Additional preventive screening is warranted in these patients and lowering the dose of estrogen in transgender women over the age of 55 should be considered. Lastly, cross-sex hormone treatment can decrease bone health in both transgender women and men (Gooren & T'Sjoen, 2018). Findings from a pilot study suggest that despite having an increased risk for osteoporosis, transgender individuals' knowledge of their risks for osteoporosis can be poor (Sedlak, Roller, van Dulmen, et al., 2017) (see the Nursing Research Profile in Chart B-3). To help reduce the risk of reduced bone mineral density, nurses should educate about osteoporosis risks and promote physical exercise and intake of vitamin D and calcium to people who are transgender and taking sex hormones (see Chapter 37 for further discussion of osteoporosis). Given these considerations, the risks of hormone treatment can be managed and rarely pose an absolute contraindication (Houlberg, 2019).

Surgical Management

People who are transgender have many different gender reassignment surgeries available to them as they **transition** from their sex assigned at birth to their gender identity (Table B-4). Just like hormone treatment, gender reassignment surgeries help reduce gender dysphoria and improve quality of life. The WPATH (2012) recommends that people who are seeking gender reassignment surgeries meet certain criteria. They recommend that the person seeking surgery have (a) persistent, well-documented gender dysphoria; (b) capacity to make a fully informed decision and to give consent for treatment; (c) age of majority in a given country; and (d) any significant medical or mental health concerns be well controlled. For certain surgeries, including hysterectomy, phalloplasty, and vaginoplasty, WPATH (2012) also recommends that the person has had 12 continuous months of hormone therapy and has had 12 continuous months of living in a gender role that is congruent with their gender identity. This is based on clinical consensus, not empirical evidence, that living 12 months in a gender role that is congruent with their gender identity gives them ample opportunity to experience and socially adjust before undergoing irreversible surgery (Colebunders, Verhaeghe, Bonte, et al., 2016).

Male-to-Female Gender Reassignment Surgeries

There are numerous different gender reassignment surgeries for transgender women (see Table B-4).

For most transgender women, breast augmentation greatly increases subjective feelings of femininity. Surgeons typically recommend the person take estrogen for at least 12 months prior to the surgery to maximize breast growth and obtain better aesthetic results.

Some transgender women choose to have genital reassignment surgery which requires two procedures, including an orchiectomy (removal of the testicles) and vaginoplasty.

Chart B-3 OSTEOPOROSIS PREVENTION AMONG TRANSGENDER PERSONS

Sedlak, C. A., Roller, C. G., van Dulmen, M., et al. (2017). Transgender individuals and osteoporosis prevention. *Orthopaedic Nursing*, 36(4), 259–268.

Purpose

Many people who are transgender take sex hormones in order to achieve desirable characteristics of the gender that they feel is consonant with their personal identity. An adverse effect of these medications is that bone mineral density can become prematurely depleted, leading to early osteoporosis. The purpose of this mixed methods pilot study was to identify osteoporosis knowledge, beliefs, and prevention behaviors among transgender adults.

Design

Participants were recruited by advertising flyers at LGBTQ community centers and by advertising via LGBTQ support groups on the Internet. In order to be included in the study, participants had to be at least 30 years of age, the age when bone mineral density is considered maximal. Eligible participants could identify with male or female gender, and had to be able to read and speak English. Thirty-one participants were recruited and consented to complete a survey, which included a series of scales such as the *Osteoporosis Knowledge Test,* the *Osteoporosis Health Belief Scale,* the *Osteoporosis Self-Efficacy Scale,* the *Dietary Calcium Rapid Assessment Tool,* and the *Yale Physical Activity Survey.* Fifteen of these participants were randomly selected to participate in online qualitative interviews that focused on their views of bone health and osteoporosis.

Findings

The majority of participants (90.3%) took sex hormones. Most participants had poor knowledge of their osteoporosis risks, with 81% receiving failing scores on the *Osteoporosis Knowledge Test.* Participants selected to partake in the interviews confirmed that their knowledge of osteoporosis and their knowledge of their osteoporosis risks were poor. Several expressed frustration that health care providers had not disclosed these risks to them previously. The mean daily dietary calcium intake for the sample was less than recommended standards as was the minutes of average daily exercise. Most participants were not taking vitamin D supplements. Of those participants who were taking vitamin D supplements, more than half were taking less than recommended dosages.

Nursing Implications

Sex hormones are commonly taken by persons who are transgender; yet, findings from this study suggest that few people who are transgender and take sex hormones have knowledge of their associated higher risk for osteoporosis. Nurses should educate people who are transgender regarding the risk for osteoporosis that is associated with sex hormones. In addition, nurses should encourage persons who are transgender and taking sex hormones to engage in strategies that can mitigate the effects of sex hormones on their bone mineral density, including increasing their dietary calcium and physical activities, and taking appropriate dosages of vitamin D supplements.

TABLE B-4 Select Gender Reassignment Surgeries

Male to Female	Female to Male
Facial feminization • Angle of mandible • Cheeks • Chin • Forehead • Nose • Upper lip	Facial masculinization • Angle of mandible • Cheekbones • Chin • Forehead
Hair transplantation	Subcutaneous mastectomy
Chondrolaryngoplasty (tracheal shave)	Hysterectomy and salpingo-oophorectomy
Voice feminization	Phalloplasty
Breast augmentation	
Orchiectomy	
Vaginoplasty	

The goals of postoperative care of the patient undergoing male-to-female genital reassignment surgery are to prevent complications and infection and to ensure patency of the neovaginal cavity. After surgery, the patient typically remains in bed for five days with a vaginal dilator in place while receiving subcutaneous low-molecular-weight heparin (LMWH) (e.g., enoxaparin; see Chapter 24 for further discussion on anticoagulation medications). After the fifth day, the dilator is periodically removed and daily cleansing of the neovaginal cavity begins. The patient will typically remain in the hospital for 8 days. After discharge, the patient is educated on how to dilate and cleanse their vaginal cavity for 3 to 6 months. Once fully healed, the patient can begin having penetrative vaginal intercourse and stop using the vaginal dilator. If the patient does not engage in regular intercourse, they will need to continue using the vaginal dilator (Colebunders, Verhaeghe, et al., 2016).

Female-to-Male Gender Reassignment Surgeries

There are also numerous different gender reassignment surgeries for transgender men (see Table B-4).

Testosterone treatment has little effect on reducing breast size, thus transgender men who desire a flat chest require a subcutaneous mastectomy. From an anatomical standpoint, subcutaneous mastectomy in transgender males is nearly identical to mastectomies for breast disease. The main difference is the removal of breast tissue and excess skin and reduction and repositioning of the nipple and areola to create an aesthetically pleasing male chest (Colebunders, D'Arpa, Weijers, et al., 2016). The complication rate of subcutaneous mastectomy is very low and carries similar risk to mastectomies for breast disease (Cuccolo, Kang, Boskey, et al., 2019) (see Chapter 58 for further discussion on mastectomy).

Some transgender men choose to have phalloplasty, which is the construction of a penis. Phalloplasty is a complicated surgery that involves numerous subprocedures.

After surgery, the patient typically remains in bed for 1 week with a suprapubic urinary diversion and transurethral catheter. The patient may be prescribed an LMWH agent, such as enoxaparin, during this time frame. However, pelvic or groin hematomas sometimes develop postphalloplasty, which must then be managed by either drains or surgical drainage, and thus the individual risks versus the benefits of prescribing an LMWH agent are carefully considered (Crane, 2016). After the 1-week mark, the transurethral catheter is removed, and the suprapubic catheter is clamped so the patient can begin voiding. The patient will typically remain hospitalized for 2 to 3 weeks after a phalloplasty for close monitoring.

Postoperative urethra fistulas and strictures/stenoses are common complications.

An alternative technique to phalloplasty is metoidioplasty, which uses the clitoris to construct a microphallus. Compared to phalloplasty, metoidioplasty has a shorter hospital stay and minimal donor site complications. However, metoidioplasty does not allow the person to void while standing nor engage in penetrative sex (Djinovic, 2018).

NURSING PROCESS

The Patient Undergoing Gender Reassignment Surgery

Assessment

Preoperatively, the nurse should first gather details about the patient's gender identity, preferred name, preferred pronouns, and surgery. A person who is undergoing gender reassignment surgery will likely feel vulnerable and emotional.

Preoperatively, the nurse ensures the patient has received education and counseling about their gender reassignment surgery, the possible risks and benefits, including complications, postsurgical outcomes, and need for possible long-term follow-up appointments. The nurse needs to assess the last time the patient took their hormone treatment (e.g., estrogen or testosterone) because certain procedures require the patient to stop hormones 2 to 3 weeks in advance of surgery. The nurse should ensure the patient completed their bowel preparation, especially in genital reassignment surgery. For patients undergoing phalloplasty, the nurse needs to assess smoking status because most surgeons require the patient to be free of tobacco products or inhaling nicotine and marijuana. (Colebunders, D'Arpa, et al., 2016). Laboratory results, including complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), and creatinine, should be assessed; however, the nurse should be aware that people who receive hormones may have alterations in their laboratory values (Tollinche, Walters, Radix, et al., 2018). For patients who are transitioning, regardless of whether the transition is female to male or male to female, the upper limit for creatinine, hemoglobin and hematocrit, and alkaline phosphatase should be based on male values. For patients who are transitioning from female to male, the lower limit of hemoglobin and hematocrit should be based on male values. For patients who are transitioning from male to female, the lower limit of hemoglobin and hematocrit should be based on female values (WPATH, 2012).

Postoperatively, the nurse assesses the patient to ensure the goals for recovery are met and that the patient exhibits absence of complications secondary to the surgical procedure(s). Gender reassignment surgeries often require very specific assessments to ensure proper healing and prevent complications. It is imperative that the nurse follow the surgeon's prescribed postoperative care guidelines and educate the patient to prevent both complications and revisional surgeries (Colebunders, Verhaeghe, et al., 2016).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for compromised dignity associated with stigmatization
- Anxiety associated with impending surgery
- Acute pain associated with surgical procedure
- Risk for infection associated with surgical procedure
- Hope associated with gender reassignment surgery

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- Venous thromboembolism (VTE)
- Tissue necrosis

Planning and Goals

The major goals for the patient include enhanced sense of dignity and respect, reduction of anxiety about the surgery and postoperative care, relief of pain, absence of infection, enhancement of hope related to life after surgery, effective peripheral tissue perfusion, and absence of postoperative complications.

Nursing Interventions

Ensuring Human Dignity

The nurse needs to promote a welcoming and safe environment for the patient undergoing gender reassignment surgery. In addition, the nurse needs to promote the use of gender-neutral language, preferred third-person pronouns, and utmost respect for the patient and their family (Johnson, Wakefield, & Garthe, 2020). The patient should be able to safely disclose their gender identity and sexual orientation. In addition, nurses and other health care providers should avoid having discussions about the patient that can be overheard by neighboring patients and staff who are not involved in care. While this principle should be applied to all patients, it is of the utmost importance to the care of people who are transgender because of concerns over discriminatory health care treatment (Tollinche et al., 2018).

People who are transgender should be roomed in accordance with their gender identity preferably in a private room.

Reducing Anxiety

The nurse provides the patient preparing for gender reassignment surgery anticipatory guidance as to what to expect during the surgery and postoperatively. The patient's preferred family should be included when possible to help reduce anxiety. Additionally, some surgery centers promote the use of relaxation techniques, such as aromatherapy, nature sounds, and relaxation exercises; the nurse should use these if available (Ertug, Olusoylu, Bal, et al., 2017).

Additionally, to help ease the patient's anxiety about postoperative care, the nurse can assist in coordinating services. People who are transgender have higher rates of anxiety and depression than cisgender people. These issues may be exacerbated during a prolonged hospital stay. Thus, the nurse should advocate for the involvement of mental health, social work, and spiritual care as needed to address all of the patient's needs (Tollinche et al., 2018).

Relieving Pain

Evidence shows that patients experiencing postoperative pain should be offered multimodal analgesia, which is the pharmacologic method of combining various groups of medications for pain relief (Manworren, Gordon, & Montgomery, 2018) (see Chapter 9 for further discussion). After surgery, patients are usually prescribed opioid (morphine, hydromorphone) and nonopioid (acetaminophen/paracetamol or NSAIDs) agents. The nurse can administer these agents as prescribed to relieve pain and discomfort. Inadequately

controlled postoperative pain can impede functional recovery and reduce quality of life (Manworren et al., 2018), thus nurses need to be vigilant about controlling the patient's pain. Patients undergoing genital reassignment surgery typically need to stay in bed for numerous days; thus, the nurse should help the patient reposition themselves to promote comfort.

Preventing and Monitoring for Infection

The patient undergoing gender reassignment surgery (e.g., older adult, weak immune system, smoker, poor nutrition, overweight) are at greater risk for developing a postsurgical infection. The nurse should follow usual procedures to prevent and monitor for infection. Preventing infection after surgery requires proper and frequent hand hygiene, maintenance of the surgical site, and administration of prescribed prophylactic antibiotics. Early signs of infection should be reported to the surgeon immediately, including increased skin redness, pain, or swelling, cloudy or discolored discharge from the surgical site, and fever.

Promoting Hope

People who are transgender often experience greater levels of depression and decreased quality of life as compared with cisgender people. However, people who undergo gender reassignment surgery often experience improved quality of life (Cai, Hughto, Reisner, et al., 2019); (Passos, Teixeira, & Almeida-Santos, 2019). The nurse should promote open communication about the patient's feelings, hopes, and goals after their gender reassignment surgery and show a positive regard and sense of hope for the patient. Additionally, the nurse may want to explore unresolved emotions or anxieties.

Monitoring and Managing Potential Complications

After surgery, the nurse assesses the patient for complications from the procedure, such as hemorrhage, VTE, and tissue necrosis.

Hemorrhage. Postoperative hemorrhage is a possible complication after gender reassignment surgery, especially following vaginectomy, which is one of the procedures during a phalloplasty (Colebunders, D'Arpa, et al., 2016). Signs and symptoms of possible hemorrhage include increased pain, frank red blood from the surgical site or rectum, increase in bloody output from any drain that might be in place (e.g., for mastectomy), and typical clinical manifestations (e.g., tachycardia, hypotension, lightheadedness, syncope).

Venous Thromboembolism. People who undergo gender reassignment surgery, especially those undergoing genital surgery and those who are transgender women, are at risk of VTE, including both pulmonary embolism (PE) and deep vein thrombosis (DVT) (Shatzel, Connelly, & DeLoughery, 2017). People who undergo genital reassignment surgery often need to stay in bed for up to 7 days, putting them especially at risk. Additionally, the estrogen hormone treatment among transgender women increases the risk. The patient is typically prescribed mechanical compression (e.g., intermittent pneumatic compression devices) and prophylactic anticoagulation with subcutaneous LMWH agents (e.g., enoxaparin) during hospitalization. Even with these prophylactic measures, some patients still develop DVT and PE, and thus the nurse should monitor for clinical signs (Colebunders, Verhaeghe, et al., 2016); (Shatzel et al., 2017) (see Chapter 24 for further discussion on VTE).

Tissue Necrosis. Tissue necrosis from vascular compromise is a complication with certain gender reassignment surgeries, including subcutaneous mastectomy and phalloplasty. After the subcutaneous mastectomy, vascular compromise may occur around the reconstructed nipple and areola (Colebunders, Verhaeghe, et al., 2016). After the phalloplasty, vascular compromise may occur in the reconstructed shaft, penis glans, or scrotum (Colebunders, D'Arpa, et al., 2016). Signs of tissue necrosis from vascular compromise include skin/tissue discoloration (blue or black), feeling cool to the touch, increased pain or decreased sensation, and poor wound healing. Tissue necrosis is a medical emergency that needs to be addressed immediately.

Promoting Home, Community-Based, and Transitional Care

Educating Patients About Self-Care. People who undergo gender reassignment surgery are typically discharged to home from the hospital within seven days after surgery. General postoperative discharge education includes promptly notifying the surgeon for a temperature greater than 38°C (100.4°F) or for the presence of unusual or bloody drainage from the wound(s). The patient is encouraged to advance the diet as tolerated at home to promote wound healing and to abstain from all tobacco products at least until the surgical wound(s) has healed. Additional education provided is dependent upon the nature of the surgery. For instance, the patient who has had a vaginoplasty or phalloplasty will receive very specific education (Charts B-4 and B-5). If the patient has had a mastectomy and has a drain in place, then the patient needs to be educated on managing the drain at home (see Chapter 58,)

The patient is discharged with specific instructions about follow-up appointments, including visits with their surgical, medical, and psychosocial providers to address their complex

Chart B-4 POSTOPERATIVE EDUCATION FOR PATIENTS WHO HAVE HAD A VAGINOPLASTY

The nurse instructs the patient about activity, bathing, swelling, hygiene, and vaginal intercourse as described below.

Activity

- Avoid strenuous activity for 6 weeks
- Avoid swimming or bike riding for 3 months
- May be uncomfortable to sit for the first month; may use donut ring to relieve pressure

Bathing

- Resume showering following first postoperative visit
- Do not submerge groin area in water for 8 weeks

Swelling

- Labial swelling is normal and will resolve in 6 to 8 weeks
- Apply ice to perineum for 20 minutes every hour while awake for 1 week postoperatively
- Increased swelling with pain should be reported to surgeon

Hygiene

- Wash hands before and after contact with genital area
- Wipe genital area from front to back to avoid contamination by bacteria from anal region

Vaginal Intercourse

- May engage in vaginal intercourse 3 months after surgery

Adapted from Meltzer, T. (2016). Vaginoplasty procedures, complications and aftercare. Retrieved on 7/10/2020 at: transcare.ucsf.edu/guidelines/vaginoplasty; University of Utah.

Chart B-5 POSTOPERATIVE EDUCATION FOR PATIENTS WHO HAVE HAD A PHALLOPLASTY

The nurse instructs the patient about activity, bathing, swelling, hygiene, and sexual activity as described below.

Activity

- Avoid strenuous activity for 6 weeks
- Do not flex at waist more than 90 degrees
- Do not lift anything heavier than 2 kg with arm with skin graft donor site

Bathing

- Lightly sponge bathe for 1 week postoperatively and then begin gently washing penis with warm soapy water
- Keep skin graft donor site dry; may use plastic bag to protect from water

Swelling

- Minor swelling is expected; however, report increased swelling in groin or change in girth of penis to surgeon

Hygiene

- Wash hands before and after contact with genital area

Sexual Activity

- Do not use penis for any sexual activities until approved by surgeon (including oral, vaginal, or anal insertion)

Adapted from Phalloplasty guide: How to prepare & what to expect during your recovery. Retrieved on 7/10/2020 at: healthcare.utah.edu/transgender-health/gender-affirmation-surgery/phalloplasty-recovery.php

needs. Nurses should advocate that these follow-up appointments be made prior to hospital discharge. Additionally, the discharge process should assist the patient in coordinating any type of necessary equipment pickup, transportation to follow-up appointments, and filling medication prescriptions, as needed.

Continuing and Transitional Care. Gender reassignment surgery is very complex, involves numerous different procedures, and can be different from surgeon to surgeon. For these reasons, it is impossible to describe every postsurgical self-care activity. The nurse needs to carefully review the discharge instructions provided by the surgical team. Genital reassignment surgery often has very specific self-care requirements of the patient. The nurse's role is to ensure the patient fully understands the self-care instructions and knows how to monitor for complications.

The patient will usually continue to see their surgeon for follow-up appointments for many months. Some procedures, such as a phalloplasty, may require follow-up appointments for up to a year after surgery. The patient will typically need lifelong hormonal treatment and should continue to follow-up with their endocrinology health care provider. Additionally, many people who undergo gender reassignment surgery continue to visit a mental health care provider for counseling.

Evaluation

Expected patient outcomes may include the following:

1. Enhanced human dignity
   a. Verbalizes feelings of satisfaction related to the level of respect given to them
2. Minimal anxiety
   a. Has facial expressions, gestures, and activity levels that reflect decreased distress
   b. Demonstrates ability to reassure self
3. Relief of pain
   a. Reports relief of pain
   b. Engages in early mobilization activities as prescribed
4. Maintenance of asepsis
   a. No evidence of infection (e.g., no fever, no leukocytosis, no increased redness or swelling of surgical sites)
5. Enhanced hope
   a. Verbalizes feelings about their quality of life after having had gender reassignment surgery
   b. Identifies future-oriented goals and hopes
6. Has no complications (no hemorrhage, VTE, or tissue necrosis)

Index

Page numbers followed by c indicate charts; those followed by f indicate figures; those followed by t indicate tables.

A

Abbreviations, for diagnostic studies, A-1
Abdomen
  auscultation of, 428–429
acute, 519–520
    appendicitis, 521–523, 521f
    diverticular disease, 523–524, 523t
    intestinal obstruction, 524–527, 525t, 526f
    peritonitis, 520–521
  inspection of, 428
  percussion of, 428
  quadrants of, 428, 428f
Abdominal aortic aneurysm, 750, 751–753, 752f
Abdominal compartment syndrome (ACS), from burn injury, 1510
Abdominal distention, in heart failure, 581
Abdominal injury, blast, 2023
Abdominal pain, 425–426, 426f
Abduction, 1116f, 1127, 1147, 1213c
Abduction pillow, 1147, 1147f
Ablation
  in catheter ablation therapy, 606, 611–612, 614 (*See also* Catheter ablation therapy)
  definition of, 599
  in electrophysiologic studies, 624
  transurethral needle, 1481
Above-knee amputation (AKA), 1221, 1222f
Abrasion, 1987c
Abscess, 509
  anorectal, 551
  brain, 1676–1677, 1677c
  formation, 12
  liver, 936–937
  lung, 351–352
  periapical, 436, 467
  peritonsillar, 1284–1285
  tooth, 467
Absent bowel sounds, 428
Absolute neutrophil count (ANC), 861
  calculation of, 1901
  definition of, 814, 858
  in neutropenia, 1901–1902, 833
Absorption (digestive), 421, 424
Absorption dressings, 1076t
Abuse
  alcohol, 180, 2049
  amyl nitrate, 2002t
  elder, 2035, 2055
  family, 2006–2007
  freon, 2002t
  gasoline, 2002t, 2022
  inhalant, 2000, 2002t
  perchloroethylene, 2002t
  propane, 2002t
  risk for, 52–53
  signs of, 70
  substance (*See* Substance abuse; *specific substances*)
  toluene, 2002t
  trichloroethylene, 2002t
Acalculous cholecystitis, 942
Acantholysis, 1074, 1095
Accessory muscles, in respiratory system assessment, 266–267
Accessory pathway, atrial fibrillation with, 610
Accommodation, 1331
Acebutolol
  for dysrhythmia, 607t
  for hypertension, 781t
Acetabular fracture, 1199
Acetaminophen
  overdose of, 2004t
Acetazolamide
  for glaucoma, 1344, 1345t
  for obstructive sleep apnea, 1288
Acetoacetate, A-3t, A-12t
Acetone, A-3t, A-12t
Acetylcholine
  in gastrointestinal system, 424t
  as neurotransmitter, 1544, 1544t
Acetylcholine receptor
  in myasthenia gravis, 1689f
  normal, 1688, 1689f
Acetylcholine receptor binding antibody, A-11t
Achalasia, 463, 478, 478f
Achilles reflex, 1560, 1560f
Achilles tendon rupture, 1186
Achlorhydria, 490
Acid
  phosphatase prostatic, radioimmunoassay of, A-3t
  total phosphatase, A-3t
Acid–base balance
  in elderly, 2039t, 2041
  regulation of, 1373
Acid–base disturbances, 185–189. *See also* Acidosis; Alkalosis
  blood gas analysis in, 189, 190t, 191c
  mixed acid-base disorders, 189, 190t
  pathophysiology of, 185–186
Acidosis, 155
  arterial blood gases in, 191c
  metabolic, 186–187, 190t
  on potassium, 174
  respiratory, 188, 190t
Acinetobacter multidrug-resistant strains, 19
Acini, 1016
Acne vulgaris, 1082–1084, 1083t
  anatomic distribution of, 1069f
  assessment and diagnostic findings in, 1082
  clinical manifestations of, 1082
  epidemiology of, 1082
  medical management of, 1082–1083, 1083t
  nursing management of, 1083–1085
  pathophysiology of, 1082
Acoustic neuroma, 1703–1704, 1324. *See also* Brain tumors, primary
Acquired immune deficiency syndrome (AIDS), 1757. *See also* human immune deficiency virus (HIV) infection
  blood transfusion, 594
  meningitis, 1674c
Acquired immunity, 1742
Acral-lentiginous melanoma, 1103–1105. *See also* Malignant melanoma
Acromegaly, 1015, 1020
Actinic cheilitis, 464t
Actinic keratoses, 1100
Activated partial thromboplastin time (aPTT), 582t
Activated protein C (APC) resistance, 850
Active dressings, 1075
Active external rewarming, 1993
Active immunotherapy, 1879
Active internal rewarming, 1993
Active transport, 155
Activities of daily living (ADLs)
  in elderly, 2035, 2043
Activity. *See* Exercise
Acuity, visual, 1332–1333
  definition of, 1331
  eyeball shape on, 1335–1336, 1335f
Acupuncture, for gastrointestinal disorders, 554
Acute bacterial rhinosinusitis (ABRS), 1275f, 1277–1279, 1278t
Acute chest syndrome, in sickle cell disease, 824
Acute confusional state, in elderly, 2050–2052
Acute coronary syndrome (ACS), 647–656

assessment and diagnostic findings in, 649–651, 649c
chest pain in, 569t
creatine kinase and isoenzymes in, 651
ECG in, 649–650, 649f, 650f
echocardiogram in, 650
myoglobin in,, 651
patient history in, 649
symptoms in, 569t
troponin in, 651
from atherosclerosis, 636
clinical manifestations of, 649
definition of, 561, 635, 647
medical management of, 651–652, 651c
nursing process for, 653–656
pathophysiology of, 648, 648f
patient assessment in, 568
symptoms in, 569t, 649c
Acute decompensated heart failure, 705
Acute hemolytic reaction, 808
Acute intermittent peritoneal dialysis, 1417
Acute ischemic stroke. *See* Stroke, ischemic
Acute lung injury, 329
Acute lymphocytic leukemia (ALL), 863–864
Acute myeloid leukemia (AML), 859–861, 860f
Acute myocardial infarction. *See* Myocardial infarction (MI)
Acute nephritic syndrome, 1391–1392, 1391f
Acute otitis media (AOM), 1302, 1314–1315
Acute pain, 226
Acute kidney injury (AKI), 1396–1401
assessment and diagnostic findings in, 1398–1399
categories of, 1396–1397
causes of, 1398c
clinical manifestations of, 1398, 1398t
definition of, 1396
in elderly, 1399
medical management of, 1400–1401
nursing management of, 1401
pathophysiology of, 1396
phases of, 1397–1398
prevention of, 1399, 1399t
Acute radiation syndrome (ARS), 2030, 2030t
Acute respiratory distress syndrome (ARDS), 329, 356–359
assessment and diagnostic findings in, 357
after burn injury, 1531
clinical manifestations of, 357
medical management of, 357
nursing management of, 357–359
pathophysiology of, 356, 356c, 357f
Acute respiratory failure (ARF), 355–356, 1531
Acute rheumatic fever, 696, 696c
Acute tubular necrosis, 1397
Acute viral rhinosinusitis (AVRS), 1275f, 1275t, 1277–1289
Acyclovir
for herpes zoster, 1087
for HSV encephalitis, 1678
Adalimumab
for psoriasis, 1093
for rheumatic disorders, 1823t
Addiction, 226. *See also* Substance abuse
Addisonian crisis, 1015, 1050–1051
Addison's disease, 1015, 1046–1048, 1048c, 1605t
Adduction, 1213c, 1116f, 1127
Adenoidectomy, 1283
Adenoiditis, 1283–1284
Adenoids, 254
Adjuvant analgesic agents, 226, 243–245
Adjuvant chemotherapy, 1471, 1921–1922, 1921t
Adjuvant hormonal therapy, 1923, 1923t, 1924c
Adolescents
nutritional assessment in, 55
Adoptive immunotherapy, 1879
Adrenal cortex, 1015f, 1016t, 1043–1044, 1043f
Adrenalectomy, 1015, 1046
Adrenal gland disorders, 1044–. *See also specific disorders*
adrenocortical insufficiency, 1046–1048, 1048c
corticosteroids for, 1052–1055, 1053t
Cushing's syndrome, 1048–1052
pheochromocytoma, 1044–1046
primary aldosteronism, 1052
Adrenal glands
anatomy and physiology of, 1043, 1043f
in fluid and electrolyte balance, 159
Adrenal medulla, 1016f, 1017t, 1043–, 1043f
Adrenal sex hormones (androgens), 1015, 1044
Adrenergic, 1551
Adrenergic agonists. *See also specific agents*
for glaucoma, 1344, 1345t
Adrenergic fibers. *See* Sympathetic nervous system
Adrenocortical insufficiency, 1046–1047, 1048c
Adrenocorticotropic hormone (ACTH), 1019
definition of, 1015
plasma, radioimmunoassay of, A-3t
Adrenogenital syndrome, 1015, 1044
Adult voiding dysfunction, 1441–1450
catheterization for, 1446–1450 (*See also* Catheterization, for urinary disorders)
conditions causing, 1442t
neurogenic bladder, 1446
urinary incontinence, 1441–1445 (*See also* Incontinence, urinary)
urinary retention, 1445–1446, 1445c
Advance directives, 1956t
definition of, 29
for elderly, 2061
Adventitia, 731
Adventitious sounds, 271, 272t
Aerosol delivery devices, 388t, 388f
Aerosol masks, 286t, 287
Afferent impulses, 1553
Afterload
definition of, 561
Ageism, 2035
Age-related disabilities, 2056. *See also* Disabilities
Age-related macular degeneration, 2044–2045, 1353–1354, 1353f
Agglutination, 1739, 1744
Agglutinins, cold, A-11t
Aging, 2037–2048
cognitive aspects of, 2046–2047
demographics of, 2035–2036, 2036f, 2036t
health care costs of, 2056–2057
pharmacologic aspects of, 2047–2048
physical aspects of, 2038–2044
psychosocial aspects of, 2044–2046
Agitation, in Alzheimer's disease, 1714
Agnogenic myeloid metaplasia (AMM), 875
Agnosia
definition of, 1543, 1559, 1608
from stoke, 1608, 1609t
tactile, 1559
types of, 1559t
Agonist–antagonist, 226
Agranulocytes, 794f, 795–796
AIDS. *See* HIV infection and AIDS

Brunner & Suddarth's

Textbook of

Medical-Surgical Nursing

Volume II

Second South Asian Edition

Trusted by nursing fraternity for more than 50 years, *Brunner & Suddarth's Textbook of Medical-Surgical Nursing* layers essential patient care information, engaging critical thinking exercises, and diverse features to help students learn critical content. The second South Asian edition, similar to the previous edition, is comprehensively updated to customize and keep pace with South Asia's health care environment by including Indian/Asian epidemiologic data of common diseases and disorders, flowcharts of pathophysiologic processes of various diseases and disorders, and psychosocial concepts, which is contemporary to South Asian scenario. Furthermore, essential medical-surgical nursing content and diseases/disorders, which are specific to South Asia, are added to make this textbook most suitable to South Asian learners.

Highlights:

- Units and chapters are organized as per the competency-based B.Sc. Nursing curriculum outlined by Indian Nursing Council (INC) for Adult Health Nursing.
- Following new topics are included: Ethical and legal issues in surgical nursing, operation theater (OT) (types, design and infrastructure), instruments and preparation of sets for common surgical procedures, types of suture materials and suture techniques used, monitoring of patients during surgical procedure, maintenance of therapeutic environment in OT, assisting in major and minor surgeries, handling of different specimens, legal aspects in OT, position and draping for common surgical procedures, wound dressing (types and techniques), National Program for Health Care of Elderly, National AIDS Control Program, NACO guidelines, current guidelines and delivery of palliative care, gender dysphoria and gender reassignment surgery, breaking bad news, skin rejuvenation, liposuction, derma fillers, legal and ethical issues in plastic surgery, and legal and ethical issues in disaster nursing in Indian scenario.
- Disease conditions such as LVH, cor pulmonale, cyst of the liver, gall bladder cancer, tumors of parathyroid gland, COVID-19, chikungunya, Pott's spine, neurocysticercosis, and swine flu have been included.
- New flowcharts for pathophysiology of various diseases and disorders and relevant illustrations have been included to make the concept easy to understand.
- The richness of the content, style of presentation, and special features of the original text such as Critical Thinking Exercises, Procedural Guidelines, Nursing Alerts, Plan of Nursing Care charts, Genetics in Nursing Practice charts, Ethical Dilemma charts, and Home Care Checklist charts have been retained.
- Online Ancillaries included.

Prof. Suresh K. Sharma, PhD, RN, FCCN, FNRS, Professor-cum-Principal, College of Nursing, All India Institute of Medical Sciences, Jodhpur, Rajasthan, has over 20 years of teaching experience in undergraduate, postgraduate, and doctoral programs in nursing. He was a University Gold Medalist in his undergraduate and postgraduate programs. He is an RN in Board of Registered Nursing, California, USA, and a receiver of Florence Nightingale Award (2001). He has been ICN-Global Nursing Leadership Fellow-2020 at Global Nursing Leadership Institute, Geneva, Switzerland. He is in the Board of Directors, International Network of Doctoral Education in Nursing (INDEN, 2022-24), USA.

Prof. Sharma is a prolific writer and has published seven textbooks in nursing, beside a number of chapters contributed and more than 150 research papers published in indexed journals of repute. He is also Founder-President, Society of Perioperative Nurses, India, and Society for Critical Care Nursing, India. He is also editor/section editor of several journals including *Journal of Caring Science* and *Journal of Medical Evidence*.

Prof. S. Madhavi, PhD, RN, Professor-cum-Principal, KMCH College of Nursing, Coimbatore, Tamil Nadu, has over 25 years of teaching experience in undergraduate, postgraduate, and doctoral programs in nursing. She was a University Rank holder in her undergraduate program. She was awarded Best Nurse Educator in Tamil Nadu in 2011. She has also been a visiting faculty to University of Wisconsin, Oshkosh, USA (2000–2003). She has been a member of Board of Studies (Nursing) of the TN Dr. MGR Medical University, Chennai. She has been a resource person for numerous workshops and conferences conducted by the professional organizations like Trained Nurses Association of India, Indian Critical Care Nurses Association, and Asia Pacific Cancer Society.

Prof. Madhavi has published many research papers in national and international nursing journals. She has authored online CNE modules on wound care and ABG analysis which are available at www. tnccne.net/ and are awarded 10 credit hours each. She was also the Executive Editor of *TNNMC Journal of Medical & Surgical Nursing*.
